Preface to the Encyclopedia of Global Environmental Change

THE ENVIRONMENT

The word *environment*, whose dictionary meaning is simply that which surrounds, has in the last few decades become a buzzword , encompassing an exceedingly diverse array of elements and social issues. Taking the original meaning as a point of departure, it is clear that we humans depend totally on the environment provided by planet Earth for the food we eat, the water we drink, and the air we breathe. Thus changes in this environment must be of vital concern. Will Earth continue to sustain humans in a way that also encourages the flourishing of the other living things with whom we share the planet? This question has loomed ever larger as it has become more evident that human activities have been inducing major changes in all of the compartments of the global environment. We have converted forests and savannas to farms and cities; we have exhumed ancient treasures of fuels and minerals; we have used the rivers and winds as convenient sewers; and we have released entirely new chemical compounds and organisms into the environment. In the 1960s, the scientific community began to use the word *environment* in this new non-specialist sense. Soon too, Departments of the Environment were created by many governments, and new scientific journals began publication while others were re-named. For example, the *International Journal of Air Pollution* became *Atmospheric Environment*! In the ensuing decades, the world community has come to see the environment in many different ways, as a life-support system, as a fragile sphere hanging in space, as a problem, a threat and a home.

GLOBAL ENVIRONMENTAL CHANGE

A broader and deeper understanding of the global aspects of environmental concerns emerged in the 1970s and 1980s, and a new phrase *global environmental change* acquired popular currency. Paleoresearch had revealed that environmental change was far from new, and by no means the sole result of the actions of heedless humans. Since the planet s formation, virtually every element of its environment has been undergoing massive changes on all space and time scales. Oxygen waxed and carbon dioxide waned in the atmosphere. Continents moved about the planet s surface like scum on a soup kettle. Great ice sheets grew and shrank. Above all, the force of life (the biosphere) emerged as a dominant driver of planetary change.

However, another vital insight began to emerge about 1980: the inescapably interlinked nature of these many environmental changes. On the very longest time scales, continental drift moved lands into different climates – but also changed the climate of the globe itself. Photosynthetic life changed the atmosphere – but also made possible more advanced life forms that could take advantage of the new environment. On shorter time scales, atmosphere and ocean often interact to produce the massive changes in the Southern Pacific that we term El Niño and La Niña, whose consequences extend across the planet, and profoundly affect even our socioeconomic systems. Indeed, we have come to realize that human-induced perturbations in the environment are becoming increasingly large, and are potentially coming to dominate the natural workings of the complex and interdependent global system that sustains life on Earth. Humans and their global environment are no longer independent; they are ever-increasingly becoming interdependent components of a single global system.

Thus, the term *global environmental change* has come to encompass a full range of globally significant issues relating to both natural and human-induced changes in Earth s environment, as well as their socioeconomic drivers. This implicitly includes concerns for the capacity of the Earth to sustain life that have motivated the development of studies of global change and sustainable development in the last few decades. Analyses of global environmental change therefore demand input from the social sciences as well as the natural sciences (and indeed also from the engineering and health sciences) – necessitating an inescapably interdisciplinary approach.

Scientists from many disciplines have been attracted to this growing field of global environmental change. This is particularly noticeable in the biological sciences through the encouragement of IGBP (International Geosphere–Biosphere Programme), which invites ecologists to expand their field of vision from the plot and landscape scales to the regional, continental and global ones, and to interact with scientists from other disciplines in exploring environmental change at these larger scales. Indeed this trend has encouraged publishers and scientific societies to introduce new journal titles, and these publications from all accounts appear to be flourishing.

At the same time, human social, economic, and cultural systems are rapidly changing under the influence of growing globalization. In the economic sphere, for example, today s discourse centers on multinational corporations, the Global

Economy, and the Globalization of Trade. Thus, the agendas of most of the physical, life, and social sciences increasingly focus on global-scale changes.

THE EVER-CHANGING ENVIRONMENT

Since the launching of Earth-viewing satellites, we have been able to see a constantly updated moving picture of our planet. Great weather systems sweep around the globe, waves of green and brown ebb and flow over the continents with the seasons, as do white waves of ice and snow. Nevertheless, a remarkable feature of the Earth system has been its relative stability. Since the dawn of life, the planet s environment has remained within a range of conditions that has supported life. Moreover, with some notable and perhaps cautionary exceptions, changes from year to year, decade to decade, millennium to millennium, have been modest, particularly during the last 10 000 years. Many features of human society exhibit similar behavior. Civilizations and cultures evolve slowly for the most part in response to environmental, economic, and social driving forces over their long lives. Great cities like Rome endure through the ages. A citizen of ancient Babylon probably would have little difficulty understanding the politics of modern Toronto.

But today we appear to be entering an era of change unprecedented since Babylon was a cluster of mud huts. There are many reasons to believe that changes greater than humankind has experienced in its history are in progress and are likely to accelerate.

Virtually every measure of human society – numbers of people and automobiles, airplanes, energy consumption, generation of waste – is increasing exponentially. While the values of a few indicators are leveling off, the magnitudes of annual increases of others remain immense.

Major changes are becoming evident in many critical elements of the environment – increasing carbon dioxide concentrations, stratospheric ozone depletion (not to mention the stratospheric Antarctic ozone hole and the possibility of a similar Arctic event), rising sea level, declining productivity of soils, widespread collapses of fisheries, dramatic declines in biodiversity, destruction of tropical forests, etc. Within living memory, the countryside around large cities has been swallowed up by suburban developments and highways. Humans are stepping on the gas pedal of the planet s environment, and perhaps recklessly breaking the survivable speed limit of global change.

Paleoclimatological studies have shown that the stable environment that we take for granted has not always prevailed. Indeed, the relatively brief period in which human civilization has developed is somewhat unusual in its equable stability. Neolithic hunters in Europe some 13 000 years ago saw their climate shift from temperate to glacial in a single short lifetime. The evolution of human society is punctuated by wars, pestilence, and technological revolutions. Major – perhaps even catastrophic – change could occur in the future, because we know it has occurred in the past.

Rapidly advancing understanding of both natural and human systems – and above all the ability to translate that understanding into quantitative models – has enabled us to explore the future of our global society and its global climate with unprecedented realism. Although prediction of the single future path that we will follow is inherently unpredictable, it is possible to map a broad range of future environmental trajectories that we might take, each completely consistent with our understanding of how the system works. Such scenario-building exercises amply confirm our concerns that the changes of the 21st Century could be far greater than experienced in the last several millennia. Business-as-usual for human society appears to imply business-as-highly-unusual for the global environment.

THE INTERLOCKING BIOGEOPHYSICAL – SOCIOECONOMIC SYSTEMS

Recognition came in the 1970s that many of the environmental issues are inter-connected through the biogeochemical cycling of trace substances, especially carbon, sulfur, nitrogen and phosphorus. In fact, in a prescient statement on the main environmental research priority of the 1980s, Mostafa Tolba (then Executive Director of the United Nations Environment Programme) and Gilbert White (then President of the Scientific Committee on Problems of the Environment) drew the attention of both the scientific and the science-policy communities to the need to understand the major global biogeochemical cycles in order to maintain the global life support systems in a healthy state (Tolba and White, 1979). Quoting from that statement,

> We draw attention to the fundamental scientific importance of understanding the biogeochemical cycles which link and unify the major chemical and biological processes of the Earth s surface and atmosphere. The results will have practical significance for all of us who inhabit an Earth with limited resources and who, by our actions, increasingly affect the quality of the human environment.

So it is that many of the global environmental issues – acid rain, stratospheric ozone depletion, climate change, nitrogen over-fertilization – are inter-related through the global biogeochemical cycles.

One of the interesting results of the study of the Earth s history has been the discovery of the global teleconnections of the Earth system, with some major climatic shifts occurring simultaneously in the two hemispheres. In an analogous way, there has been recognition for a long time that human social, economic, and cultural systems are globally inter-related. That these are connected in turn to the

Earth system was implicitly recognized as early as the 1972 Stockholm Conference on the Human Environment.

To manage the human responses to this enormously varied but at least moderately coupled world system in an era of increasing global change through the diverse array of local, national and international organizations is indeed a daunting challenge. An essential first step is to describe past and present states, then to explain the various phenomena observed, and finally to develop predictive models (or at least a range of scenarios) describing the future behavior of this total Socioeconomic–Cultural–Environmental system. In this process, environmental scientists must learn how to assimilate better the new information constantly being received, although uncertainties, often large, will continue to exist. Within this mix, rational and effective policies must be developed that will balance the risks and costs of global environmental change in an adaptive way. Only then will we be able to even formulate, much less start to implement, rational and effective policies that cope effectively with global change. The prospect of change tempts us to think in terms of winners and losers. However, such analyses often do not play out in simple ways. For example, a modest increase in rainfall would cause farmers to rejoice while vacationers would despair. However, greater farm production can lead to lower commodity prices, thereby reducing farm incomes while making vacation food purchases less expensive. Human society is pretty well adapted to the present environment, so change is necessarily a challenge.

In the longer-term, much depends on the ability of societies to respond, to adapt. Societies will differ in the resources – natural, human, and technological – that are available to them. They will also differ in terms of the values and priorities they attach to physical, social, and environmental goals, and in the social and political mechanisms that they employ to seek these goals. These differences in the human world of generations yet unborn may be as great – and as significant – as the changes in the global environment. A major challenge for our times is to develop frameworks for understanding complex interdisciplinary issues of this complexity.

No discussion of change and the future can be complete without consideration of risk. Projections of the future, however imaginative or soundly based, necessarily center on plausible, surprise-free scenarios – population will increase, economies will advance, climate will change – all typically slowly and smoothly. However, such projections made at the beginning of the 20th Century would have missed two World Wars, the automobile, aviation, space travel, television, and McDonald s in Beijing. By definition, genuine surprises cannot be predicted. However, an understanding of the impacts of past surprises may help us to make our society and our world somewhat more robust in the face of the unknown surprises that await us.

THE HUMAN DIMENSIONS OF GLOBAL ENVIRONMENTAL CHANGE

The human dimension of global change has been defined as the ways in which individuals and societies contribute to global environmental change, are influenced by it, and adapt to it. Many empirical studies have been undertaken that describe human activities in physical terms, based on various kinds of indicators. Rates of deforestation, urbanization, and changing levels of emissions of greenhouse gases are only some measurable contributors to environmental change. But the dynamics of human activities and global change are much more complex, and they reflect the complexities of the human–nature relationship.

While the sheer burden of human activity on the planet is important, we know that the major forces at work are human beings operating together through political systems, corporations, interest groups, and beliefs that sway whole peoples. These raise questions about the nature of choice, about the hopes, dreams, and frustrations that impel people forward, or block them. At the moment, for instance, the dream of the good life – which has been a critical element of every religious tradition in the world – is increasingly being defined in terms of material possessions and powerful images that are shown on global media. Can this particular version of human happiness be sustained on a limited planet? Some people say that it can; others say that it cannot.

The central questions about the role of human beings in global environmental change revolve around social, cultural, economic, ethical, and even religious issues. These are becoming more and more pressing, and more and more foundational as human beings deliberately or inadvertently modify more and more of the planet. It is also obvious that in this generation the modification of organisms and ecosystems may well extend to the modification of human beings themselves. Among the fundamental questions are: What motivates us towards saving or harming the environment? How do we see ourselves with regard to nature? What is our responsibility to this and future generations? Who do we think we are, and who would we like to become? Appropriately enough, Volume Five of this Encyclopedia wrestles, in many different voices, with these ultimate questions that remain intimately linked with the sweep of physical, chemical, biological, geographical, and institutional changes documented and discussed throughout the earlier four volumes.

The Brundtland philosophy urges us not to reduce options for future generations. Implementation of this idea is, however, difficult. For example, it often seems more compelling to alleviate current poverty than to protect the environment and renewable resources for future generations. Many scientists agree that new approaches are needed to meld the social with the natural sciences in the policy arena. Some of the new methodologies that go beyond the physical sciences

are described in Volumes Four and Five of this Encyclopedia, e.g., post-normal science, integrated environmental assessment, and the precautionary principle.

In a commentary in which he described the 21st Century as the century of the environment, Edward O. Wilson began by referring to the growing *consilience* (the interlocking of causal explanations across disciplines) so that the interfaces between disciplines become as important as the disciplines themselves. He then stated that this interlocking amongst the natural sciences will in the 21st Century also touch the borders of the social sciences and humanities. In the environmental context, environmental scientists in diverse specialities, including human ecology, are more precisely defining the arena in which that species arose, and those parts that must be sustained for human survival (Wilson, 1998).

This is a major challenge for environmental scientists. Already through DNA techniques, for example, it is possible to trace back connections amongst prehistoric peoples through the last Ice Age to modern times.

THIS *ENCYCLOPEDIA OF GLOBAL ENVIRONMENTAL CHANGE*

More than two million papers are published every year in science and medicine, a twentyfold increase since 1940 that taxes the resources of concerned citizens, scientists, university departments, research institutes and libraries. At the same time, many policy-motivated organizations find it difficult to draw together the necessary expertise for resolving the newly emerging environmental issues. The scientific literature relating to the environment is burgeoning. However, research syntheses are in general still scattered across a broad spectrum of journals and books, and information on global environmental change is not readily available in an inter-related way. In particular, it is quite uncommon for contributions from the natural sciences to appear in the same journal or workshop proceedings as contributions from the social sciences and the humanities.

This *Encyclopedia of Global Environmental Change* is a comprehensive and integrated reference in the broad area of global environmental change that will be conveniently accessible and productively usable by students, managers, administrators, legislators, and concerned citizens. The Encyclopedia consists of five volumes of interrelated material:

Volume 1 The Earth system: physical and chemical dimensions of global environmental change (Michael C MacCracken and John S Perry, editors)

Volume 2 The Earth system: biological and ecological dimensions of global environmental change (Harold A Mooney and Josep G Canadell, editors)

Volume 3 Causes and consequences of global environmental change (Ian Douglas, editor)

Volume 4 Responding to global environmental change (Mostafa K Tolba, editor)

Volume 5 Social and economic dimensions of global environmental change (Peter Timmerman, editor)

The first four volumes cover the broad issues of the science and politics of global environmental change. Volume Five adds an often understated but extremely important aspect, linking as it does, global environmental change to the socioeconomic, cultural and ethical dimensions of human societies. Here will be found a rich panoply of writings by people who are not natural scientists but who have thought deeply about the environment. It places global environmental change in a refreshing historical, sociological and cultural context. In many contributions, the time horizons of most interest are the last hundred and the next hundred years. However, some contributions dip backward millions of years. Throughout, the emphasis is upon the dynamics of the various processes discussed – how and why did they change? A second recurrent theme is the interconnection of processes and changes – What produces change? What is impacted by change? Finally, we attempt to deal even-handedly with natural and human-induced change, and with impacts on both the natural world and human society. From the numerous diverse articles in the Encyclopedia, we believe that the user can obtain a coherent picture of this complex and dynamic system of which we all are a part.

To assist in promoting this coherence, each volume begins with a group of extended essays on major topics that embrace the field covered in that volume. These are intended to provide an introduction to the topic, a convenient road map through cross-references for exploring the Encyclopedia. Then there follows, in alphabetical order, shorter articles on a variety of scientific topics, descriptions of scientific programs, definitions, acronyms, and biographies of leading contributors to the field – from Charles Darwin, through the Russian ecologist Vernadski, to the three most recent environmental Nobel Laureates – Crutzen, Rowland and Molina. Indeed, these definitions, biographies and acronym definitions are, we believe, a uniquely valuable feature of the Encyclopedia. In the case of acronyms of international organizations and programs, it is no exaggeration to state that a young environmental scientist requires not only a good understanding of science, but also a good knowledge of acronyms, if they are to follow the discussions taking place at many international meetings! Also included in the alphabetic listings are abundant cross-references to related topics in the same or other volumes.

The substantive scientific articles that comprise the meat of the Encyclopedia are original contributions by active scientists from around the world, and thus

represent authoritative and up-to-date summaries of the state of current knowledge, direct from the producers of this knowledge. A number of these articles break new ground in synthesizing and summarizing our understanding from novel viewpoints and in unconventional ways. Thus, readers will find a wide variety of styles and approaches within the articles, reflecting in a unique way the rich diversity of today s world science. The articles have also had the benefit of careful reviews, particularly by our Editors.

The scientific essays and some of the program descriptions begin with a few italicized paragraphs written for non-specialists. These are not intended to be abstracts of the paper to follow, but rather are aimed at providing the reader with an introduction into why the topic is important and where it fits into the broader aspects of global change – a kind of encouragement to read on. Reading on should not be too difficult a task, since most of the scientific essays are written at the level of journals such as *Scienti c American* and *AMBIO* that are intended for the non-specialist. The Encyclopedia will be a valuable source of information for everyone with a general interest or a need-to-know in the various environmental fields (the natural sciences, socio-economics, engineering, the health sciences, and policy analyses) particularly as they relate to global-scale environmental change, its drivers, and its consequences. It is also expected that among the audiences for each volume will be practitioners and researchers in the fields covered by the other four volumes. We believe that this rather unusual – indeed unique – Encyclopedia will be used in a variety of ways.

1. Some people will employ it simply as a convenient source of information on specific topics – What has been happening recently to the sea ice in the Arctic Ocean? Who was Roger Revelle? What is soil mineralization? What is ICSU or IGBP? What is the Kyoto Protocol? What is deep ecology?
2. Serious students in the environmental sciences may begin by reading one or all of the introductory essays, which present highly compressed crash courses in a range of central topics.
3. We believe that the substantive specialized articles that constitute the bodies of the volumes are productively and enjoyably readable in their own right.
4. Finally, a case has been made by one of the volume editors (Peter Timmerman) for encyclopedia browsing as an enjoyable and productive pastime (*see* Encyclopedias: Compendia of Global Knowledge, Volume 5).

We believe that these five volumes are in the tradition of the human aspiration towards the compilation of global knowledge that sparked the preparation of the first encyclopedias in the 18th Century.

Our Editors have had the benefit of a marvellous postgraduate education in the course of the Encyclopedia s evolution! We are immensely grateful to the many, many authors in our virtual university who have contributed their wisdom to this project.

ACKNOWLEDGMENT

Many helpful comments and draft paragraphs were received from the Volume Editors during the preparation of this Preface.

Preface to Volume One

Volume One of this Encyclopedia deals with the physical and chemical dimensions of the Earth system, including for example the atmosphere, the oceans, the cryosphere, and those aspects of the land surface particularly relevant to interactions with other components of the Earth system. These unique characteristics of our planet provide the foundation for the living and human worlds that are treated in other volumes of this Encyclopedia.

This volume begins with a group of extended review essays, followed by a large number of shorter articles. Together, these articles cover various aspects of the history, current state, and possible future states of the Earth system, including the interactions among the components of this system. Special attention is given to historical trends in various environmental indicators, both in the past century and extending back through geological time. There are also articles on what we have learned, and the tools used to gain knowledge about the functioning of this complex system, from field programs to model simulations. Although interactions of the environment with human activities are for the most part treated in other volumes, some of the effects of human intervention in environmental change, for example climate change and stratospheric ozone depletion, are included here. Because of the special importance of organized international observing, data management, and research programs in the Earth sciences, there are also numerous articles on relevant international institutions and programs. Finally, science is created by scientists, and we include brief biographies of a selection of leading individuals. Throughout, we have attempted to focus on the most dynamic aspects of the system, on the factors and processes that produce change, and on the programs and individual scientists most concerned with measuring and understanding change.

We have endeavored to construct a volume broad enough in scope to illuminate every corner of the relevant geophysical sciences, while remaining concise and readily usable by the non-specialist. The articles in the volume have for the most part been contributed by active researchers deeply expert in their fields. Other informational material has been assembled and summarized from a variety of public sources. Thus, we believe that this volume, like the Encyclopedia as a whole, represents a uniquely valuable source of focused, timely, and authoritative information relating to the issues of global environmental change.

Assembling this volume has been an immensely rewarding experience for us, refreshing and expanding our knowledge and understanding. We believe that the result will similarly expand the knowledge and understanding of its readers. We hope that its users will not simply open its pages for a definition or a number, but will take the time to read the extended essays and follow the network of cross-references that mirror the interactions of the planet s components. We believe that the users of this and other volumes of the Encyclopedia will share in our gratitude to the numerous contributors to its contents, and we hope that this unique compendium will to some extent help to illuminate the common future of our species and our planet.

Our planet is, as far as we know, unique in its diversity, complexity, capacity to support life, and never-ending change. The very earth beneath our feet, which we perceive as solid, is on geological time scales a boiling uid bearing the wandering continents like foam on a cauldron. The uid envelope in which we live the atmosphere and ocean is in constant motion, driven by the evolving ow of energy from our star, the Sun. The benign climate that nurtures life is governed by the atmosphere s composition, which itself was shaped by life. Earth is a restless planet.

Today, with burgeoning human populations and increasingly complex societies and economies, the consequences of environmental change are growing. Moreover, humanity itself has become a force for change comparable in magnitude to the geological forces of the past. Virtually every characteristic of every corner of the global environment bears the ngerprints of humankind.

This volume is predicated on the concept that the past, present, and future of our global environment can only be fully understood by considering the planet as an integrated whole: the Earth System. However, as in all complex puzzles, this understanding can best be built one piece at a time. Hence, this volume presents a disaggregated assembly of focused articles that provide entry points for the student and reader into the maze of phenomena, processes, and linkages that drive the great environmental machine in which we live. It strives to paint the giant canvas of our planet through a patchwork of brushstrokes by many hands in the hope that like the Earth it depicts the whole will be greater than the aggregate of its parts.

For most of the brief tenure of our species on this planet, we humans have experienced our environment only as a patchwork of snapshots. The world of the Neolithic hunter or the Mesopotamian farmer was circumscribed by his limited experience in his short life. Beyond his hunting territory or his farm, the Earth was a frightening mystery. As our societies and technologies developed, humans moved farther a eld, venturing across oceans and deserts and gradually acquiring some notion of a wider world. Eventually, the planet was circumnavigated, both poles were explored, and virtually every patch of its surface felt human footsteps. The number of individual snapshots in our album of the Earth increased immeasurably, but still largely remained an unconnected assemblage of individual observations.

ONE EARTH, ONE SYSTEM

Today, however, as we begin a new millennium, our view of the Earth is radically different. Past explorations revealed to us the surface of the globe in its in nite variety. A few seminal thinkers, such as the pioneering meteorologist Hadley, drew on fragmentary observations to synthesize larger pictures, for example of the circulation of the global atmosphere. However, our giant leap into space in the concluding decades of the last century revealed, for the rst time, the reality of our world. We could for the rst time see our planet as a single entity, a unique oasis in the inhospitable vastness of space. In the words of MacLeish (1968) (see Figure 1):

> To see the Earth as it truly is, small and blue and beautiful in that eternal silence where it oats, is to see ourselves as riders on the Earth together, brothers on that bright loveliness in the eternal cold brothers who know now they are truly brothers.

This growing intuitive, in some respects spiritual, view of the Earth as a uni ed whole was paralleled in the world of science. Many threads of understanding converged on the concept that, despite its variegated complexity, the Earth s past, present, and future could be fully understood only if all the diverse elements of our planetary environment were considered as a uni ed system. As our horizons in time and space expand, these interactions assume greater and

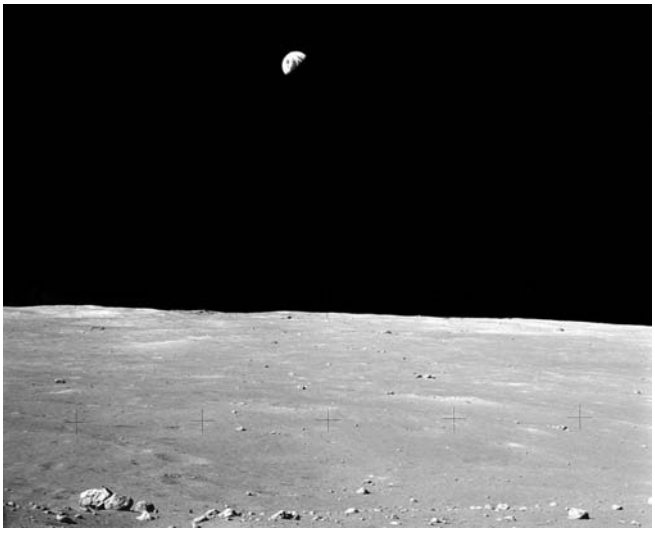

Figure 1 Our Earth, a lone oasis of air, water, and life in the cold desert of space, as seen in December 1968 by the first Apollo mission to orbit the Moon. (*Source* NASA)

greater importance, and the behavior of virtually any single component can be understood only as part of the system as a whole (*see also* **The Human Dimensions of Global Change**, Volume 5).

INSIGHTS FROM THE PAST

One impetus to this view came from study of the Earth s past. As evidence accumulated from geological records, deep-sea sediments, ice cores and other sources of indirect evidence, it became evident that all components of the natural world have been constantly changing and interacting since the planet s birth. The early Earth exuded gases, including water vapor, to form the planet s fluid envelope of air and water. The moving plates of its surface formed continents and mountains that shaped the wind and ocean margins and basins that held the ocean. These provided the cradle for the most powerful force of change – life. Living organisms found ways to harness the Sun s energy to power photosynthetic chemistry that slowly changed the planet s surface, atmosphere, and climate into the equable regime that we know.

EARTH AS GAIA

Indeed, as has been pointed out by Lovelock (1972), an observer from a distant planet could readily detect that Earth is a living planet: the atmospheric abundance of oxygen and paucity of carbon dioxide could not be supported for long by an inert body governed by inorganic chemistry alone. Today s life depends vitally on an oxygen-rich environment created by life itself. Thus, the Earth System inescapably includes the living system. The essential unity of the physical and living systems of the planet in quasi-equilibrium is comparable to the complex web of interactions that preserve the equilibrium of a living organism, a phenomenon known in biology as *homeostasis*.

Whatever the processes, the Earth has, in fact, somehow long maintained a remarkably stable and remarkably temperate environment for life. Indeed, Lovelock (1972) speculated it is illuminating to think of the Earth as a single living creature, managing its interacting systems so as to preserve the conditions for its continued welfare. To emphasize its uniqueness and individuality, he named this hypothetical planetary creature Gaia, after the ancient Greek mother-goddess of the Earth. Lovelock s insight, founded equally on science, poetry, and perhaps a touch of mysticism, has provided a powerfully inspiring vision of the complex and ever-changing system of which we are a part (*see* **Gaia**, Volume 2; **Gaia Hypothesis**, Volume 5).

IMPLICATIONS FOR SCIENCE AND UNDERSTANDING

In more practical terms, the vision of an intricately interconnected, ever-changing world has important implications for science s quest for understanding. If the world were static – if ocean currents, snow and ice boundaries, and vegetation were exactly the same from season to season and from year to year – then we could meaningfully study each component separately and at our leisure. We could combine observations of ocean currents taken centuries ago with those taken yesterday, without taking account of changing winds or rain or river flows. Oceanographers would have no need to learn the history of the ocean s waters and currents from geologists and biologists, nor provide geologists and biologists with insights on how the oceans might have shaped sediments and climate.

The luxury of such splendid isolation is denied to science by the hard facts of our planet s history. The bottom waters of the ocean slowly upwelling to the surface today gained their temperature and physical characteristics from the climate, precipitation, and river flow of a millennium past. The resources of coal and oil upon which our civilization depends are fossil remnants of long-vanished plants that grew on wandering continents under climates markedly different from ours. Thus, the fundamental task of observing our environment can only be accomplished in the framework of an ever-changing Earth System.

An enormous gulf lies, however, between recognizing a system s components and characteristics, and understanding how it works, not to mention predicting its future behavior. How can science come to grips with the complexity of Earth? To say that something is complex and interconnected is to say that it can be considered in many parts, each of which may hopefully be studied individually. Thus, just as an automobile mechanic focuses successively

on one component after another until the engine runs smoothly, scientists focus on individual components of the system – atmosphere, oceans, ice and snow, rivers and lakes, living ecosystems, and so on. Each of these systems presents its own cascade of complexity, but within a delimited and hopefully more tractable scope. No one can hope to understand the Earth as a whole, but it may be possible to understand a raindrop.

This *reductionist approach* is, at once, science s most powerful weapon, and science s most crippling handicap. Deep understanding of tightly delimited systems and processes can be developed only by ruthlessly discarding all that lies outside the spotlight of inquiry, and by organizing scientific effort in terms of rigorous scientific disciplines. A lifetime may not be enough to reach full understanding of a single microbe, or for that matter, a single thunderstorm. But, through the focused efforts of many lifetimes, a well-stocked library of knowledge can be built up. The challenge then is to transform this untidy pile of building materials stored in a host of disciplinary warehouses into a coherent edifice of understanding, to move from piecemeal insights about individual components and processes to a coherent predictive vision of the system as a whole.

Today s science is guided by a vision of the Earth System as an intricate machine composed of numerous components, each potentially a subject for focused research and steadily improving understanding. A schematic diagram of such a framework is presented in Figure 2.

An illustrative example of the interactions between components of the system is provided by the El Niño/Southern Oscillation phenomenon. Meteorologists had long known about long-period swings in pressure across the Pacific. Oceanographers had long known about temperature and circulation patterns in the tropics. Fishermen had long known about irregular and sudden warmings off the coasts of Ecuador and Peru. Field observing programs, powerfully aided by satellite observations, permitted researchers to gain insights into the ocean s effects on tropical weather systems, and the atmosphere s influence on the oceans.

But none of these insights by itself led to clear understanding and useful prediction. Eventually, union of observations, analyses, and insights from atmosphere and ocean, not only in the tropical Pacific, but from all around the globe, led to numerical models and, for the first time, scientifically based and highly successful seasonal predictions. It was found that the essence of the phenomenon, and the essential basis for prediction, lay in the interaction between ocean and atmosphere, not simply in processes and events within either medium.

GLOBAL CHANGE

Although the record of the past is a history of constant change in all aspects of our planetary environment, the last decades of the 20th century brought a new focus on environmental change.

First, advances in our knowledge of the Earth s past brought a new realization of its variability, and of the possibility that these fluctuations seen in the past might reoccur. While in the 19th century Agassiz revealed the outlines of a past ice age, research in the 20th century showed a series of glaciations interrupted by brief interglacial respites much like our own. Indeed, some raised the possibility that the balmy interglacial in which we live, the *Holocene*, might be coming to its natural end after some 10 millennia. The knowledge of past changes, and the possibility of future changes, naturally heightened the need to understand the processes of change itself.

Our knowledge of the present similarly advanced. Observing networks for weather prediction had begun in the 19th century, and grown with the steady expansion of world populations and trade. During World War II and the following years, exciting new tools for probing the atmosphere, ocean, and solid earth emerged, culminating in the deployment of powerful observing systems on Earth-orbiting satellites. For the first time, the planet could be observed as a whole through networks of well-calibrated instruments. Increasingly, these measurements became unified through internationally coordinated observing systems. The resulting databases provided a powerful foundation for research and immeasurably advanced understanding of the Earth System.

At the same time, there was a growing perception that burgeoning human society was becoming ever more sensitive to environmental change. For example, as agriculture spread across the American plains, tornadoes that once stirred grasslands and stampeded buffaloes now tore through airports and trailer parks. As coastal settlements crowded ever closer to the water s edge, storms and storm surges posed ever-greater threats to life and property. As populations increased, and possibilities for migration decreased, variations in rainfall produced human and ecological tragedy in climatically marginal regions such as the African Sahel. Accelerating globalization held economies and food supplies everywhere hostage to environmental changes in distant breadbaskets. Environmental change was no longer an academic curiosity for scholars, but a burning concern for all humankind.

HUMANITY'S HEAVY FOOTPRINTS ON THE EARTH

Perhaps the most pressing and prominent concern for environmental change, however, was the growing realization that human activities were impacting the global environment as powerfully as the geological forces of the past, a prospect foreseen a generation earlier by Vernadsky (1926) and Lotka (1924).

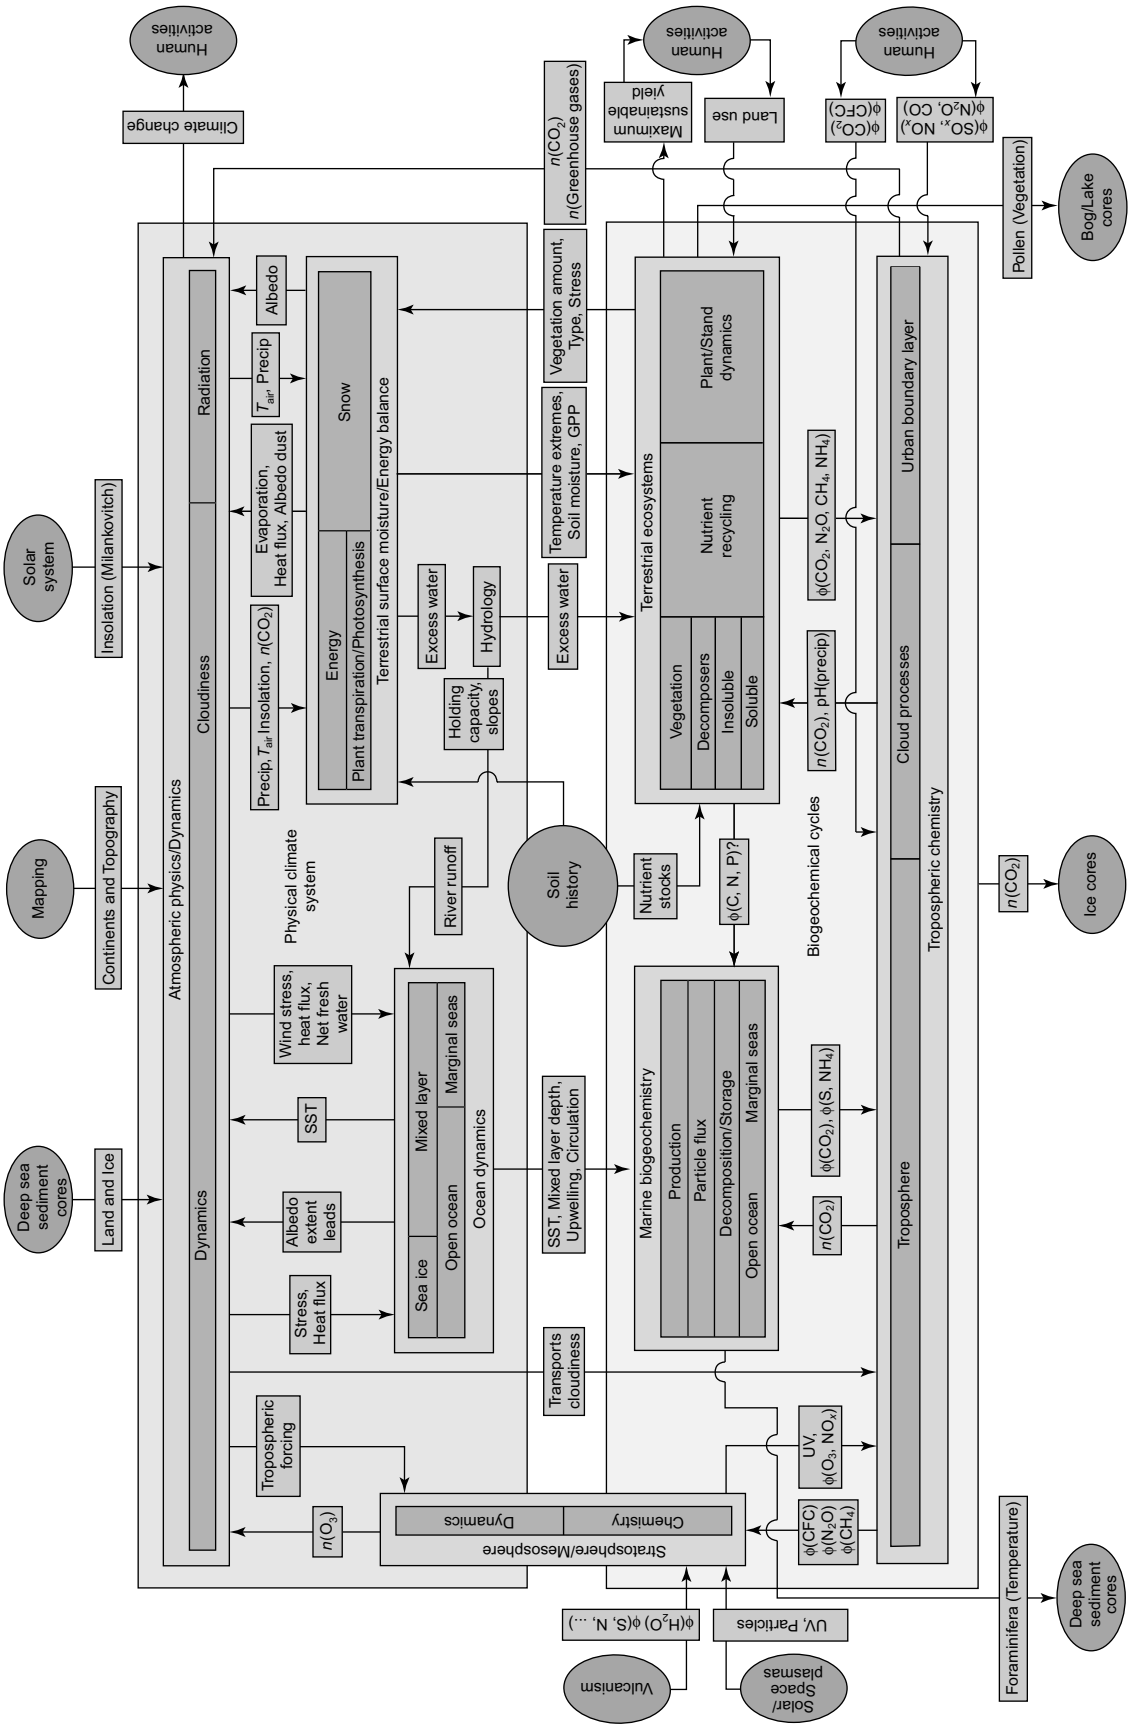

Figure 2 Conceptual model of Earth system processes operating on timescales of decades to centuries. In the figure, $n \bullet x \bullet$ refers to number density and $\phi \bullet x \bullet y \bullet$ indicates functional dependence. (*Source:* NASA, 1988)

In the 19th century, the mechanisms of the natural greenhouse effect that maintains the Earth s equable climate were largely elucidated. The climate to which we are accustomed is maintained by surprisingly small concentrations of a few key gases in the atmosphere – mainly water vapor, carbon dioxide, ozone, and methane – that absorb and radiate thermal energy. It was clear that burning of fossil fuels – coal, oil, gas – released carbon atoms (that had been entombed in eons past) in geological formations. By transforming forests into farms, pastures, and cities, we release additional quantities of carbon dioxide, and we have altered virtually every factor that determines climate, such as the absorption of solar energy, the fluxes of water and energy, the runoff of water into rivers and streams, and the roughness of the surface as encountered by the wind. Numerical models indicate, for example, that removing the forests of the Amazon would reduce precipitation to the point where reforestation would be unlikely.

By the end of the 20th century, quantitative estimates of possible effects of these atmospheric changes on climate had been made. Concerns lay dormant, however, until detailed measurements in mid-20th century showed incontrovertibly that concentrations of key greenhouse gases, principally carbon dioxide, were indeed increasing alarmingly. Data on past concentrations of carbon dioxide obtained from ice cores confirmed that atmospheric concentrations had increased markedly since pre-industrial times. Projections of the impacts of continued increases on climate confirmed the estimates made a half century earlier, heightening apprehension.

At the same time, exquisitely sensitive techniques for measuring trace constituents in the atmosphere were developed. Lovelock found that human-made gases such as the chlorofluorocarbons (CFCs) were detectable throughout the globe, even in the center of the oceans. Questions were also raised about the possible impact of emissions from the burgeoning fleets of aircraft thronging the stratosphere, particularly the fuel-hungry supersonic aircraft then being proposed. These concerns prompted greatly enhanced research efforts in global atmospheric chemistry.

In parallel, changes in stratospheric ozone were noted, and linked to emissions of synthetic chemicals, primarily the CFCs employed in refrigeration and many industrial processes. Discovery of the virtual disappearance of stratospheric ozone over Antarctica in the early Southern Hemisphere spring helped to focus international attention, leading to international agreements to control emissions of harmful chemicals. Fortuitously, a sound scientific basis for these agreements had been laid by almost two decades of intensive research.

Paralleling these changes in the physical environment, life scientists documented massive changes in the living world – increasing extinction of species, introduction of alien species into sensitive environments, changes and losses in natural habitats, and degradation of soils. These issues are treated in Volumes 2 and 3 of this encyclopedia.

Thus, in the final quarter of the 20th century, the concepts of environmental change, and humankind s role in driving change, were high on both the scientific and policy agendas. Often equated to the single issue of climate change, the phenomenon of accelerating change in all components of the global environment is, in fact, a far broader and even more complex challenge to science and society – a challenge that has been addressed by national and international programs focused on global change. This growing context of awareness and concern for the entire spectrum of change in our planetary environment prompts and shapes this *Encyclopedia of Global Environmental Change*.

COMPONENTS OF THE EARTH SYSTEM

This encyclopedia, as a whole, is designed to offer the concerned citizen, student, or general reader, an introduction to the immense range of topics relevant to the issues of global environmental change in all its aspects. The present volume focuses on the physical Earth System – the atmosphere, oceans, solid earth, and the space environment in which our planet is immersed. While striving to present the basic knowledge base needed for understanding, our emphasis is on the elements of the system that exhibit the most marked changes or exert the most significant influence upon change – particularly change on a global scale.

As suggested above, the most prominent concerns at the start of the 21st century center on global climate, and hence much of the volume will deal with the elements of the global climate system. However, the concept of global environmental change, in truth, encompasses a far wider range of environmental factors important to human life, notably changes in the biological and chemical environment. These are in large part treated in the second volume.

In introducing this volume, we have highlighted the need to study the Earth as an integrated system, in order to understand, and hopefully predict, its changes. However, as we noted above, this broad foundation of knowledge is built on a multitude of deep foundations of closely delimited study. Similarly, the reader seeking understanding must find points of entry that address specific questions.

Thus, the articles in this volume dedicated to the notion of an integrated system are highly specific and narrowly focused. They have been designed to provide in-depth information on individual topics, while hopefully recognizing throughout that the elements described are components of an integrated system. In this introductory essay, we attempt to present a rough sketch of the physical Earth. Our subject, and thus the canvas upon which we must paint, is dauntingly large. Hence, we must use the largest brushes and the broadest strokes while striving to produce a reasonable likeness of our planet, leaving to the expert articles of

the volume s body the task of completing the portrait with realism and fidelity.

How can we best disaggregate the intricate machine in which we live? What are the leading figures that must appear on our sketchpad? On the broadest scale of abstraction, the following components provide a basic framework for understanding, and a context for the specifically focused articles that follow.

Our Planet

The ball of rock upon which we live is believed to have coalesced from the debris of our solar system about 4.5 billion years ago. Its raw materials slowly sorted themselves out into the ingredients we know today. The planet is, to a good approximation, a ball a little over 40 000 km in circumference, slightly bulging at the equator because of centrifugal forces arising from its rotation. It lies almost 150 million km away from its sun. On average, its parent star bathes it in a stream of energy at an average rate of about 1366 W m^{-2}, but the energy received at the surface varies markedly over the sphere as a function of latitude, season, and cloud cover. The Earth s mildly elliptical orbit currently takes it closest to the Sun in January and farthest away in July. However, because the Earth s axis of rotation is tilted with reference to the plane of its orbit, the hemispheres receive seasonally varying amounts of radiation. Over much longer times, the parameters of the Earth s orbit slowly change in response to gravitational forces from our sister planets.

Internally, the primordial ingredients have separated into a dense metallic core surrounded by lighter viscous layers surmounted by the crustal plates upon which we live. Slow convective processes bring new materials to the surface, and suck existing crust downward, while the plates themselves migrate over the planet s surface like patches of ice in a lake. Earthquakes and volcanoes mark the boundaries at which the plates collide, which for the most part form a continuous network of mid-ocean ridges spanning the globe. This slowly seething mass receives a steady rain of debris from space, occasionally including comets and minor asteroids. One of the latter is hypothesized to have exterminated the dinosaurs some 65 000 000 years ago; one of the former flattened a Siberian forest in the 20th century.

Inherent in this brutally compressed description is an image of ceaseless change. Over geological time, the continental rafts upon which land-borne life evolved have moved from tropics to poles and split into continental islands, carrying with them both their characteristic geology and their life forms. The slow oscillations of Earth s orbit, and the inclination of its axis, redistribute solar radiation over the seasons and latitudes. On relatively short time scales, its daily rotation rate fluctuates detectably due to friction with the ever-changing atmosphere.

Atmosphere

The lighter ingredients of the primordial Earth became its fluid envelope – its ocean and atmosphere. The composition of the atmosphere evolved markedly over time due to continued emissions, chemical reactions, escape of lighter constituents into space, and finally by the emergence of photosynthetic life in the last 600 million years or so. The atmosphere is today composed primarily of nitrogen and oxygen, with lesser but vital concentrations of water vapor, carbon dioxide, and other trace gases.

On a global scale, the atmosphere is frighteningly thin: thinner than an onion skin over the planet s surface, half of the atmosphere s mass lies within 5.5 km of the surface. Nevertheless, it plays a special role in Earth s story, for it is the atmosphere that provides the principal fuels for life, carbon and oxygen, and maintains the equable climate indispensable to life. A tenuous layer of ozone shields the surface from the Sun s deadly streams of ultraviolet radiation. Without an atmosphere, Earth would suffer a climate as inhospitable as that of the Moon, with an average temperature some 34 °C colder than we now enjoy, and daily temperature swings of hundreds of degrees. In the greenhouse provided by a wispy blanket of gases such as water vapor, carbon dioxide, methane, ozone, and the industrially produced CFC s, much of the heat radiation emitted by the surface is absorbed by the atmosphere. The atmosphere then emits heat radiation back downward to warm the surface along with the heat absorbed by solar radiation. As a result, the Earth s surface is much warmer than that of a naked planet.

The atmosphere, moreover, serves as the working fluid in a giant planetary heat engine whose furnace lies in the tropics facing the Sun and whose radiator is in the polar regions inclined toward space. Due to the planet s rotation, air and the energy it carries, cannot move directly from equator to pole. Instead, the flow sorts itself out into a triad of circulation cells, complicated by moving turbulent eddies. In this complex circulation, energy derived from the Sun drives atmospheric motions that ultimately transport the atmosphere s share of energy from the tropics to the Arctic and Antarctic. En route, this turbulent flow gives rise to a menagerie of weather systems.

Rather arbitrarily, we characterize the conditions brought to us by the atmosphere as weather or climate – the former referring to the day-to-day sequence of sunshine and storm, the latter to the more or less steady annual cycle of the statistical properties of the weather (e.g., average temperature, frequency of precipitation, etc.). Viewed from the perspective of Earth s history, however, we see that the atmosphere supports a continuum of change on all time scales.

The atmosphere is more than simply a heat-driven machine, however. It transports a host of substances across the face of the globe, and provides a cauldron for their transformation. Its turbulent motions carry water from its

reservoir in the oceans, produce clouds and precipitation that intercept and re ect solar radiation, transport and release heat, and provide rain and snow for the thirsty continents. The atmosphere also carries a host of particulate and gaseous materials Saharan dust, hydrocarbons and gases emitted by vegetation, pollution from human industry and transportation all the while transforming them into acid deposition, smog, and sometimes essential nutrients for life. These mostly invisible particles also play a crucial role in the formation of clouds and rain by providing essential nuclei for condensation.

Thus, the atmosphere is without doubt the most dynamic element of the Earth System. It is also the most vulnerable to human in uences, primarily because of its thin and tenuous nature. In terms of sheer mass alone, human emissions into the atmosphere are no longer negligible in uences on this wispy lm of air that clings to our rock in space. Moreover, our equable climate depends crucially on the particular concentrations of a small group of radiatively active greenhouse gases. Directly and indirectly, human activities are markedly in uencing all of these. By burning coal and oil, we return to the atmosphere, over a few centuries, the carbon that was entombed by biological processes over hundreds of millions of years. Industrial and agricultural emissions of gases such as the CFC s and methyl bromide participate in photochemical and radiative processes, and catalytically destroy ozone in the stratosphere, where its presence is important both in climate and in its role as a shield against ultraviolet radiation. On local and regional scales, emissions of hydrocarbons, nitrous oxides, sulfur dioxide and a host of other chemical species contribute to a diverse array of environmental impacts such as increasing near-surface smog episodes that are damaging both to health and agriculture, and lead to acid deposition that damages vulnerable lakes.

These fundamental changes in the all-enveloping and ever-changing planetary atmosphere in which we swim demonstrate vividly the shortcomings of MacLeish s (1968) insight: we humans are no longer simply riders on this planet we are its drivers.

Ocean

Today, about 70% of our planet s surface is covered by water (H_2O) the vast world ocean. The molecules of H_2O of which they are comprised are thought to have been outgassed from the primordial Earth, and retained by its gravity. As noted above, the basins in which the ocean now resides, averaging about 4 km in depth, are products of the tectonic movements that have shaped Earth s crust. Thus, the boundaries of the oceans have constantly changed over time as the continents have drifted, and the ocean basins are bisected by a global system of mid-ocean ridges marking the rifting of the continental plates.

Given humanity s propensity to settle near the water s edge, sea level is a continuing concern. Global sea level is determined rst by the topography of the basins and their margins how deep is the bathtub, how high its rim? On a dynamic Earth, many regions show long-term rises or falls in local sea level. For example, Scandinavia and parts of eastern North America are still rising as they recover from the weight of the great glaciers that last covered much of these regions over 10 000 years ago, and locally perceived changes in sea level re ect these motions. Sea level also depends on the varying amount of water in the oceans. During the great glaciations, for example, much of the Earth s water resided on land as mountains of ice, and sea level was about 150 m lower. Further, the great currents of the ocean are associated with strong gradients in sea level. At the beginning of the 21st century, concerns regarding global sea level center on projected rises resulting from melting of land-borne ice and, more speculatively, increases in the ow of Antarctic ice into the world ocean.

The chemistry of the oceans is also shaped by their solid earth containers. Runoff from the continents carries sediments and dissolved salts into the oceans, feeding the descending plate boundaries and keeping the ocean salty. The presence of salt means that sea water s density is determined by both salinity and temperature.

Earth s domination by the ocean has many consequences. First, water is a unique substance. Chemically, it serves as a solvent and reaction medium for innumerable substances. Thus, the ocean annually absorbs and re-emits vast quantities of atmospheric gases, notably carbon dioxide, through a web of life processes. Fluxes of carbon dioxide into and out of the ocean play a major role in the global carbon cycle that fuels life, and in determining atmospheric concentrations of carbon dioxide.

The ocean absorbs, transports, and re-emits remarkable quantities of heat, particularly as it undergoes phase transformations between ice and liquid, or between liquid and vapor. Approximately one-half the heat transported from the tropics to the poles is moved by the ocean. A number of its physical characteristics crucially determine important aspects of our environment. Because fresh water reaches its maximum density at about 4 °C above its freezing point, a stable top layer of water rapidly cools in winter, and ice can form and oat in lakes. The ocean s salt lowers this temperature of maximum density, and sea water thus cools steadily to a freezing point at about • 1.8 °C. Finally, the sea surface freezes in a slurry of crystals that reject much of the water s salt, providing an additional source of salty, dense water that sinks to the ocean depths.

The ocean s structure is as complex as the atmosphere s. Over most of its extent, a layer averaging about 100 m thick is churned by wind and waves, altered by daily and seasonal heating and cooling, and lightened by freshwater rain and runoff. This mixed layer forms an ever-changing lid over

cooler and more dense waters that only slowly mix with the surface waters, except in areas where the winds blow the surface mixed layer away. Much of the ocean s activity, particularly its biological activity, takes place in coastal regions where rivers and upwelling from the deeper ocean provide essential nutrients.

Today s oceans participate in a gigantic planet-wide circulation of water driven by heating and cooling, density differences due to varying salinity, and the force of the winds, a circulation that Wallace Broecker of the Lamont-Doherty Earth Observatory has termed the *conveyor belt*. This globe-encircling stream has important consequences for climate. The northward-flowing surface current of the western North Atlantic, for example, transports a major fraction of the heat deposited in the tropics by incoming solar radiation to warm Europe, especially in winter. Descending currents in the North Atlantic and the Southern Ocean carry dissolved atmospheric gases deep into the ocean s bottom water, which may not again reach the surface in this millenium. At its northern boundary in the Arctic, the continent-girdled Arctic Ocean is almost entirely covered by multi-year ice, with seasonally varying ice packs extending southwards. Slow circulations carry Arctic waters and ice southward. In the southern polar regions, the giant continent of Antarctica is girdled again by ice whose extent varies markedly over the seasons.

To land-dwellers, the most significant oceanic influences are felt through the atmosphere. On the largest scale, the capacity of the oceans to absorb, transport, and liberate heat, greatly tempers the climates of the continents, particularly regions downwind from the major oceans. Comparison of the climates of the US Pacific Northwest, the Dakotas, Labrador, the British Isles, and Siberia forcibly demonstrates the ocean s influence; all are at about the same latitude, yet their climates differ greatly. It is not surprising, therefore, that shorter-term fluctuations in the ocean have large impacts on global climate. Prominent among these are the irregularly periodic swings in atmospheric circulation and ocean temperature known as the Southern Oscillation, and most vividly evident as the El Niño (often termed together as ENSO). This rapid and massive warming of the eastern tropical Pacific produces torrential rains along the South American coast, and a worldwide chain of climatic anomalies. Arising as it does from interactions between ocean and atmosphere, its understanding and prediction have been a difficult challenge for science. However, observation and research in the latter decades of the 20th century yielded successful predictive models.

Cryosphere

Liquid water dominates the Earth s surface; but frozen water also plays a crucial role in the planet s workings. Unlike other substances found on Earth, ice and snow exist relatively close to their melting point and frequently change phase from solid to liquid and back again, producing dramatic changes in the landscape. Snow and ice march with the seasons across continents and oceans, making the domain of frozen water – the *cryosphere* – a dynamic component of the Earth System.

In terms of spatial extent, seasonal snow cover is the largest single component of the cryosphere. In winter, snow covers about 47 million km^2, principally in the Northern Hemisphere. Due to its influence on energy and moisture budgets, snow cover is an important variable influencing climate. It produces large differences between summer and winter land surface reflectance, or *albedo*, since snow reflects up to 90% of incoming solar energy whereas soil or vegetation may reflect only 10–20%. Snow cover also absorbs much heat as it melts, providing significant thermal inertia in high latitudes.

The largest quasi-permanent accumulations of ice at present are the ice sheets that cover Greenland and Antarctica. The latter, for example, covers about 12 million km^2, and reaches over 4 km in thickness. In Greenland and East Antarctica, the ice rests on solid ground above sea level. On the other hand, most of the West Antarctic Ice Sheet is grounded below sea level. These ice masses result from the slow accumulation of snow in regions of perpetual cold. The resulting domes of ice slowly flow at speeds up to a few km $year^{-1}$ into ice streams and, in Antarctica, into immense thick ice sheets extending into the surrounding ocean. These sheets calve into floating icebergs – sometimes the size of a small country – that populate the high latitudes of the oceans.

Other long-standing ice masses reside in mountain glaciers. Here also, ice accumulations flow down through valley glaciers sometimes many kilometers in length, and carrying large amounts of rocky debris. If they reach the sea, as in Greenland, they provide a source of icebergs.

Large areas of the northern oceans are covered by seasonally varying amounts of sea ice that forms in winter and largely melts back in summer. As ice forms, it rejects salts and entrains air, becomes lighter, and thus forms a thickening cap on the ocean that forms an insulating layer between ocean and atmosphere At the same time, the cold, salty, and dense waters produced by freezing sink to fill the deep ocean and form an important link in the global ocean conveyor system.

In essence, the polar ice caps of our planet thus constitute seasonally expanding and contracting continents of ice that rank among the most dynamic elements of the Earth System. Each winter, for example, the sea-ice around Antarctica grows to roughly twice the size of the continent. In contrast, Arctic sea ice is largely confined to the landlocked Arctic basin, where much of it endures and thickens over several years.

The Earth s ice continents have waxed and waned even more markedly on geological time scales. Ever since the continents drifted into their present northern cluster, great glaciations have swept over much of the planet with a periodicity apparently linked to the Milankovitch orbital cycles. Cores obtained from glacial ice, land deposits, and deep-sea sediments provide records of these glacial advances, and the comparatively brief intervening interglacial periods, such as the Holocene, in which we live, and the preceding Eemian about 125 000 years ago. At the peak of the last glacial advance, about 20 000 years ago, ice masses thousands of meters thick extended deep into Europe and the northern tier of US states, forcing atmospheric circulation into patterns very different from today, and depressing the Earth s very crust. Much of the planet s water was locked up in ice, leaving the ocean about 150 m lower and exposing land bridges between continents.

Today, permanent ice has retreated to mountains and the poles, where it presumably will contribute to seed the next glacial advance. Even in these strongholds, however, ice is not safe from the influence of humankind. The warming climate due to increasing greenhouse gases threatens to shrink the extent of glaciers, permafrost and sea ice. Moreover, increasing amounts of pollutants such as persistent organic compounds, heavy metals, and even radioactive species are transported by winds, currents, and rivers from lower latitudes into polar regions.

Thus, the world of solid water is, in truth, no less fluid and dynamic than the realms of gas and liquid, nor is it immune from the heavy footsteps of human society.

Hydrosphere

Air, ocean, and ice on this particular planet share one vital constituent: water. Earth has rightly been termed the water planet, because of the central role of this unique substance in the workings of its physical system and of the life that it supports.

Water is such a ubiquitous substance that its remarkable properties and myriad uses are easy to overlook. It dissolves innumerable substances, and forms a medium for the chemistry that shapes our world and its life – water erodes our monuments and pumps through our own veins. Life mostly lives in the temperature band between water s freezing and boiling points. Indeed, water is the only common substance found naturally in solid, liquid, and gas forms. Water vapor is a key architect of the natural greenhouse effect that maintains Earth s climate. The large amounts of energy absorbed and released in its heating, cooling, and changes of phase, permit it to transport heat efficiently and make it a powerful buffer for heating and cooling. The Earth as we know it is, in great measure, a product of this single substance that defines the hydrosphere – the water-inhabited region extending from the deepest ocean to the tops of the highest clouds.

The oceans cover about 70% of the planet s surface and contain about 97% of the planet s water. The remaining 3% occurs as fresh waters, three-quarters of which are locked up in the cryosphere. Most of the remaining fresh water is groundwater held in soils and rocks; less than 1% of it occurs in lakes and rivers. Water vapor in the atmosphere is negligible in mass, but is vital to the hydrologic cycle that supports our environment and life.

The hydrologic cycle transfers water from the oceans through evaporation into the atmosphere, thence to the continents, and finally, over and beneath the land surface, back to the oceans. Overland, the path of the water involves a complex set of processes: precipitation, evaporation, interception, transpiration, infiltration, percolation, and runoff. Some of these processes extend throughout the entire hydrosphere, the layers of the atmosphere, and the crust within which water may be found.

About 30% of the solar energy that reaches the Earth from the Sun is expended on evaporating water from the oceans. This condenses into clouds, rain, snow, and dew. Water fuels storms, and by freezing into ice crystals, is responsible for separating electrical charge, and producing lightning. Rain irrigates the land, replenishes subterranean aquifers, chemically weathers rocks, erodes and shapes landscapes, nourishes life, and fills the rivers, which carry dissolved chemicals and sediments back into the oceans. The green mantle of life on our planet acts as a buffer and regulatory valve, capturing water and gradually releasing it to runoff and returning it into the atmosphere by evapotranspiration.

Water also plays a vital role in the geochemical cycles such as the carbon cycle. Calcium is weathered from continental rocks and is then returned to the oceans, where it combines to form calcium carbonates (such minerals constitute the shells of marine life). Eventually the carbonates are deposited on the seafloor and form limestones. Some of these carbonate rocks are later dragged deep into the Earth s interior and melted, producing carbon dioxide that can vent back into the atmosphere, mostly through volcanoes. These cycles of water, carbon dioxide, and oxygen through physical and biological systems are fundamental in maintaining the balance of the planetary environment.

Human activities influence this cycle in both obvious and subtle ways. By replacing forests with pastures and pavements, we speed the flow of runoff into rivers and streams, with resulting erosion and flooding. Waste products leach into aquifers, while exploitation of ground water drains lakes and wetlands. Emissions such as sulfur dioxide change air chemistry, producing acidic rain and deposition. Changes in atmospheric aerosols due to land use and industrial activity alter the processes of cloud formation and precipitation, changing rainfall and cloud reflectivity. Humans play an increasing role in

the processes of the hydrosphere, both as actors and victims. *See also* Circulating Freshwater: Crucial Link between Climate, Land, Ecosystems, and Humanity, Volume 5.

BIOSPHERE

From the standpoint of our species, the most important layer of our planet s shell is the biosphere – the realm in which life is possible. But, as we have seen, life permeates all elements of our global environment; life crucially depends on its environment; and life powerfully shapes that environment. A planet different from ours would have no life; a planet without life would be far different from Earth. The realm of life, the biosphere, is treated in Volume 2 of this encyclopedia; however, let there be no doubt that life is an integral part of this living planet. As Vernadsky (1926) realized, Living matter is no accidental creation, but forms an essential part of the structure of the Earth .

CONCLUSION

Throughout this whirlwind tour of our planet, several overarching themes have emerged.

Diversity and Complexity

At their root, all the workings of the global environment are governed by a small number of fundamental laws of physics and chemistry. However, the concrete manifestations of these laws are infinitely complex and diverse. A lifetime may not be enough to understand fully a brief storm, let alone longer-term glacial cycling. Somehow we must piece together an understanding of our planet from fragmentary, crude, and imperfect insights into the infinite variety of our world. We are like students rummaging through the pages written in a gigantic dictionary of some foreign tongue – the words may be important, but many of them and the grammar that interconnects them remain unknown and undefined.

Interconnection and Interaction

We have seen that it is virtually impossible to discuss any component of our planet without speaking of other elements. The winds are driven by heating and cooling, but the oceans are the main reservoirs of heat. Snow and ice are creatures of the weather, but also powerfully influence global climate. The land shapes the chemistry and motions of air and ocean, but winds, currents, rain, and chemistry over time shape the land. Above all, life depends on air, soil, and water, but life is in itself among the most powerful agents of change.

Dynamics and Change

Since its beginnings, Earth has been a restless place. The planet has seen a variety of atmospheres, climates far warmer than today s, great glacial periods, and ever-wandering continents. On all time scales from a morning to an eon, Earth changes, and all the components of its planetary machine adjust to new patterns. Thus, study of our planet can never be a static science. Dynamics and change are intrinsic to Earth science, not optional.

With complexity, interconnection, and change comes chaos. As Lorenz elegantly demonstrated, even the simplest system embodying these characteristics has a distinct limit to its predictability because any error, however small, in any component grows in magnitude with time and effects a chain of consequent changes in other components of the system. Within broad existential constraints, every page of Earth s history is thus only one of many possible pages that could have been written by the hand of time. Nevertheless, the constraints imposed on the Earth system by the physical laws governing conservation of mass, momentum, energy, and species do create a limiting envelope that constrains the system s changes. These limits can be used to help project how the range of conditions is likely to change in response to various influences. Looking to the future, we can thus map out only the broadest features of the landscape through which we and our planet will blaze a single trail.

Inherent in this existential reality is the possibility of surprise. We cannot assume that the pace of change will always be measured and smooth. Quite to the contrary, the record of the past shows innumerable examples of rapid, sometimes catastrophic change. Our Neolithic ancestors in Europe, for example, saw their climate abruptly shift from increasing warmth to near-glacial cold in perhaps a decade. We cannot assume that our path along the road of time will never stray into a pothole or two.

Human Influence and Impact

Permeating this diverse, complex, interlinked, dynamic, and chaotic system is a relatively new source of change. Prehistoric hunters decimated large herbivores, set fires to create savannahs, and markedly changed the landscapes of the continents. Agriculture transformed still more of the planet s surface, and significantly altered flows of water, sediments, and chemicals. Finally, industry mobilized vast quantities of fuel and materials for human purposes, dispersing wastes into earth, water, and atmosphere, influencing chemical and biological processes from the depths of the ocean to the thinnest reaches of the atmosphere – and even threatening the climate itself. Truly, as Vernadsky foresaw, humankind has become a new geological force. See Volume 3 for many examples of human impacts on the environment.

THE EARTH SYSTEM – OUR COMMON HOME

Thus, our planet is composed of many complex parts; these parts interact in complex ways; they all continually change in response to each other; and they are all being increasingly disturbed by human actions. Conceptually, climate represents the average behavior of a global heat engine that is driven by the Sun, utilizing air and water as working fluids, with strong influences from natural and human activities. Forecasting weather beyond a few days requires atmospheric observations over the entire Earth. Predicting a season ahead requires knowledge of the world s oceans. Assessing a century s change in climate requires projecting the development of human society and economy. We, therefore, have no choice but to understand and learn to deal with Earth in all its parts and with all its passengers as a system – a regularly interacting or interdependent group of items forming a unified whole.

The only truly comprehensive encyclopedia of this changing Earth is the Earth itself. This volume comprises simply a collection of snapshots of the planet taken with diverse lenses, centers of attention, and points of view. We hope, however, that these will provide useful stepping-stones toward an understanding of the complex dynamic system of which we are an integral and increasingly important part. As Martin Luther King said, We are caught in an inescapable network of mutuality, tied in a single garment of destiny. Whatever affects one directly, affects all indirectly . Increasingly true of the human condition, this mutuality has always been true of the Earth System in which humanity exists.

Earth System Processes

KEVIN TRENBERTH

National Center for Atmospheric Research/Climate Analysis Section, Boulder, CO, USA

We experience weather every day in all its incredible variety. Most of the time it is familiar, yet it never repeats exactly. We also experience the changing seasons and associated kinds of weather. In summer, fine sunny days may be interrupted by outbreaks of rain and thunderstorms. Outside of the tropics as winter approaches, the days get shorter, it gets colder and the weather typically fluctuates from warmer and fine spells to cooler and rainy or maybe snowy conditions. In the tropics, the seasonal variations are more often experienced as monsoonal fluctuations between a wet season and a somewhat longer dry season. These seasonal changes are the largest climate changes we experience at any given location. Because they arise in a well understood way from the regular orbit of the Earth around the Sun, we expect them, and we look forward to them. We plan summer vacations and winter ski trips accordingly. Farmers plan their crops and harvests around the seasonal cycle. By comparison, variations in the average weather from one year to the next are quite modest, and longerterm changes in climate occurring over decades or human lifetimes may be even smaller. Nevertheless, these variations can be very disruptive and costly if we do not expect them. Climate changes, lasting decades to millennia, have occurred in the past as a result of various natural influences. Interannual variations are also an important ingredient of climate and can arise through, for example, interactions between the atmosphere and the oceans, as is the case with El Niño. This article discusses weather and climate variations in the context of the Earth system as a whole, and provides a basis for understanding the reasons why climate may vary, and how these variations may be manifested in terms of weather. The main focus of this article is on the atmosphere, which is the most variable component of the Earth system; it is also where we live and it provides the air we breathe. But the atmosphere interacts with the oceans, the land surface and its vegetation, and with the other components of the climate system, so those too are important, even from this perspective. Their role in climate is also addressed in this article. Like the oceans, the atmosphere is a global commons (Soroos, 1997) (see ***Commons, Tragedy of the***, *Volume 5). It is globally connected and air that is over one nation can easily lie over another on the next continent a day later. Recent attempts by manned balloons to circumnavigate the globe have dramatically shown how the winds can carry a balloon half way around the world in a week or less and that air currents can often take the balloon in unwanted directions. So the atmosphere belongs to no one nation; rather all nations may use it for their own purposes (such as discharging pollution into it) and thus it is also subject to abuse and the phenomenon known as the "tragedy of the commons" (Hardin, 1968) in which the best interests of an individual or individual nation may conflict with the health of the commons itself. Human influences on climate change, often referred to as "global warming," are therefore also discussed. The Earth System includes many other important processes and phenomena that are covered elsewhere in this Encyclopedia. Even in the atmosphere alone, environmental problems include ozone depletion and the "ozone hole," acid rain, air quality and pollution, and, a few decades ago, radioactivity and atomic bomb test debris. Other problems exist in the oceans and on land, such as biodiversity, deforestation, desertification, exploitation of water resources and fisheries, and so on. Many of these environmental problems can be exacerbated by climate change, so that it is the intersection of these problems and climate change that will make for major challenges in the years ahead.*

THE EARTH AND CLIMATE SYSTEM

Our planet orbits the Sun once per year at an average distance of 1.50×10^{11} m. Looking directly at the Sun, the Earth receives an average radiation of 1368 W m^{-2} at this distance. This value is referred to as the total solar irradiance; this value used to be called the "solar constant" even though it does vary by small amounts with

the sunspot cycle and related changes on the Sun (*see* Solar Irradiance and Climate, Volume 1). The Earth s shape is close to that of an oblate spheroid, with an average radius of 6371 km, but it varies from 6378 km at the equator to 6357 km at the poles. The Earth s daily rotation is about an axis with a current tilt, relative to the ecliptic plane, of 23.5°. The Earth s annual orbit around the Sun is slightly elliptical, presently bringing the Earth closest to the Sun on January 3rd (called *perihelion*). The rotation gives rise to the seasons because the Northern Hemisphere (NH) points more toward the Sun in June while it is the Southern Hemisphere s (SH) turn in late December.

The Earth also turns on its axis once per day with an angular velocity of $7{\bullet}292 \times 10^{-5}\,s^{-1}$. This rotation gives us the day–night cycle. A consequence of the Earth s roughly spherical shape and the rotation is that the average solar radiation received at the top of the Earth s atmosphere is the solar constant divided by 4, which is the ratio of the Earth s surface area ($4\pi a^2$, where a is the mean radius) to that of the cross-section (πa^2). On timescales of tens of thousands of years, the Earth s orbit slowly changes, the shape of the orbit is altered, the tilt changes, and the Earth precesses on its axis like a rotating top, all of which combine to alter the latitudinal and seasonal distribution of solar radiation received by the Earth (*see* Orbital Variations, Volume 1). These variations have been associated with the Earth s glacial cycling (*see* Milankovitch, Milutin, Volume 1).

The rotation of the Earth provides a centrifugal force outward, away from the axis of rotation. This force is greatest on the equator at the Earth s surface. Meanwhile, the equatorial bulge in the Earth s shape, which presumably arises from the rotation, provides a greater gravitational attraction than at high latitudes. Thus, it is not a coincidence that the effective net gravity at the surface, which is a combination of the actual gravitational attraction and the centrifugal force, is almost constant and at right angles to the surface, thereby allowing the Earth to be treated as a sphere for many purposes.

The Earth System can be altered by effects or influences from outside the planet, usually regarded as externally imposed. Most important are the Sun and its output, the Earth s rotation rate, Sun–Earth geometry and the slowly changing orbit, the physical make up of the Earth system such as the distribution of land and ocean, the geographic features on the land, the ocean bottom topography and basin configurations, and the mass and basic composition of the atmosphere and ocean. These components determine the mean climate, which can be affected by variations due to these natural causes. For example, a change in the average net radiation at the top of the atmosphere due to perturbations in the incident solar radiation or the emergent infrared radiation leads to a change in heating. Changes in the net incident radiation energy at the Earth s surface can occur from the changes internal to the Sun or, for example, from changes in atmospheric composition such as may arise from natural events like volcanoes, which can create a cloud of debris that blocks a portion of the incoming solar radiation. Other forcings that might be regarded as external include those arising as a result of human activities.

The internal interactive components in the climate system (Figure 1) include the atmosphere, the oceans, sea ice, the land, snow cover, land ice, and fresh water reservoirs. The greatest variations in the composition of the atmosphere involve water in various phases, which include water vapor, clouds of liquid water, ice crystal clouds, and rain, snow, and hail (*see* Hydrologic Cycle, Volume 1). However, other constituents of the atmosphere and the oceans can also change, thereby bringing considerations of atmospheric chemistry, marine biogeochemistry, and land surface exchanges into climate change.

The atmosphere is the most volatile part of the climate system; for example, winds in jet streams at about 10 km (32800 feet) altitude often exceed $50\,m\,s^{-1}$ (112 miles per hour) and sometimes even double these values. Changes in weather can occur in just a few hours. The atmosphere is quite a thin envelope around the planet, with 90% of its mass of $5{\bullet}1 \times 10^{18}$ kg within about 16 km (roughly 10 miles) of the surface (about one four hundredth the radius of the Earth). This relative shallowness of the Earth s atmosphere often allows the atmospheric motions to be considered as occurring at the Earth s surface. For example, satellite photographs of Earth appear to show clouds hugging the surface.

The atmosphere is composed of several fairly distinct layers. Immediately above the surface is the troposphere, which extends upwards to about 10 km in the extratropics and 16 km in the tropics. About 80–90% of the atmosphere is contained in the troposphere. It is defined as the layer where the temperature generally decreases with altitude and is the region where most of what we call weather occurs. The troposphere is the region where vertical air movements occur and produce clouds and precipitation in rising air and clear skies in gently subsiding air.

The second layer is the stratosphere, which extends to about 50 km in altitude. Because this is a region where temperatures generally increase with height, it is very stable, resists vertical motions, and is highly stratified (as the name implies). Many jet aircraft fly in the lower stratosphere in the relatively non-turbulent conditions above tropospheric weather systems. In this region, oxygen molecules, consisting of two oxygen atoms, are broken apart by intense solar radiation in the ultraviolet and participate in a process to form ozone molecules, in which three atoms of oxygen are combined. So the main ozone layer is contained in the stratosphere (*see* Stratosphere, Chemistry, Volume 1). Its presence shields the surface from harmful ultraviolet rays, making it possible for life to exist (*see* Ultraviolet Radiation, Volume 1).

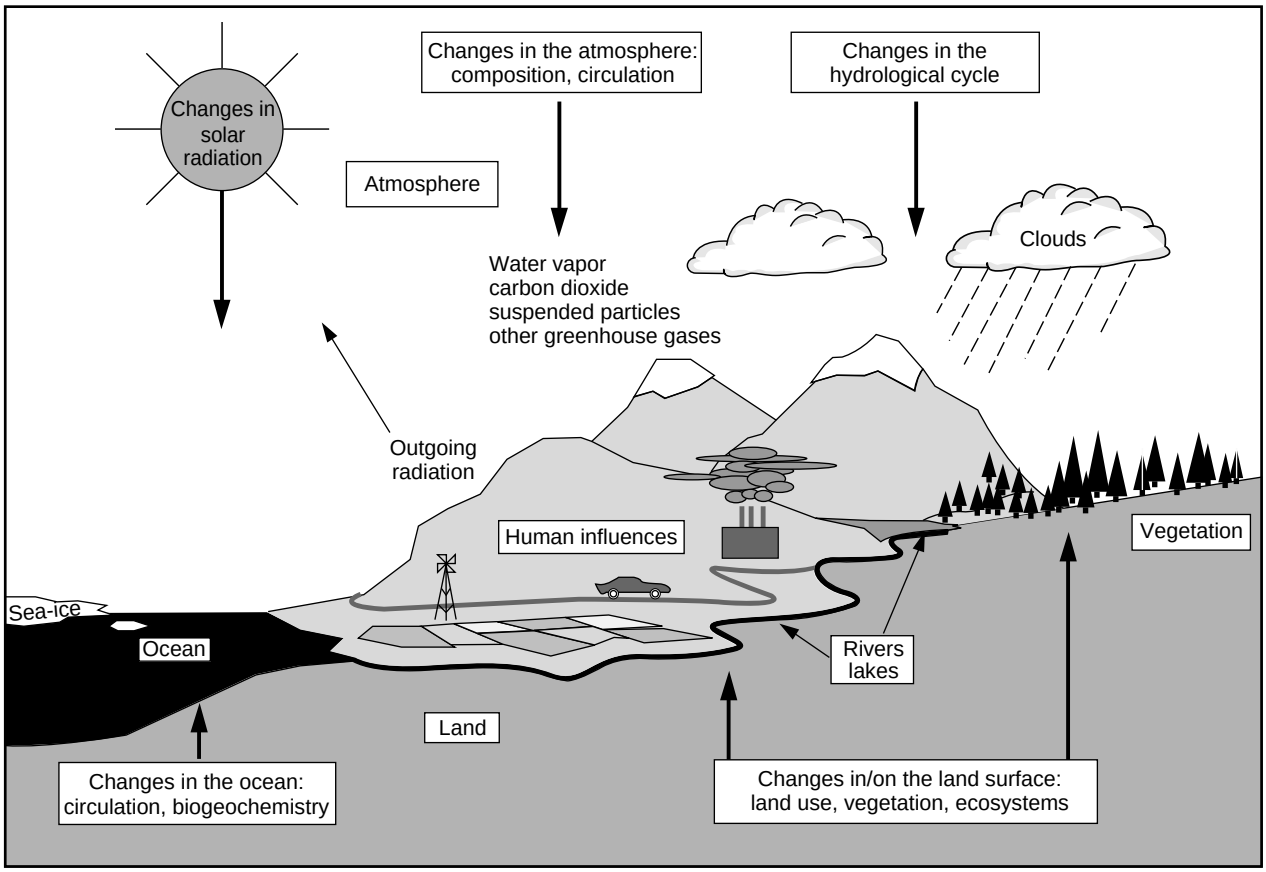

Figure 1 Schematic view of the components of the global climate system (bold), their processes and interactions (thin arrows) and some aspects that may change (bold arrows). (Adapted from Trenberth *et al.,* 1996)

Moving upward, the third atmospheric layer is the mesosphere, which extends to roughly 80 km with temperatures decreasing with altitude. Above the mesosphere is the thermosphere, in which the temperature again increases with height. The thermosphere contains only 0.01% of the atmosphere and it is in this region that atmospheric gases are ionized by energetic and short ultraviolet solar radiation, so that it includes most of the ionosphere. The ionosphere is particularly important because it influences radiowave transmission.

The other main fluid component of the climate system is the oceans. The oceans contain slightly more than 97% of the roughly $1{\bullet}3 \times 10^9\,\mathrm{km}^3$ of water on Earth. They cover 70.8% of the surface, although with a much greater fraction in the SH (80.9% of the area) than the NH (60.7%), which has substantial implications for climate. Ocean currents can be $\bullet\ 1\,\mathrm{m\,s}^{-1}$ in strong currents like the Gulf Stream, but are more typically a few $\mathrm{cm\,s}^{-1}$ at the ocean s surface. The average depth of the ocean is 3795 m. The oceans are stratified opposite to the atmosphere, with warmest waters near the surface. The cold deep abyssal ocean turns over only very slowly on time scales of hundreds to thousands of years.

Other major components of the climate system include sea ice, the land and its features (including the vegetation, albedo (reflective character), biomass, and ecosystems), snow cover, land ice (including the semi-permanent ice sheets of Antarctica and Greenland and glaciers), and rivers, lakes and surface and subsurface water. The components in the climate system (Figure 1) are shown together with the main interactions and sources of climate change.

WEATHER AND CLIMATE

For the Earth, on an annual mean basis, the excess of incoming solar radiation over outgoing longwave radiation in the tropics, and the deficit at mid to high latitudes (Figure 2), sets up an equator-to-pole temperature gradient that results, with the Earth s rotation, in a broad band of westerlies in each hemisphere in the troposphere. Embedded within the mid-latitude westerlies are large-scale weather systems which, along with the ocean, act to transport heat polewards to achieve an overall energy balance, as described below.

In the atmosphere, phenomena and events are loosely divided into the realms of weather and climate . The

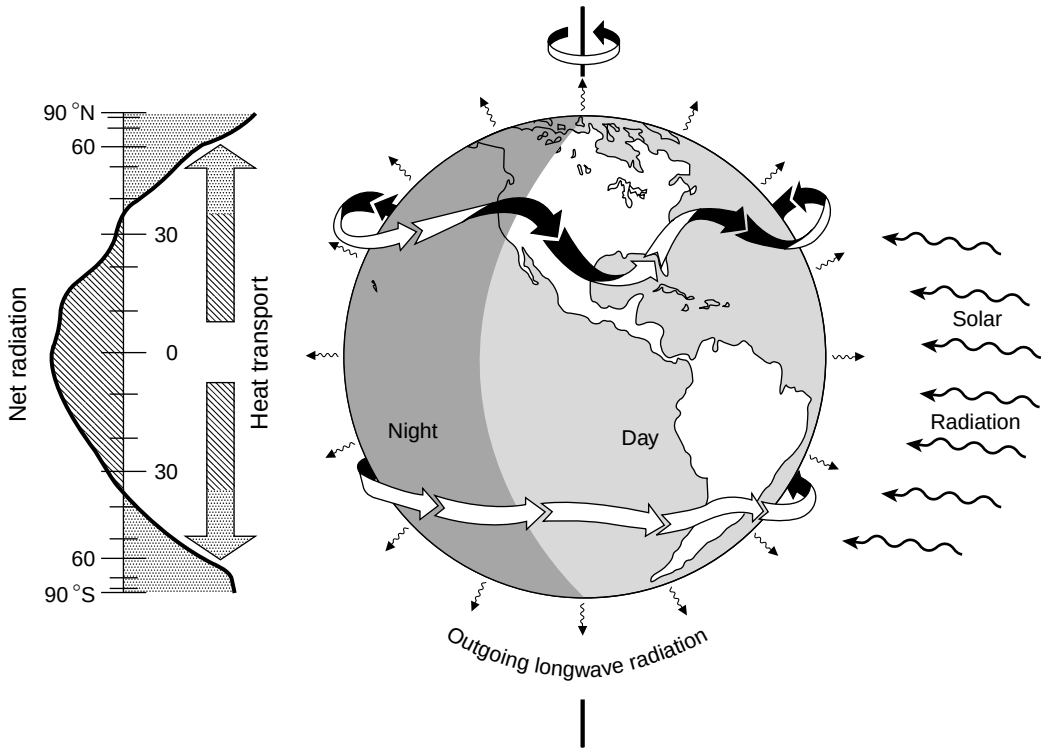

Figure 2 The incoming solar radiation (right) illuminates only part of the Earth while the outgoing longwave radiation is distributed more evenly. On an annual mean basis, the result is an excess of absorbed solar radiation over the outgoing longwave radiation in the tropics, while there is a deficit at middle to high latitudes (left), so that there is a requirement for a poleward heat transport in each hemisphere (broad arrows) by the atmosphere and the oceans. The radiation distribution results in warm conditions in the tropics but cold at high latitudes, and the temperature contrast results in a broad band of westerlies in the extratropics of each hemisphere in which there is an embedded jet stream (shown by the ribbon arrows) at about 10 km above the Earth's surface. The flow of the jet stream over the different underlying surface (ocean, land, mountains) produces waves in the atmosphere and geographic spatial structure to climate. [The excess of net radiation at the equator is 68 W m^{-2} and the deficit peaks at -100 W m^{-2} at the South Pole and -125 W m^{-2} at the North Pole; from Trenberth and Solomon, 1994]. (From Trenberth *et al.*, 1996)

large fluctuations occurring in the atmosphere from hour-to-hour and day-to-day constitute the weather. Weather is described by such elements as temperature, air pressure, humidity, cloudiness, precipitation of various kinds and winds. Weather occurs as a wide variety of phenomena ranging from small cumulus clouds to giant thunderstorms, from clear skies to extensive cloud decks, from gentle breezes to gales, from small wind gusts to tornadoes, from frost to heat waves and from snow flurries to torrential rain. Many such phenomena occur as part of much larger-scale organized weather systems that consist, in middle latitudes, of cyclones (low pressure areas or systems) and anticyclones (high pressure systems) and their associated warm and cold fronts (*see* Atmospheric Motions, Volume 1). Tropical storms (referred to as hurricanes if exceeding certain intensity (64 knots or 74 miles per hour) in many regions or typhoons in the western North Pacific) are organized, large-scale systems of intense low pressure that occur in low latitudes (*see* Hurricanes, Typhoons and other Tropical Storms - Dynamics and Intensity, Volume 1). Weather systems migrate, develop, evolve, mature, and decay over periods of days to weeks and constitute a form of atmospheric turbulence. These weather systems arise mainly from atmospheric instabilities driven by heating patterns from the Sun and their evolution is governed by nonlinear chaotic dynamics, so that they are not predictable in an individual deterministic sense beyond about two weeks into the future (*see* Chaos and Predictability, Volume 1). Examples of weather systems are the cyclones and anticyclones and associated cold and warm fronts, which arise from the equator-to-pole temperature differences (Figure 2) and thus have their origin in the Sun–Earth geometry and the distribution of solar heating. The atmosphere responds by continual attempts to reduce those temperature gradients by producing, in the NH, southerly winds to carry warm air polewards and cold northerly winds to reduce temperatures in lower latitudes, while in the SH, the southerlies are cold and the northerly winds are warm. Another example is convection, which gives

rise to the clouds and thunderstorms, driven by solar heating at the Earth s surface, that produce buoyant thermals, which rise, expand and cool, and produce rain along the way.

Climate is usually defined to be average weather and thus is thought of as the prevailing weather, which includes not just average conditions but also the range of variations. It is often described in terms of the mean and other statistical quantities that measure the variability. Climate extends over a period of time and possibly over a certain geographical region. Climate involves variations in which the atmosphere is influenced by and interacts with other parts of the climate system and the external forcings (Figure 1).

It is the sum of many weather phenomena that determines how the large-scale general circulation of the atmosphere works (i.e., the average three dimensional structure of atmospheric motion); and it is the circulation that essentially determines climate. This intimate link between weather and climate provides a basis for understanding how weather events may change as the climate changes. There are many very different weather phenomena that can take place under an unchanging climate, so a wide range of conditions occurs naturally. Consequently, even with a modest change in climate, many if not most of the same weather phenomena will still occur after the change.

This latter point can be illustrated by consideration of the mean and natural variability, and the effects of a change in the mean while leaving the variability unchanged. Many atmospheric variables, such as temperature, follow a normal (bell-shaped) frequency distribution quite closely. An example for temperature is shown in Figure 3 for a simple case where the bell-shaped distribution of anomalies of temperature, defined as departures from the mean annual cycle, is shifted to correspond to a warmer climate. For any change in mean climate, there is likely to be an amplified change in extremes. If the mean temperature is 15 °C and the standard deviation is 5 °C, 95% of the values fall within plus or minus two standard deviations, or between 5–25 °C, on a given day. Then, if the mean temperature is increased by 2.5 °C but with the same variability, there is only a small change in occurrence of temperatures near the mean. The biggest percentage change is for the extremes: the frequency of occurrence of temperatures above 25 °C increases by well over 100% while similar decreases occur

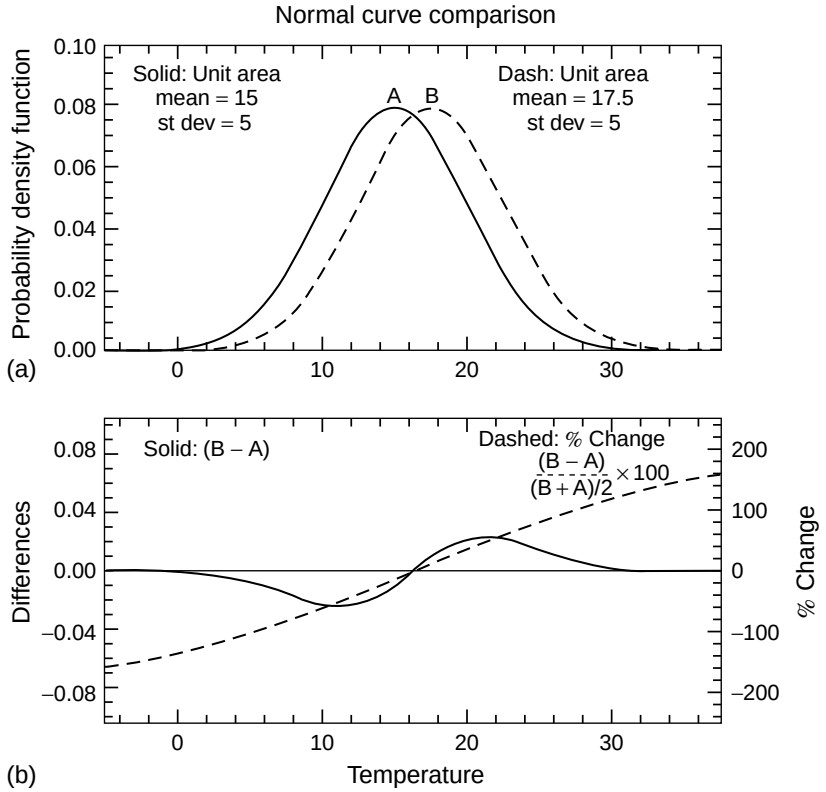

Figure 3 The two bell curves in (a) show the distribution of a climate variable (temperature in this case) before and after a climate change. The units are given in degrees Celsius. In this example, the climate change is assumed to shift the mean temperature by half a standard deviation (or 2.5 °C) but with no change in the spread of the curve (or equivalently the standard deviation, which is set to 5 °C). In (b), the differences in frequency of occurrence that result are shown as actual values (left axis) and as percentages (right axis)

for temperatures below 5 °C. The wide range of natural variability associated with day-to-day weather is the reason that we are unlikely to notice small climate changes except for the extremes.

Changes in any of the climate system components, whether internal and thus a part of the system, or from the external forcings, cause the climate to vary or to change. Thus climate can vary because of alterations in the internal exchanges of energy or in the internal dynamics of the climate system. Examples are El Niño and La Niña events, which arise from natural coupled interactions between the atmosphere and the ocean centered in the tropical Pacific. As such they are a part of the year-to-year climate and they lead to large and important systematic variations in weather patterns (events such as floods and droughts) throughout the world. Often, however, climate is taken to refer to much longer time scales – the average statistics over a 30-year period is a widespread and long-standing working definition. On these longer time scales, ENSO events vanish from mean statistics but become strongly evident in the measures of variability, such as the extremes. However, the mean climate is also influenced by the variability. These considerations become very important in the development of models of the climate system designed to serve as tools to simulate and project climate change.

THE DRIVING FORCES OF CLIMATE

The Global Energy Balance

The shortwave radiation from the Sun provides the source of energy that drives the climate. Much of this energy is in the visible part of the electromagnetic spectrum, although some incoming radiation extends beyond the red part of the spectrum into the infrared and some extends beyond the violet into the ultraviolet. As noted earlier, because of the roughly spherical shape of the Earth, at any one time half the Earth is in night (Figure 2). Because solar radiation is coming from just one direction, the average amount of energy incident at the top of the atmosphere is one quarter of the solar constant, or about 342 $W m^{-2}$. About 31% of this energy is scattered or reflected back to space by molecules, tiny airborne particles (known as aerosols) and clouds in the atmosphere, and by the Earth s surface. This leaves about 235 $W m^{-2}$ on average to warm the Earth s surface and atmosphere (Figure 4).

To balance the incoming energy, the Earth itself must radiate, on average, the same amount of energy back to space (Figure 4). It does this by emitting thermal longwave radiation in the infrared part of the spectrum. The amount of thermal radiation emitted by a warm surface depends on its temperature and on how absorbing it is. For

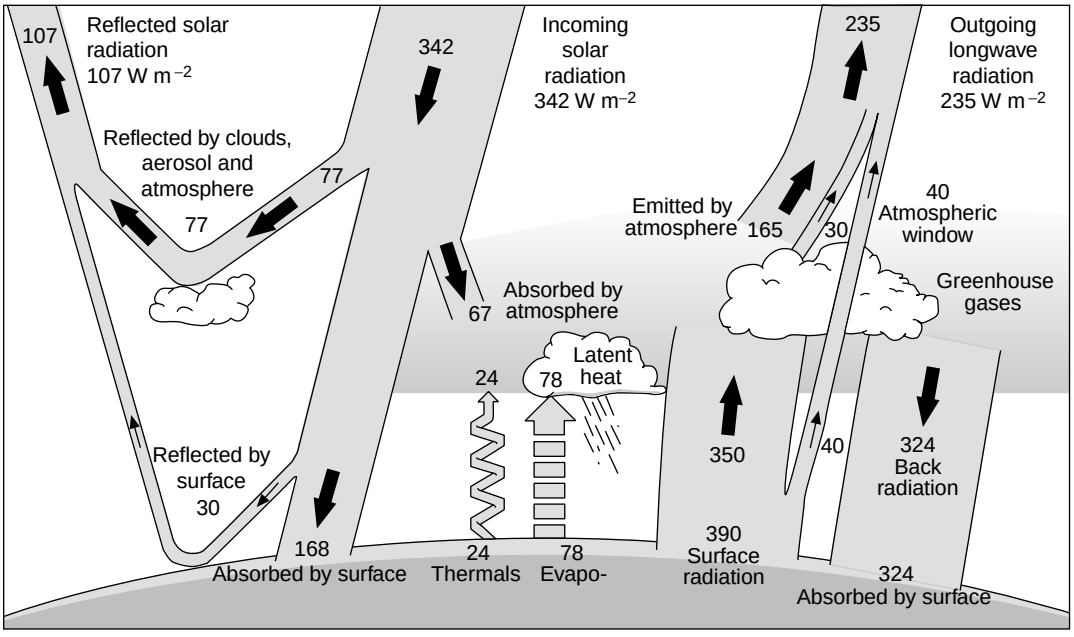

Figure 4 The Earth's radiation balance. The net incoming solar radiation of about 342 $W m^{-2}$ is partially reflected by clouds and the atmosphere, or at the surface, but 49% is absorbed by the surface. Some of that heat is returned to the atmosphere as sensible heat and most as evapotranspiration that warms the atmosphere by release of latent heat during precipitation. The rest of the energy absorbed at the surface is radiated upward as thermal infrared radiation, most of which is absorbed by the atmosphere and re-emitted both up and down, producing a greenhouse effect because the radiation lost to space comes from cloud tops and parts of the atmosphere that are much colder than the surface. (From Kiehl and Trenberth, 1997)

a completely absorbing surface to emit 235 W m^{-2} of thermal radiation, it would have a temperature of about $-19\,^{\circ}$C. This is much colder than the conditions that actually exist near the Earth s surface, where the annual average global mean temperature is about 14 °C. However, because the temperature in the troposphere falls off quite rapidly with height, a temperature of $-19\,^{\circ}$C is reached typically at an altitude of about 5 km above the surface in mid-latitudes. This provides a clue about the role of the atmosphere in making the surface climate warmer and thereby hospitable (*see* Energy Balance and Climate, Volume 1).

The Greenhouse Effect

Some of the infrared radiation leaving the atmosphere originates at or near the Earth s surface and is transmitted relatively unimpeded through the atmosphere; this is the radiation from areas where there are no clouds and which is emitted in the part of the spectrum known as the atmospheric window (Figure 4). The bulk of the radiation emitted from the surface, however, is intercepted and re-emitted both up and down. The emissions to space occur either from the tops of clouds at different atmospheric levels (which are almost always colder than the surface), or by gases present in the atmosphere that absorb and emit infrared radiation. Most of the atmosphere consists of nitrogen and oxygen (composing about 99% of dry air), which are transparent to infrared radiation. It is the water vapor, which varies in amount from 0 to about 3%, carbon dioxide and some other minor gases present in the atmosphere in much smaller quantities that absorb some of the thermal radiation leaving the surface and re-emit radiation from much higher and colder levels out to space. These radiatively active gases are known as greenhouse gases because they act as a partial blanket for the thermal radiation from the surface and enable the surface to be substantially warmer than it would otherwise be, analogous to the effects of a greenhouse. (While a real greenhouse does work this way, the main heat retention in a greenhouse comes through protection from the wind.) This blanketing is known as the natural greenhouse effect. In the current climate under clear sky conditions, water vapor is estimated to account for about 60% of the greenhouse effect, carbon dioxide 26%, ozone 8% and other gases 6% (Kiehl and Trenberth, 1997) (*see* Greenhouse Effect, Volume 1).

Effects of Clouds

Clouds also absorb and emit thermal radiation; as a result, they have a blanketing effect similar to that of the greenhouse gases. However, clouds are also bright reflectors of solar radiation and thus also act to cool the surface. While on average there is strong cancellation between the two opposing effects of shortwave and longwave cloud heating, the net global effect of clouds in our current climate, as determined by space-based measurements, is a small cooling of the surface. A key issue is how clouds will change as climate changes. This issue is complicated by the fact that clouds are also strongly influenced by particulate pollution, which tends to lead to much smaller cloud droplets, and thus makes clouds brighter and more reflective of solar radiation. These effects may also influence the timing and amounts of precipitation. In addition, if cloud altitude changes, the climate can be affected. If cloud tops get higher, the radiation to space from clouds is at a colder temperature and so this reduction in the loss of the energy from the Earth produces a warming influence. However, more extensive low clouds would be likely to produce cooling because of their high reflectivity and so their greater influence on solar radiation.

The Hydrological Cycle

The Earth contains roughly $1{\bullet}3 \times 10^9$ km^3 of water. Slightly more than 97% of the water is in the oceans and is therefore salty. The fresh water in rivers, lakes, glaciers, and underground aquifers make up roughly 36×10^6 km^3 of water. About 220 000 km^3 of fresh water is in the lakes and rivers and 12 000 km^3 is in the atmosphere. Of the fresh water, 28×10^6 km^3 is locked up frozen in ice sheets, ice caps and glaciers. Most of the ice is contained in the Antarctic ice sheet which, if melted, would increase sea level by about 65 m. By contrast, Greenland contains the equivalent of about 7 m of sea level and the other glaciers and ice caps contain about 0.5 m (*see* Glaciers, Volume 1). Most of the remaining 8×10^6 km^3 of fresh water is stored underground as ground water (*see* Hydrologic Cycle, Volume 1).

The hydrological cycle involves the transfer of water from the oceans to the atmosphere, to the land and back to the oceans, both on top of and beneath the land surface. Water is evaporated from the ocean surface, and as water vapor it is typically transported thousands of kilometers before it is taken up in clouds and weather systems and is precipitated out as rain, snow, hail or some other frozen pellet back to the Earth s surface. Over land, some precipitation infiltrates or percolates into soils and some runs off into streams and rivers. Ponds and lakes or other surface water may evaporate moisture into the atmosphere, and can also freeze so that water can become locked up for a while. The surface water weathers rocks and erodes the landscape, and replenishes subterranean aquifers. Over land, plants transpire moisture into the atmosphere.

A schematic view of the cycling of water through the climate system is given in Figure 5. This figure not only shows the main water reservoirs and the amounts in each in units of 10^3 km^3, but also gives the volumetric flows between ocean, land and atmosphere (based on results from Trenberth and Guillemot, 1998). In units of 10^3 km^3 per

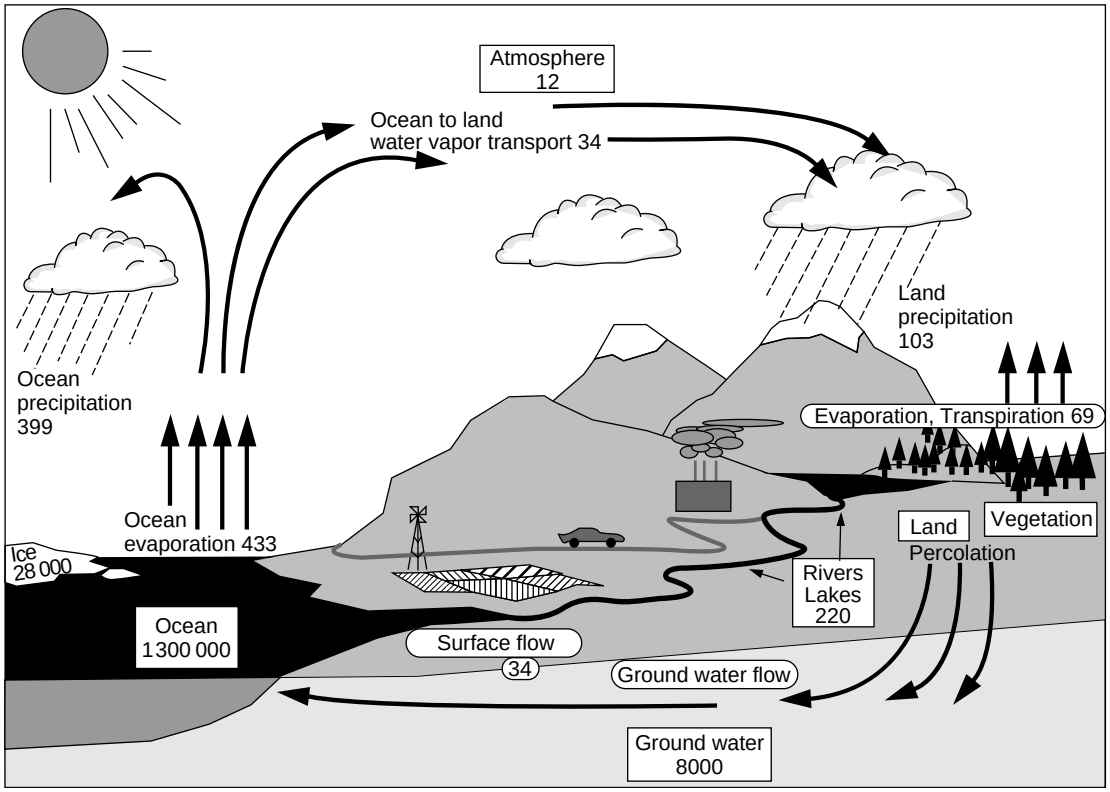

Figure 5 The hydrological cycle, showing the reservoirs of water in square boxes and amounts in units of 10^3 km^3. The figure also shows the flows of water between reservoirs (in oval boxes) in units of 10^3 km^3 year^{-1}

year, evaporation over the oceans (433) exceeds precipitation (399), leaving a net of 34 units of moisture transported onto land as water vapor. On average, this flow must be balanced by a return flow over and beneath the ground through river and stream flows, and subsurface ground water flow. Consequently, precipitation over land exceeds evapotranspiration by this same amount (34). Not surprisingly, perhaps, the average precipitation rate over the oceans exceeds that over land by 72% (allowing also for the differences in areas). It has been estimated (Trenberth, 1998) that on average over 80% of the moisture precipitated out comes from locations over 1000 km distant, highlighting the important role of the winds in moving moisture around.

The Role of Oceans

The oceans cover 70% of the Earth s surface and through their fluid motions, their high heat capacity, and their ecosystems play a central role in shaping the Earth s climate and its variability. The most important characteristic of the oceans is that they are wet and, while obvious, this is sometimes overlooked. Water vapor, evaporated from the ocean surface, provides latent heat energy to the atmosphere during the precipitation process. Wind blowing on the sea surface drives the large-scale ocean circulation in its upper layers. The ocean currents carry heat and salt along with the fresh water around the globe (*see* Ocean Circulation, Volume 1; Salinity Patterns in the Ocean, Volume 1). The oceans therefore store heat, absorbed at the surface, for varying durations and release it in different places, thereby ameliorating temperature changes over nearby land and contributing substantially to variability of climate on many time scales. Additionally, the ocean thermohaline circulation (*see* Thermohaline Circulation, Volume 1), which is the circulation driven by changes in sea water density arising from temperature (thermal) or salt (haline) effects, allows water from the surface to be carried into the deep ocean, where it is isolated from atmospheric influence and hence it may sequester heat for periods of a thousand years or more. The oceans also absorb carbon dioxide and other gases and exchange them with the atmosphere in ways that change with ocean circulation and climate change. In addition, it is likely that marine biotic responses to climate change will result in subsequent changes that may have further ramifications.

The Role of Land

The heat penetration into land occurs mainly through conduction, except where water plays a role, so that heat penetration is limited and slow. Temperature profiles taken

from bore holes into land or ice caps therefore provide a blurry coarse estimate of temperatures in years long past (see Pollack *et al.*, 1998 and Ground Temperature, Volume 1). Consequently, surface air temperature changes over land occur much faster and are much larger than over the oceans for the same heating and, because we live on land, this directly affects human activities.

The land surface encompasses an enormous variety of topographical features and soils, differing slopes (which influence runoff and radiation received) and water capacity. The highly heterogeneous vegetative cover is a mixture of natural and managed ecosystems that vary on very small spatial scales. Changes in soil moisture affect the disposition of heat at the surface and whether it results in increases in air temperature or increased evaporation of moisture. The latter is complicated by the presence of plants, which can act to pump moisture out of the root zone into the leaves, where it can be released into the atmosphere as the plant participates in photosynthesis; a process called *transpiration*. The behavior of land ecosystems can be greatly influenced by changes in atmospheric composition and climate. The availability of surface water and the use of the Sun s energy in photosynthesis and transpiration in plants influence the uptake of carbon dioxide from the atmosphere as plants transform the carbon and water into usable food. Changes in vegetation alter how much sunlight is reflected and how rough the surface is in creating drag on the winds, and the land surface and its ecosystems play an important role in the carbon cycle and fluxes of water vapor and other trace gases.

The Role of Ice

Major ice sheets, like those over Antarctica and Greenland, have a large heat capacity but, like land, the penetration of heat occurs primarily through conduction so that the mass experiencing temperature changes from year to year is small. Temperature profiles can be taken directly from boreholes into ice (see Dahl-Jensen *et al.*, 1998 for temperatures directly from boreholes in the Greenland ice sheet). The temperature profiles suggest that the upward heat flow from the underlying ground is about $51\,\mathrm{mW\,m^{-2}}$, which is very small compared to the various components of the Earth s energy balance. On century timescales, however, the ice sheet heat capacity becomes important. Unlike land, the ice can melt, which has major consequences on longer timescales through changes in sea level.

A major concern has been the possible instability of the West Antarctic Ice Sheet (WAIS) because it is partly grounded below sea level. At the present rate of accumulation, the time needed to restore the ice is estimated as over 10 000 years (Oppenheimer, 1998) so that changes are very slow and occur on millennial time scales unless an instability arises (*see also* Antarctica, Volume 1). If warming alters the grounding of the ice sheet, making it float, it becomes more vulnerable to rapid disintegration, ultimately leading to a rise in sea level of 4–6 m. The present assessment by Oppenheimer is that the risk of substantial change in WAIS contributing to major sea level rise in the 21st century is small, but the risk increases in future centuries as human-induced global climate change progresses. However, there is concern that, after a certain critical point is reached, such changes may be irreversible and unstoppable once begun.

Sea ice is an active component of the climate system and varies greatly in areal extent with the seasons, but only at higher latitudes (*see* Sea Ice, Volume 1). In the Arctic where sea ice is confined by the surrounding continents, mean sea ice thickness is 3–4 m thick and multi-year ice can be present. Around Antarctica the sea ice is unimpeded and spreads out extensively, but as a result the mean thickness is typically 1–2 m.

The Role of Heat Storage

The different components of the climate system contribute on different timescales to climate variations and change. The atmosphere and oceans are fluid systems and can move heat around through convection and advection (in which the heat is carried by the currents, whether small-scale short-lived eddies or large-scale atmospheric jet streams or ocean currents). Changes in phase of water, from ice to liquid to water vapor, affect the storage of heat. However, even ignoring these complexities, many facets of the climate can be deduced simply by considering the heat capacity of the different components of the climate system. The total heat capacity considers the mass involved as well as its capacity for holding heat, as measured by the specific heat of each substance.

The atmosphere does not have much capability to store heat. The heat capacity of the global atmosphere corresponds to that of only a 3.2 m layer of the ocean. However, the depth of ocean actively involved in climate is much greater than that. The specific heat of dry land is roughly a factor of 4.5 less than that of sea water (for moist land the factor is probably closer to 2). Moreover, heat penetration into land is limited by the low thermal conductivity of the land surface; as a result only the top two meters or so of the land typically play an active role in heat storage and release (e.g., as the depth for most of the variations over annual time scales). Accordingly, land plays a much smaller role than the ocean in the storage of heat and in providing a memory for the climate system. Similarly, the ice sheets and glaciers do not play a strong role, while sea ice is important where it forms.

The seasonal variations in heating penetrate into the ocean through a combination of radiation, convective overturning (in which cooled surface waters sink while warmer

more buoyant waters below rise) and mechanical stirring by winds. These processes mix heat through what is called the *mixed layer*, which, on average, involves about the upper 90 m of ocean. The thermal inertia of the 90 m layer can add a delay of about 6 years to the temperature response to an instantaneous change (this time corresponds to an exponential time constant in which there is a 63% response toward a new equilibrium value following an abrupt change). As a result, actual changes in climate tend to be gradual. With its mean depth of about 3800 m, the total ocean would add a delay of 230 years to the response if rapidly mixed. However, mixing is not a rapid process for most of the ocean so that in reality the response depends on the rate of ventilation of water between the well-mixed upper layers of the ocean and the deeper, more isolated layers that are separated by the thermocline (ocean layer, below the mixed layer, exhibiting a strong vertical temperature gradient). The rate of such mixing is not well established and varies greatly geographically. An overall estimate of the delay in surface temperature response caused by the oceans is 10–100 years. The slowest response should be in high latitudes where deep mixing and convection occur, and the fastest response is expected in the tropics. Consequently, the oceans are a great moderating effect on climate changes, especially changes such as those involved with the annual cycle of the seasons.

Generally, the observed variability of temperatures over land is a factor of two to six greater than that over the oceans. At high latitudes over land in winter there is often a strong surface temperature inversion whose strength is very sensitive to the amount of stirring in the atmosphere (Trenberth, 1993). Such wintertime inversions are significantly affected by human activities; for instance an urban heat island effect exceeding 10 °C has been observed during strong surface inversion conditions in Fairbanks, Alaska. Strong surface temperature inversions over mid-latitude continents also occur in winter. In contrast, over the oceans, surface fluxes of heat into the atmosphere keep the air temperature within a narrow range. Thus it is not surprising that over land, month-to-month persistence in surface temperature anomalies is greatest near bodies of water. Consequently, it is clear that for a given heating perturbation, the response over land should be much greater than over the oceans; the atmospheric winds are the reason why the observed factor is only in the two to six range.

A further example of the role of the oceans in moderating temperature variations is the contrast in the mean annual cycle of surface temperature between the NH (60.7% water) and SH (80.9% water) (Figure 6). The amplitude of the 12-month cycle between 40 and 60 °latitude ranges from • 3 °C in the SH to ∼12 °C in the NH. Similarly, in mid-latitudes from 22.5–67.5 °latitude, the average lag in temperature response relative to peak solar radiation is 32.9 days in the NH versus 43.5 days in the SH (Trenberth, 1983),

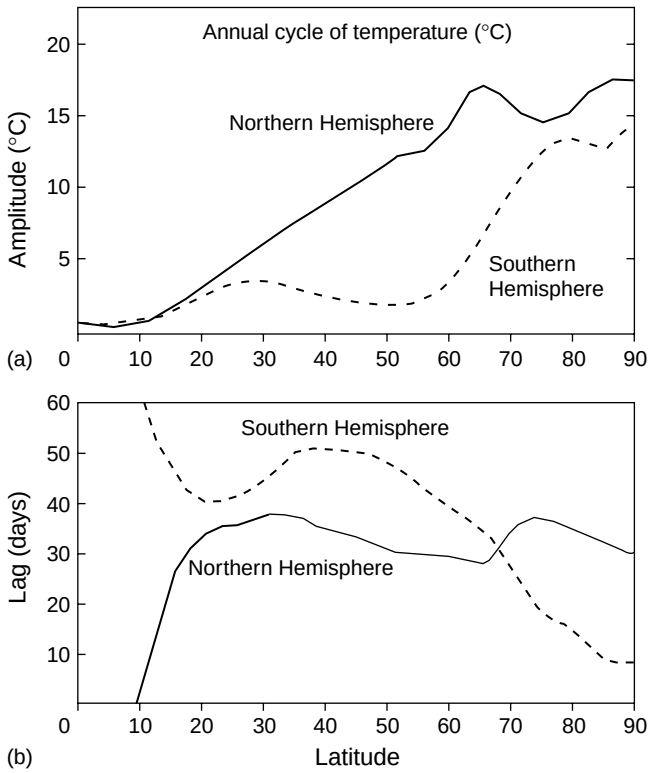

Figure 6 Amplitude of the annual cycle in zonal mean surface temperatures in °C as a function of latitude (a), and the lag of the temperature response behind the Sun in days (b). (From Trenberth, 1983)

again reflecting the difference in thermal inertia. Even the sea surface temperatures (SSTs) in the two hemispheres undergo quite different amplitudes in the annual cycle, and average SSTs are higher in the NH versus the SH at each latitude because of the land distribution and the winds that blow from land to ocean.

Atmosphere–Ocean Interaction: El Niño

Understanding the climate system becomes more complex as the components interact. El Niño events are a striking example of a phenomenon that would not occur without interactions between the atmosphere and ocean. El Niño events involve a warming of the surface waters of the tropical Pacific Ocean (*see* El Niño and La Niña: Causes and Global Consequences, Volume 1). Ocean warming takes place from the International Dateline to the west coast of South America and results in changes in the local and regional ecology. Historically, El Niño events have occurred about every 3–7 years and alternated with the opposite phases of below average temperatures in the tropical Pacific, dubbed La Niña. In the atmosphere, a pattern of change called the Southern Oscillation is closely linked with these ocean changes, so that scientists refer to the total phenomenon as ENSO (*see* El Niño/Southern

Oscillation (ENSO), Volume 1). Then El Niño is the warm phase of ENSO and La Niña is the cold phase.

The strong SST gradient from the warm pool in the western tropical Pacific to the cold tongue in the eastern equatorial Pacific is maintained by the westward-flowing trade winds, which drive the surface ocean currents and determine the pattern of upwelling of cold nutrient-rich waters in the east. Because of the Earth s rotation, easterly winds along the equator deflect currents to the right in the NH and to the left in the SH and thus away from the equator, creating upwelling along the equator. Low sea-level pressures are set up over the warmer waters while higher pressures occur over the cooler regions in the tropics and subtropics. The moisture-laden winds tend to blow toward low pressure so that the air converges, resulting in organized patterns of heavy rainfall and a large-scale overturning along the equator called the Walker Circulation (*see* Walker Circulation, Volume 1). Because convection and thunderstorms preferentially occur over warmer waters, the pattern of SSTs determines the distribution of rainfall in the tropics, and this in turn determines the atmospheric heating patterns through the release of latent heat. The heating drives the large-scale monsoonal-type circulations in the tropics, and consequently determines the winds.

If the Pacific trade winds relax, the ocean currents and upwelling change, causing temperatures to increase in the east, which decreases the surface pressure and temperature gradients along the equator, and so reduces the winds further. This positive feedback leads to the El Niño warming persisting for a year or so, but the ocean changes also sow the seeds of the event s demise. The changes in the ocean currents and internal waves in the ocean lead to a progression of colder waters from the west that may terminate the El Niño and lead to the cold phase La Niña in the tropical Pacific. The El Niño develops as a coupled ocean–atmosphere phenomenon and, because the amount of warm water in the tropics is redistributed, depleted and restored during an ENSO cycle, a major part of the onset and evolution of the events is determined by the history of what has occurred one to two years previously. This means that the future evolution is potentially predictable for several seasons in advance.

The changes in atmospheric circulation are not confined to the tropics but extend globally and influence the jet streams and storm tracks in mid-latitudes. For El Niño conditions, higher than normal sea level pressures over Australia, Indonesia, Southeast Asia, and the Philippines signal drier conditions or even droughts. Dry conditions also prevail for Hawaii, parts of Africa, and extend to the northeast part of Brazil and to Colombia. Intense rains prevail over the central and eastern Pacific, along the west coast of South America and over parts of South America near Uruguay and southern parts of the United States in winter.

OBSERVED CLIMATE CHANGE

Global aspects

We usually view the climate system from our perspective as individuals on the surface of the Earth. Just a few decades ago, the only way a global perspective could be obtained was by collecting observations of the atmosphere and the Earth s surface made at points over the globe and analyzing them to form maps of various fields, such as temperatures. The observational coverage has increased over time, but even today it is not truly global because of the sparse observations over the southern oceans and the polar regions. Earth observing satellites have changed this, as two polar-orbiting sun-synchronous satellites can provide global coverage in about six hours, and geostationary satellites provide images of huge portions of the Earth almost continuously (*see* Earth Observing Systems, Volume 1). The satellites have revealed the myriad cloud types and patterns of infinite variety, and glimpses of the surface underneath. Over land, changes in vegetation and snow cover with the seasons and from year to year can be seen. However, it is difficult to see below the ocean surface and observations in the ocean domain remain few and far between.

In the more distant past, instrumental observations are not available at all and the nature of the weather and climate has to be estimated from proxy indicators (*see* Natural Records of Climate Change, Volume 1). These are organisms that are known to be sensitive to changes in temperature and precipitation, such as trees (through the width and composition of annual tree rings), corals (through annual layers in coral colonies), glaciers (through annual layers of snow and ice), and deposits of small organisms and pollen from plants or land dust on the bottoms of lakes and in marine sediments in oceans. Such fossil indicators can give some estimate of past climate, although the geographical coverage diminishes rapidly the further back in time we go because the most recent ice age obliterates the evidence of the earlier ones.

Even for instrumental observations, the long time-series of high quality observations needed to discern small changes are often compromised by spurious effects, and special care is required in interpretation. Most observations have been made for other purposes, such as weather forecasting, and therefore typically suffer from changes in instrumentation, instrument exposure, measurement techniques, station location and observation times, and in the general environment (such as the building of a city around the measurement location) and there have been major changes in distribution and numbers of observations. Adjustments must be devised to take into account all these influences in estimating the real changes that have occurred.

Analysis of observations of surface temperature show that there has been a global mean warming of about 0.7 °C

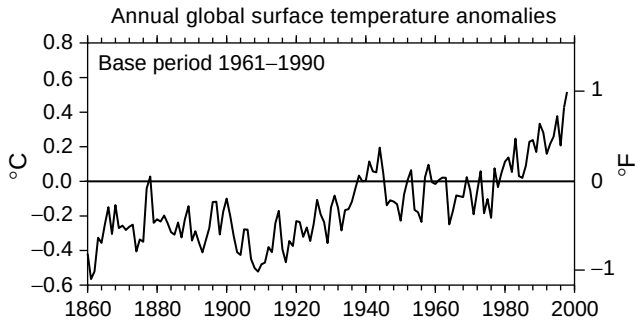

Figure 7 Global annual mean temperatures from 1860–1998 as departures from the 1961–1990 means. (Courtesy Jim Hurrell, adapted from data provided by Hadley Centre, UKMO, and Climate Research Unit, University East Anglia)

over the past one hundred years (*see* The Global Temperature Record, Volume 1); see Figure 7 for the instrumental record of global mean temperatures. The warming became noticeable from the 1920s to the 1940s, leveled off from the 1950s to the 1970s and took off again in the late 1970s. The calendar year 1998 was by far the warmest on record, exceeding the previous record held by 1997. The 1990s were the warmest decade on record. Information from paleodata further indicates that these years are the warmest in at least the past 1000 years, which is as far back as a hemispheric estimate of temperatures can be made (Mann *et al.*, 1999 and *see* Little Ice Age, Volume 1; Medieval Climatic Optimum, Volume 1). The melting of glaciers over most of the world and rising sea levels confirm the reality of the global temperature increases. The observed trend for a larger increase in minimum than maximum temperatures is linked to the associated increases in low cloud amount and aerosol as well as the enhanced greenhouse effect (Dai *et al.*, 1998). There is good evidence for decadal changes in the atmospheric circulation and some evidence for ocean changes. Changes in precipitation and other components of the hydrological cycle vary considerably geographically. Changes in climate variability and extremes are beginning to emerge, but global patterns are not yet apparent.

Changes in climate have occurred in the distant past as the distribution of continents and their landscapes have changed, as the so-called Milankovitch changes in the orbit of the Earth and the Earth s tilt relative to the ecliptic plane have varied the insolation received on Earth, and as the composition of the atmosphere has changed, all through natural processes (*see* Earth System History, Volume 1; Orbital Variations, Volume 1). Recent evidence from ice cores drilled through the Greenland ice sheet (e.g., Bond *et al.*, 1997) have indicated that changes in climate may often have been quite rapid and large, and not associated with any known external forcings (*see* Climate Change, Abrupt, Volume 1). Understanding the spatial scales of this variability and the processes and mechanisms involved is very important as it seems quite possible that strong non-linearities may be involved that result in large changes from relatively small perturbations by provoking positively reinforcing feedback processes in the internal climate system. Changes in the thermohaline circulation in the Atlantic Ocean are one way such abrupt changes might be realized (*see* Thermohaline Circulation, Volume 1). An important question therefore is whether there might be prospects for major surprises as the climate changes.

Spatial Structure of Climate and Climate Change

Because of the land/ocean contrasts and obstacles such as mountain ranges, the mid-latitude westerly winds and the embedded jet stream in each hemisphere contain planetary-scale waves (Figure 2). These waves are usually geographically anchored but can change with time as heating patterns change in the atmosphere. A consequence is that anomalies in climate on a seasonal time scales typically occur over large geographic regions with surface temperatures both above and below normal in different places. The same is true even on much longer time scales. Figure 8 shows that the recent warming has been largest over most of the northern continents, much less over the eastern half of the US, and with cooling over the North and South Pacific and North Atlantic (Trenberth and Hurrell, 1994; Hurrell, 1996; Trenberth and Hoar, 1996, 1997). These changes are known to be dominant in the northern winter and associated with changes in the atmospheric circulation and influences such as El Niño. On a year by year basis, extensive regions of both above and below normal temperatures are the rule, not the exception, as should clearly be expected from the wave motions in the atmosphere.

Temperatures vary enormously on all space and time scales. At individual locations there is a large diurnal cycle, e.g., at Boulder, Colorado (at 40 °N in the central US) from $-7\,^{\circ}$C to $+7\,^{\circ}$C in early January and 15 °C to 30 °C in mid-July. There is also a large annual cycle in daily-average temperature, in this case a 23 °C range. The standard deviation is a measure of the variability. A rule of thumb is that 95% of values fall within ± 2 times the standard deviation and 68% of the values fall within ± 1 standard deviation of the mean. The standard deviation of daily temperature anomalies at Boulder is 4.5 °C while for monthly means, the value drops to 2.1 °C as the vagaries of day to day weather are averaged out. Note that for the daily values, in this case, 71% fall within ± 1 standard deviation of the mean and there are some extreme values well outside ± 2 standard deviations. Both situations arise from the annual cycle, which exhibits much less variability in summer and much greater variability in winter. Spatial averages also average out the pluses and minuses, as illustrated in Figure 9, which presents the

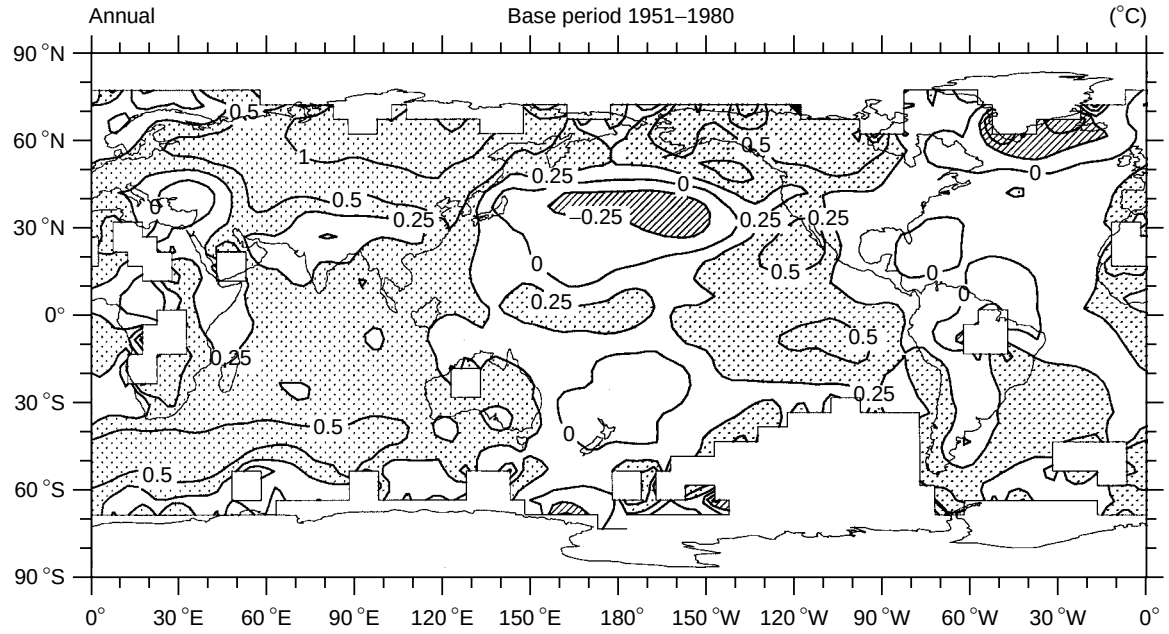

Figure 8 Annual mean surface temperature anomalies for the period 1981–1997 relative to a baseline set of temperatures for 1951–80 . (Courtesy J. Hurrell, adapted from data provided by Hadley Centre, UKMO, and CRU, University East Anglia)

monthly temperature anomalies for Boulder, Colorado, the US, and the globe. For the US as a whole the standard deviation is 1.2 °C and for the globe it is 0.24 °C. Only in the latter is the global warming really apparent. It becomes even clearer in yearly averages (Figure 7).

Figure 9 shows that small trends in global mean values are not readily perceived in regional or local values, simply because of the large natural weather-related variability; this has implications for predictability. The latter depends on the size of the signal from some climate forcing versus the noise of natural variability. As indicated above, the noise (variability) is large locally but can be reduced by spatial and temporal averaging. Consequently, random weather variations mean that local predictions for a month are less reliably determined than averages over large areas and over longer times.

ANTHROPOGENIC CLIMATE CHANGE

Human Influences

Climate can vary for multiple reasons and, in particular, human activities can lead to changes in several ways. There have been major changes in land use over the past two centuries. Conversion of forest to cropland, in particular, has led to a higher albedo in places such as the eastern and central US and changes in evapotranspiration, both of which have probably cooled the region, in summer by perhaps 1 °C and especially in autumn by more than 2 °C, although global effects are less clear (Bonan, 1997, 1999). In cities, the building of concrete jungles allows heat to be soaked up and stored during the day and released at night, moderating nighttime temperatures and contributing to an urban heat island. Space heating also contributes to this effect. Urbanization changes also affect the runoff of water, leading to drier conditions unless compensated by the cooling influences of water usage and irrigation. However, these influences, while causing real changes in urban areas, are quite local. Widespread irrigation on farms can have more regional effects, and so management and storage of water in general is important.

Combustion of fossil fuels not only generates carbon dioxide and heat, but also generates particulate pollution (e.g., soot, smoke) as well as gaseous pollution that can become particulates (e.g., sulfur dioxide, nitrogen dioxide; which get oxidized to form tiny sulfate and nitrate particles) (*see* Aerosols, Troposphere, Volume 1). Other gases, such as carbon monoxide, are also formed in burning and, as a result, the composition of the atmosphere is changing. Several other gases, notably methane, nitrous oxide, the chlorofluorocarbons (CFCs) and tropospheric ozone are also observed to have increased from human activities (especially from biomass burning, landfills, rice paddies, agriculture, animal husbandry, fossil fuel use, leaky fuel lines, and industry), and these are all greenhouse gases. However, the observed decreases in lower stratospheric ozone since the 1970s (*see* Stratosphere, Ozone Trends, Volume 1), caused principally by human-introduced CFCs and halons, contribute to a small cooling in that region (Intergovernmental Panel on Climate Change (IPCC), 1994).

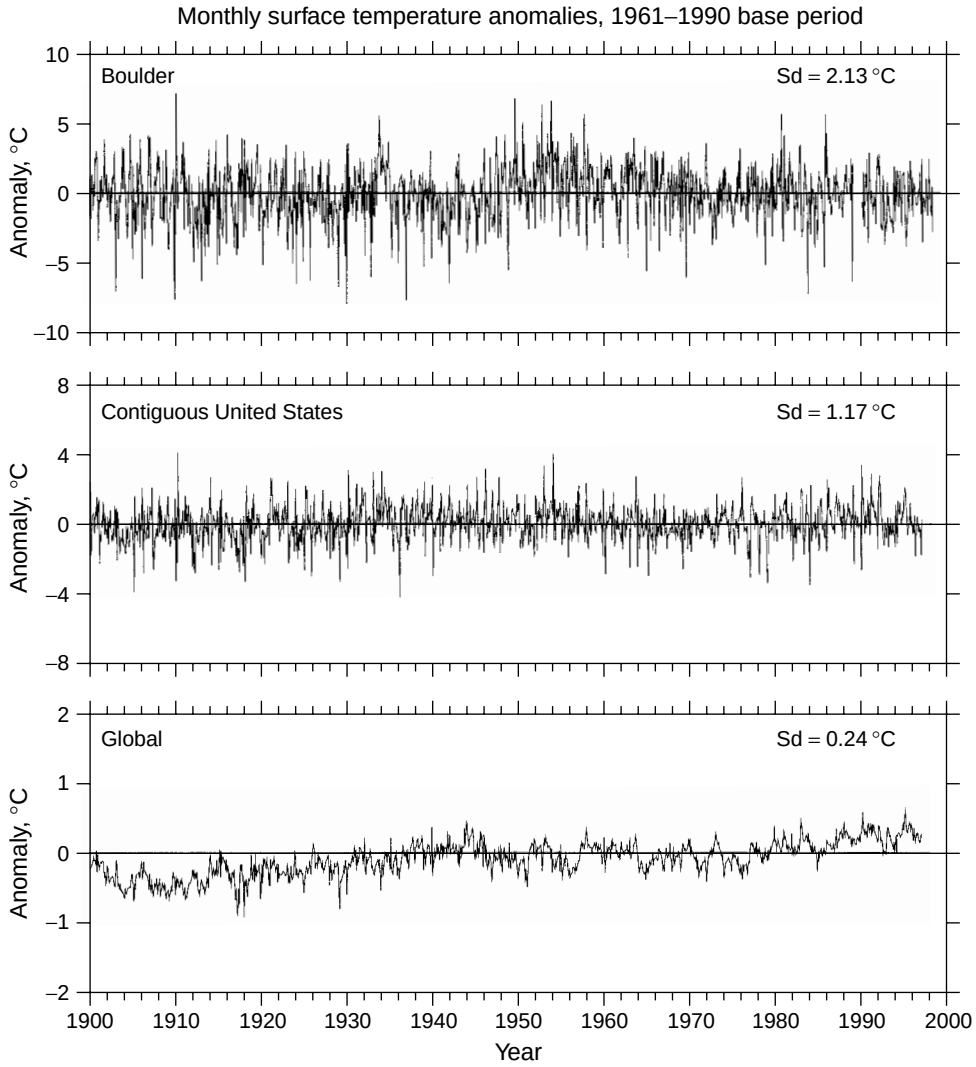

Figure 9 Monthly temperature anomalies for Boulder, Colorado, the US and the globe. The standard deviations (Sd) are listed as 2.13 °C for Boulder, 1.17 °C for the US and 0.24 °C for the globe. The anomalies, defined as departures from the mean annual cycle, are relative to the 1961–90 base period

The Enhanced Greenhouse Effect

The amount of carbon dioxide in the atmosphere has increased by more than 30% over the past two centuries since the beginning of the Industrial Revolution, an increase that is known to be due largely to combustion of fossil fuels and the removal of forests (*see* Carbon Dioxide, Recent Atmospheric Trends, Volume 1). Most of this increase has occurred since World War II. Because carbon dioxide is recycled through the atmosphere many times before it is finally removed from the active atmosphere-ocean-vegetation resevoirs, the excess concentration has a lifetime exceeding a hundred years. As a result, continuing emissions will lead to a continuing build-up in the atmospheric concentrations. In the absence of controls, future projections are that the rate of increase in carbon dioxide emissions (*see* Trends in Global Emmisions: Carbon, Sulfur, and Nitrogen, Volume 3) may accelerate and concentrations could double their pre-industrial values within the next sixty or so years (IPCC, 1994). Effects of implementing the Kyoto Protocol of 1997 (*see* United Nations Framework Convention on Climate Change and Kyoto Protocol, Volume 4) are quite uncertain but may delay doubling of pre-industrial values by perhaps 15 years (Wigley, 1998), and thus would buy time but would not solve the problem.

Effects of Aerosols

Human activities also affect the amount of aerosol in the atmosphere, which influences climate in other ways. The main direct effect of aerosols is the scattering of some solar radiation back to space; which tends to cool the Earth s

surface. Aerosols can also influence the radiation budget by directly absorbing solar radiation leading to local heating of the atmosphere and, to a lesser extent, by absorbing and emitting thermal radiation. A further influence of aerosols is that many of them act as nuclei on which cloud droplets condense. A changed concentration therefore tends to affect the number and size of droplets in a cloud and hence alters the reflection and the absorption of solar radiation by the cloud. Recent evidence highlights the possible importance of this effect, although the magnitude is very uncertain (Hansen *et al.*, 1997 and *see* Aerosols, Effects on the Climate, Volume 1).

Aerosols occur in the atmosphere from natural causes; for instance, they are blown off the surface of deserts or dry regions. The eruption of Mt. Pinatubo in the Philippines in June 1991 added considerable amounts of aerosol to the stratosphere (*see* Aerosols, Stratosphere, Volume 1; Volcanic Eruption, Mt. Pinatubo, Volume 1), which for about two years, scattered solar radiation leading to a loss of radiation at the surface and a cooling there. Human activities contribute to aerosol particle formation mainly through injection of sulfur dioxide into the atmosphere (which contributes to acid rain) particularly from power stations and through biomass burning.

Because aerosols resulting from human activities typically remain in the atmosphere for only a few days, they tend to be concentrated near their sources, such as near and downwind of industrial regions. The cooling therefore exhibits a very strong regional pattern, and the presence of aerosols adds further complexity to possible climate change as it can help mask, at least temporarily, global warming arising from increased greenhouse gases. However, the aerosol effects do not cancel the global-scale effects of the much longer-lived greenhouse gases, and significant climate changes can still result.

CLIMATIC RESPONSE

Feedbacks

We use the global warming as a specific example of climate change to highlight the issues of determining a climatic response to a particular climate forcing. Determining the climatic response to a change in the radiative forcing is complicated by feedbacks. Some of these can amplify the original warming (positive feedback) while others serve to reduce it (negative feedback) (*see* Climate Feedbacks, Volume 1).

If, for instance, the amount of carbon dioxide in the atmosphere were suddenly doubled, but with other things remaining the same, the outgoing long-wave radiation would be reduced by about $4\,\mathrm{W\,m^{-2}}$ and this energy would be trapped in the surface–atmosphere system. To restore the radiative balance, the surface–atmosphere system must warm up. In the absence of other changes, the warming at the surface and throughout the troposphere would be about $1.2\,^{\circ}\mathrm{C}$. In reality, many other factors will change, and various feedbacks come into play, so that the best estimate of the average global warming for doubled carbon dioxide is $2.5\,^{\circ}\mathrm{C}$ (IPCC, 1990, 1995). In other words the net effect of the feedbacks is positive and roughly doubles the response otherwise expected.

Increased heating therefore leads naturally to expectations for increases in global mean temperatures (often mistakenly thought of as global warming), but other changes in weather are also important. Increases in greenhouse gases in the atmosphere produce global warming through an increase in downwelling infrared radiation, and thus not only increase surface temperatures but also enhance the hydrological cycle because much of the heating at the surface goes into additional evaporation of surface moisture. Global temperature increases signify that the water-holding capacity of the atmosphere increases and, together with enhanced evaporation, this means that the actual atmospheric moisture increases (*see* Water Vapor: Distribution and Trends, Volume 1), as is observed to be happening in many places (Trenberth, 1998). It follows that naturally occurring droughts are likely to be exacerbated by enhanced drying. Thus droughts, such as those set up by El Niño, are likely to start sooner, plants will wilt sooner, and the droughts may become more extensive and last longer with global warming. Once the land is dry, then all the solar radiation goes into raising temperature, bringing on sweltering heat waves.

Further, globally there must be an increase in precipitation to balance the enhanced evaporation. The presence of increased moisture in the atmosphere implies stronger moisture flow converging into all precipitating weather systems, whether they are thunderstorms, or extratropical rain or snowstorms. This leads to the expectation of enhanced rainfall or snowfall events, which is also observed to be happening (Karl and Knight, 1998; Trenberth, 1998).

The main positive feedback thus comes from water vapor as the amount of water vapor in the atmosphere increases as the Earth warms and, because water vapor is an important greenhouse gas, it amplifies the warming. However, increases in cloud may act either to amplify the warming through the greenhouse effect of clouds or reduce it by the increase in albedo; which effect dominates depends on the height and type of clouds, and varies greatly with geographic location and time of year (*see* Cloud- Radiation Interactions, Volume 1). Ice-albedo feedback probably leads to amplification of temperature changes in high latitudes. It arises because decreases in sea ice and snow cover, which have high albedo, decrease the radiation reflected back to space and thus produces warming that may further decrease the sea ice and snow cover extent. However, increased open water may lead to more

evaporation and atmospheric water vapor, thereby increasing fog and low cloud amount, offsetting the change in surface albedo.

Other more complicated feedbacks may involve the atmosphere and ocean, e.g., cold waters off of the western coasts of continents (such as California or Peru) encourage development of extensive low stratocumulus cloud decks which block the Sun and this helps keep the ocean cold. A warming of the waters, such as during El Niño, could eliminate the cloud deck and lead to further sea surface warming because of an increase in solar radiation. El Niño itself involves strong positive and negative feedbacks that are the essence of this natural phenomenon. Warming of the oceans from increased carbon dioxide may diminish the ability of the oceans to continue to take up carbon dioxide, thereby enhancing the rate of change.

A number of feedbacks involve the biosphere and are especially important when considering details of the carbon cycle and the impacts of climate change. For example, in wetland soils rich in organic matter, such as peat, the presence of water limits oxygen access and creates anaerobic microbial decay, which releases methane into the atmosphere. If climate change acts to dry the soils, aerobic microbial activity develops and produces enhanced rates of decay, which releases large amounts of carbon dioxide into the atmosphere. Similarly, in areas of permafrost, natural gas hydrates (*see* Methane Clathrates, Volume 1), which are a crystalline form of water and mostly methane, can be destabilized by permafrost melting, releasing methane or carbon dioxide into the atmosphere, depending on the nature of the associated microbial activity that develops. Empirical evidence from ice cores reveals very strong parallel changes in temperatures, carbon dioxide and methane over the past 400 000 years through the major glacials and interglacials, suggesting that atmospheric concentrations of these greenhouse gases somehow responded to the climate changes underway and reinforced the changes through positive feedbacks. Much remains to be learned about these feedbacks and their possible influences on predictions of future carbon dioxide concentrations and climate.

Modeling of Climate

To quantify the response of the climate system to changes in forcing it is essential to account for all the complex interactions and feedbacks among the climate system components and this is done using numerical models of the climate system based upon well established physical principles. Global climate models include representations of all processes indicated in Figure 1. With comprehensive climate models, experiments can be run with and without increases in greenhouse gases and also other influences, such as changes in aerosols. The best models encapsulate the current understanding of the physical processes involved in the climate system, the interactions, and the performance of the system as a whole. They have been extensively tested and evaluated using observations (*see* Model Simulations of Present and Historical Climates, Volume 1; Projection of Future Changes in Climate, Volume 1). While models are exceedingly useful tools for carrying out numerical climate experiments, they are not perfect, and so have to be used carefully (Trenberth, 1997).

Attribution of Climate Change

It is desirable to examine and evaluate the past observational record by running models forced with realistic radiative forcing, although the latter is not that well known. It is in this way that models can be further tested and it may be possible to attribute the observed changes to particular changes in forcing, such as from volcanic or solar origins, and to achieve detection of the effects of human activities and specifically the effects from increases in aerosols and greenhouse gases.

Examining observed changes and comparing with the signature provide by models may enable attribution of the changes to the changes in atmospheric composition, and in 1995 the Intergovernmental Panel on Climate Change (IPCC) assessment concluded that the balance of evidence suggests that there is a discernible human influence on global climate . Since then the evidence has become stronger (*see* Climate Change, Detection and Attribution, Volume 1).

For the observational temperature record (Figure 7), the best evidence compiled to date suggests that solar variability has played a small role but has contributed to some of the warming of the twentieth century – perhaps 0.2 °C – up to about 1950 (Cubasch *et al.*, 1997). Changes in aerosols in the atmosphere, both from volcanic eruptions, from increased visible pollutants and their effects on clouds have also contributed to reduced warming, perhaps by a couple of tenths of a degree C (Hansen *et al.*, 1993). Some year-to-year fluctuations may have arisen from volcanic debris, such as the temporary cooling in 1991 and 1992 following the eruption of Mount Pinatubo in June 1991 (Hansen *et al.*, 1997). Heavy industrialization following World War II may have contributed to the plateau in global temperatures from 1950–1970 or so. Natural fluctuations arising from interactions between the atmosphere and the oceans have probably also contributed to decadal fluctuations of perhaps as much as 0.1 °C in global mean temperatures, and El Niños contribute to the interannual variations, typically of one or two tenths degree C warming. It is only after the late 1970s that global warming from increases in greenhouse gases has probably emerged as a clear signal in global temperatures.

Projection of Climate Change

When a model is employed for projecting changes in climate it is first run for many simulated decades without any changes in external forcing in the system. The quality of the simulation can then be assessed by comparing the mean, the annual cycle and the variability statistics on different time scales with observations of the climate. In this way the model is evaluated (*see* Model Simulations of Present and Historical Climates, Volume 1). The model is then run with changes in external forcing, such as with a possible future profile of greenhouse gas concentrations. The differences between the climate statistics in the two simulations provide an estimate of the accompanying climate change. However, definitive projections of possible local climate changes, which are most needed for assessing impacts, are the most challenging to do with any certainty.

Projections have been made of future global warming effects based upon model results to the year 2100 (*see* Projection of Future Changes in Climate, Volume 1). Because the actions of humans are not predictable in any deterministic sense, future projections necessarily contain a what if emissions scenario. In addition, for a given scenario, the rate of temperature increase depends on the model and features such as how clouds are depicted, so that a range of possible outcomes exists. The IPCC projections (IPCC, 1996) for a mid-range emissions scenario in which carbon dioxide concentrations approximately double 1990 values by the year 2100 produces global mean temperature increases ranging from 1.3 to 2.9 °C above 1990 values with a best estimate of about 2 °C. However, somewhat larger temperature increases have been projected in the IPCC s Third Assessment Report (IPCC, 2001) as a result of projections that sulfur dioxide emissions are likely to be controlled. Note that while these projections include crude estimates of the effects of sulfate aerosol they deliberately omit other possible human influences such as changes in land use. A major concern is that the projected rates of climate change will exceed anything seen in nature in the past 10 000 years.

Earth System History

W RICHARD PELTIER

University of Toronto, Toronto, Canada

In our collective effort to better understand the changes in the global environment that humankind has begun to induce, the end state of which we are as yet unable to clearly discern, it is vital that we establish an appropriate context in which to appreciate the magnitude of our in uence. This requires an appreciation of the history of Earth's evolution and knowledge of the processes that have controlled it. Only by re ection upon the nature and rates of environmental changes that have occurred naturally, in the absence of human in uence, since the planet rst formed, will we be able to appreciate how truly unprecedented are the changes we seem to have initiated. This article is therefore directed towards providing a review of existing knowledge of the evolution of the Earth system, not only of the variability of surface climate through time, but also of the changing properties of the surface itself and of the solar stimulus through which climate is most signi cantly controlled. Of fundamental concern in this discussion will be the issue of the way in which carbon dioxide, a primary greenhouse gas, has covaried with the dynamical state of solid Earth itself and the evidence from a variety of geological archives as to how surface climate responded to these variations. The existing lack of a consensus explanation of the co-evolution of continental ice volume and atmospheric carbon dioxide concentration constitutes one of the most signi cant outstanding problems in paleoclimatology.

EARTH FORMATION AND THERMOCHEMICAL HISTORY: GEODYNAMIC CONTROLS

The fact that Earth formed approximately 4.56 billion years ago (Ga) by accretion of dust and planitesimal sized objects out of the primordial solar nebula is no longer disputed. Detailed simulations of the accretion process strongly suggest that this occurred on a time scale of approximately 100 million years, rapidly enough that internal temperatures were raised sufficiently close to (or above) the melting point that gravitational differentiation of the elemental composition could occur. This composition is well approximated by that of those meteorites called type II carbonaceous chondrites, which continue to infall to the Earth s surface as subtle reminders of the mechanism through which the planet was born. Following this relatively rapid process of Earth formation, the internal structure of the planet was very similar to that which exists at present and which has come to be extremely well understood on the basis of detailed interpretations of the elastic waves that are generated by the occurrence of earthquakes. This structure (see Figure 1) consists of a primarily iron core containing a small quantity of a light alloying element such as silicon, the innermost part of which is solid and the outer part of which is liquid, surrounded by a solid iron-magnesium silicate mantle and an overlying crust. During the entire process of Earth formation, which occurred simultaneously with the formation of the other planets (both terrestrial and gas giant planets) in our solar system, the Sun itself was already burning brightly. It had formed through gravitational collapse of most of the hydrogen gas that comprised the original nebula, most of the rest having coalesced to form the gas giant Jupiter and Saturn. The Sun has existed for approximately 4.6 billion years. In what follows we will have reason to understand that a main sequence star such as our Sun burns ever more brightly as it ages, and the hydrogen gas in its core is thereby transformed into helium.

The Earth s surface, the stage upon which modern global change is occurring, has always been an extraordinarily unstable platform. This is extremely well documented on the basis of the geological investigations that have been conducted over the past two centuries. That the Earth s surface is in a state of high agitation is clear on the basis of observations of the process of continental drift and plate tectonics (*see* Plate Tectonics, Volume 1). Figure 2 illustrates the current state of surface kinematic motions of the twelve plates, into which the surface of the Earth may be divided. In the interiors of these plates the motion of the surface crust is primarily that of a rigid body with the motion being characterized by a constant angular velocity around a fixed pole of rotation. In a frame of reference in

which the collectivity of plates exhibits no net rotation, the relative velocities of the plates vary between approximately 10 cm year^{-1} and 2 cm year^{-1} with an average value of approximately 4 cm year^{-1}. This kinematic depiction of the process of surface plate tectonics was originally inferred on the basis of geological information, specifically from the alternately normal and reversed polarization of the magnetic anomalies of known age which are observed to run parallel to mid-ocean ridges. However, within the past two decades it has been confirmed in detail using the space geodetic technique of very long baseline (radio) interferometry (VLBI) in which arrays of radio telescopes are employed to accurately measure the relative motion of points on the Earth s surface.

A major accomplishment of the past several decades of research in the area of solid Earth geophysics has been to establish that it is through the process of thermal convection in Earth s mantle that the surface plate tectonic

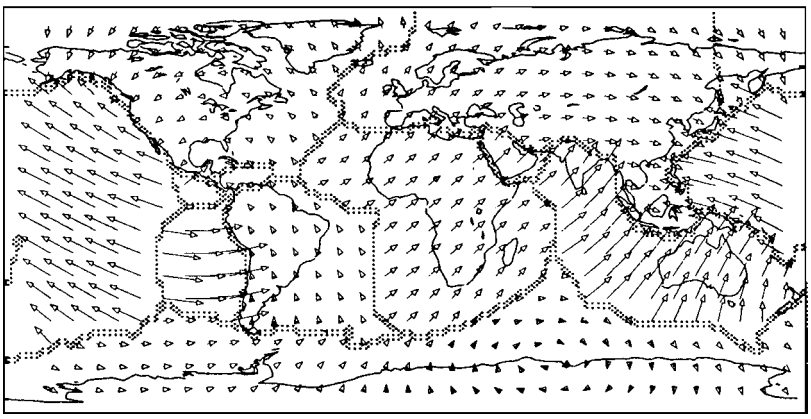

Figure 2 Tangential velocities of material at the Earth's surface in the no net rotation frame of reference based upon a standard geologically derived surface plate reconstruction. Regions of convergence correspond to deep ocean trenches (subduction zones) and regions of divergence correspond to mid-ocean ridges

process described above is maintained. Figure 3 illustrates this physical process through a sequence of depictions of the internal temperature field of the mantle, from a spherical axially symmetric model of the convection process that span a simulated time interval of several 100 million years. Clearly evident on the basis of this simulation is the occurrence of avalanche like events during which intense downwellings of cold material occur across the Spinel post Spinel phase transformation at 660 km depth in the Earth that marks the boundary between the lower mantle and the overlying transition zone (see Figure 1). One of the most recent discoveries concerning the physics of the mantle convection process concerns this influence of the endothermic transformation upon the circulation of the mantle, which drives the motion of the surface plates. This influence is such as to cause the circulation to develop a highly intermittent form in which relatively long periods of quiescence, during which the circulation is significantly layered, are followed by relatively brief periods of highly energetic activity that are triggered by the avalanche-like process and during which the flow is negligibly layered.

Figure 4 presents an early histogram of the number of radiometrically dated rock samples from the surface of the continents as a function of sample age. This figure strongly suggests that the real Earth has undergone a process of thermal and chemical evolution, which is characterized by a degree of intermittency that is very similar to that exhibited by the numerical model from which snapshots of the internal mantle temperature field are shown in Figure 3. The histogram in Figure 4 is therefore indicative of the temporal variability of the process through which continental crust is created by the irreversible differentiation of mantle material. This process involves melting and volcanic outgassing and leads to the creation of continental crust that is strongly enriched in the large ionic radii lithophile elements, included among which are the radioactive elements uranium, thorium and potassium. The episodicity evidenced in this histogram, of the time dependence of the process of crust formation (and thus volcanic out-gassing), is to be interpreted as being controlled by or at least closely connected to, the so-called Wilson cycle of supercontinent creation and destruction. This cycle refers to the fact, now well established on the basis of paleomagnetic and geological evidence that, at various times in the past, all or most of the continental fragments were collected together to form so-called supercontinents. Referring to the conventional geological time scale shown on Figure 5, the most recent epoch during which this occurred was during the Carboniferous period approximately 300 million years ago (Ma) when the supercontinent of Pangea was located near the south magnetic pole (shown later in Figure 7). Prior to this, in the so-called Neoproterozoic period, which lasted from approximately 1 Ga until 545 Ma, the supercontinents of Rodinia and Pannotia (shown later in Figure 13) were apparently in place at a similar south magnetic polar location, at 600 Ma, in the case of Pannotia, and near the beginning of the Neoproterozoic in the case of Rodinia. Inspection of the histogram shown on Figure 5 will show that the times during which supercontinents had formed coincide with the times during which new continental crust is being formed least efficiently. Likewise it is apparently during times when the supercontinents are being actively rifted and when, presumably, volcanic out-gassing is especially intense, that new continental crust is being formed most efficiently. It is interesting to note that the time scale of several hundred million years which separates the episodes of supercontinent aggregation is very similar to the time scale between distinct episodes of avalanche activity determined on the basis of the previously discussed numerical model of the mantle convection process in which

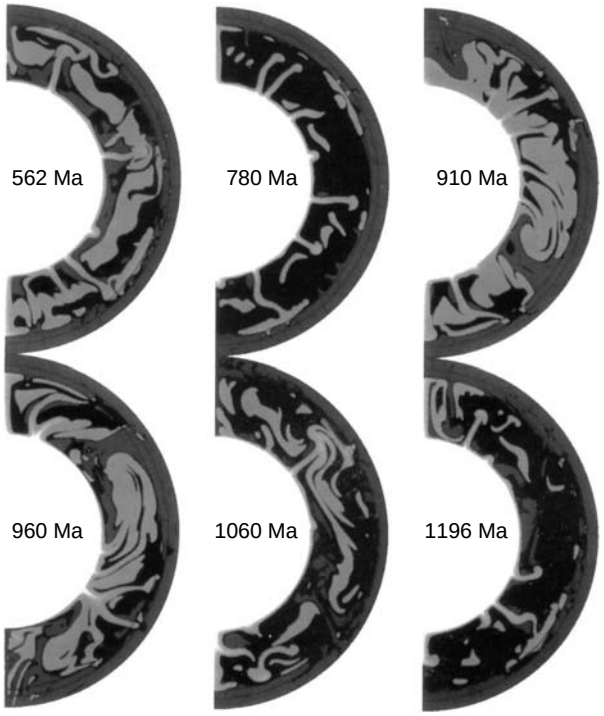

Figure 3 Internal mantle temperature fields from an axi-symmetric numerical model of the mantle convection process. The lighter colors denote hot upwelling material that originates through instability at the core-mantle boundary whereas the darker regions correspond to cold downwelling material. The six frames cover a range of (simulated) time of 634 million years during which period there occurs an interval in which intense avalanches of cold material descend across the 660 km depth seismic discontinuity. The 660 km phase change interface, which is due to the Spinel–Perovskite and Magnesiowustite phase transformation, is endothermic and so is able to initially inhibit the flow of cold downwelling material across it. Eventually, however, the thermal boundary layer caused by this inhibition of radial flow becomes convectively unstable and an avalanche occurs

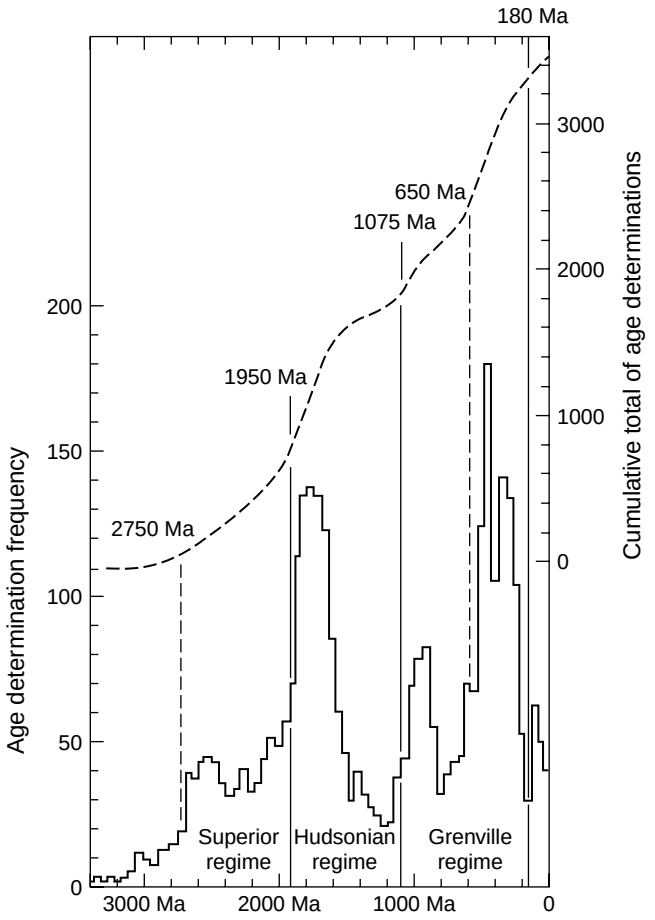

Figure 4 Age histogram of continental rocks showing the number of dated samples as a function of sample age. (Reprinted with permission from Dearnly (1965). Copyright 1965 Macmillan Magazines)

the endothermic phase transformation at 660 km depth plays an important role.

The possible importance of this line of argument to the understanding of ultra low frequency climate variability will be clear on the basis of Figure 6, which shows the reconstructions of atmospheric carbon dioxide through time that have been produced by Robert A Berner of Yale University (*see* Carbon Dioxide Concentration and Climate Over Geological Times, Volume 1), reconstructions that he has designated GEOCARB1 and GEOCARB2. In these best currently available reconstructions of atmospheric carbon dioxide concentration since the end of the Neoproterozoic epoch at 545 Ma, it will be observed that carbon dioxide concentration rose dramatically during the breakup of Pangea subsequent to 300 Ma and also during the breakup of Pannotia subsequent to 600 Ma. Because we expect volcanic out-gassing to be especially intense during an episode of supercontinent rifting and because carbon dioxide is a primary output of surface volcanism, we may usefully understand the paleo-carbon dioxide reconstruction of Berner as being deeply linked to the Wilson cycle of supercontinent creation and destruction. To the extent that this connection is as secure as appears to be the case, we may furthermore link episodes of supercontinent rifting to episodes (*see* Plate Tectonics, Volume 1), during which the mantle convective circulation is relatively layered. Similarly, episodes of supercontinent formation may be linked to episodes of occurence of avalanche events during which initially dispersed continental fragments are drawn together at the stagnation point at the Earth s surface, which is located immediately above the avalanche of material that is occurring across the 660 km depth interface. To the extent that the GEOCARB reconstructions of atmospheric carbon dioxide concentration are reasonable facsimiles of reality, it therefore seems clear that profound geodynamic controls actively contribute to the determination of the climatic state

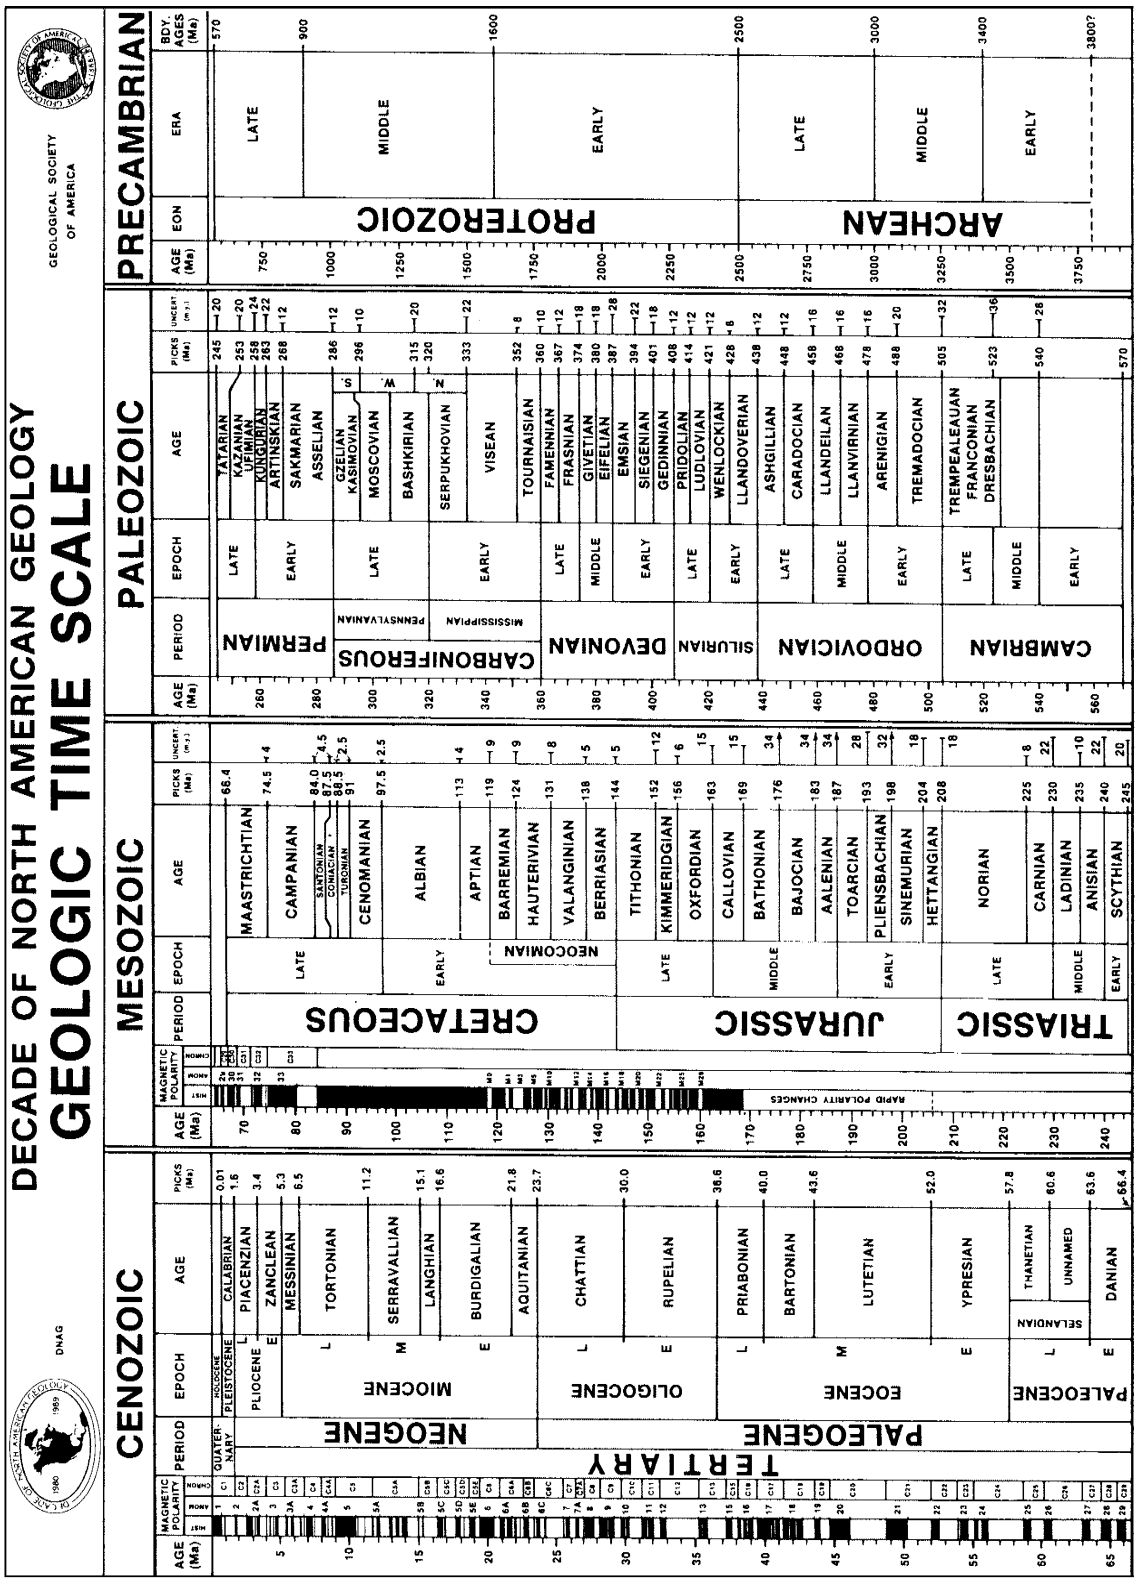

Figure 5 A detailed chart depicting the geological time scale of the Earth, and the names of periods, epochs and ages

found at Earth s surface at any particular epoch in the past. We may usefully investigate this hypothesis by focusing firstly upon those (relatively infrequent) times in the past, which are well defined in the GEOCARB reconstruction, when carbon dioxide concentrations are believed to have been relatively low. These being the late Pleistocene epoch (900 thousand years ago (ka) to present), the Carboniferous epoch (∼300 Ma) and perhaps also the Neoproterozoic (∼600 Ma). It will prove most illuminating to focus upon the two oldest epochs first.

ICE AGE CLIMATES OF THE CARBONIFEROUS AND NEOPROTEROZOIC: CONSEQUENCE OF A WEAK SUN AND LOW ATMOSPHERIC CARBON DIOXIDE

During the Carboniferous epoch centered upon approximately 300 Ma, the supercontinent of Pangea was centered over the south geomagnetic pole in the configuration shown on Figure 7. In attempting to understand the surface climate state that existed on the Pangean supercontinent, it is critical to appreciate that the solar luminosity at that time would have been lower than present by about 3%. This is indicated in Figure 8, which displays the results of two different theoretical models of solar evolution that differ only modestly from one another. Also indicated on Figure 7 by the star symbols are the locations on Pangea where there is clear geological evidence that the surface was heavily glaciated at that time. In order to demonstrate at least a first order understanding of why the Carboniferous supercontinent should have been glaciated, a simple climate model that includes a detailed description of neither the atmosphere nor the oceans can nonetheless be useful. Consider the surface climate as being controlled by a simple balance of energies that may be described schematically as follows

$$C \times [\text{time rate of change of surface temperature}] = Q_o(1-\alpha) - \varepsilon\sigma T_s^4 - \text{divergence of latitudinal heat transport} \quad (1)$$

In Equation (1), $Q_o = 1370\,\mathrm{W\,m^{-2}}$ is the solar constant, $\sigma = 5.67 \times 10^{-8}\,\mathrm{W\,m^{-2}\,K^{-4}}$ is the Stefan–Boltzman constant, T_s is the surface temperature in degrees Kelvin, α is the surface albedo which depends upon surface type (i.e., land, sea, sea ice, land ice, etc.), and ε is the infrared (IR) emissivity. The latitudinal heat transport in the actual climate system is effected by the circulations of the atmosphere and oceans. At the level of the energy balance description, which is the basis of Equation (1), this may be parameterized in terms of the mid-latitude value of the pole-to-equator temperature gradient. The parameter C in Equation (1) is the surface heat capacity which may be assumed to be a function of latitude and longitude in such a way as to differentiate continents from oceans and ice covered from non-ice covered regions. In ice covered regions the surface albedo is typically of order 0.8 whereas under ice free conditions it is typically of order 0.3 or somewhat lower.

We may augment the model of surface temperature change embodied in Equation (1) by connecting it to a model of global glaciology that may be described in a similarly schematic fashion:

$$[\text{time rate of change of continental ice sheet thickness}] = G - \text{divergence of ice flux} \quad (2)$$

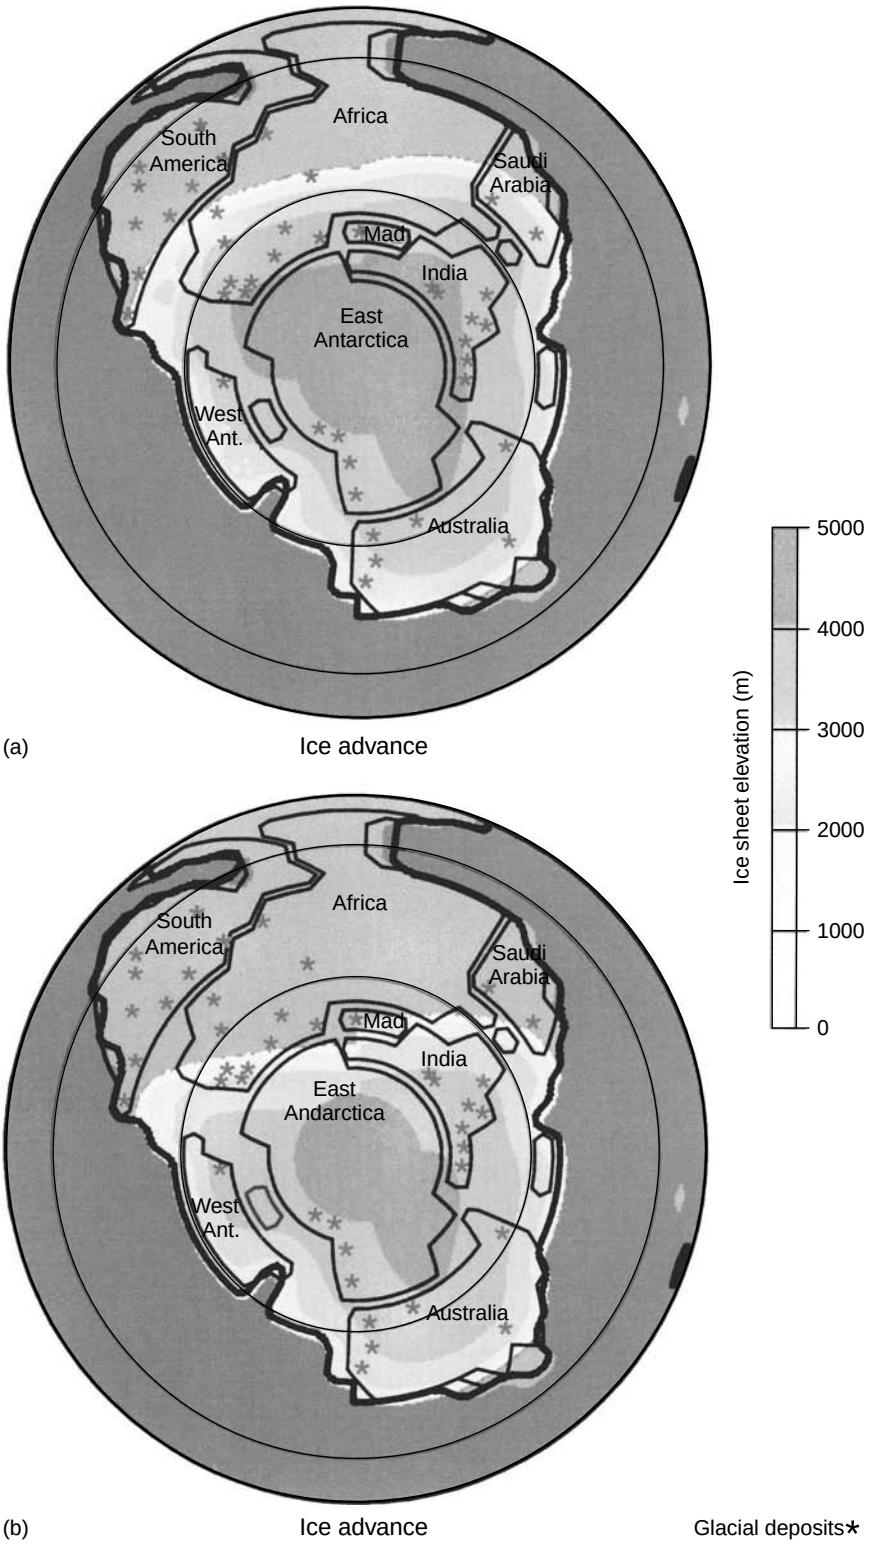

Figure 7 Reconstruction of the supercontinent of Pangea that existed around the south magnetic pole during the Carboniferous period approximately 300 Ma. The locations on each of the named continental fragments of which Pangea was constructed, where there exist indications of heavy continental glaciation, are indicated by stars. Theoretical predictions of the extent of maximum and minimum glaciation calculated by the climate model described in the text are superimposed upon the two maps of Pangea. (From Hyde *et al.* (1999). Reprinted with permission of Springer-Verlag)

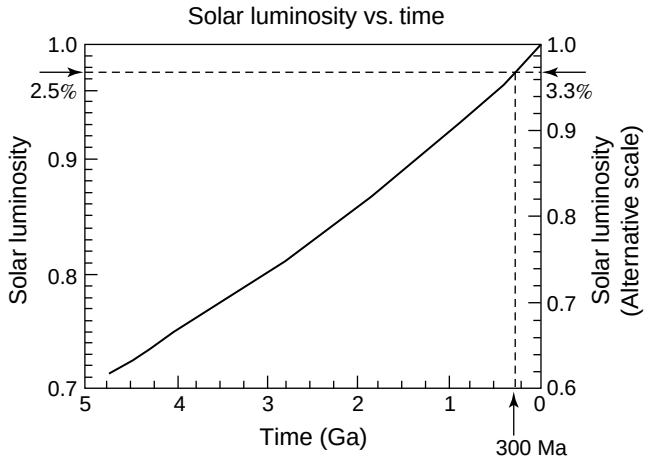

Figure 8 Solar luminosity as a function of time for two different models of the evolution of a main sequence star having properties equal to those of our Sun (from Endal *et al.*, 1981)

In this equation, G is the so-called mass balance function, which is positive over that portion of a continental ice sheet that is experiencing a net accumulation of mass (typically in the interior region) and negative around the periphery where net ablation occurs. These two governing equations of the ice sheet coupled energy balance climate model are strongly coupled by virtue of the fact that the latitude and longitude dependent precipitation rate depends upon temperature as do the rates of accumulation and ablation.

These processes are further strongly linked through the glacial isostatic adjustment (GIA) effect whereby the surface of the solid Earth is depressed by the weight of an ice load. Because of the fact that the temperature in the atmosphere decreases strongly as a function of height, and because the height with respect to sea level of the ice sheet surface is strongly influenced by the GIA effect, this process has an important influence on surface climate and thus the glaciation–deglaciation process. In simple climate models of the kind being discussed, the GIA process may be adequately described (schematically) by the relationship:

$$[\text{time rate of change of bedrock elevation } h'] = \frac{(h' - h'_{\text{o}})}{\tau} + \frac{(p_I/p_m)H}{\tau} \tag{3}$$

in which h'_{o} is the initial longitude and latitude dependent bedrock topography, τ is the relaxation time constant, ρ_I and ρ_m are the densities of ice and the Earth's mantle, respectively, and H is ice thickness.

The final ingredient that is in general required to activate a model of this kind consists of the effective time variations of the solar luminosity that are caused by time variations in the geometry of Earth's orbit around the Sun. If we define by Q_{s} and Q_{w} the summer and winter (half year) effective solar constants, then detailed mathematical analysis shows that the deviations of these quantities from their present values are simply:

$$\Delta Q_{\text{s}} = \left(\frac{\partial S_{\text{s}}}{\partial \varepsilon}\right) \Delta\varepsilon - m\Delta(e \sin s) \tag{4}$$

$$\Delta Q_{\text{w}} = \left(\frac{\partial S_{\text{w}}}{\partial \varepsilon}\right) \Delta\varepsilon + m\Delta(e \sin s) \tag{5}$$

in which ε and e (see Figure 9 for illustration) are, respectively, the obliquity of the spin axis of the planet with respect to the normal to the plane of the ecliptic, and the orbital eccentricity (*see* Climate Model Simulations of the Geological Past, Volume 1). The parameter m is:

$$m = \frac{2TQ\cos\theta}{\pi^2(1-e^2)^{1/2}} \tag{6}$$

in which T is the duration of the tropical year, and θ is the latitude of a point on Earth s surface. In Equations (4) and (5), s is the angle of perihelion and S_{s} and S_{w} are as follows:

$$S_{\text{s}} = \frac{QT}{2\pi(1-e^2)^{1/2}} [f_{\text{o}} + \cos\varepsilon \sin\sigma] \tag{7}$$

$$S_{\text{w}} = \frac{QT}{2\pi(1-e^2)^{1/2}} [f_{\text{o}} - \sin\varepsilon \sin\sigma] \tag{8}$$

Given a detailed reconstruction of the orbit of the Earth through time from the solution of the gravitational n-body problem for the planetary system as a whole (see e.g., Laskar, 1988; Quinn *et al.*, 1991), we have detailed knowledge of $\varepsilon(t)$ and $e(t)$ and so may compute the variations of solar insolation reaching Earth s surface due to changes in the geometry of its orbit. Although we are now able to accurately compute these variations over the past several million years of Earth history, we cannot obtain an accurate model of this contribution to solar forcing for the Carboniferous epoch. On such time scales the influence of deterministic chaos becomes clearly evident when integrating the gravitational n-body problem backwards in time from present values of the ephemeris. What we can do,

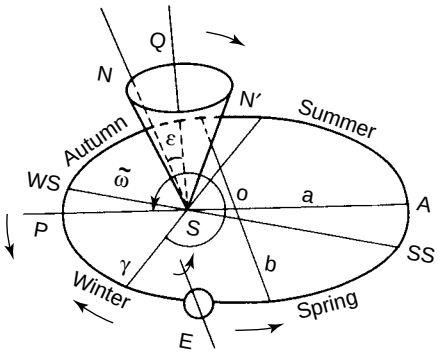

Figure 9 Orbital geometry of the Earth around the Sun (*see* **Orbital Variations**, Volume 1)

however, is to make the not unreasonable assumption that the dominant amplitudes and time scales of variations in ε and e were not then substantially different from present and include the influence of these variations on the predicted Pangean climate, recognizing that the phase of the variations so predicted will be meaningless.

Figure 10 shows the calculated variation of the quasi-equilibrium ice volume as a function of the particular level of atmospheric carbon dioxide concentration assumed in integrating the above described ice sheet coupled energy balance model of planetary climate. At $1 \times CO_2$, the ice volume equilibrates at a relatively high level, varying from approximately $10^8\,km^3 - 1.5 \times 10^8\,km^3$. The maximum and minimum spatial extents of the calculated Pangean ice sheet are shown in parts (a) and (b) of Figure 7, respectively. These extremes are observed to nicely cover the surface area within which evidence exists that intense glaciation occurred. Figure 10 also shows ice volume predictions for atmospheric carbon dioxide concentrations of both $2\times$ and $3\times$ the modern (preindustrial) value. In the former case the quasi-equilibrium ice volume calculated by the model drops to about half of that delivered by the $1 \times CO_2$ model whereas, in the latter case, glaciation is predicted not to occur at all. Inspection of the GEOCARB model inference of the concentration of carbon dioxide in the atmosphere at 300 Ma, shown previously in Figure 6, demonstrates the model to suggest that this level was tightly constrained to a concentration near the present value. This is entirely consistent with the result of the ice sheet coupled energy balance climate model which, in the case of $1 \times CO_2$, accurately reproduces the observed extent of glaciation on the super continent of Pangea. Figure 11 demonstrates that the success of the model is equally strongly dependent upon the assumed 3% reduction in solar luminosity. When the

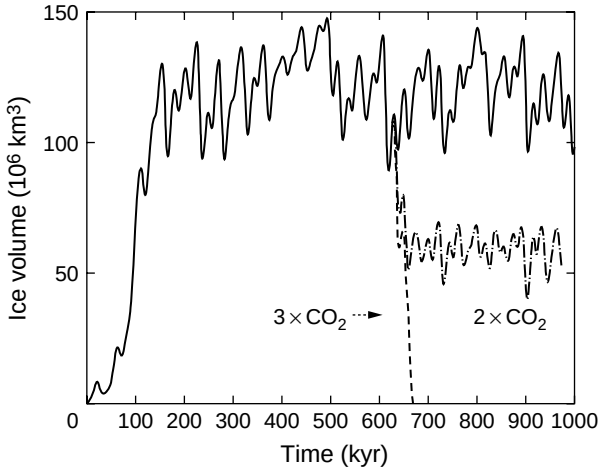

Figure 10 Ice volume verses time on the Pangean supercontinent for three different levels of atmospheric carbon dioxide concentration (from Hyde *et al.,* 1999. Reprinted with permission from Springer-verlag)

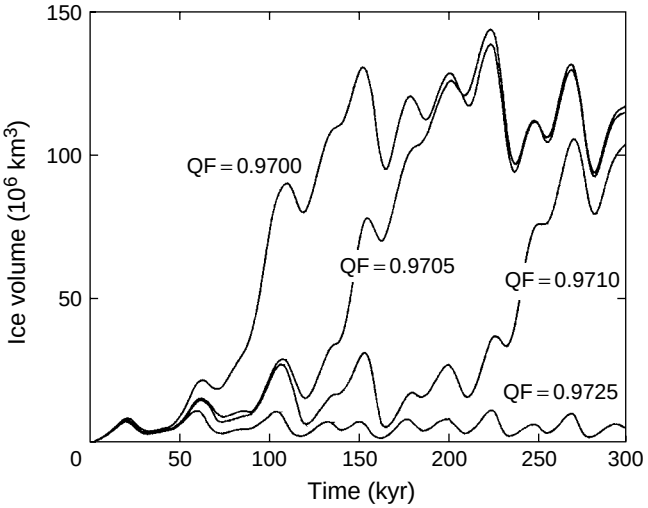

Figure 11 Ice volume vs. time for Pangea, assuming modern values of the atmospheric carbon dioxide concentration and for several values of the reduction in solar luminosity (from Hyde *et al.,* 1999. Reprinted with permission from Springer-verlag)

parameter QF = 1, the assumed solar luminosity is equal to its modern value; QF = 0.97 thus corresponds to a 3% reduction. Inspection of the Figure shows that when QF = 0.9725, so that the assumed reduction of the solar constant is only 2.75%, then no significant glaciation occurs at all.

Reaching still further back in the history of Earth system evolution, into the Neoproterozoic era which extended from ∼1 Ga−∼545 Ma, we enter the range of time within which the most extensive episodes of glaciation in Earth history are believed to have occurred. These glaciations, called the Marinoan and Veranger glaciations, are estimated to have occurred at some time within the intervals from ∼760 to 700 Ma and from ∼620−580 Ma, respectively, although the accuracy with which the times of occurrence of these events have been dated and their durations determined is still a subject of active debate. It is nevertheless known that intense continental glaciation extended to the equator during at least the Veranger episode and that these glaciations were marked in the geological record by highly significant changes in strontium, sulfur and carbon isotopes.

This epoch of Earth history was also a critical interval in biological evolution as it was during the Neoproterozoic epoch that the first appearance of metazoans (multi-celled animals) occurred. This critical event may well have preceded the earliest Marinoan phase of deep glaciation. It has been suggested that the Earth s surface may well have been entirely ice covered during the deepest Veranger phase of glaciation and this has led to the widespread use of the *Snowball Earth* appellation to describe the climatic state that would have existed at this time (Hoffman *et al.*, 1993). The issue as to whether an entirely ice covered Earth, with thick continental ice sheets on the continents

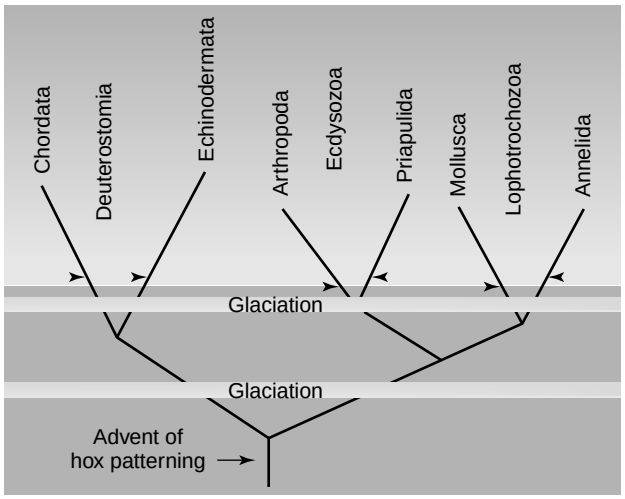

Figure 12 This diagram depicts the temporal association between the two phases of glaciation that occurred in the late Neoproterozoic (the Sturtian and Veranger events) and the onset of the Cambrian period at the beginning of which there began an intense acceleration in the process of biological evolution (from Runnegar, 2000. Reprinted with permission from *Nature*. Copyright 2000 Macmillan Magazines)

and sea ice covering the oceans, is required to satisfy the geochemical and geological data remains a subject of debate. If the Earth were entirely ice covered, there clearly exists a potentially serious problem for biological evolution because it is rather unclear how metazoans could have survived to serve as the required substrate for the extremely rapid proliferation and diversification of life that began at the outset of the Cambrian epoch (545 Ma). This problem is described graphically in Figure 12. Because the first appearance of metazoans preceded the episode of deepest glaciation and because it has been suggested on the basis of genetic clock analyses that these multi-celled animals were the ancestors of the Ediacaran fauna whose fossil remains first appear following the Varanger ice age, it seems evident that the metazoans were not only not eliminated by the snowball event, but that their rate of evolution may in fact have been accelerated because of it.

We may investigate the climate of the late Neoproterozoic ice age by applying the same ice sheet coupled climate model as was successfully employed to understand the Carboniferous glaciation of Pangea (see Hyde *et al.*, 2000 for detailed discussion). Figure 13 shows the south (magnetic) polar supercontinent of Pannotia, which was in place during the late stage of the Neoproterozoic. Based upon the results shown previously on Figure 8, it is evident that at 600 Ma, during the Varanger phase of glaciation, solar luminosity would have been reduced by approximately 6% from its modern level. Based on the results of the GEOCARB model shown on Figure 6, which shows large differences between the GEOCARB1 and GEOCARB2 reconstructions for this period, the atmospheric carbon dioxide level at that time is highly uncertain. We may nevertheless employ the model to ask whether a snowball state of complete glaciation could have occurred, and if so, at what level of atmospheric carbon dioxide concentration such conditions might arise. Results of an initial investigation of this kind are shown on Figure 14, part (a) of which shows land ice volume

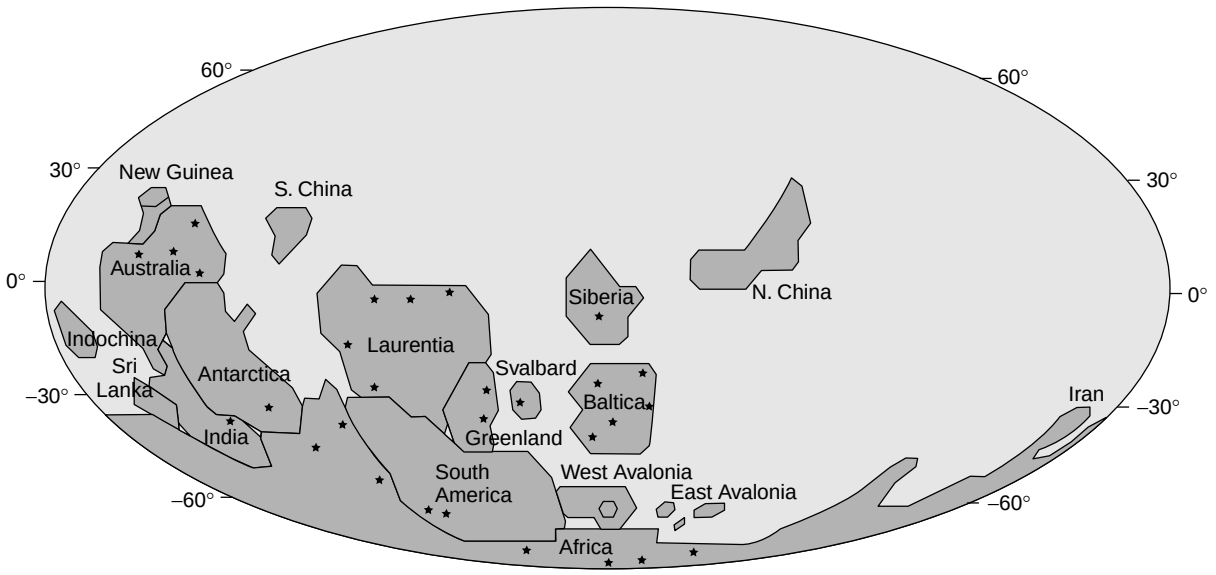

Figure 13 An approximate reconstruction of the supercontinent of Rodinia during the Veranger glaciation at 600 Ma. The stars on the individual continental fragments represent locations from which evidence exists of intense continental glaciation having occurred at this time (from Hyde *et al.*, 2000. Reprinted with permission from *Nature*. Copyright 2000, Macmillan Magazines)

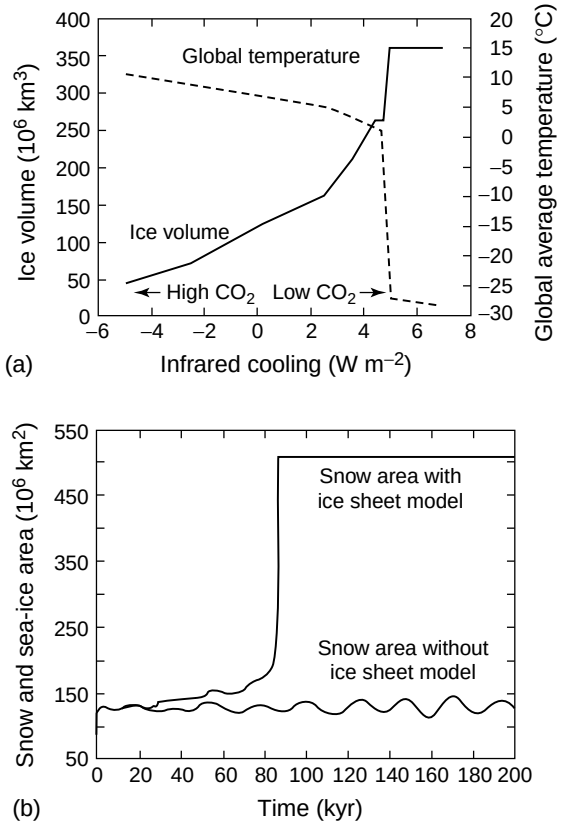

Figure 14 (a) Land ice volume and mean surface temperature on Rodinia as a function of the assumed degrees of IR cooling due to the decrease in atmospheric carbon dioxide concentration; (b) the impact on the evolution of the area of Rodinia covered by snow of excluding the ice-dynamics component of the model (from Hyde *et al.*, 2000. Reprinted with permission from *Nature*. Copyright 2000, Macmillan Magazines)

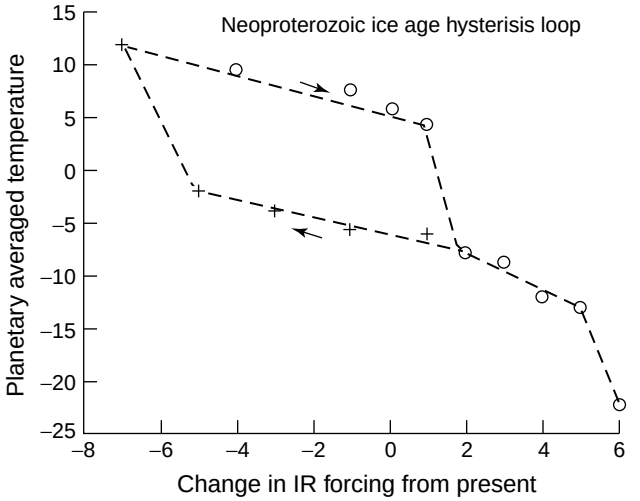

Figure 15 Mean surface temperature of the Earth as a function of the degree of IR cooling caused by varying the concentration of carbon dioxide in the atmosphere. Note the hysteresis involved in determining the thermal state of the system on cooling out of a hot state, as opposed to warming out of a cold state. On the cold branch of the hysteresis loop the solutions are characterized by states of heavy glaciation that include, however, a significant area of open water at the equator which could serve as an equatorial refugium in which complex marine life could have survived (from Crowley *et al.*, 2001)

and globally averaged surface temperature as a function of the degree of cooling (in $\mathrm{W\,m^{-2}}$ by infrared radiation (IR)) associated with the level of carbon dioxide reduction. Results indicate that at a level of IR cooling of $\sim 5\,\mathrm{W\,m^{-2}}$ the model exhibits a bifurcation into a state of total ice cover in which the mean surface temperature falls to a value near $-30\,^{\circ}\mathrm{C}$ (the average surface temperature at present is approximately $14.5\,^{\circ}\mathrm{C}$). Part (b) of the same figure demonstrates the extremely important role played in this model by the explicitly described continental ice sheet dynamics. In the absence of the physics associated with the accumulation and flow of the continental ice sheets, the bifurcation into the state of complete continental ice cover (represented here by the area of the surface that is covered by snow) does not occur even though the carbon dioxide level has been reduced to approximately half of its preindustrial value.

A somewhat more complete classification of the solution space of the ice sheet coupled energy balance climate model is shown in Figure 15, where the quasi-equilibrium planetary average temperature is plotted as a function of the degree of IR cooling in $\mathrm{W\,m^{-2}}$. Clearly evident on this diagram is that, in the range between -5 and $+2\,\mathrm{W\,m^{-2}}$ of IR cooling, there exist two possible quasi-equilibria, one of which corresponds to a relatively high mean surface temperature while the other corresponds to a relatively low mean surface temperature. The cold branch is a branch that I refer to as consisting of *oasis* solutions. These are solutions in which, although all of the continents are covered by thick continental ice sheets and sea ice covers all of the high latitude and some of the low latitude oceans, there nevertheless exists an equatorially confined open water refugium within which metazoans could clearly have survived. The hard snowball state occurs only for levels of IR cooling in excess of $6\,\mathrm{W\,m^{-2}}$. At lower levels of IR cooling, the issue of whether the solution lies on the hot branch or the cold oasis branch of the hysteresis loop is determined by the initial condition, which is perturbed by the change in carbon dioxide concentration. If the system begins to exit a cold state because carbon dioxide is increasing, say due to the influence of volcanic out-gassing, then one remains on the cold oasis branch until a critical degree of warming is applied. On the contrary, if one is cooling from a warm state because the carbon dioxide level is decreasing, then one remains on the warm branch of the hysteresis loop until a critical degree of cooling is applied.

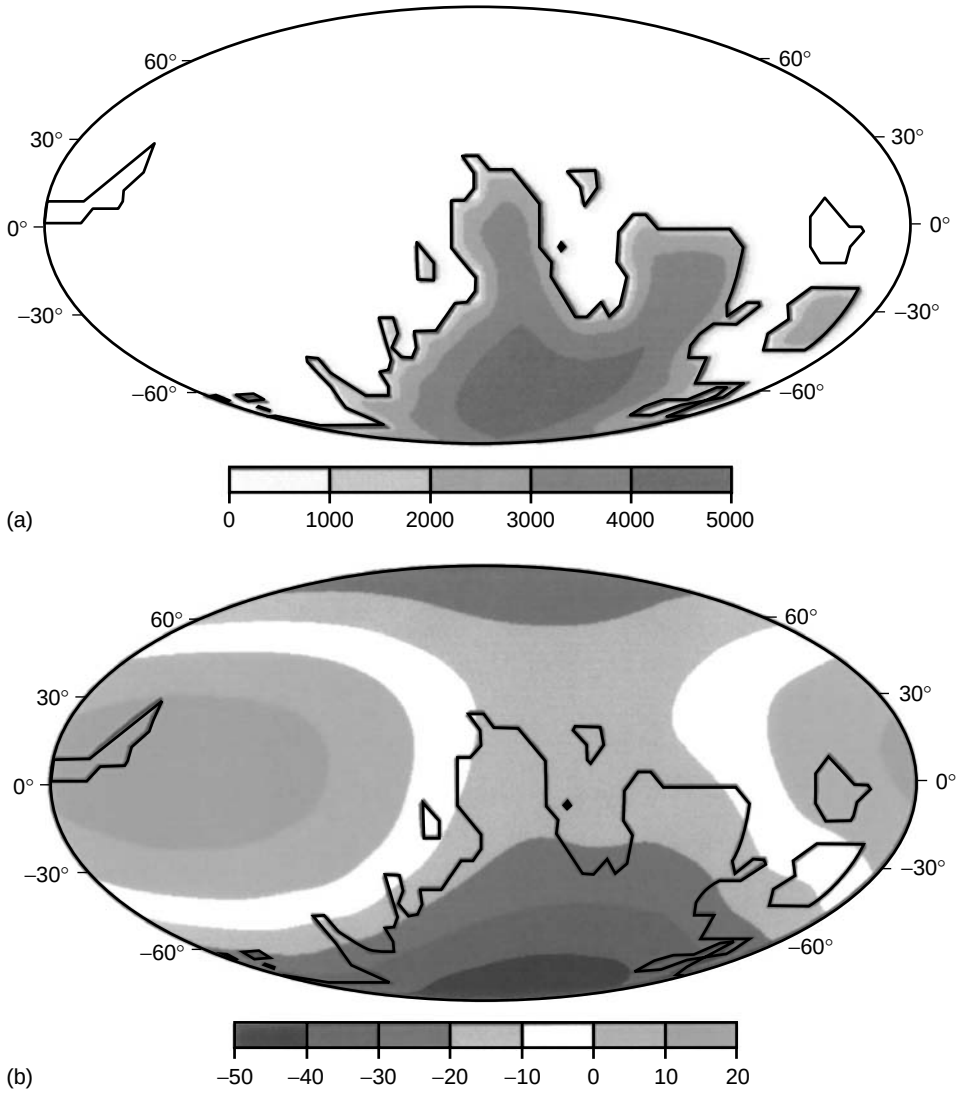

Figure 16 A typical oasis solution calculated by the University of Toronto intermediate complexity climate model for the case of the Late Neoproterozoic, with −6% solar forcing and the CO_2 concentration set at 75% of its preindustrial value. Panel (a) shows the elevation of the ice sheets (m); Panel (b) shows mean annual temperature (°C) (from Crowley *et al.*, 2001)

Figure 16 shows a typical oasis solution, in terms of mean annual temperature, for late Neoproterozoic climate with the solar constant reduced by 6% and the carbon dioxide level at three quarters of its preindustrial value. Although there exist continents near the equator that are covered by thick ice sheets, there is nevertheless a large area of the equatorial ocean which is free of sea ice.

It is important to remember that the simple climate model that is represented by the schematic Equations (1–3) is one in which many climatologically significant processes are not represented at all. These unrepresented processes include all impacts associated with ocean dynamics, both those due to the wind driven circulation and those due to the thermohaline circulation (THC). Also unrepresented are all influences upon radiative transfer processes associated with the presence of clouds in the atmosphere and with a changing water vapor concentration in the air caused by evaporation from the sea surface. Furthermore, the model contains only a crude thermodynamic treatment of the formation and movement of sea ice. Perhaps most importantly it contains no explicit treatment of the transports of heat and momentum in the atmosphere by the movement of the air. Although some of these processes are represented in parameterized form in the simple ice sheet coupled energy balance climate model, the parameterizations have been determined by tuning the model to the modern climate. Because the climate of the late

Neoproterozoic is profoundly different from that of the present day, one must be cautious in accepting the results delivered by a model of this type until they are confirmed by application of a more complete model of the climate system.

Modern atmosphere–ocean general circulation models are fully capable of being employed to provide the required tests of the simulations of such models of intermediate complexity. The GENESIS2 model (see Thompson and Pollard, 1995) has already, in fact, been applied in an initial test of the existence of the refugium solutions revealed by the simpler model (Hyde *et al.*, 2000). Although this test did not include any of the influences of ocean dynamics, it did include diurnal solar forcing, interactive clouds, semi-Lagrangian water vapor transport and a six-layer sea ice model. In this model, simulations with 0.5 and 1.0 times the preindustrial carbon dioxide levels quickly delivered oceans that were entirely ice covered whereas a doubled carbon dioxide experiment resulted in ice free tropical oceans, although the model continued to drift to lower temperatures. At a level of 2.5 times the preindustrial atmospheric carbon dioxide concentration, the solution was characterized by an apparently stable, equatorial open water refugium that covered the entire equatorial belt. A much more complete model of the climate system than GENESIS2 is clearly required to incorporate the full influence of ocean dynamics on the climate of the late Neoproterozoic.

The Climate System Model (CSM) of the US National Center for Atmospheric Research has been employed to perform this additional test and results are shown in Figure 17. They characterize an apparently stable solution at $1 \times CO_2$ and 6% solar constant reduction in terms of surface air temperature, sea surface temperature (SST), precipitation and sea ice extent. The solution is clearly characterized by an extensive equatorial open water refugium. The zonally averaged overturning stream function characteristic of this solution, shown in Figure 18, is representative of the THC. The results demonstrate that the deep circulation is rather weak in this apparently stable state, which is consistent with the anoxia of the oceans that was apparently characteristic of the Veranger glacial epoch. The fact that this preliminary oasis solution has been obtained with the atmospheric carbon dioxide concentration at the preindustrial level, whereas the ocean dynamics free GENESIS2 model delivers a hard snowball climate under these conditions, is likely to be indicative of the profound impact of the dynamics of the oceans upon late Neoproterozoic climate. This is believed to be the case because ocean dynamics is acting as a negative feedback, which tends to inhibit the formation of sea ice at the equator. Although the computation of climate states such as this using fully coupled atmosphere–ocean GCMs is very expensive in terms of the computational resources required, the cost effectiveness of this technology continues to improve. The near future of such investigations will therefore include intensive analyses of the solution space of these most complex characterizations of ancient climate regimes.

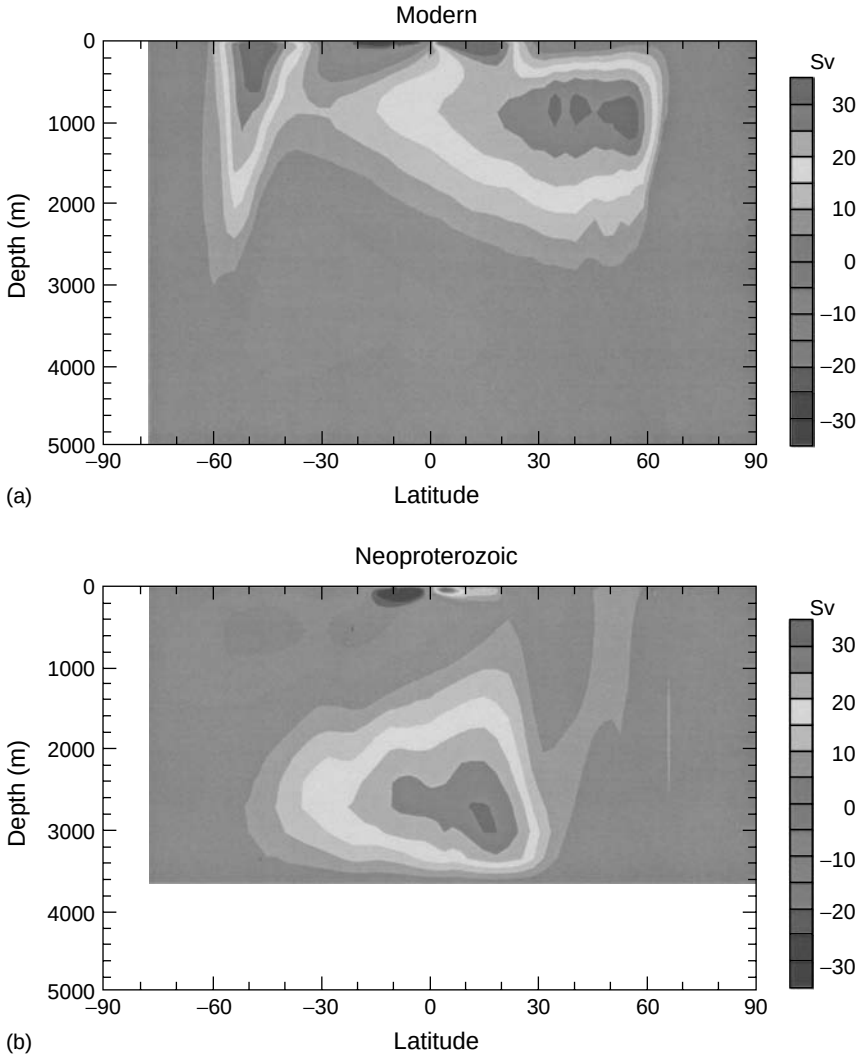

Figure 18 Shows zonal average of the meridional overturning streamfunction in Sverdrups (1 Sv = $10^6\,m^3\,s^{-1}$) for the global ocean for both the (a) Modern and (b) Neoproterozoic climates. For the purpose of the latter simulation the oceans were assumed to be of a uniform depth of 4 km

THE LATE PLEISTOCENE ICE AGE: CARBON DIOXIDE COVARIATION IN ORBITALLY FORCED GLACIAL CYCLES

Although the base of geological data that may be invoked to constrain the ancient glacial climates of the Carboniferous and Neoproterozoic epochs is rather modest, the same is not the case for the Pleistocene epoch. This epoch extended from approximately 2.4 Ma until the onset of the current Holocene period that began at approximately 10 ka. Because the oldest ocean floor on the planet is everywhere less than approximately 150 Ma in age, geological data from the ocean floors could not be invoked to constrain the characteristics of the Carboniferous and earlier glacial epochs, as it is entirely absent. During the Pleistocene epoch, however, such data are extremely abundant and furthermore may be placed accurately on a calendar year time scale using both direct and indirect methods of dating. The most important data from the ocean floors consist of mass spectrometric measurements of the stable isotopes of oxygen taken up by foraminifera extracted from deep sea sedimentary cores. The isotopic ratio, generally expressed as $\delta^{18}O$, is defined as follows (Equation 9):

$$\delta^{18}O = \frac{[^{18}O]}{[^{16}O]} - \text{SMOW} \tag{9}$$

in which $[^{18}O]$ and $[^{16}O]$ are, respectively, the concentrations of the heavier and less abundant and lighter and more abundant isotopes of oxygen measured on the test of

a particular species of foraminifera, whereas SMOW represents the same ratio measured in standard mean ocean water. The utility of the $\delta^{18}O$ measurement as a proxy indicator of climate variability, when measured in a deep sea sedimentary core, arises because the climate related processes of evaporation and precipitation are processes that fractionate mass. When water vapor is produced by evaporation from the surface of the sea, the influence of isotopic fractionation causes the vapor to be isotopically lighter (richer in ^{16}O) than the mean molecular weight of the oceanic reservoir from which it was extracted. The more water that is irreversibly extracted from this reservoir and locked into ice sheets on the continents, the heavier isotopically becomes the ocean that is left behind. While they live, the foraminifera, both benthic species living at the ocean bottom and planktonic species living near the surface, record the characteristic $\delta^{18}O$ of the ocean reservoir. When the foraminifera die, their shells fall to the ocean floor, younger overlying older as this detritus accumulates. An excellent proxy for the amount of land ice that existed on the continents as a function of time can thus be reconstructed by measuring the $\delta^{18}O$ of foraminifera extracted from progressively greater depth in a given sedimentary core. Although the isotopic ratio is also sensitive to temperature, the temperature contamination of the ice volume signal is relatively modest when based on measurements from a benthic species, which by definition inhabit the abyssal ocean.

An example of one such set of measurements from Ocean Drilling Project (ODP) core 677, which was drilled from the Panama Basin off the west coast of the northern part of South America, is shown in Figure 19(a). The

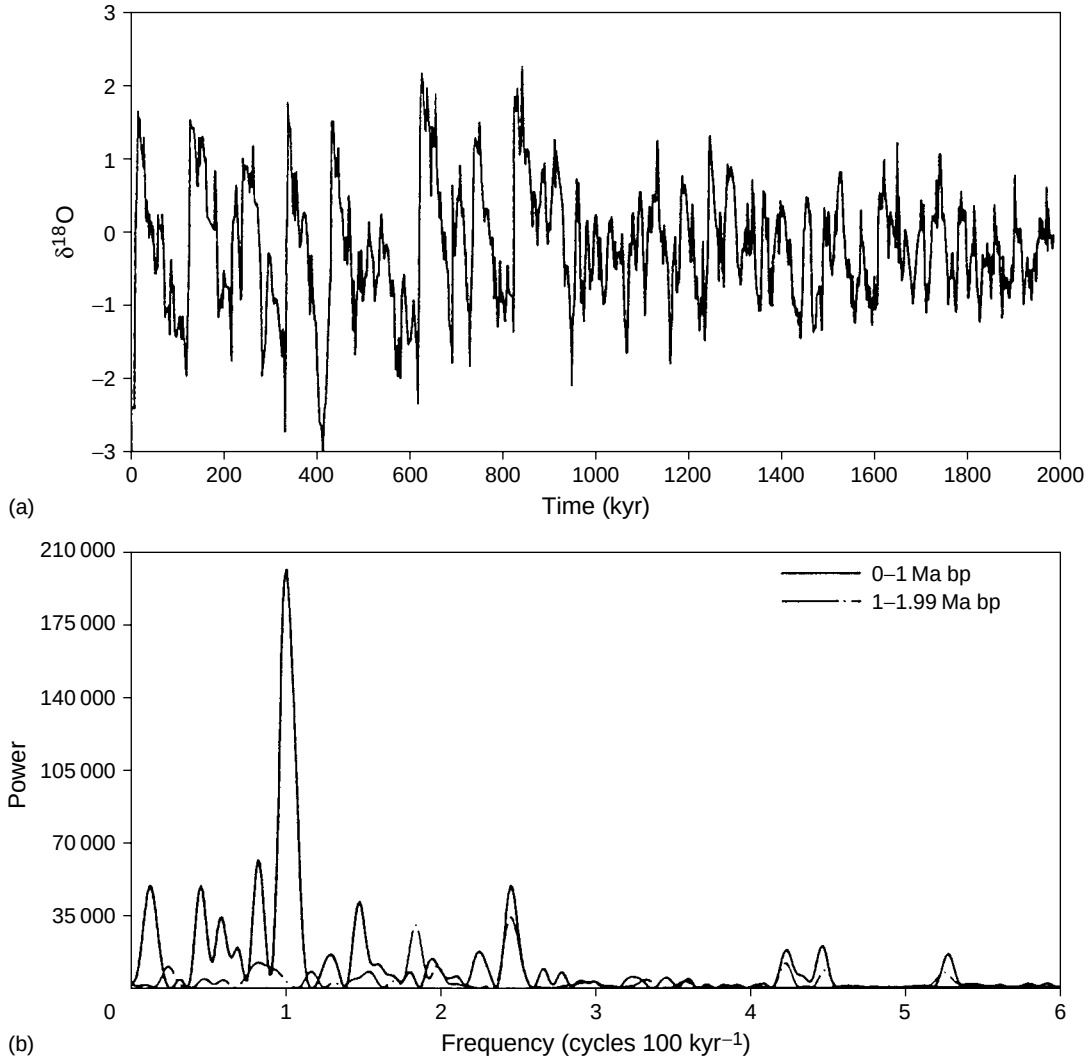

Figure 19 (a) The $\delta^{18}O$ record from the Panama Basin ODP 677 deep sea sedimentary core on an orbitally tuned time scale. (b) Power spectra of the most recent and immediately preceding million year segments (Ma BP – millions of years ago, before present) of the record in part (a)

mass spectrometrically measured $\delta^{18}O$ data are plotted in Figure 19(a) on a calendar age time scale rather than as a function of depth, the depth versus age relation having been determined by tuning to the orbital insolation anomaly time series for Northern Hemisphere summer delivered by Equation (4), when the orbital reconstruction of Laskar (1988) is employed to define the time series of $\varepsilon(t)$ and $e(t)$. The most striking demonstration of the validity of this method of determining a calendar year chronology for the isotopic record from a deep sea sedimentary core was provided by employing it on the ODP 677 data set and showing that if the method were correct, then there would have to be a significant error in the previously assumed age of 730 000 years for the most recent Brunhes–Matuyama reversal in the direction of the Earth s magnetic field. Subsequent to the calculation by orbital tuning that the age of this reversal was actually 780 000 years (Shackleton *et al.*, 1990), the new age was confirmed by applying the $^{40}Ar/^{39}Ar$ dating technique to a suite of volcanic rocks from Hawaii in which the reversal was recorded.

Inspection of the $\delta^{18}O$ data on the orbitally tuned time scale immediately reveals that throughout the latter half of the Pleistocene epoch, beginning about 900 000 years ago, continental ice volume has varied in an oscillatory fashion with a dominant characteristic time scale very close to 100 000 years. This is confirmed by the power spectral analyses of the $\delta^{18}O$ record shown in part (b) of Figure 19. Whereas the power spectrum of the earlier 1 Ma of the record has essentially no power at this period, during the most recent 1 Ma the variance in the time series is strongly focused at this time scale. Also evident in both of these power spectral partitions, however, is the spectral line at a period of 41 000 years which is the dominant time scale on which the orbital obliquity ε varies, as well as the triplet of spectral lines at periods near 19 000, 21 000 and 23 000 years (*see* Orbital Variations, Volume 1). The origin of this triplet of spectral lines may be understood by inspection of Equation (4), which shows that the variation of orbital eccentricity e, which has a dominant period of 100 000 years, acts so as to modulate a variation of insolation that would otherwise occur at the precession period of 21 000 years. The Fourier decomposition of the low frequency eccentricity modulation of the higher frequency precessional singlet gives rise to the splitting of the singlet into the multiplet seen in this spectrum on Figure 19(b) (to use the language of spectroscopy). The power spectrum of the time series of orbital insolation itself contains effectively no power at the period of the eccentricity modulation of the precessional effect, as is clearly evident by inspection of Equation (4). The important climatological issue that is posed by the proxy ice volume time series from ODP core 677 therefore concerns the nature of the nonlinear effects that must be involved in transforming the orbital climatological forcing into a climate system response that is dominated by variance at a period that is not present in the power spectrum of the excitation.

In order to address this important issue, one additional piece of information is required concerning the way in which other climatologically important Earth system properties vary during a typical 100 000 year late Pleistocene ice age cycle. To this end Figure 20 shows a sequence of such records from both ice cores ($\delta^{18}O$ from Camp Century Greenland, deuterium from Vostok, Antarctica, carbon dioxide from Vostok, Antarctica, and dust from Vostok, Antarctica), deep sea sedimentary cores ($\delta^{18}O$ from a stack of records from the SPECMAP suite of deep sea sedimentary cores), and lake cores (a paleo-precipitation record based upon a palynology based reconstruction from La Grande Pile). These records all encompass the most recent 100 000 year ice age cycle and demonstrate that these various climate proxy data sets all exhibit a high degree of correlation with the ice volume reconstruction based on deep sea sediment. Of greatest interest from the current perspective, however, is the strong correlation between the record of carbon dioxide concentration in the atmosphere measured on air bubbles in the Vostok ice core and the proxy record of continental ice volume. This correlation is clearly such that when ice volume is greatest, carbon dioxide concentration is lowest and vice versa, once more suggesting that atmospheric carbon dioxide concentration is playing a critical role in the process of continental glaciation and deglaciation. A critically important question is whether the apparent covariation of carbon dioxide concentration with ice volume occurs because carbon dioxide is a prime mover of the ice age cycle or whether it is simply a, perhaps weak, amplifier of the cycle. Note that the net variation of the carbon dioxide concentration through a typical cycle is approximately 80 parts per million by volume (ppmv) which is to be compared to the mean pre-industrial level of 280 ppmv so that in the state of deepest glaciation the atmospheric carbon dioxide concentration is reduced by almost 30%, not an insignificant depression as we will see.

We may address the issue of the mechanics of the glaciation–deglaciation process by once more invoking the simple ice sheet coupled energy balance climate model that is embodied in the schematic Equations (1–3) (*see also* Climate Model Simulations of the Geological Past, Volume 1). In comparison with the integrations of this model that were employed to investigate the Carboniferous and Neoproterozoic glaciations, for the purpose of which the atmospheric carbon dioxide level was held fixed, however, we will force the model for present purposes with both orbital insolation variations and with the variation of atmospheric carbon dioxide concentration. For the purpose of these integrations, furthermore, the initially non-glaciated surface topography and land–sea distribution of the planet are taken equal to their modern values, the spatial distribution of the precipitation rate is taken equal to its modern

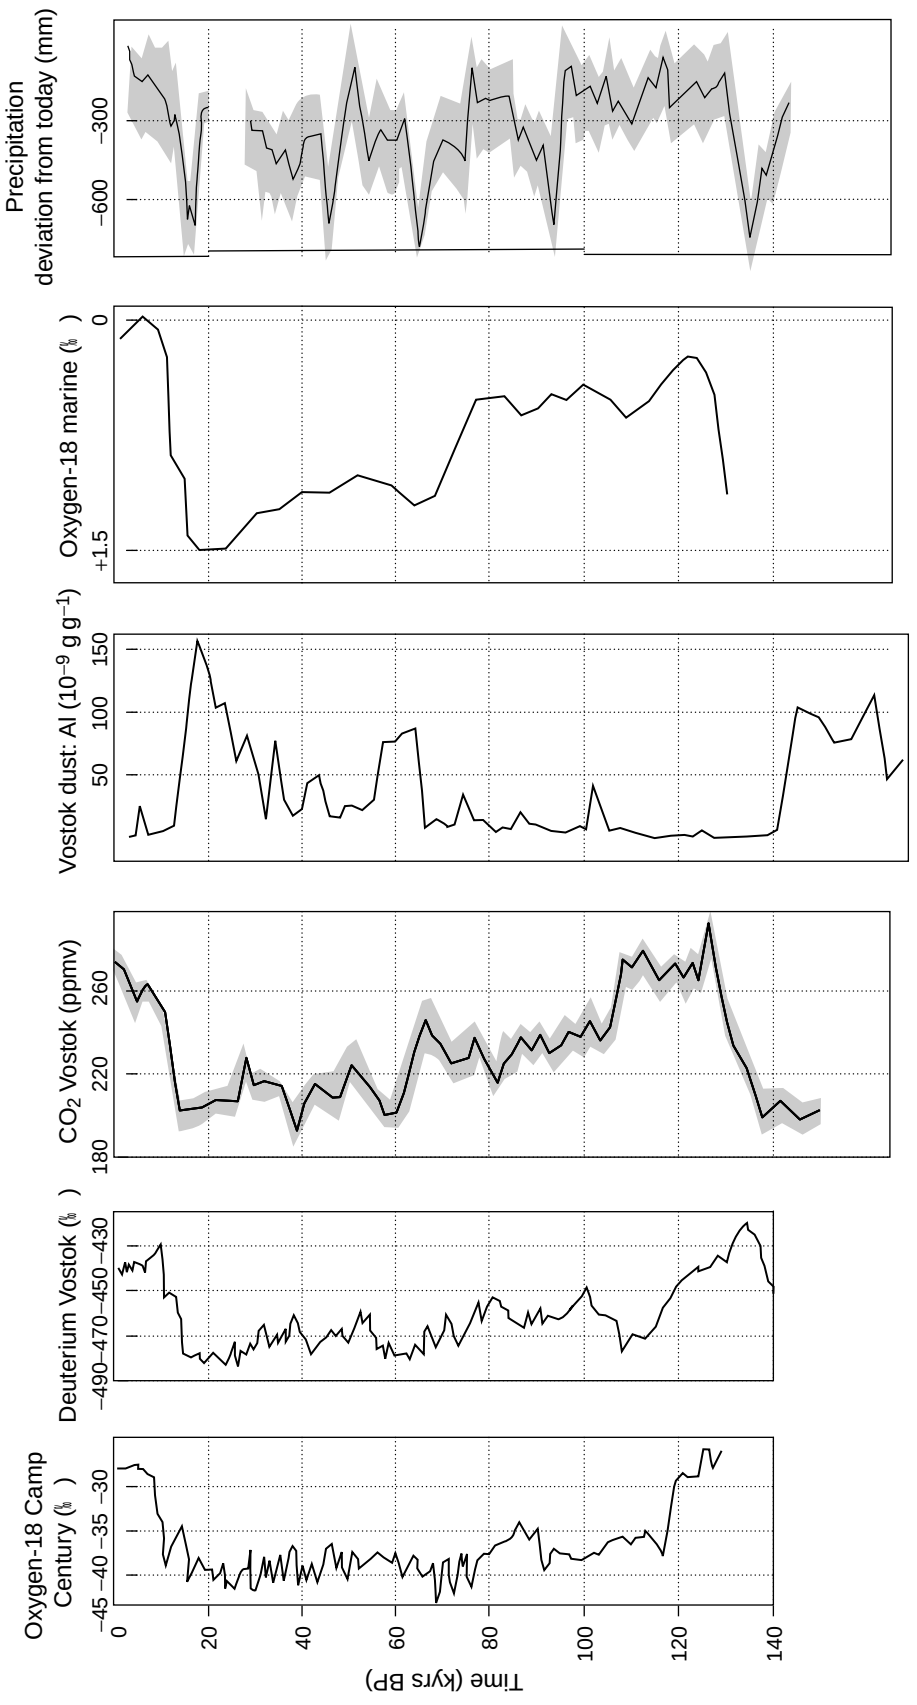

Figure 20 Six proxy climate time series for the most recent 100 kyr ice age cycle. This graphic was produced by the international Past Global Changes (PAGES) core project of the International Geosphere–Biosphere Programme using data from sources indicated

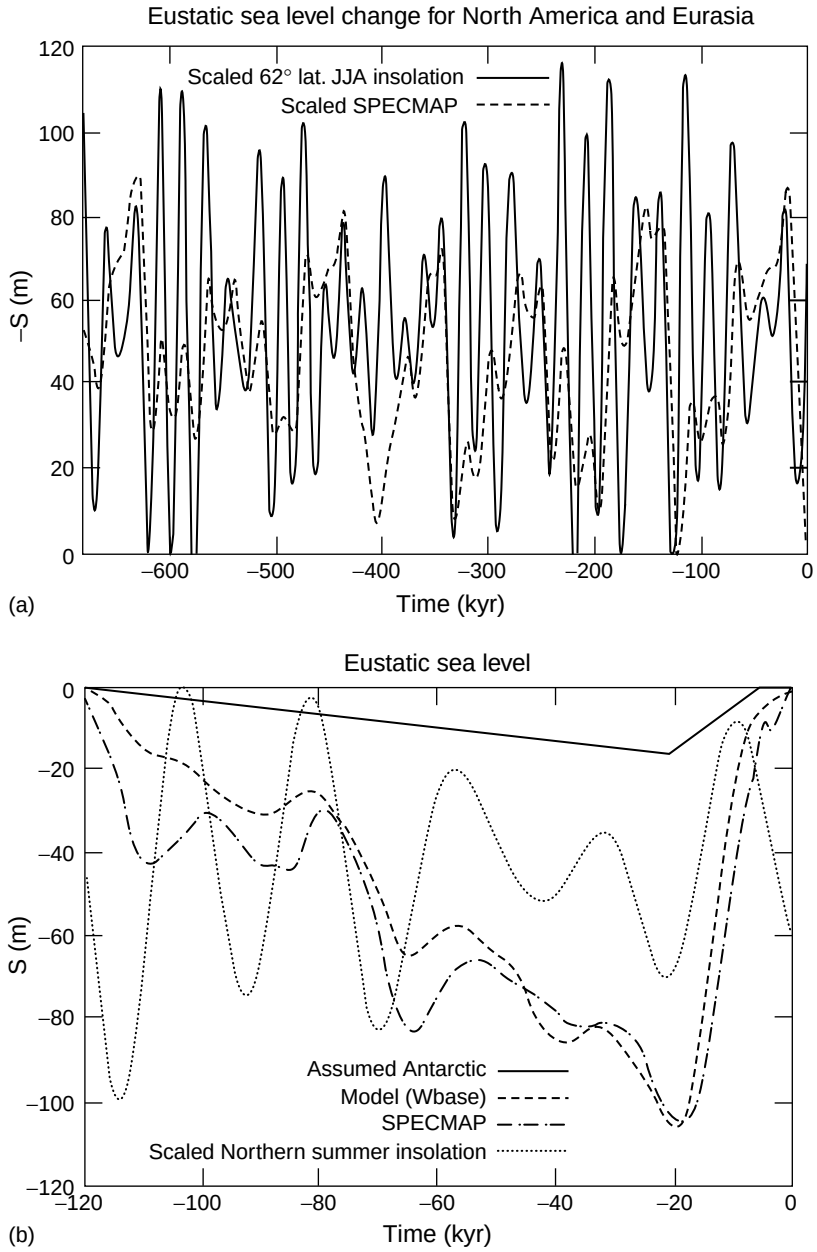

Figure 21 (a) June-July-August (JJA) orbital insolation anomaly at 62 °N latitude (scaled) and the SPECMAP $\delta^{18}O$ record derived on the basis of deep sea sediments which is scaled to the contribution to eustatic sea level history from the deglaciation of North America (NA) and Eurasia (EA). (b) Eustatic sea level history predicted by the ice sheet coupled climate model (Wbase) compared with the last glacial cycle from the SPECMAP record and to (scaled) Northern Hemisphere summer insolation

pattern although the rate is modulated by the surface air temperature in order to account in an approximate way for the fact that the hydrological cycle is less intense under colder conditions.

Figure 21 shows, in plate (a), the (scaled) June, July, August (JJA) insolation anomaly used to force the model together with the SPECMAP proxy for land ice volume over the period subsequent to about 650 ka. Plate (b) of the same Figure shows the same information concerning the orbital climate forcing and the $\delta^{18}O$ proxy for ice volume response together with the output ice volume response from the orbitally forced ice sheet coupled climate model over the time interval from the Eemean interglacial period at 120 ka (oxygen isotope stage (OIS) 5e) to the present. Included in the ice volume response curve is an assumed 15 m eustatic sea level variation derivative of (primarily West)

Antarctica. Intercomparison of the proxy ice volume record and the model simulated record shows that the theoretical model result mimics the observations extremely well, being characterized by a relatively slow glaciation phase lasting approximately 90 thousand years (kyrs) and a relatively rapid deglaciation phase lasting approximately 10 kyrs. The canonical 100 kyr ice age cycle, which has the character of a nonlinear relaxation oscillation, is therefore well explained by a model incorporating a relatively simple set of key processes.

Figure 22 illustrates the detailed structure of the Laurentide ice sheet that is calculated by the model at Last Glacial Maximum (LGM) at 21 ka, both in terms of the surface topography of the ice complex and in terms of the basal temperature distribution. These results demonstrate that the model not only delivers the correct time dependence of the growth and decay of the mass of glacial ice, but also the distinct Cordilleran, Laurentian and Innuitian ice sheet components. Inspection of the temperature distribution at the base of the ice sheet shows that the LGM Laurentide and Innuitian ice sheets are expected to have been frozen to the bed whereas the Cordilleran ice sheet may have been near the melting point at its base.

A fundamental question that clearly arises concerning this theory of the 100 kyr ice age cycle concerns the physical processes that drive the sharp terminations which characterize the deglaciation phase of the cycle. Detailed analyses demonstrate that there are three interlinked contributions, which together control the occurrence of these events. Firstly, there is the strength of the orbital insolation forcing, which is modulated at the period of 100 kyrs by the variation of orbital eccentricity. Secondly, there is the temporal variation of the atmospheric carbon dioxide concentration, which, as shown previously in Figure 20, is itself characterized by a slow decrease during glaciation and a rapid rise during deglaciation. Finally, there is the physics of the process of glacial isostatic adjustment (GIA), which introduces a strong positive feedback on the process of deglaciation by virtue of the enhancement of the temperature in the ablation zone of the ice sheet as it melts back into the deep isostatic depression created by the LGM surface load.

All three of these ingredients appear to be required in order for the ice sheet coupled climate model to deliver an acceptable synthetic ice volume history. Because the carbon dioxide forcing is the only one of these three ingredients that is not explicitly modeled but rather is assumed known on the basis of the measurement of carbon dioxide from air bubbles in the Vostok ice core, and because the carbon dioxide record so precisely contains the 100 kyr sawtooth cycle itself, it seems clear that we will not be able to claim to fully understand this intense climate oscillation until we are able to fully explain why atmospheric carbon dioxide concentration varies in this way. At present there

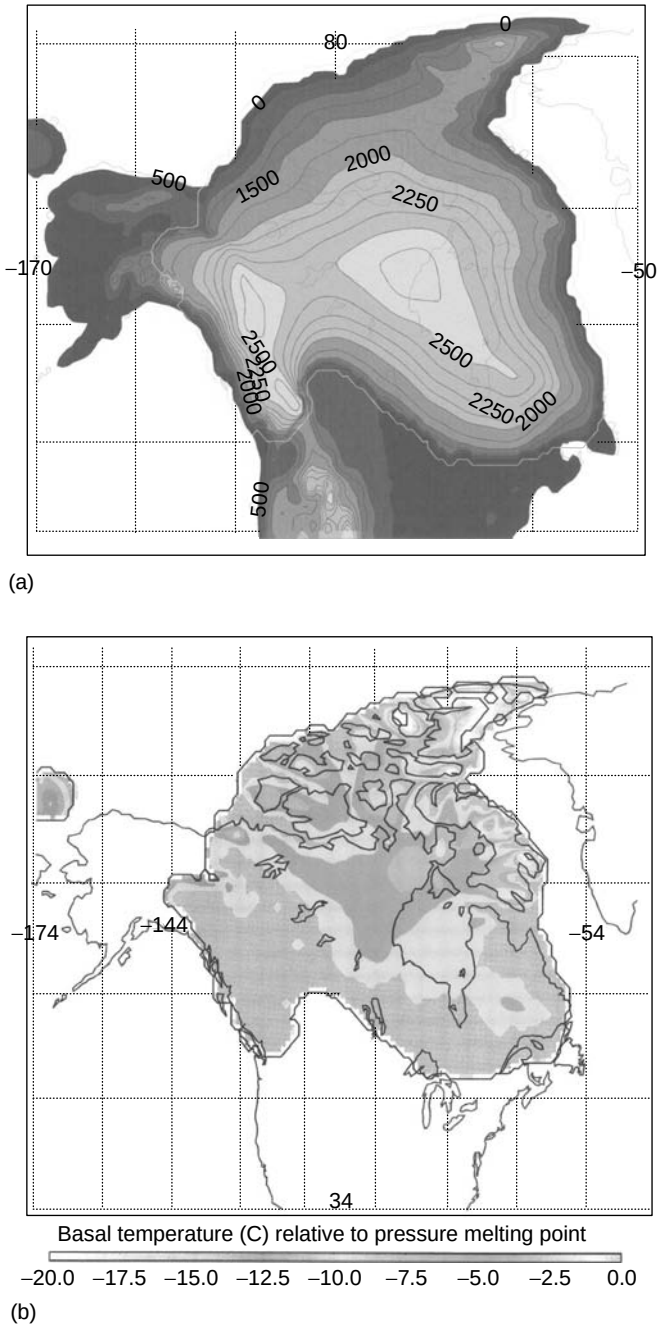

Figure 22 (a) Elevation with respect to sea level at LGM of the Laurentide ice sheet over North America as simulated by the ice sheet coupled climate model described in the text; (b) temperatures at the bedrock ice sheet interface for the Laurentide ice sheet simulated by the climate model (from Tarasov *et al.*, 1999)

is no generally accepted explanation although there does exist a number of potentially explanatory hypotheses. These inevitably invoke some combination of a biological pump and a solubility pump. The latter relies simply upon the

fact that the equilibrium concentration of carbon dioxide dissolved in the surface waters of the oceans depends upon temperature such that the lower the temperature the greater the amount of carbon dioxide that will be drawn down from the atmosphere into the oceans. As the system cools during glaciation we must therefore expect the atmospheric carbon dioxide concentration to fall for this reason alone; this fall of the CO_2 concentration would continue so long as deep water continued to form and the thermohaline circulation (THC) remained active.

Although no fully satisfactory demonstration has been provided that this influence could not be dominant in

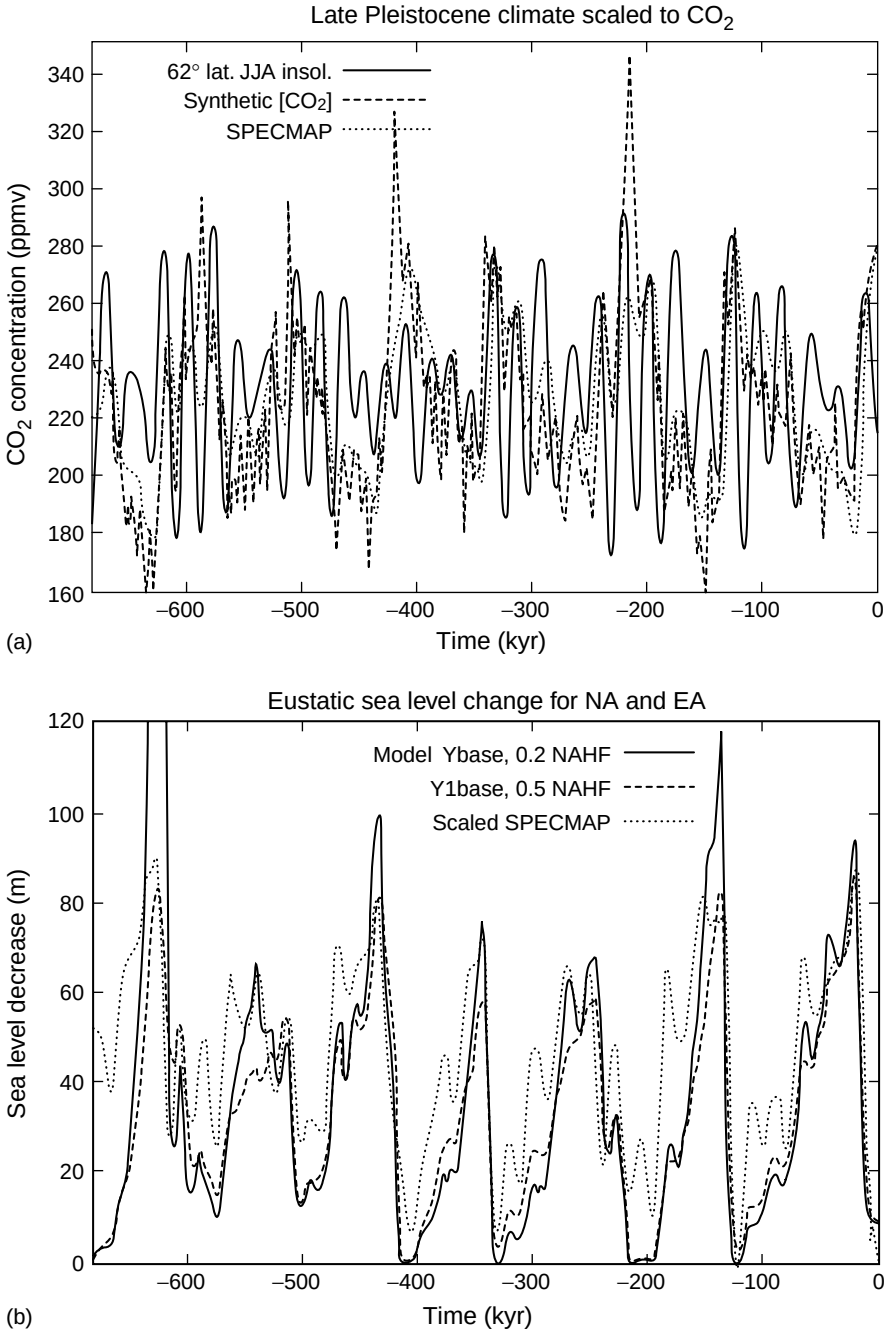

Figure 23 (a) JJA insolation and carbon dioxide forcing compared to the SPECMAP ice volume proxy for the most recent 650 kyr of Earth history; (b) Ice volume histories (represented in terms of decrease in eustatic sea level for North America (NA) and Eurasia (EA)) simulated using the ice sheet coupled climate model for two versions of the model which differ as to the amount of additional forcing due to variation through time of the strength of the thermohaline circulation. (Ybase and Y1base), both of which are compared to the SPECMAP ice volume proxy

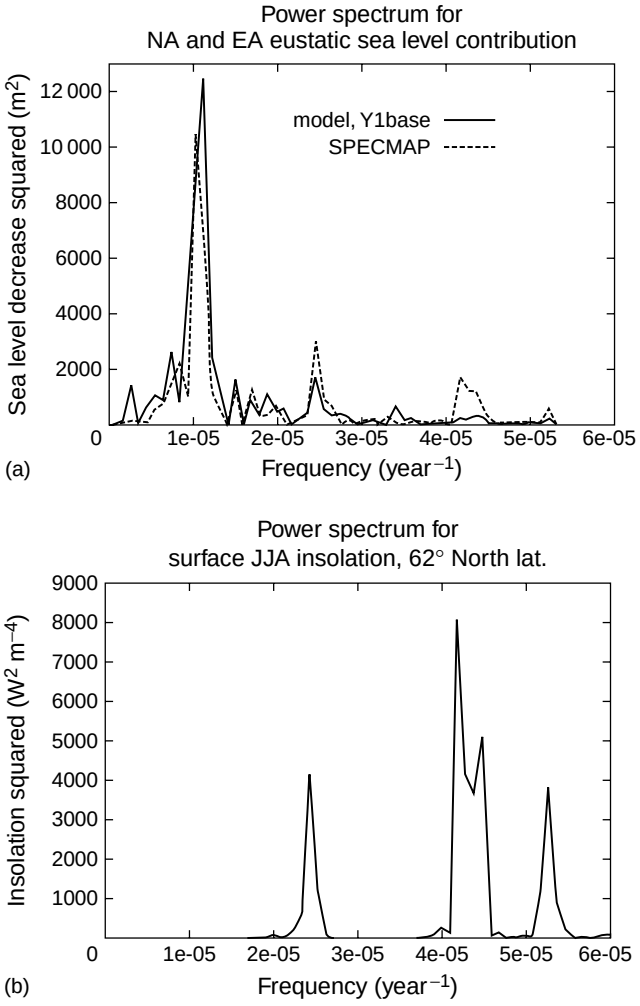

Figure 24 (a) Comparison of the power spectra of the Y1base model of ice volume variability from Figure 23 with the power spectrum of the SPECMAP record; (b) power spectrum of the JJA insolation anomaly employed to force the Y1base model

explaining the 100 kyr cycle in the CO_2 concentration, it is generally believed that the biological pump is the primary mechanism involved in the fall of the CO_2 concentration under glacial conditions. One hypothesis as to how this might work involves the iron fertilization of those regions of the present ocean in which biological productivity is low because of the low level of this element. Inspection of Figure 20 shows that glacial conditions are characterized by strongly enhanced levels of terrigenous dust in the atmosphere. It has been suggested that the iron content of this dust might act so as to dramatically increase net ocean productivity during glacial times, thereby explaining the carbon dioxide cycle. The existing lack of a consensus explanation of the coevolution of continental ice volume and atmospheric carbon dioxide concentration constitutes one of the most significant outstanding problems in paleoclimatology. It is conceivable that these pumps could operate asymmetrically with solubility dominant during glaciation, an asymmetry that could explain the recent results of Shackleton (2000).

In spite of this outstanding problem, we may further probe the ability of the above described model of the 100 kyr ice age cycle by employing a longer input record of the atmospheric CO_2 concentration, four ice age cycles of such data now existing from Vostok, in conjunction with a longer input record of the astronomical forcing. Figure 23(a) shows both these inputs to the model, together with the SPECMAP ice volume proxy, while Figure 23(b) shows two different versions of the ice volume simulation (in terms of the implied eustatic sea level variation) along with a scaled version of the SPECMAP record. These two versions of the model of the 100 kyr cycle include two different levels of the atmospheric heating and cooling that is assumed to occur due to time variations in the strength of the thermohaline circulation as the Earth system undergoes transitions from glacial to interglacial conditions. This additional thermal influence has very little effect on the glaciation and deglaciation of the North American continent. The same is not true for the northwestern European ice complex, which lies downstream in the atmosphere from the main regions of deepwater formation in the Greenland, Iceland and Norwegian (GIN) Seas. Figure 24(a) shows the power spectrum of one of the synthetic ice volume records from Figure 23 together with the power spectrum of the SPECMAP time series itself. Comparison of these two spectra demonstrates that the model appears to successfully explain the dominance of variability on the 100 kyr time scale even though the orbital forcing has no power at all at this period.

MILLENNIUM TIME SCALE CLIMATE VARIABILITY UNDER GLACIAL CONDITIONS: DANSGAARD–OESCHGER OSCILLATIONS, HEINRICH EVENTS AND THE BÖLLING–ALLERØD YOUNGER–DRYAS HOLOCENE TRANSITION

Although the simple ice sheet coupled climate model employed as a vehicle for understanding episodes of glaciation in both the distant and more recent past has proven to be very effective for this purpose, it fails entirely when confronted with observations of ice age climate variability on time scales that are sub-orbital. The primary source of observational data that constrain the nature of climate variability on the millennium time scale is once more the isotopic records of the $\delta^{18}O$ ratio, but now measured in ice core ice rather than the tests of foraminifera from deep sea sedimentary cores. Figure 25 shows the $\delta^{18}O$ record from the European Greenland Ice Project (GRIP) ice core that

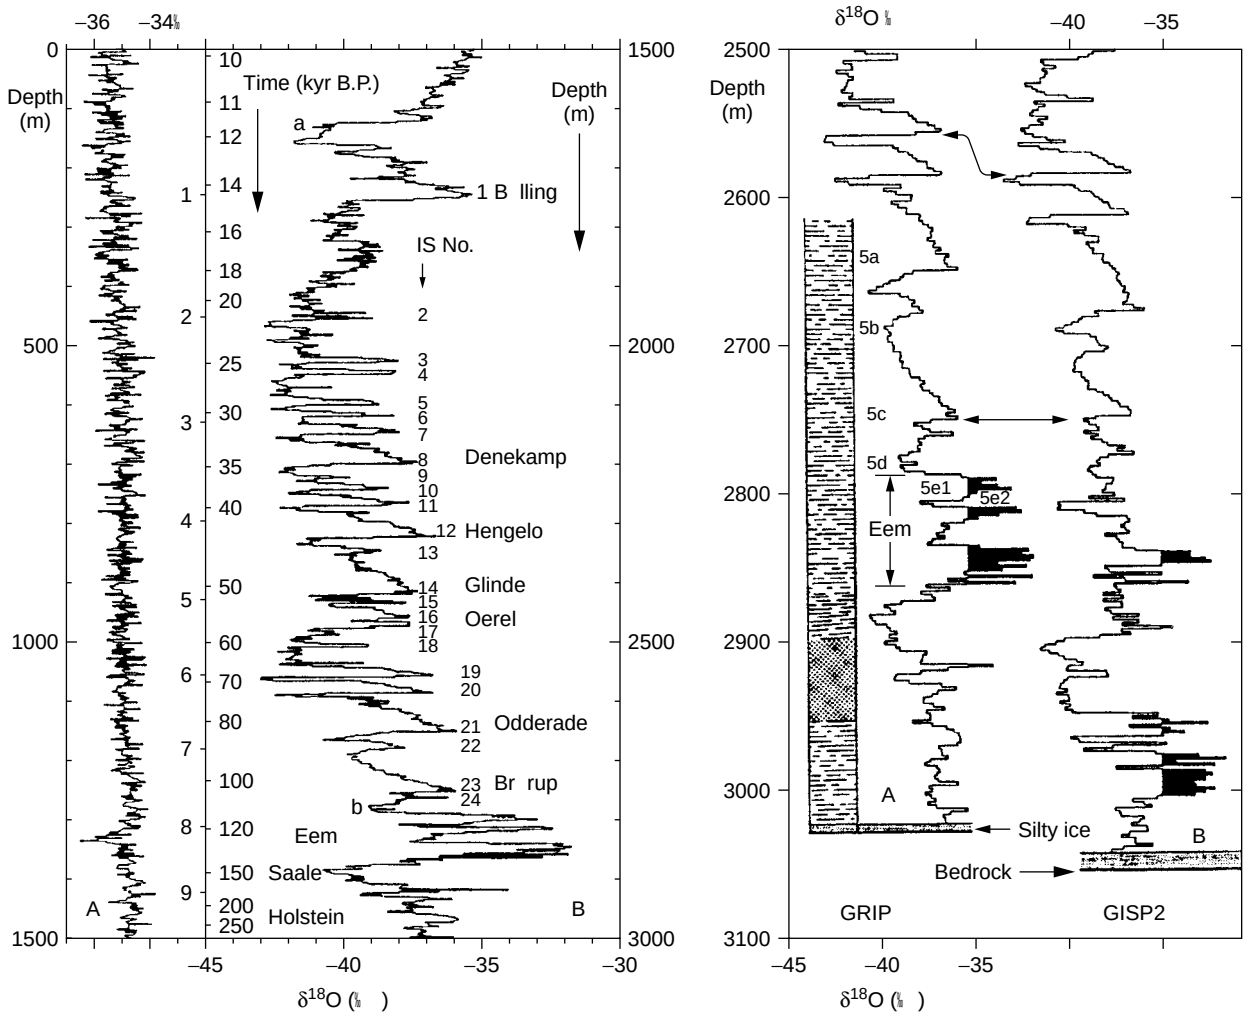

Figure 25 The $\delta^{18}O$ record from the deep ice core drilled at Summit, Greenland by the European GRIP project. The Eemian segment of this record is also compared to the equivalent segment from the American GISP2 record obtained from a deep ice core drilled at a nearby location (from Johnsen *et al.*, 1994)

was drilled at Summit, Greenland. This record is essentially identical to the American Greenland Ice Sheet Project 2 (GISP2) record except in the OIS 5 section, which is also shown on this Figure for both cores. When measured in ice sheet ice, the $\delta^{18}O$ climate proxy is indicative of the temperature of the air from which the precipitation was derived that formed the ice. Inspection of this Figure, in which the data are shown both as a function of depth in the core and as a function of time in calendar years, demonstrates that the temperature of the air over Greenland has been rather stable during the Holocene epoch, except perhaps for the event which occurred near 8.2 ka, whereas during marine OIS 3, which extends from approximately 30 ka–~65 ka, the record is characterized by the occurrence of large amplitude millennium time scale variability. The most recent calibrations of the $\delta^{18}O$ air temperature thermometer suggest that the peak to peak variations in air temperature during these oscillations are on the order of at least 10 °C (*see* Climate Change, Abrupt, Volume 1). That this millennium time scale variability is recorded not only in Greenland ice but also in the oceans is clear on the basis of the oxygen isotopic and other records shown in Figure 26. All these records are from a deep sea sedimentary core (MD 2024) that was drilled on Orphon Knoll, a site located at ~50 °N latitude and 45 °W longitude, to the southeast of the Labrador Sea. This is a site at which the deep sea sedimentary isotopic record samples the Western Boundary Under Current. This deep current of the thermohaline circulation is one in which deep water flows southwards. The Orphon Knoll site is especially important as it lies in the path of the iceberg discharges that occurred episodically through Hudson Strait due to calving instabilities on the eastern flank of the Laurentide ice sheet. These discharge events, called Heinrich events (*see* Heinrich (H-) Events, Volume 1), are clearly marked in Figure 26 by the symbols H0–H6 which correspond to

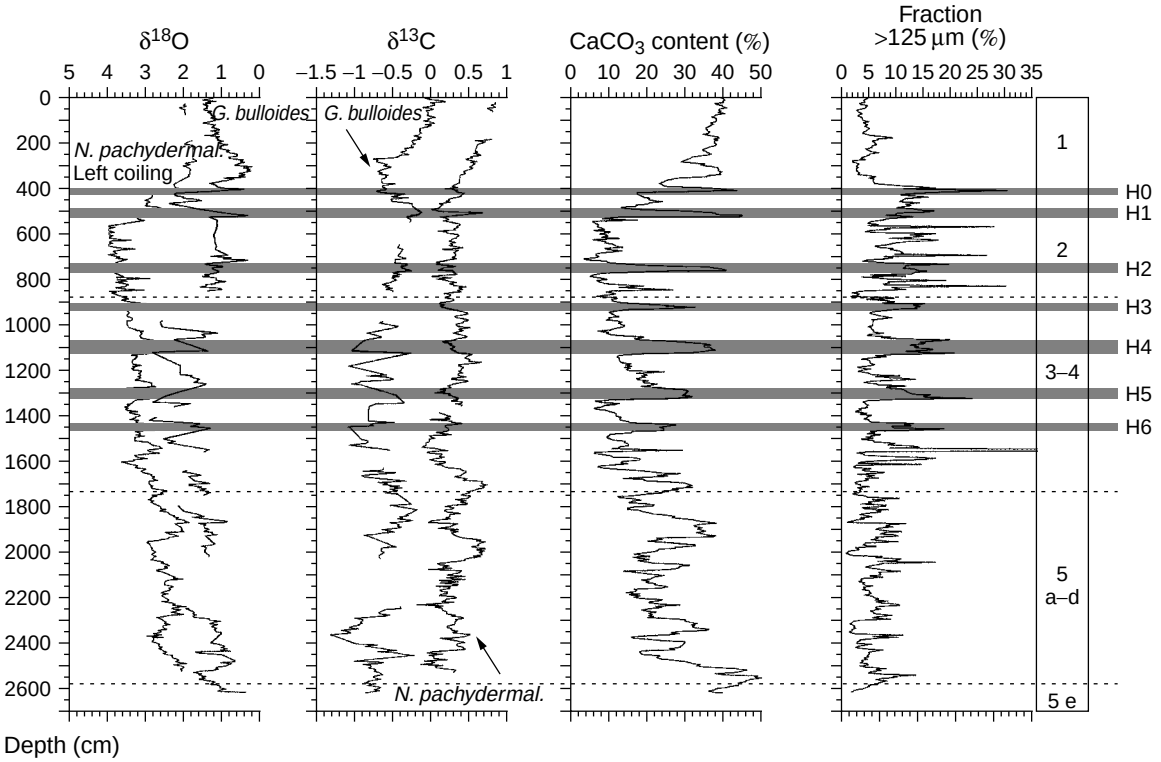

Figure 26 Heinrich event data from the deep sea sedimentary core MD-2024 from the Orphan Knoll in terms of $\delta^{18}O$, $\delta^{13}C$, $CaCO_3$ content and size fraction >125 μm data. The horizontal bars denote the times of occurrence of Heinrich events H0–H6 (from Hillaire-Marcel and Bilodeau, 2000)

horizons in the sedimentary core in which the concentration of ice rafted debris is exceptionally high. This can be seen clearly in the final part of this figure, which shows the fraction of particles of size greater than 125 μm as a function of depth in the core. Detailed intercomparison of the ice core (Figure 25) and sedimentary core (Figure 26) records shows that Heinrich events labeled H3–H6 appear to precede the most pronounced rapid warming events recorded in the European GRIP ice core; these warming events are named Denekamp, Hengelo, Glinde and Oerel, respectively. These Heinrich events therefore appear to coincide with cold phases of the millennium time scale variability, which end in a much more rapid episode of warming. A single millennium time scale oscillation therefore appears to have the same relaxation oscillation form as does the previously discussed 100 kyr cycle itself, in that the cooling phase is relatively long lived whereas the warm phase is extremely abrupt. Of particular note is the fact that the most intense warming phases of the millennium time scale variability, which follow the individual Heinrich events, are themselves followed by a sequence of progressively weaker millennium time scale oscillations. From the cold ambient climate of the glacial period to a relatively warm interstadial climate (the individual interstadials that occur during marine OIS 3 are denoted IS on Figure 25). Because this pattern is repeated several times during OIS 3, it has come to be referred to as the Bond cycle after its discoverer, Gerard Bond of the Lamont–Doherty Earth Observatory of Columbia University. The basic millennium time scale variability is referred to as the Dansgaard–Oeschger (D–O) oscillation and was first discovered by the persons for whom the oscillation is named on the basis of analyses of oxygen isotopic data derived from the earliest Greenland ice cores (*see* Dansgaard- Oescheger Cycles, Volume 1). It is clearly an extremely interesting question in environmental physics as to the reason for the existence of this complex, large amplitude, sub-orbital millennium time scale phenomenology.

The origins of these rapid oscillations between cold glacial climate and warm interstadial conditions appear to involve an interaction between the large continental ice sheets that surrounded the North Atlantic basin under glacial conditions, as illustrated in Figure 27, and the thermohaline circulation of the ocean(s) itself. Although the basic mechanism of oscillatory behavior has yet to be demonstrated in a complete coupled atmosphere–ocean–sea ice–land surface processes model, several models of intermediate complexity have shown behavior that is consistent with the primary ice core and deep sea sedimentary core observations. The basic geometry of one such intermediate complexity model, shown on Figure 28, consists of a series of three north south oriented two-dimensional (latitude–depth)

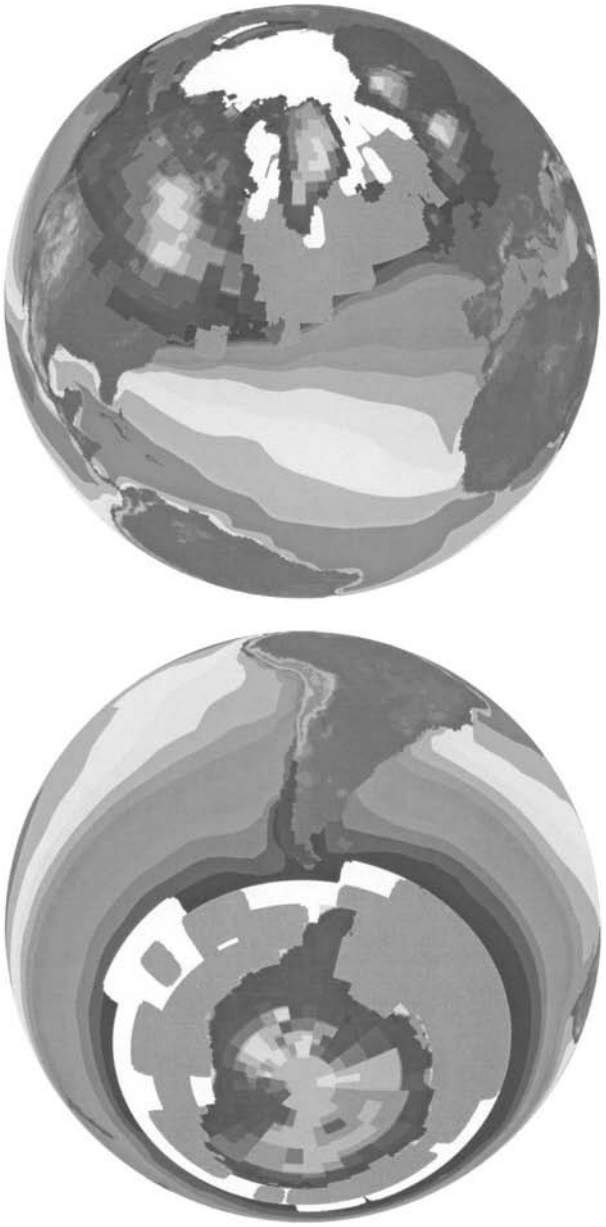

Figure 27 Northern and Southern Hemisphere land ice and sea ice extents at LGM approximately 21 000 calendar years ago. Also shown, in various shadings, are the sea surface temperatures (lighter shadings are warmer). Northern Hemisphere summer sea ice is shown as white whereas the Northern Hemisphere winter sea ice extent is shown as a grey extension of the winter distribution

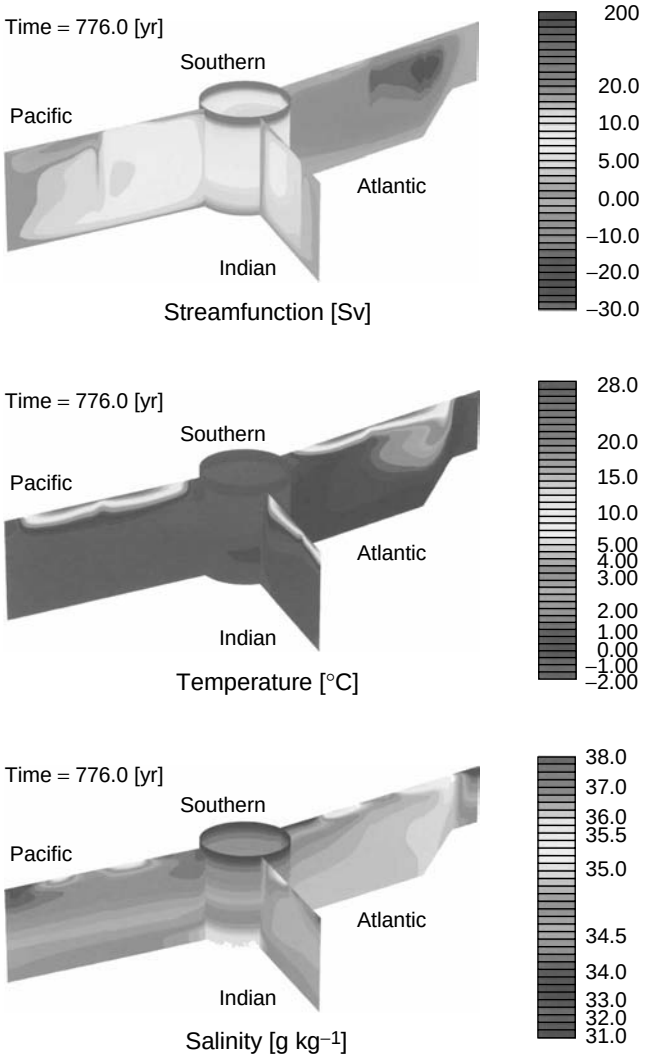

Figure 28 Flywheel geometry of a simple model of the THC of the global ocean showing examples of each of the three 2-dimensional dynamical fields (stream function, temperature and salinity) which the model explicitly predicts as a function of time. The units of stream function are Sverdrups (1 Sv = 10^6 m^3 sec^{-1})

ocean basins arranged in a flywheel pattern, and interconnected through a fourth two-dimensional basin that is of conical form and situated so as to represent the circumpolar Southern Ocean. This model of the global thermohaline circulation is coupled to the same energy balance model of the atmosphere employed as one element of the ice sheet coupled climate model described by schematic Equation (2). Because the thermohaline circulations in the individual basins of the model are described as hydrostatic, the deep-water formation process must be parameterized, as is the case in a conventional ocean general circulation model. The surface boundary conditions imposed on the individual basins consist of specified precipitation–evaporation fluxes (P–E = freshwater flux) and a restoring boundary condition on temperature that continuously nudges the surface temperature towards that calculated by the energy balance climate model. It is the mixed nature of these boundary conditions that allows the model to exhibit a mode of dynamical behavior that may, when the P–E boundary condition is appropriately selected, mimic extremely well the behavior implied by the Summit, Greenland isotopic observations.

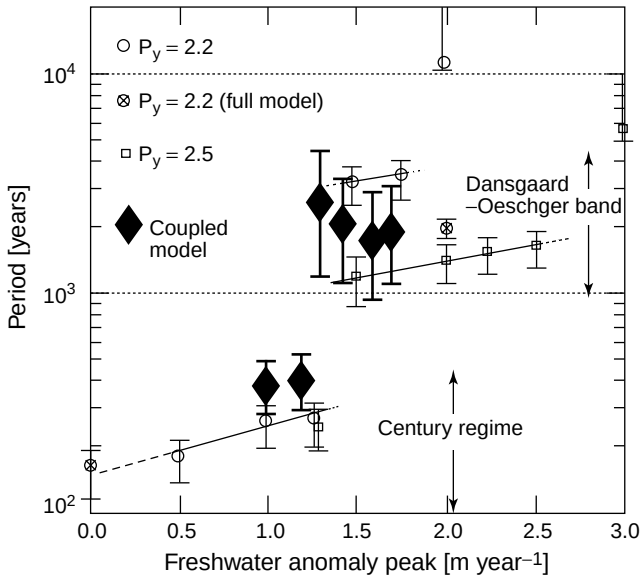

Figure 29 Bifurcation diagram for the multiple 2-dimensional basin model of the THC showing the characteristic period of the temporal variability of the THC in the Atlantic basin of the model as a function of the magnitude of the anomalous freshwater forcing that is applied as a Gaussian function of latitude to the northern part of the Atlantic basin. Note that as the peak anomaly is increased above $\sim$1.25 m year^{-1} the system undergoes sharp transition into a new state characterized by a variability time scale of 1000–3000 years (from Sakai and Peltier, 1997)

Figure 29 presents a bifurcation diagram for this model of the thermohaline circulation (THC) of the oceans. The diagram plots a measure of the dominant period of the temporal variability in the strength of the THC in the Atlantic basin as a function of the strength of the anomaly in P–E that is applied as a function of Gaussian form to the northern part of the basin in which North Atlantic Deep Water (NADW) forms under present-day climate conditions. Inspection of this diagram demonstrates that as the strength of the applied anomaly increases from zero (this corresponding to the present P–E distribution), the characteristic period is initially short and of order a century or so. However, there is a critical strength of the anomaly which, if exceeded, results in a bifurcation into a state of THC activity in which the characteristic period is of order 1–3 millennia. This result is quite precisely the period of the oscillatory behavior of the THC that would be necessary to explain the δ^{18}O oscillations which dominate the proxy climate record from the Greenland ice core during marine OIS 3.

Insight into the change of physical behavior of the simulated ocean circulation that is associated with the bifurcation is provided by Figures 30 and 31. The first of these Figures shows a series of 20 kyr simulations of the meridional heat transport in the Atlantic Basin of the model as a function of the strength of the anomaly in P–E that is applied to the northern part of the basin over the region where deep water forms. Inspection of this sequence of time series shows that, as the maximum amplitude of the P–E anomaly exceeds a value of approximately 1.15 m year^{-1}, the heat transport changes from a state of quasi-steady variation in which weak variability exists with a characteristic period of centuries, to a state of large amplitude strongly oscillatory behavior on the millennium time scale. For a modest post-bifurcation amplitude of the P–E anomaly, the system is primarily in a state characterized by strong meridional heat transport. As the maximum magnitude of the anomaly increases, however, the millennium time scale behavior is transformed such that the oscillations consist of 1–3 millennium-spaced excursions from a state of null heat transport into a state of strong heat transport (note that negative heat transport in this model corresponds to transport from the south to the north). For a sufficiently large applied perturbation, the THC dies and the northward heat transport vanishes entirely except for weak small amplitude fluctuations.

Figure 31 describes the impact of the bifurcation in terms of the output of North Atlantic surface air temperature delivered by the energy balance component of the coupled model. Comparison with the results on Figure 30, which shows the average air temperature estimates for both the summer and winter seasons, demonstrates that, when the northward heat transport is low, the surface air temperature is low. This is an entirely expected consequence of the fact that northward heat transport ceases when North Atlantic deep water (NADW) ceases to form. In the present climate; the formation of NADW during winter in the Greenland, Iceland and Norwegian seas heats the atmosphere at an annually averaged rate of approximately 100 W m^{-2} (all primarily during the winter season). This heating contributes in a telling way to moderation of the climate of northwestern Europe. It is important to note that the amplitude of the millennium time scale variations of North Atlantic air temperature simulated by this model are on the order of 6 °C. This is of the same order as those which have been inferred on the basis of the GRIP and GISP2 δ^{18}O measurements at Summit, Greenland. The hypothesis that the millennium time scale variability observed in these ice cores is caused by millennium time scale variability in the THC of the oceans would therefore appear to be well justified.

Seen from a mathematical perspective, the transition that occurs in the nature of model solutions as the perturbation to the P–E distribution increases in strength, wherein the solution changes its character from quasi-steady to intensely oscillatory, is termed a Hopf bifurcation. Such occurrences in nonlinear dynamical systems are extremely common in circumstances in which multiple equilibria or multiple quasi-equilibria exist. In the present circumstance, for weak P–E perturbation the North Atlantic THC is strong and

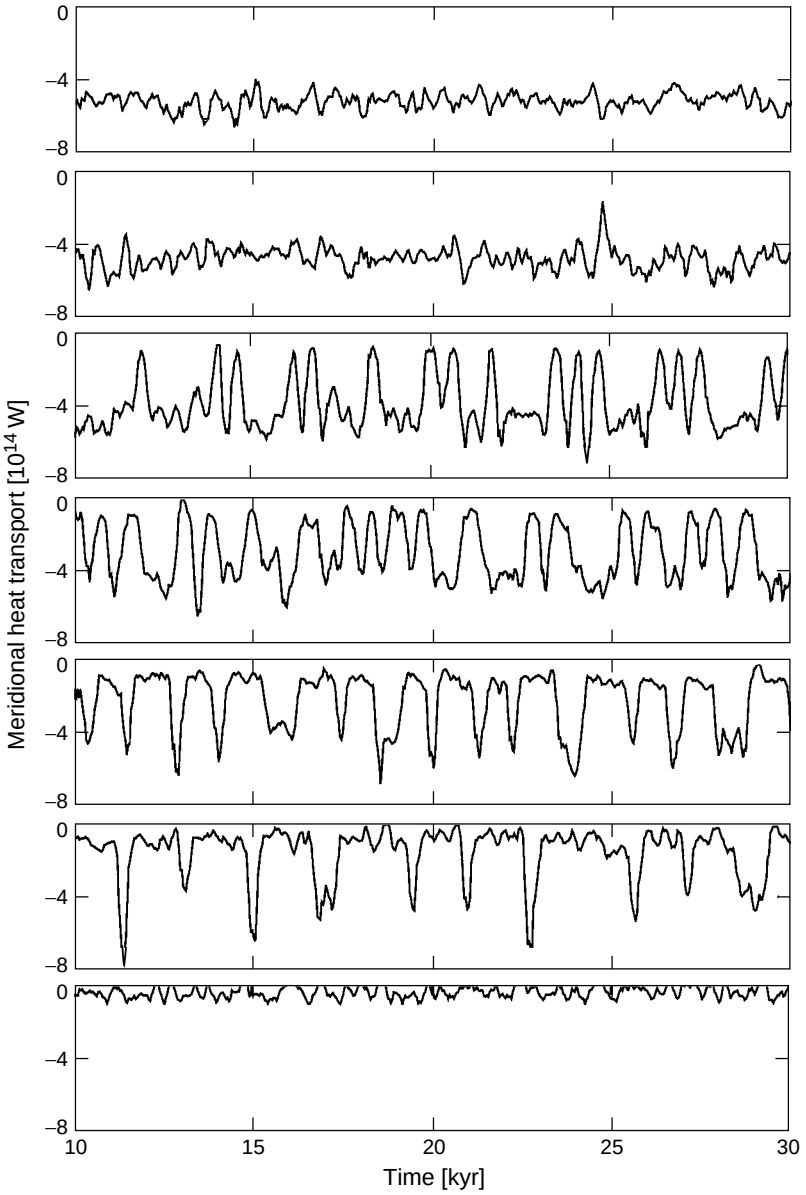

Figure 30 Northward heat flux in the Atlantic basin of the coupled model for a range of values of the peak freshwater anomaly applied to the northern part of the North Atlantic basin

essentially steady, consistent with the Holocene segment of the GRIP ice core shown on Figure 25. For a strong positive P−E perturbation NADW ceases to form and the THC stops entirely! In the intermediate range, a Hopf bifurcation occurs that induces oscillatory behavior on the millennium time scale. This oscillator may legitimately be referred to as a salt-oscillator, but it is of a kind that is quite different from that previously suggested by Professor Wallace Broecker of Columbia University. This is because the basic oscillation does not require covariation in P−E, which would presumably be connected with time dependence of the iceberg flux contribution to effective P−E. Rather it occurs under conditions of constant P−E. An explicit depiction of the covariation of sea surface salinity (SSS) during the Hopf bifurcation induced millennium time scale variability in this model is provided in Figure 32, which demonstrates that the deep circulation is shut down when the high latitude SSS is low. That full glacial THC conditions do indeed correspond to a state of strongly depressed SSS in the North Atlantic was originally demonstrated by Dr J-C Duplessy of the Gif-sur-Yvette Laboratory at Saclay, France.

Although the basic origins of the millennium time scale climate variability during OIS 3 is therefore very well explained by the existence of a Hopf bifurcation induced oscillation of THC strength, which occurs in the absence of

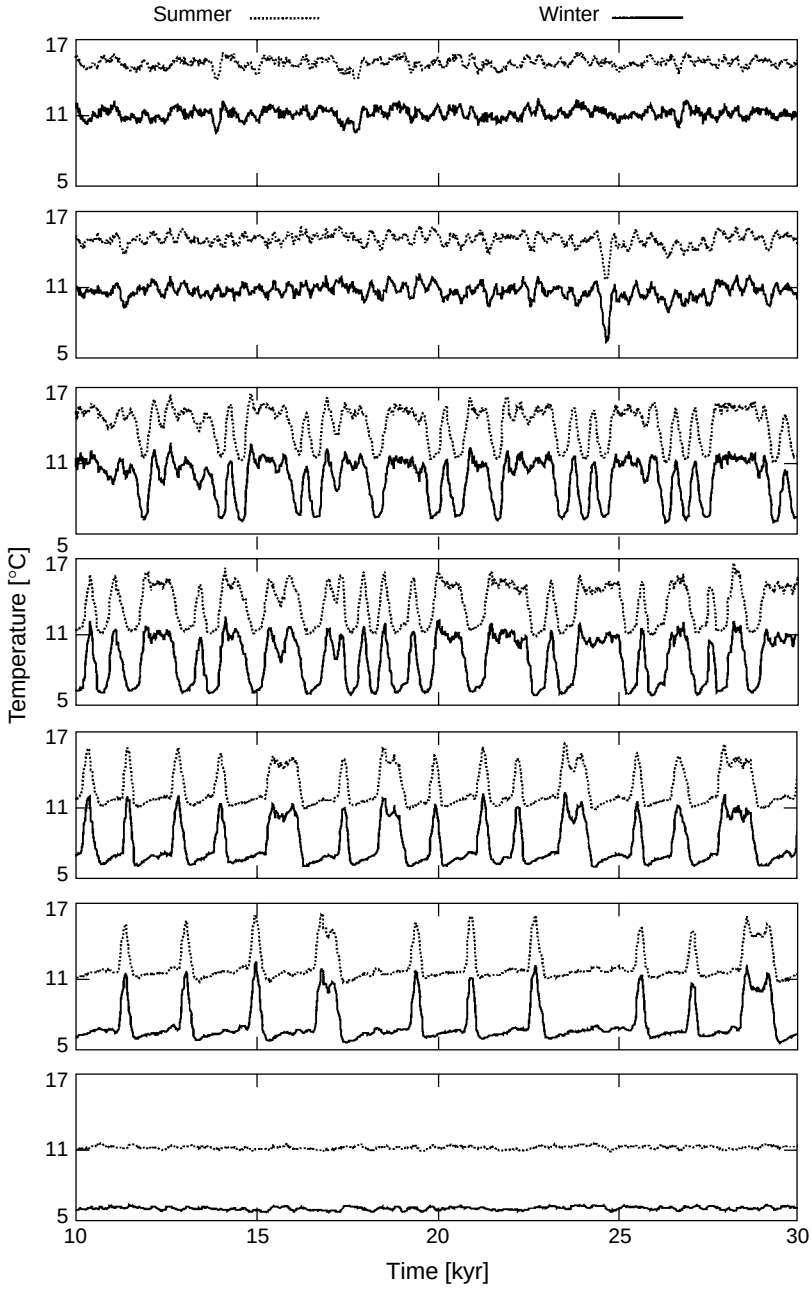

Figure 31 Same as Figure 30 but for the summer and winter air temperature time series

time dependence of the boundary condition on P−E, it is also clear that this boundary condition could not have been constant under glacial conditions. Because effective P−E includes not only the atmospherically derived precipitation and the evaporation from the sea surface, but also the freshwater added to the surface ocean by the melting of the icebergs, it is clear that effective P−E must have varied considerably due to the variability of the iceberg flux that is documented in the episodic nature of the occurrence of individual Heinrich events. It seems reasonable to suggest that the episodic Heinrich activity be viewed as a stochastic contribution to the net freshwater forcing of the surface of the North Atlantic Ocean. It remains unclear as to the extent to which the episodic nature of this activity is phase entrained to the underlying millennium time scale D−O oscillation that appears to be so well explained by the Hopf bifurcation. However, it would not be unexpected that the calving instability on the eastern flank of the Laurentide ice sheet might phase lock to some degree onto the primary metronome provided by the D−O oscillation. It is the interplay of these influences that appears to be responsible for the Bond cycle.

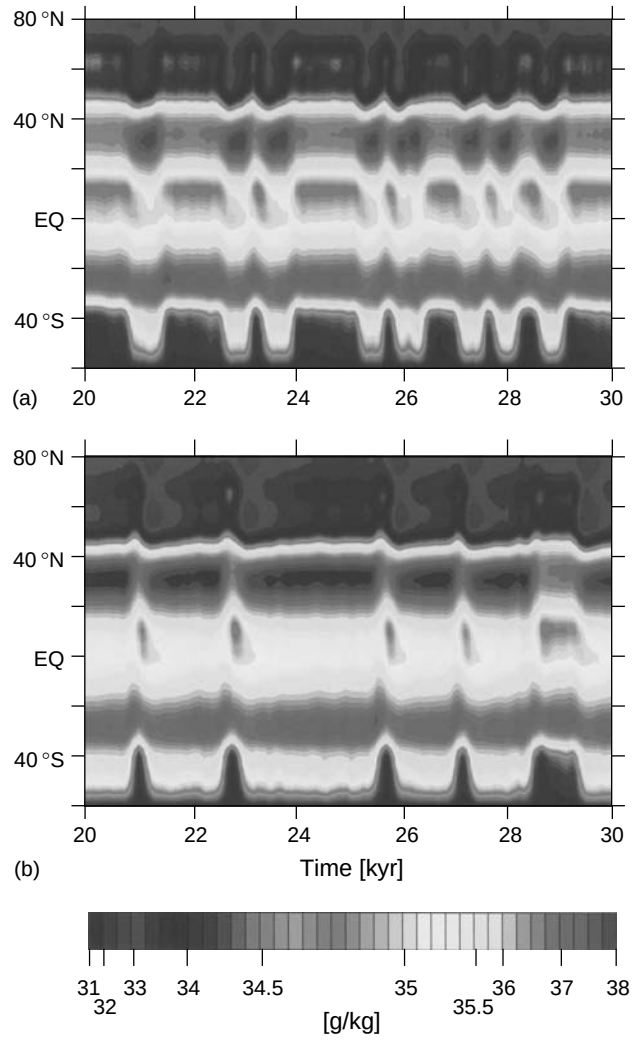

Figure 32 Latitude verses time variations in the SSS of the North Atlantic basin of the climate model for a series of D–O oscillations

SUMMARY: LESSONS IN CLIMATOLOGY FROM THE GEOLOGICAL RECORD OF EARTH SYSTEM HISTORY

It should be abundantly clear on the basis of the previous discussion of the history of Earth evolution, from the Neoproterozoic through to the Cenozoic epoch, that this most recent billion years is a period during which Earth has experienced a sequence of three episodes of significant cooling associated with the appearance of massive continent scale ice sheets. These cold phases of evolution have occupied no more than approximately 20% of this period, however, the remainder of which was characterized by climates considerably warmer than present. A primary determinant of climatic state during this period appears to have been the concentration of carbon dioxide in the atmosphere of the planet. Also contributing significantly to the long time scale evolution of surface climate has been the variation of solar luminosity and the variation of what one might refer to as polar continentality. It appears that the latter influence has perhaps been insufficiently appreciated in the past.

Even less well understood has been the apparently strong control upon the atmospheric carbon dioxide concentration that has been exerted by the so-called Wilson cycle of supercontinent creation and destruction. In particular it appears that it is during episodes of supercontinent break up that massive volcanic out-gassing leads to a significant rise of the atmospheric CO_2 concentration. Furthermore, it would appear that during the breakup phase, the mantle convective circulation may be most significantly layered by the influence of the endothermic phase transformation at 660 km depth. In contrast, continental fragments may be brought together to form a supercontinent by the occurrence of internal mantle avalanches that develop through episodic convective destabilization of the internal thermal boundary layer that forms across the 660 km discontinuity during periods of strongly layered flow. This demonstrates that, on the longest time scales, the evolution of Earth s surface climate is tightly linked to surface plate tectonics and thus to the mantle convection process.

During the Pleistocene epoch, the link between episodes of deepest glaciation and the concentration of carbon dioxide in the atmosphere is equally apparent in the strong correlation between the $\delta^{18}O$ inferred 100 kyr cycle of continental ice volume variability and the covariation of the CO_2 concentration. The same simple ice sheet coupled climate model that serves as an excellent basis for understanding the Carboniferous and Neoproterozoic glacial epochs, also explains the way in which the variations in the effective intensity of the Sun, caused by the changing geometry of Earth s orbit, is able to cause quasi periodic variations of continental ice volume at 100 kyr period. This model is successful, however, only as a consequence of the interplay between the astronomical forcing, the action of the glacial isostatic adjustment process in amplifying the deglaciation process once ice sheets become sufficiently large, and the fact that the CO_2 concentration itself varies on the 100 kyr time scale. One of the most outstanding problems in paleoclimatology is to provide a detailed understanding of the reason why the CO_2 concentration covaries with ice volume. It has even been suggested in the recent literature that the CO_2 concentration may lead ice volume at the period of 100 kyr and therefore should most properly be viewed as a prime mover of the 100 kyr ice age cycle rather than simply being an amplifier (Shackleton, 2000). What we can safely say on the basis of the analyses that have been performed with the ice sheet coupled climate model, however, is that in the absence of the additional forcing of ice volume by the variation of the CO_2 concentration the model could not explain this primary mode of late Pleistocene climate variability.

With each distinct 100 kyr cycle of late Pleistocene glaciation, during the equivalent within each cycle of OIS 3, there has also existed strong variability in surface climate on sub-orbital time scales of millennia. This higher frequency mode of climate change appears to be very tightly linked to variations in the strength of the THC. This component of the general circulation of the oceans has apparently been rather steady throughout the last 10 000 years of the Holocene epoch. However, during OIS 3 there was strong evidence that the strength of the overturning circulation in the Atlantic Basin exhibited quasi-periodic oscillations between a state of strong overturning and a state of essential quiescence. A range of different models of the THC have now been shown to exhibit such oscillatory solutions when they are subjected to sufficiently intense freshwater forcing over the region in which deepwater would otherwise form when this component of effective P−E is unperturbed from its modern distribution. The transition into the oscillatory mode of behavior in these models occurs via a classical Hopf bifurcation. When the excess freshwater forcing exceeds the critical value but is less than would be required to arrest the THC entirely, these models exhibit spontaneous oscillatory behavior even when the boundary condition on P−E is kept constant. This regime appears to provide the explanation of the millennium time scale D−O oscillation. The Heinrich events, which occur episodically during the cold phase of one of the fundamental D−O oscillations, are associated with massive iceberg calving events that appear to be triggered by instability of the eastern flank of the Laurentide ice sheet and repeat approximately every 10 kyr. Following each Heinrich event induced cooling of North Atlantic climate state, a sequence of D−O oscillations occurs, with decreasing amplitude which together form a Bond cycle of oscillations. One explanation of the Bond cycle, which fits well with the Hopf bifurcation explanation of the more fundamental D−O oscillation, is that it arises as a consequence of stochastic forcing of the D−O phenomenon due to the temporal variability of the iceberg flux.

In the course of the foregoing discussion of climate system history, I have not mentioned at all the Heinrich events labeled H0 and H1 on Figure 26. They immediately follow and precede, respectively, the Younger Dryas (Y−D) climatic cooling event, which interrupted the general trend to warmer climate that began subsequent to the last glacial maximum (LGM) as the Northern Hemisphere continents began to deglaciate. H1 appears to coincide with the B lling warm period, which was accompanied by a massive discharge of freshwater to the global ocean, a discharge which is extremely well documented by what has been called meltwater pulse 1a that is so clearly registered in the coral based and uranium−thorium (U−Th) dated relative sea level history at the island of Barbados in the Caribbean Sea that has been recovered by Richard Fairbanks of the Lamont−Doherty Earth Observatory of Columbia University. This meltwater event appears to have been derived from the Laurentide ice sheet, which was centered on Hudson Bay at LGM. The pulse could have been derivative of an outburst flood of water from the base of the ice sheet. Although this event was sufficient to cause the THC to decrease in intensity, the shutdown associated with Y−D cooling may have been caused by additional freshwater loading due to the meltback of the Fennoscandian ice complex. The Y−D event is therefore an example of a millennium time scale cooling event that is known to have been induced by the shutdown of the THC in the Atlantic Basin caused by an increase in high latitude freshwater forcing, the shutdown lasted approximately 1 kyr and the circulation appears to have recovered spontaneously after this length of time once the anomalous meltwater forcing had ceased to operate.

One clear message that is delivered by these analyses of the rapid climate changes that have occurred in the past is one that has a strong bearing on what we might expect concerning future global changes in the Earth System. Probably the most important characteristic of Earth s climate system is that it is intensely nonlinear. It is because of its intrinsic nonlinearity that the climate system may evolve in such a way as to provide surprises because of the occurrence of bifurcations through which the system may execute transitions between dramatically different modes of behavior once a particular threshold is exceeded. If the greenhouse gas warmed world into which the system appears to be evolving should cross such a threshold, say through an increase of P−E over the North Atlantic which was sufficient to cause THC collapse, we could very well be surprised to discover the imperfect degree to which our current models allow us to know what these thresholds might be. Analyses of Earth System History clearly demonstrate that such thresholds do exist and that, once they are crossed, significant changes do occur.

Earth Observing Systems

SUSHEL UNNINAYAR AND ROBERT A SCHIFFER

Columbia, MD, USA

In the 20th century, we saw dramatic advances in our understanding of how the Earth System functions, much of which may be attributed to substantial improvements in the technology used for Earth observing and modeling. We have also come to realize that the planet faces the potential of rapid environmental changes, including global and regional climate change, rising sea level, deforestation, deserti cation and land degradation, ozone depletion, acid rain, reduction in biodiversity, and depletion of natural resources such as fresh water and ecosystem diversity. Such changes would have a profound impact on all nations, yet important scienti c questions remain unanswered. Many processes controlling the Earth's global climate and regional environments have yet to be fully observed. The quantitative detection of subtle changes in the global system continues to be problematic, especially the attribution of cause. Earth observing systems must simultaneously address the needs for long-term observational continuity with stringent delimits on inter-annual and inter-decadal accuracy, while concurrently assimilating new methods and observing instruments to improve our understanding and modeling of detailed processes better than before. The transition of proven research observing instruments to operational systems is critical to the evolution of Earth observing. As a result of decades of development in Earth observing technology, we may now be on the brink of being able to observe nearly all aspects of the Earth System.

Neither a surface-based and/or in situ *observing system nor a space-based system has the capacity to singularly observe the Earth System. The scienti c and technological challenge is to determine the optimal mix of both, that maximizes their unique capabilities while applying innovative methods to compensate for or reduce the uncertainties and errors inherent in each. Importantly, better cross-connections and links between observing systems are needed, as inter-disciplinary approaches are developed to address the broad range of pressing environmental issues and applications related to the management of natural resources.*

KEY EARTH SYSTEM PARAMETERS AND VARIABLES

The global Earth System may be defined as comprising the atmosphere (troposphere, stratosphere and mesosphere), the hydrosphere (oceans and other important components of the hydrological cycle such as lakes, rivers, and subterranean waters), the land surface and biosphere (soils, vegetation cover, continental fauna and flora, and the fauna and flora of the oceans), the cryosphere (the ice fields of Greenland and the Antarctic, other continental glaciers, snow fields and sea ice), and the geosphere/lithosphere (continents and their topography, ocean bottom structure, the Earth s crust and molten core, tectonic motions and volcanic and earthquake processes, among others). Recent additions to this list are the chemosphere (chemical constituents and exchanges), and the technosphere (technology, anthropogenic forcing, land use changes, deforestation, resettlement programs, etc.). The latter two are increasingly becoming major forcing components of the Earth System. They are a direct consequence of the rapid escalation of human activity over the past century. One could call this the homo-sphere, and this age the Anthropocene, a term reportedly coined by Paul Crutzen (*see* Anthropocene, Volume 1).

Observing the Earth System requires the definition of a key set of parameters or variables that collectively describe its dynamic character. It is sometimes mathematically convenient to consider internal state variables and forcing or feedback variables for each component of the Earth System, as detailed in Table 1. A state variable, as the name implies, would provide monitoring information on the basic internal structure and state of a system or subsystem. A forcing or feedback variable would comprise a parameter that could change the state of a system or subsystem. Consonant with such an approach, the set of variables identified in Table 1 could be considered a minimum set to adequately describe the state and behavior of the physical Earth System when considering time scales ranging from days to years and decades. For longer time scales, processes and interactions within the solid Earth

Table 1 Summary of state and forcing/feedback variables required to observe the major components of Earth System[a]

State variables (Sv)	External forcing or feedback variables (Fv)
(1) Atmosphere	
Wind (*I*/*s*)	SST (*I*/*S*)
U/A temperature (*I*/*S*)	Land surface soil moisture/temperature (*I*/*S*)
Surface air temperature (*I*/*s*)	Land surface structure and topography (*I*/*S*)
Sea level pressure (*I*)	Land surface vegetation (*I*/*S*)
U/A water vapor (*I*/*S*)	GHGs, ozone and chemistry, aerosols (*i*/*S*)
Surface air humidity/wv (*I*/*s*)	Evaporation and evapotranspiration (*i*/*s*)
Precipitation (*I*/*S*)	Snow/ice cover (*I*/*S*)
Clouds (*i*/*S*)	SW and LW radiation budget – surface (*i*/*s*)
Liquid water content (*i*/*S*)	Solar Irradiance and SW/LW radiation budget (*S*)
(2) Ocean	
Upper ocean currents (*I*/*s*)	Ocean surface wind & wind stress (*i*/*S*)
Surface ocean temperature (*I*/*S*)	Incoming surface shortwave radiation (*i*/*s*)
Sea level/surface topography (*I*/*S*)	Downwelling longwave radiation (*i*/*s*)
Upper ocean surface salinity (*I*/*s*)	Surface air temperature/humidity (*I*/*s*)
Sea ice (*I*/*S*)	Precipitation (fresh water/salinity flux) (*i*/*s*)
Mid and deep ocean currents (*i*)	Fresh water flux from rivers & ice melt (*i*/*s*)
Sub-surface thermal structure (*I*)	Evaporation (*i*/*s*)
Sub-surface salinity structure (*I*)	Geothermal heat flux–ocean bottom (*i*)
Ocean biomass/phytoplankton (*i*/*S*)	Organic & inorganic effluents (into ocean) (*i*/*s*)
(3) Land and Water (Non-ocean)	
Topography/elevation (*I*/*S*)	Incoming shortwave radiation (*I*/*s*)
Land cover (*I*/*S*)	Net downwelling longwave radiation (*i*/*s*)
Soil moisture/wetness (*I*/*s*)	Surface winds (*I*)
Soil structure/type (*I*/*s*)	Surface air temperature and humidity (*I*/*s*)
Vegetation/biomass vigor (*I*/*S*)	Evaporation and evapotranspiration (*i*/*s*)
Water runoff (*I*/*s*)	Precipitation (*I*/*S*)
Surface ground temperature (*I*/*S*)	Land use and land use practices (*I*/*s*)
Snow/ice cover (*I*/*S*)	Deforestation (*i*/*s*)
Sub-surface temp and moisture (*I*/*s*)	Human impacts – land degradation (*i*/*s*)
Soil C, N, P, nutrients (*I*)	Erosion, sediment transport (*i*/*s*)
Necromass (plant litter) (*i*)	Fire occurrence (*I*/*S*)
Sub-surface biome/vigor (*i*)	Volcanic effects (on surface) (*I*/*s*)
Land use (*I*/*s*)	Biodiversity (*i*/*s*)
Ground water (and subterranean flow) (*i*)	Chemical (fertilizer/pesticide and gas exchange) (*i*)
Lakes and reservoirs (*I*/*S*)	Waste disposal and other contaminants (*i*)
Rivers and river flow (*I*/*s*)	Earthquakes, tectonic motions (*I*/*S*)
Glaciers and ice sheets (*I*/*S*)	Nutrients and soil microbial activity (*i*)
Water-turbidity, N, P, dissolved O (*I*/*s*)	Coastal zones/margins (*I*/*S*)

Abbreviations: SST, sea surface temperature; U/A, upper air; N, nitrogen; P, phosphorous; O, oxygen; C, carbon.

[a] In parenthesis, *I*(or *S*) denotes measurements that can be made by *in situ* (or observing systems for space-based) instruments and that operational or systematic (research) observing systems/networks and international programs exist. An *i*(or *s*) denotes that the *in situ* (or space-based) measurements made are restricted in space and/or time coverage, or that operational monitoring and data exchange systems do not exist, or that the measurements made are insufficient in accuracy or precision. In some cases, observing systems for the parameters flagged by an *i*(*s*) may be scheduled for significant improvements in the near future.

need to be taken into account, as well as solar, orbital and planetary gravitational interactions. It is underscored that the distinction between state and forcing variables is, to an extent, an artifact of the partitioning of the Earth System into land, atmosphere and ocean. In doing so, a state variable for one component could be, and often is, a forcing or feedback variable for another component. However, a partitioning of the Earth System becomes useful, if not necessary, to enable observing systems and models to be constructed. Table 1 contains a summary of the parameters that need to be monitored to document the state of the total Earth System. The table may be elaborated into one of substantially greater complexity if detailed processes are taken into account. Here, we apply a large- to global-scale filter to reduce the number of macro variables needed to define the Earth System from the perspective of

a particular time window of research and application. The table may be considered fairly comprehensive, but by no means exhaustive. It is presented to provide a framework for Earth observations.

In Table 1, emphasis is placed on geophysical parameters, and a selection of atmospheric chemistry and land–ocean biospheric parameters that are involved in the interaction between the atmosphere and the land and ocean. The parameters include large-scale estimates of vegetation cover and ocean biological productivity, both of which are important aspects of the global carbon cycle, as well as parameters that capture hydrological processes that comprise the global water cycle. They are needed because they represent sub-components of the Earth System that contain inherent memory as far as the time scales of atmospheric processes are concerned, and therefore extend the prediction time range for weather, climate and their impacts on the environment. Certain aspects of the Earth System, such as soil and water nutrients, and chemical discharge, are included due to their importance in assessments of anthropogenic impact on the environment and ecosystems.

CURRENT REQUIREMENTS AND OBSERVING ISSUES

The Earth observing system that is required for the 21st century needs to be an integrated system comprising substantial space-based assets such as remote sensing satellites, surface-based remote sensing instruments such as radar and lidar, and *in situ* instrument networks. Each set of observations should provide a three-dimensional snapshot of each component (or sub-component) of the total system. Repeated observations would provide information on the time evolution (and history) and change of the system. The space and time resolutions required are often determined on the basis of the dominant spatial and temporal features that need to be described quantitatively, and how fast these features change. In principle, however, it is not sufficient to monitor only the dominant scales, because a large number of interactive processes occur on rather small space and time scales – even down to 1 s and 1 m or less. At present, it is not impractical to continually observe the global system at these scales, nor can the data be effectively used. It is customary to obtain very high resolution data sets during special observing experiments of limited duration, in order to understand and model processes, while operating global observing systems (GOSs) at much lower time and space resolutions. These global observations need to remain accurate over time in order to meet monitoring, diagnostic analysis and modeling needs.

The accuracy, precision, and absolute calibration over the observation periods required for climate change and global change purposes are considerably more stringent than those for real time or near real time applications. Though there are notable exceptions, at present few operational observing systems (and observing practices) maintain accuracy and calibration over long periods of time. Most operational observing systems and networks were established for relatively short-term operational applications dominated by the annual solar cycle within which temperatures, for example, can vary between a monthly average of -20 to $+40\,^{\circ}$C, vegetation cover (green leaf area) from 0 to 100%, rainfall from 0 to 500 mm (or much more) between seasons, and so forth depending on location. (In some locations, even the diurnal variation could be very high; for example, up to $50\,^{\circ}$C between day and night in summer in Colorado, USA, or in the Sahara, in continental Africa.) That is, the intra-annual signal is relatively large, and thereby relatively easy to monitor. In contrast, the inter-annual to decadal change signals may be very small and pose significant problems as regards their monitoring and detection. The change in global average temperature, which rose $0.6 \pm 0.2\,^{\circ}$C during the 20th century, illustrates the aforementioned differences in the signal associated with seasonal change and long-term climate change. Correspondingly, observing technology and data processing methods need to be capable of addressing the large differences implied in signal to noise ratio. Evaluating the causes of change and the regional impacts of predicted global change are equally, if not more, complicated and troublesome. Observations must be able to initialize and validate the numerical models used to simulate the Earth System and project future changes.

The introduction of errors and discontinuities in the measurement of absolute values of change on a global or large-scale basis (which could also be national and regional) arise for several reasons, not all of which are electronic sensor related. For surface or near surface and *in situ* measurements, the station or observing network s resolution and coverage on a global basis are usually insufficient. The term *in situ* is commonly used in reference to direct instrumental measurements, in contrast to remotely sensed observations. Surface-based station networks are, by and large, *in situ* stations making observations of, for example, air temperature, humidity, precipitation, winds and pressure. However, surface-based radar stations (precipitation, and wind shear) are not *in situ* stations but rather remote sensing platforms. Instruments measuring soil moisture and temperature at the root zone, the subterranean water table depth, and ocean temperature and salinity at 1000 m depth are examples of *in situ* measurements that are not surface-based. Generally, major problems exist in monitoring oceanic areas (which cover approximately 70% of the Earth s surface) by surface-based or *in situ* station networks. Thus, for example, measuring precipitation globally and observing and quantifying the components of the global hydrological cycle (this includes cloud and convective processes, etc.) are almost impossible with traditional observing systems;

satellite technology will be indispensable. Problems are encountered even over land surface areas on account of changes (often undocumented) in instrument calibration, instrument relocation, and observing practices. Moreover, most land stations are located near populated or cultivated areas, leaving mountainous areas, wetlands, swamps, forests and other remote or inaccessible areas poorly sampled. While having the capacity to provide global coverage, existing space-based observing systems suffer from many problems such as: inadequate time resolution, uncertain vertical resolution, and uncertain or unknown calibration and accuracy between years. These problems can significantly complicate the monitoring and detection of inter-annual (variability) and decadal change. Complicating matters further, accurate sensor calibration is necessary although not entirely sufficient; calibration accuracy and time continuity must be ensured for the end product, namely, the physical, geophysical or chemical or biological parameter, to be accurately measured and monitored.

Notwithstanding various problems with the international implementation of observing systems and networks, significant advances have been made in deploying *in situ* observing networks. Examples include the tropical atmosphere–ocean buoy array deployed in the Pacific during the 10 year World Climate Research Program s Tropical Ocean Global Atmosphere (TOGA) experiment that focused on understanding the processes involved in the El-Niño/Southern Oscillation (ENSO). Another example is the ocean drifting profiler buoys used during the World Ocean Circulation Experiment (WOCE). Following the experience gained during TOGA and WOCE, plans are in place to deploy up to 3000 drifting/profiling buoys to cover all Earth s oceans on a continuing, operational basis. Substantial strides have also been made in establishing networks of instruments to measure the fluxes of carbon dioxide (CO_2), methane (CH_4), water vapor and other gases between the land surface and the atmosphere as a part of investigations into the carbon cycle. Improvements have also been made in instruments and land networks to measure surface ozone and ultraviolet (UV) radiation, and geophysical and biogeochemical exchange parameters in the ocean.

In recent years, space-based technology has also advanced to a point that we are able to accurately observe and globally sense nearly every aspect of the Earth System and to understand the processes that are central to determining the Earth s climate. Active and passive remote sensing systems spanning a wide range of spatial, spectral and temporal scales contribute to capturing and documenting the variability of the Earth s atmosphere, the oceans and continental land surface processes. On-board sensor calibration has taken a major step forwards with the new millennium technology satellite technology. Concurrent, multi-sensor observations of clouds, aerosols and other atmospheric constituents at unprecedented detail permit adaptive atmospheric corrections to be applied so that a desired signal such as ocean temperature or ocean color or vegetation can be obtained with greatly improved accuracy and resolution. Space-based platforms, with their unique capacity to observe the Earth on a global basis, complement surface and *in situ* measurements.

Together with advances in computing and information systems technology, modern data assimilation techniques and prediction models, a powerful combination of tools is available for Earth science research, the adaptive management of natural resources, and the mitigation of the impacts of natural hazards.

SPACE/TIME RESOLUTIONS AND ACCURACY

At any one point in time, global scale observational requirements are often described either in terms of what is possible with the technology at hand, or by the spatial and temporal resolutions of the best available mathematical/numerical or conceptual models of the Earth System. In parallel, local to regional scale requirements have evolved in response to specific (and sometimes widespread) user application sectors such as agriculture, forestry, water resources management, and flood forecasting. Thus, to an extent, the specification of requirements has been a somewhat arbitrary exercise based on a combination of local needs, regional or global scale feasibility, modeling technology, and scientific understanding. It is also a complex exercise in the current setting of inter-disciplinary research. That is, requirements for the observation of a particular parameter can be drastically different between different scientific disciplines and user applications sectors. Requirements also can change substantially with time and improved understanding of physical processes. A case in point is measurement of precipitation, temperature and wind, all commonly known variables. Prior to the 1980s, synoptic meteorological requirements called for observations every 3 h at a spatial resolution of about 500 km. Five hundred kilometers was also, coincidentally, the best resolution of operational weather forecast models at the time. The spatial resolution requirement was refined to between 50 and 100 km in the late 1990s due to higher resolution weather and climate models. This was possible because of advances in computational speeds, data storage technology and data communications bandwidth. However, the measurement of precipitation for hydrological applications dealing with water runoff, river flows, ground water recharge, and water resource management among others, requires observations at much higher resolutions, typically better than 1 km.

The specification of required accuracies can also be made in one of several different ways, depending on how the observations are used. For land cover and vegetation

mapping purposes, a spatial accuracy of 10% (by area) or even lower (15%) might suffice for broad categorization purposes, and for the study of relationships between biomes and average climate and soil conditions. However, for the study of deforestation rates, much better accuracy is needed because the rate of deforestation is a second order term requiring the calculation of inter-annual differences over time between differences over time within a year. Similarly, the accuracy usually specified for the measurement of upper atmospheric winds, based on the limits of the capabilities of rawinsondes and surface-based instruments, may have been sufficient for operational weather forecasting in the 1980s and hazard warnings, but could produce unacceptable errors in second order calculations for divergence fields, momentum fluxes and surface ocean wind stress.

As alluded to before, time scales also enter into the determination of required measurement accuracies. The measuring system should be able to resolve the rate of change of the parameter in question. Moreover, the accuracy of an instrument measuring temperature at a single point would not necessarily be applicable to an accuracy with which global average temperature is measured to detect change over 100 years. That is the accuracy with which the same single point represents an area surrounding the point (often as large as 250 000 km^2) must also be known or estimated before an accuracy measure for a network can be determined. As an example, global temperature change is estimated to be approximately of the order of 0.55 °C over the last 100 years. This would suggest that the combined global network of land stations, ships, ocean buoys and satellites (when applicable), when averaged together, should be accurate to of order 0.005 °C so that the magnitude of the global change signal can be identified over a relatively limited observational period. That is, it would be desirable if the combined uncertainty of all measurements taken by various platforms and over the globe over one year did not exceed the magnitude of the expected signal. Certain types of random errors can be reduced by data averaging over time and space. However, systematic errors, instrument drift, changes in observing practices and instruments, as well as changes in the environment of the instrument cannot easily be removed without an exact knowledge of the performance of the instrument, its environment, and its representativeness over time. From this example, it should be clear that the specification of accuracies, and even to some extent, space/time resolutions, is not a simple undertaking.

In the case of global climate change, the measurement accuracy of the composite GOS can only be vaguely known in absolute terms. Credibility is given to the global change signal by the fact that all sub-sets of data from the existing (composite) observing system, whether it draws from land stations alone, ocean stations alone, or ships, etc., seem to show similar trends over the period of observational record. Some controversy and debate continues over explaining the differences between satellite observations over the past 20 years and observations of surface stations, with the satellite systems showing differences in magnitude and, sometimes, even sign (*see* The Global Temperature Record, Volume 1; Tropospheric Temperature, Volume 1).

Due to such a disparate range in the types of observing requirements that need to be specified and the various theoretical and empirical means by which requirements can be determined, this overview merely presents specifications for Earth observing as a consolidation of a somewhat broad range of applications-dependent space and time resolutions, and approximate accuracy requirements. They are presented to give the reader a sense of the order of magnitude requirements for the measurement of Earth System parameters. It should be noted that the specification of individual sensor accuracy is a simpler matter, and depends on the electronic characteristics of the instrument alone, an accuracy that can be tested in a laboratory. In contrast, the accuracy of an Earth observing network is much more difficult to verify and validate, especially on a global scale. Various sampling methods and observing system simulation experiments are used to develop observational requirements. None of them is necessarily universally applicable. That is, their results would, *de facto*, depend on the particular application for which the observation is used.

Notwithstanding the above commentary, the requirements as specified by various disciplines would provide observational data that capture the dominant processes and the structure of the most important phenomena within a component of the Earth System. Summaries of observational requirements in terms of space and time resolutions and accuracies for the variables and parameters identified in Table 1 are presented in Tables 2 and 3 for state and forcing or feedback variables, respectively.

We want to reiterate that, by and large, these requirements are not met by existing observing systems, particularly on a global scale. Surface-based and *in situ* observing networks generally suffer from a lack of global coverage on account of the world s oceans. The accuracies possible with *in situ* instruments and those of remote sensing instruments can also be somewhat different. In instances where a parameter is observed using more than one observing technology, the two instrument types may see slightly different properties. For example, satellite measurements of SST actually measure sea surface skin temperature, whereas the majority of *in situ* SST measurements are at 1–10 m in depth, depending on the intake manifold depth of ocean vessels making the measurement. Operational satellite platforms typically suffer from insufficient time resolution or coarse resolution observations or both. The newest systems

Table 2 Summary of approximate, though representative, requirements for Earth System state variables and parameters[a]

State variables (Sv)	Horizontal Resolution	Vertical Resolution	Time Resolution	Accuracy/Units
(1) Atmosphere				
Wind	50–100 km	0.1–0.5 km	3 h	2–5 m/s
U/A temperature	50–100 km	0.1–0.5 km	3 h	0.5–1.0 K
Surface air temperature	50–100 km	N/A	3 h	0.5–1.0 K
Sea level pressure	50–100 km	N/A	3 h	0.5 hPa
U/A relative humidity/wv	50–100 km	0.1–0.5 km	3 h	5%
Surface relative humidity/wv	50–100 km	N/A	3 h	1–5%
Precipitation (liquid/solid)	50–100 km	N/A	3 h	0.1 mm/5%
Clouds	50–100 km	By type	3 h	10% cover
Liquid water content	50–100 km	Column total	3 h	5% ($kg\ m^{-2}$)
(2) Ocean				
Upper ocean currents	50–500 km	N/A	1 week–1 mo	$cm\ s^{-1}$
Upper ocean temperature	50–500 km	20 m	15 d–1 mo	0.3–0.5 K
Sea level/surface topography	100–1000 km	N/A	1 mo–1 year	mm–cm
Upper ocean salinity	50–500 km	20 m	1 week–1 mo	Parts per trillion (ppt)
Sea ice	25–100 km	10 cm	1 d–1 mo	2%–10%
Mid/deep ocean currents	100–1000 km	0.1–1 km	3 mo–10 years	$cm\ s^{-1}$ (tbd)
Mid/deep ocean thermal structure	100–1000 km	0.1–1 km	3 mo–10 years	0.5 K (tbd)
Mid/deep ocean salinity structure	100–1000 km	0.1–1 km	3 mo–10 years	ppt (tbd)
Ocean biomass/ phytoplankton	100–500 km	0.01–1 km	3 mo–10 years	10% (tbd)
(3) Land and Water (Non-ocean)				
Topography/elevation	1–1000 km	1 cm–1 m	1–10 years	1 cm–1 m
Land cover	1 m–100 km	N/A	1–5 years	5%
Surface soil moisture/ wetness	1–100 km	10 cm deep	1 d–3 mo	$0.02\ m^3\ m^{-3}$
Soil structure/type	1–10 000 ha	30 cm, 1 m	1–10 years	5%
Vegetation (biomass above ground)	1–100 km	1 m (tbd)	1 wk–10 years	5–10% ($kg\ ha^{-1}$)
Water runoff	1–100 km	N/A	1 h–1 mo	5%
Surface ground temperature	1–100 km	10 cm deep	3 h–1 wk	0.5–1 K
Snow/ice cover/depth	1–100 km	Depth	1 d–1 mo	10%
Sub-surface temp and moisture	1–100 km	20 cm, 1 m	1 d–3 mo	0.5 K/5% (cm)
Soil C, N, P, nutrients	1–10 000 ha	30 cm, 1 m	1–10 years	5% ($g\ m^{-2}$)
Necromass	1–100 km	N/A	1 year	10% ($g\ m^{-2}$)
Sub-surface biomass	1–100 km	N/A	1 year	10% ($g\ m^{-2}$)
Land use	1 m–100 km	N/A	1–5 years	%–m^2 (tbd)
Ground water (and subterranean flow)	100 km (tbd)	Depth	3 mo–1 year	5% ($cm\ s^{-1}$)
Lakes and reservoirs	1–100 km	Actual depth	1 week–1 mo	5% (s^{-1})
Rivers and river flow/discharge	1–100 km	N/A	1 h–1 mo	5% ($m^3\ s^{-}$)
Glaciers and ice sheets	1–100 km	Depth	1 year–10 years	$10\ kgm\ m^{-2}\ year^{-1}$
Water-turbidity, N, P, dissolved O	1–100 km	1 m	3 mo–1 year	%, ppt/ppm

Abbreviations: ppm, parts per million; WA, upper air; WV, water vapor; N, nitrogen; P, phosphorous; O, oxygen; C, carbon; d, days; mo, month.

[a] Exact accuracy and resolution vary with application and the inherent time/space scales of the involved Earth processes. Lower resolutions typically reflect large to global scale specifications often defined by operational models of the Earth System component(s). The high-resolution end of the range specified usually represents the space or time scale required for local-to-regional applications. Research projects usually require even higher space/time resolutions and better accuracy.

Table 3 Description: as in Table 2, but for forcing and feedback variables

External forcing or feedback variables (Fv)	Horizontal Resolution	Vertical Resolution	Time Resolution	Accuracy/Units
(1) Atmosphere				
SST	50–500 km	N/A	15 d–1 mo	0.3–0.5 K
Land surface-ground temperature	50–100 km	N/A	3 h–1 d	0.5–1 K
Land surface structure and topography	50–100 km	1 cm–1 m	1 d–1 year	1 cm–1 m
Land surface vegetation	50–100 km	1 m (tbd)	1 wk–1 mo	5–10%
GHGs, ozone and chemistry, aerosols	50–100 km	Variable	3 h–1 year	10% (Various)
Soil moisture/temperature at depth	50–100 km	10 cm	3 h–1 d	5%/0.5 K
Snow/ice cover/type	50–100 km	N/A	1 d–1 mo	10% (by area)
SW and LW radiation budget-surface	50–100 km	N/A	3 h–1 wk	2–10 $W m^{-2}$
Solar irradiance, SW/LW radiation budget	50–100 km	N/A	3 h–1 wk	2–10 $W m^{-2}$
(2) Ocean				
Ocean surface wind and wind stress	100–500 km	N/A	1 d–1 mo	2 $m s^{-1}$, 0.01 $N m^{-2}$
Incoming/downwelling SW/LW radiation	100–500 km	N/A	1 d–1 mo	5–10% ($W m^{-2}$)
Downwelling longwave radiation	100–500 km	N/A	1 d–1 mo	5–10% ($W m^{-2}$)
Surface air temperature/humidity	100–500 km	N/A	1 d–1 mo	0.5 K/5%
Precipitation/evaporation (salinity flux)	100–500 km	N/A	1 d–1 mo	5% (0.1 mm)
Fresh water flux from rivers and ice melt	100–500 km	N/A	1 d–1 mo	10%
Ocean boundaries and bottom topography	100–500 km	Tbd	1–10 years	10 m
Geothermal heat flux – ocean bottom	1000 km (tbd)	N/A	10 years	tbd ($W m^{-2}$)
Organic and inorganic effluents (into ocean)	Variable	N/A	1 year	Various
(3) Land and Water (Non-ocean)				
Incoming shortwave radiation	50–100 km	N/A	1 h–1 d	1–5% ($W m^{-2}$)
Net downwelling longwave radiation	50–100 km	N/A	1 h–1 d	1–5% ($W m^{-2}$)
Surface winds	50–100 km	N/A	1 h–1 d	2 $m s^{-1}$
Surface air temperature and humidity	50–100 km	N/A	1 h–1 d	0.5 K/1–5%
Evaporation and evapotranspiration	50–100 km	N/A	1 h–1 d	0.1 mm/5%
Precipitation (liquid/solid)	50–100 km	N/A	1 h–1 d	0.1 mm/5%
Land use and land use practices	50–100 km	N/A	1–5 years	Various
Deforestation	50–100 km	N/A	1 m–1 year	5%
Human impacts – land degradation	50–100 km	N/A	1 year–10 year	5%
Erosion, sediment transport	50–100 km	N/A	1 year–5 years	5–10% (tbd)
Fire occurrence	50–100 km	N/A	1 d–1 year	Various
Volcanic effects (on surface)	1–100 km	N/A	1 d–1 year	Various
Biodiversity	1–100 km	N/A	1–10 years	Various
Chemical (fertilizer, pesticide) infusion	Variable	N/A	1 mo–1 year	Various
Waste disposal and other contaminants	Variable	N/A	1 mo–1 year	Various
Earthquakes, tectonic motions	1–100 km	1 cm	1 d–10 year	Various
Soil microbial activity	1–100 km	N/A	1 week–1 year	Various
Coastal zones/margins	1–100 km	N/A	1 week–1 year	Various

Abbreviations: SW short wave; Lw long wave; d, days; mo, months.

(both *in situ* and satellite) attempt to overcome some of these problems.

IN SITU OBSERVING SYSTEMS, NETWORKS AND PROGRAMS

Observing systems and networks are usually developed and deployed to meet certain objectives pertaining to either the need to characterize a particular feature of the Earth System or to predict a future state of a component (or components) of the combined, integrated Earth System. Thus, the prediction time scale or time window will determine the number of parameters that must be observed. For time scales of hours to a few days, the primary feature that is changeable is weather, for which one needs to observe only the atmosphere in some detail. All other parameters may be specified as forcing functions. As the prediction time scale is increased to months, seasons, years and decades, many of the parameters specified as unchanging forcing functions must also be monitored, and their dynamics incorporated into Earth System models. Moreover, human dimensions and environmental concerns demand that a host of observations be made supporting a range of applications sectors. Over the years, a large number of programs have been implemented both within countries and internationally through the coordinated, cooperative efforts of all countries by mutual agreement.

The basic state variables required to characterize the structure and variability of the atmosphere, identified in Table 1, include vertical profiles of temperature, water vapor or humidity, and wind. Weather and climate parameters, such as surface air temperature and humidity, clouds and precipitation, surface pressure, and solar radiation, are also needed. For time scales beyond a few days, seasonal to inter-annual climate variability and prediction applications, observations are also required of the sub-surface layers of the land and ocean boundaries. For longer-term diagnostics and prediction, more complex observations are necessary of the ocean circulation and the land surface (including vegetation) and ground hydrology and the mid and deep ocean circulation. Current modeling technology involves the time integration of land–atmosphere–ocean coupled models. These models need observational data for initialization, validation, and for improvements to the parameterization of processes. Climate and global change issues demand observations of greenhouse gases, ozone and ozone precursor chemical species together with better characterizations of land use and land cover. The major *in situ* global and/or international observing systems and programs that monitor these variables are described in the following sections.

World Weather Watch (WWW): the earliest weather-related instrumental observations may be traced back to the mid-17th century, with the invention of the barometer by Torricelli in 1644. Precipitation was, of course, measured for several centuries before that. The first attempt (1780) to establish a worldwide network of weather stations, reporting three observations per day, is attributed to Karl Theodore, Prince Elector of the Palentine (Germany), an ardent supporter of the arts and sciences. The first modern day effort to internationally coordinate meteorological observations from networks of stations in all countries was made through the creation of the World Meteorological Organization (WMO) in 1950 following the World Meteorological Convention, adopted at the Twelfth Conference of Directors of the International Meteorological Organization (IMO) in 1947. The WMO commenced operations as the successor to IMO in 1951 and, later that year, was established as a specialized agency of the United Nations (UN) by agreement between the UN and the WMO. The WWW, coordinated by the WMO, is arguably one of the oldest and best established global systems for the observation, collection, and international exchange of meteorological and climate data from surface-based, *in situ*, and satellite-based observing systems. The Fourth Congress of the WMO formally initiated the WWW in June 1963 to collect and analyze weather and environmental information on a worldwide scale through a fully integrated system. The WWW comprises observing systems on land, sea, in the air and in outer space, and advanced data communications and data processing systems operated by the member states of the WMO (*see* Radiosondes, Volume 1). Three primary systems constitute the WWW: The Global Observing System (GOS); the Global Data Processing System (GDPS); and the Global Telecommunications System (GTS). The GOS includes about 9500 surface synoptic land stations, 700 upper-air land-based stations, 7500 mobile ship stations, 3000 aircraft stations, 250 ocean buoys, 200 background air pollution monitoring stations, and several polar orbiting and geostationary satellites providing meteorological and other environmental observations. The GDPS and GTS components operate through a system of three World Meteorological Centers, 26 Regional Specialized Meteorological Centers, 30 Regional Telecommunications Hubs, and about 190 National Meteorological Centers, linked together by a data transmission network.

WWW- U/A-Synoptic: *in situ* atmospheric upper air (U/A) temperature, moisture, wind, and pressure (replacing height). Currently, about 700 U/A synoptic sounding stations profile the atmosphere on an operational global basis coordinated through cooperative agreements between countries under the WWW of the WMO. This network has formed the backbone of WMO s operational system. To meet current requirements, WMO s Commission for Basic Systems calls for eight soundings per day at a horizontal resolution of approximately 100 km. Typically, however, observations are made once or twice per day. In recent years, the number of stations and/or the number

of soundings per day have decreased even in developed countries. Conventional radiosondes and rawinsondes are also beginning to be replaced in some regions by global positioning system (GPS)-Sondes that are more expensive. The WWW also includes operational geostationary and polar orbiting satellites. The geostationary satellites (approximately six are required for global coverage) carry an imager (typically one visible and four infrared (IR) channels) and a sounder with more spectral bands than the imager to desire atmospheric profiles of temperature and humidity.

WWW- Surface-Synoptic: surface land–ocean *in situ* air temperature, precipitation, moisture, winds, pressure, clouds, solar radiation. Approximately 9500 land-based surface synoptic stations spread around the globe make four to eight observations per day, under the auspices of the WWW of WMO. Over the ocean surface, a sub-set of the above observations is made by approximately 7500 ship and 250 buoys. Ship (of opportunity) observations are made mostly under the auspices of the WMO/WWW Voluntary Ocean Observing System. The 250 buoys are implemented jointly by WMO and the International Oceanographic Commission (IOC) as a part of the Global Ocean Observing System (GOOS) program. Several land stations also measure solar radiation (sunshine duration) and some (relatively few) measure spectral solar radiation. Some stations also measure pan evaporation. Ship based precipitation measurements are prone to error and not considered reliable.

WMO- Global Climate Observing System (GCOS): climate variables. In response to concerns about climate and global change, several internationally coordinated observing systems were established in the 1990s. Under the GCOS, a sub-set of the WMO/GOS has been designated as reference climate station network. In 1995, a network of about 148 U/A reference stations was established. Soon after, in 1996, a network of approximately 900 surface reference climate stations was also established to measure temperature, precipitation, moisture, pressure, wind, clouds and solar radiation. The surface and U/A climate reference station networks represent a first step towards establishing an integrated GCOS. The GCOS program plans to expand this observation program to include key measurements that capture the climate of the oceans and the land surface and vegetation as well. GCOS also draws data from space-based platforms such as meteorological, geostationary and polar orbiting satellites. However, baseline reference platforms have not been established yet for space-based measurements. The objectives of GCOS are to establish a global climate observing strategy based on existing operational and systematic research observing systems that would provide climate-quality data with long-term continuity for climate research and applications. The term climate-quality refers primarily to the need for tighter accuracy, calibration and time-continuity standards than those typically specified for shorter-term operational applications (*see* GCOS (Global Climate Observing System), Volume 1).

IOC/WMO GOOS: upper ocean surface and sub-surface temperature, currents, salinity. The GOOS, declared an operational system in 1999, is based on a long history of long-term monitoring of ocean conditions, coordinated by the IOC of the United Nations Education, Science and Cultural Organization (UNESCO) jointly with WMO, in order to facilitate the provision of detailed now-casts and forecasts of ocean conditions for the benefit of coastal states and national and international marine users. About 7500 ships are a part of the WMO/WWW Voluntary Observing Ship (VOS) program, measuring surface meteorological parameters as well as surface ocean parameters such as temperature. Designated ships routinely deploy expendable bathy-thermographs (XBTs, which are instrument packages that drop downward through the ocean reporting data back) to obtain ocean temperature profile data. Some also deploy expendable conductivity–temperature depth probes to obtain temperature and salinity profile data. The operational ocean observing system includes networks of moored and drifting buoys under WMO/IOC GOOS and WMO/WWW. About 300 drogued (to 15 m depth) drifting buoys measure ocean currents in the Pacific. Other aspects of GOOS implemented through national and regional efforts in pilot projects are: (1) the Euro GOOS Association comprising 22 operational agencies from 14 countries to implement six pilot projects in the Baltic Sea, Arctic Ocean, Mediterranean Sea, Black Sea, North West Shelf and the Atlantic Ocean; (2) the tropical Pacific – the TOGA program and the TOGA automated observations array of moorings for ENSO predictions, led by the US; (3) the PIRATA array in the tropical Atlantic, led by Brazil; and (4) the five coastal GOOS projects being developed in the US. Under the auspices of GOOS and the Integrated Global Observing Strategy (IGOS), the implementation of the first operational array of upper ocean sensors, Array for Real-time Geostrophic Oceanography (ARGO), is underway. The goal of the international ARGO program is to operate 3000 free-drifting ocean profiling floats, to cover the global oceans for the first time, by year 2004. The floats are being contributed and deployed by Australia, Canada, France, Germany, Japan, South Korea, the UK and the US, all of which have already begun deployment or have plans to do so. Other countries are expected to join in the deployment of the floats. ARGO measures temperature and salinity profiles and drift (i.e., ocean currents) in all of the Earth s oceans. The float drifts at about 2 km in depth and cycles up to the surface approximately every 10 days to transmit the data via satellite links. ARGO represents the oceanic counterpart to the instrumented weather balloons used to make measurements of the atmosphere. A spacing of around 3° or approximately

350 km at the equator is planned. ARGO originated as a research instrument, the Autonomous Lagrangian Circulation Explorer, deployed at around 1000 m depth, during several oceanographic experiments, including the WOCE. Other instruments, such as acoustic current doppler profilers (ADCP) to measure ocean currents, are also used operationally and in research mode, although on a somewhat limited, regional basis. For example, TOGA and WOCE obtained ADCP data during hydrographic surveys on research oceanographic ships and a few selected VOS lines (*see* Global Ocean Observing System (GOOS), Volume 2).

WMO- GAW (Global Atmosphere Watch): ozone, CO_2, CH_4, chlorofluorocarbons (CFCs), precipitation chemistry and environmental pollution. Environmental pollution concerns led to the establishment, in 1989, of the GAW by the WMO. The WMO/GAW is seen as an umbrella program for the Background Air Pollution Monitoring Network (BaPMON) of the UN Environment Programme (UNEP) that was implemented by the WMO in 1968, and the Global Ozone Observing System (GO_3OS), established in 1957 by the WMO. The BaPMON network consists of about 200 stations worldwide. The measurements taken and the number of stations include (approximately): 160 that measure precipitation chemistry; 95 that measure atmospheric turbidity; 80 that measure suspended particulate matter; 38 that measure CO_2 concentrations; 26 that measure surface ozone; 9 that measure CH_4 concentrations; and about 5 that measure CFC concentrations. The GO_3OS has a worldwide network of approximately 150 monitoring stations. These ground-based stations have been complemented by remote sensing instruments on both operational and research satellite systems. The number of measured parameters varies, sometimes substantially, from station to station, but the core program calls for observation of a fairly broad range of parameters such as: CO_2; CFCs and their substitute compounds identified in the Montreal Protocol; CH_4; nitrous oxide; ozone (surface, total column, vertical profile); radiation (including UV-B); atmospheric turbidity; total aerosol load; water vapor; chemical composition of rainfall and snow; reactive gas species (sulfur dioxide (SO_2), nitrogen oxide, etc.); particulate concentration and chemical composition; and the concentration of some radionuclides. Data are stored at a number of WMO centers operated by member states on behalf of the organization (*see* GAW (Global Atmosphere Watch), Volume 1).

IOC- Global Ocean Sea Level Observing System (GLOSS): ocean sea level (*in situ*). GLOSS is an international network of sea level measuring stations, coordinated by the IOC, to monitor sea level, a parameter considered to be a good indicator of upper ocean heat content. GLOSS comprises about 300 high quality tide gauges/stations spaced approximately 1000 km apart along coastlines and ocean islands. GLOSS operates a set of tide gauges as a part of its monitoring activities. A sub-set of these stations (approximately 30–40) is also connected as a network called the global geodetic reference system established by the International Earth Rotation Service. The development of new geodetic techniques based on very long baseline interferometry, the GPS, and absolute gravity measurements has created the opportunity to link these tidal gauges to a highly accurate global reference system. GLOSS is coordinated by the IOC through the permanent service for mean sea level (PSMSL), Bidston Observatory, UK. The PSMSL also archives historical data from about 1400 tide gauge stations worldwide, some with data records beginning about 1880.

GTOS (Global Terrestrial Observing System): terrestrial land/water ecosystems, biodiversity, pollution and toxicity. The GTOS was established in 1996 by five international organizations: the Food and Agricultural Organization (FAO) of the UN, the International Commission on Science (ICSU), UNESCO, UNEP and the WMO. The GTOS secretariat, located at FAO headquarters in Rome, Italy, provides for the day-to-day operations of the program, including liaison with GCOS and GOOS. Unlike the GOSs that exist for climate and for the oceans, there is no single organization that can provide comprehensive information (or the means for gaining access to it) on land and water resources, biodiversity and pollution impacts. The central mission of GTOS is to address this problem by linking existing networks and terrestrial observing systems to provide policy makers, resource managers and researchers with access to the data needed to detect, quantify, locate, understand and warn of changes (especially reductions) in the capacity of terrestrial ecosystems to support sustainable development. This is achieved by focusing on five issues of global concern: changes in land quality; availability of freshwater resources; loss of biodiversity; pollution and toxicity; and climate change.

ICSU- World Glacier Monitoring Service (WGMS): glaciers and ice sheets. Over 750 glaciers in 21 countries are monitored by the WGMS, which is based at the Swiss Federal Institute of Technology (ETH) in Zurich, Switzerland. The WGMS, a cooperative effort between ICSU, UNEP, UNESCO, WMO and ETH, was established in 1986, combining the ICSU/Permanent Service on Fluctuations of Glaciers, established in 1967, and the ICSU/World Glacier Inventory, established in 1976.

Global Environmental Monitoring System (GEMS): air quality, water quality, food. Under UNEP s Earth-watch program, GEMS was established in 1975, involving over 30 international monitoring projects implemented by FAO, UNEP, UNESCO, World Health Organization (WHO) and WMO. GEMS concentrates primarily on five areas: climate; trans-boundary pollution; terrestrial renewable resources; oceans; and the health consequences

of pollution. GEMS/Air (urban air quality monitoring project, WHO/UNEP) was initiated in 1973 by the WHO; the program became a part of GEMS/UNEP in 1975. The objective of the program is to monitor SO_2 and suspended particulate matter in urban areas; the network includes approximately 170 monitoring stations in 80 urban sites in over 47 countries. Most cities have established three monitoring sites: one in an industrial zone, one in a commercial zone, and one in a residential area. Data are managed by the US Environmental Protection Agency s (EPA s) laboratory at Research Triangle Park, North Carolina. GEMS/Water (Assessment of fresh water quality, UNEP/WHO/Canada) was initiated in 1976 as a freshwater monitoring network, operated by WHO and UNEP with support from UNESCO and WMO. The US EPA provides quality control support to the program. Eight laboratories, covering over 40 countries, participate in the AQC program. Assessments include: toxic chemicals, nutrients and pollutants discharged from major river basins to the world s oceans and inland seas. A computerized database is maintained at the WHO Collaborating Center on Surface and Ground Water Quality, at Canada s National Water Research Institute. GEMS/Water publishes global water quality data every five years, as well as biennial reports on special global water quality issues. GEMS/Food (food contamination and monitoring project), WHO/UNEP/FAO, was initiated in 1976 to provide reliable and internationally comparable information to governments, the CODEX Alimentarius Commission, other relevant institutions, and the general public, on contaminants in food. Over 40 countries participate by providing data on levels and trends of chemical contaminants in food, including polychlorinated biphenyls (PCBs), lead and cadmium, organophosphorous pesticides such as dichlorodiphenyltrichloroethane, aldrin, dieldrin, and aflotoxins. Microbial contamination of food is not covered by the project. Data are available for the period beginning in 1977 from the WHO. Collaborating institutions for quality assurance include the International Agency for Research on Cancer in Lyon, France for aflotoxins; the Ministry of Agriculture, Fisheries and Food, UK, for metals (cadmium, mercury and lead); and the National Food Administration, Sweden, for organochlorine compounds (organochlorine pesticides and PCBs). The Isototopes-In-Precipitation Network, International Atomic Energy Agency (IAEA)/WMO, was initiated in 1958 by the IAEA in collaboration with the WMO. In 1977, it was extended to fit within the framework of UNEP s GEMS. In 1988, over 80 network stations were in operation, while another 82 nationally implemented stations contributed data. Approximately 50% of the collected precipitation samples are analyzed in the IAEA laboratories in Vienna, Austria (*see* UNESCO (United Nations Educational Scienti c and Cultural Organization) and the Environment, Volume 4).

National observing systems and networks: all parameters and variables. National observing networks and programs make more measurements than those internationally exchanged. For parameters that are internationally exchanged, observational network density within a country is usually much higher than the data exchanged globally to meet international agreements. Depending on the policies adopted by individual countries, national data may or may not be available for international access. By and large, most scientific programs call for the free and open access and exchange of data for research purposes. Such a policy has been in place under the auspices of the ICSU World Data Centers, and most internationally coordinated programs under the UN agencies. The extent to which the parameters identified in Table 1 are regularly measured on a national basis varies widely between countries.

SPACE-BASED OBSERVING SYSTEMS AND PROGRAMS

All satellite systems possess certain similar characteristics: they carry instruments which sense electromagnetic radiation in spectral bands that are related, via retrieval algorithms, to some property of the Earth s atmosphere, the ocean or the land surface. The precise technology used, spectral discrimination, number of channels and view angles differ, but they possess common objectives in terms of what they wish to see from the standpoint of applications and research. Most satellites carry passive sensors that detect the natural radiation reflected or emitted by an object. Increasingly, however, new generation satellites carry active sensors such as synthetic aperture radar (SAR), microwave radar and laser scatterometers. In recent years, there have been well articulated moves towards the establishment of an IGOS that would encourage partnerships between countries to coordinate their efforts so as to comprehensively observe the global Earth System. Operational weather satellites are internationally coordinated by WWW of the WMO. Research and experimental Earth observing satellites are coordinated by the Committee on Earth Observing Satellites (CEOS), and the IGOS-partners. Interdisciplinary programs such as the International Geosphere–Biosphere Programmes and the World Climate Research Programmes among others, rely on data from both operational and research satellite systems. Several international observing system programs have also been established in recent years that endeavor to coordinate both satellite and *in situ* measurements to meet the requirements of specific research and applications objectives, notably: GCOS; GOOS; and GTOS. The lead agencies for their coordination are, respectively, the WMO in

Geneva, Switzerland, the IOC in Paris, France, and the FAO in Rome, Italy.

The parameters that are measured by space-based remote sensing satellites are identified in Tables 1, 2, and 3 by an *S*.

Operational Polar Orbiting Environmental Satellites (POES)

The first meteorological satellite observations of the Earth began with the launch by NASA (US National Aeronautics and Space Administration) of the first Television and IR Observation Satellite (TIROS-I) on the 1st of April 1960. This satellite demonstrated the feasibility of observing the Earth s cloud cover and weather by means of slow-scan television cameras in an Earth-orbiting, spin stabilized satellite.

TIROS-II was launched on the 23rd of November 1960, to demonstrate, in addition to the wide- and narrow-angle television cameras, an experimental five-channel scanning IR radiometer and a 2-channel non-scanning IR device. These instruments measured the thermal energy of both the Earth s surface and the atmosphere in order to provide data on the planet s heat balance and add a new dimension to the understanding of weather. A series of these TIROS satellites, developed by NASA and operated by the National Oceanic and Atmospheric Administration (NOAA), was launched throughout the 1960s. The NOAA/TIROS satellites continuously orbit the Earth from North to South Pole and back (hence the name polar orbiting) at an altitude of approximately 470 nautical miles (870.44 km or 540.86 statute miles).

The NOAA/TIROS series (and other similar satellites) basically carry scanning radiometers as imaging and radiometric devices and sounders to obtain information on the vertical profiles of selected parameters. Key instrument packages include: (1) the advanced very high resolution scanning radiometer (AVHRR), currently a five-channel cross-track scanning instrument, providing image and radiometric data in the visible, near-IR, and far-IR portions of the spectrum, is used to observe clouds, land-water boundaries, snow and ice, water vapor, temperature of clouds, and land and sea surface; (2) the TIROS operational vertical sounder, a three-part TIROS system to measure temperature profiles of the Earth s atmosphere from the surface to about 10 hPa, water content of the Earth s atmosphere, and total column ozone content of the atmosphere; (3) the high resolution IR sounder (HIRS), a 20-channel, step-scanned visible and IR spectrometer used to produce tropospheric temperature and moisture profiles; (4) the stratospheric sounding unit, a three-channel, pulse modulated, step-scanned, far-IR spectrometer used to produce temperature profiles of the stratosphere; and (5) the microwave sounding unit (MSU), a four-channel, step-scanned spectrometer with a response in the 60-Ghz oxygen band, used to produce temperature profiles in the atmosphere in the presence of clouds. The satellite also carries a space environment monitor to measure energetic particles emitted by the Sun. Earth radiation budget experiment (ERBE) radiometers, flown on NOAA 9, 10 and later satellites, were designed to measure all radiation striking and leaving the Earth. The present two-POES system will continue through 2002 with AVHRR-3 and HIRS-3 as core instruments. NOAA-L, the most recent in the series of NOAA/POES satellites, was launched in September 2000. The current NOAA/POES series will be operational for the next 12 years, after which it will be replaced by the National Polar Orbiting Environmental Satellite series, jointly sponsored by the US NASA, NOAA, and the Department of Defense.

Other countries with operational polar orbiting satellites include the Russian Federation and China. Since the 1970s, the Russian Federation has operated a polar orbiting series of satellites based on the meteorological (METEOR) system spacecraft for the exploration and monitoring of the Earth s natural resources. The METEOR series was started in 1985 and continues to be operational. NASA s total ozone mapping spectrometer, and the scanner for radiation budget, among other instruments, will be integrated on board the next in the METEOR series of satellites (METEOR-III), possibly in 2001. China operates a Fengyun-1 (FY-1) polar orbiting satellite series. The first of the FY-1 series was launched on the 7th of September 1988. An improved version, particularly in terms of IR images, was launched in September 1990, followed by FY-C in the late 1990s. The main instrument on the first satellites (FY-1-A, B) was the Chinese advanced very high resolution radiometer, a visible and IR scanning radiometer with five channels and a resolution of 1.1 km at the sub-satellite point. FY-1C has a 10-channel multispectral visible and IR scanning radiometer (resolution: 1.25 to 5 km) to observe clouds, the Earth s surface, middle and upper atmospheric water vapor, SST, snow/ice, soil moisture, and ocean color.

Operational Geostationary Environmental Satellites (GOES)

Geostationary satellites observe the Earth from above the equator, and maintain their position relative to a location at the surface of the Earth at an altitude of 35 790 km or 22 240 miles. The satellite travels around the Earth in the same direction as the rotation of the Earth with an orbital period equal to that of the rotation of the Earth (23 h, 56 minutes, 04.09 s). The US GOES satellites, developed by NASA and operated by the NOAA, are positioned longitudinally around 75 °W and 135 °W. A worldwide network of operational geostationary meteorological satellites provides

visible and IR images of the Earth s surface and atmosphere. The satellite systems include: the GOES satellites operated by the US; METEOSAT (launched by the European Space Agency (ESA), and operated by the European Meteorological Satellite Organisation); the Japanese geostationary meteorological satellite; and the geostationary satellites operated by India and China (the Fengyun-2 series). GOES carries three major sensor systems: (1) a multispectral imaging instrument capable of simultaneously sweeping one visible and four IR channels in a north to south swath across an east to west path, providing full disk imagery once every 30 minutes; (2) a sounder with more spectral bands than the imager, to produce high quality profiles of temperature and moisture, capable of stepping one visible and eight IR channels in a north to south swath across an east to west path; (3) the space environment monitor to measure the condition of the Earth s magnetic field, solar activity and radiation around the spacecraft. The spacecraft also carries a data collection system and a search and rescue transponder. Other satellites are comparably instrumented.

Earth Resources Mapping and Surface Characterization Satellites

Landsat (USA): Landsat is a series of satellites designed to gather data on the Earth s resources including: land use inventories; geological and mineralogical exploration; crop and forestry assessment; and cartography. The first Landsat-1 was developed and launched by NASA in 1972, following the early success of NASA s TIROS and Nimbus series, to expand the possibilities for Earth remote sensing from space in response to not only geologists and biologists but also a broad community of farmers, miners, timber and water resource managers, and engineers. The multispectral scanner (MSS) proved to be so valuable that a version of it has been flown on each of the first five Landsat missions. With the 1982 launch of Landsat-4, the thematic mapper (TM) was introduced. TM was a significant improvement over the MSS, providing greater resolution in the visible and near-IR regions (30 m versus 80 m resolution), and three additional spectral bands. The Landsat-3 version of the MSS was also flown to provide data continuity. Lansat-6 failed to reach orbit in 1993, but Landsat-5 continued to provide coverage well beyond its design lifetime. Landsat-7 was launched in 1999 to provide continuity and enhanced coverage to characterize, monitor, manage, explore, and observe the Earth s land surface. Landsat-7 s payload consists of the enhanced thematic mapper plus (ETM+). New features on Landsat-7 include a panchromatic band with 15-m spatial resolution, a thermal IR channel with 60-m resolution and both high and low gain, and on-board radiometric calibration. ETM+ still provides continuity with the TM that flew on Landsat-4 and Landsat-5.

SPOT- Image (France-CNES [Centre National d'Etudes Spatiales]): the SPOT satellite Earth observation system (EOS) was designed by the CNES, France, and developed with the participation of Sweden and Belgium. The system comprises a series of spacecraft plus ground facilities for satellite control and programming, image production and distribution. SPOT is sun-synchronous (descending node is at 10.30, local time), in near-polar orbit, with a repeat time-cycle duration: 26 days, 369 orbital revolutions per cycle, 822 km altitude, 98° inclination, and $14 + 5/26$ revolutions per day. The satellite s payload comprises two identical high resolution visible (HRV) imaging instruments that can operate simultaneously or individually in panchromatic and multispectral modes. The position of each HRV entrance mirror can be commanded by ground control to observe a region of interest not necessarily vertically beneath the satellite. Each HRV offers an oblique viewing capability. The viewing angle is adjustable through $\pm 27^\circ$ relative to the vertical. In panchromatic mode, imaging is performed in a single spectral band corresponding to the visible part of the spectrum without the blue, covering $0.51-0.73\,\mu m$. The panchromatic mode supplies black/white images at 10 m pixel resolution, primarily for applications calling for fine geometric detail. The multispectral mode images in three spectral bands: XS1: $0.5-0.59\,\mu m$ (green); XS2: $0.61-0.68\,\mu m$ (red); and XS3: $0.79-0.98\,\mu m$ (near IR). By combining data recorded in these channels, color composite images can be produced at 20 m pixel resolution. Different land surface features (e.g., vegetation, fresh snow, white limestone, dry ground, water, sand, etc.) are distinguished due to their different spectral signatures in these three bands. SPOT 1 was launched on the 22nd of February 1986, and withdrawn from active service on 31 December 1990. SPOT 2 was launched on the 22nd of January 1990 and is still operational. SPOT 3 was launched on the 26th of September 1993 but malfunctioned on November 14th, 1996. Since 1998, SPOT 4, with an increased life expectancy of five years, has been fully operational, and brings enhanced capability over its predecessors with the inclusion of a short-wave IR (SWIR) band offering better discrimination of crops and plant cover. With Spot 4, Spot 1 and Spot 2, the Spot program now comprises three fully operational satellites in orbit. Spot 5, scheduled for launch in 2001, will ensure continuity of service and further improved performance.

ERS (Earth Resources Satellite) Series (ESA): ERS-1 was launched by the European Space Agency in 1991, followed by ERS-2 in 1995. The series concentrates on global and regional environmental issues, making use of microwave techniques that enable a range of measurements to be made of land, sea and ice surfaces independent of cloud cover. The core instruments on ERS-1 comprise an active microwave instrument combining the functions of a SAR and a wind scatterometer. The SAR operates in

image mode for the acquisition of wide-swath, all weather images over the oceans, polar regions, coastal zones and land. In wave mode, the SAR produces imagettes (5 km^2) at regular intervals, for the derivation of the length and direction of ocean waves. The wind scatterometer uses three antennae for the generation of sea surface wind speeds and direction. The radar altimeter provides accurate measurements of sea surface elevation, significant wave heights, various ice parameters and an estimate of sea surface wind speed. ERS also carries an along track scanning radiometer (ATSR), which combines an IR radiometer and a microwave sounder for the measurement of SST, cloud top temperature, cloud cover and atmospheric water vapor content. ERS-1 is in a near-polar orbit at a mean altitude of 780 km with an instrument payload comprising active and passive microwave sensors, and a thermal IR radiometer (inclination: 98.52°; repeat cycles: three-day, 35-day, 176-day; orbits per day: 14.3; period: about 100 minutes). ERS-2 is a more sophisticated version of ERS-1, and includes, in addition to ERS-1 instruments, the global ozone monitoring experiment instrument for atmospheric chemistry measurements and a microwave sounder.

RADARSAT (Canada): RADARSAT-1, launched in 1995, is an advanced Earth observation satellite to monitor environmental change and support resource sustainability. The payload comprises a Synthetic Aperture Radar (SAR), a powerful microwave instrument that will transmit and receive signals to see through clouds, haze, smoke, and darkness, and obtain high quality images of the Earth in all weather at any time of the day or night. Using a single frequency, C-Band (5.3 GHz SAR), the RADARSAT has the unique ability to shape and steer its radar beam over a 500 km range. User defined beam selections can have image swaths from 100–500 km, with resolutions from 10–100 m, respectively. Incidence angles range from less than 20° to more than 50°. Repeat time is 24 days. The satellite provides complete daily coverage of the Arctic, views of any part of Canada every three days, and achieves complete coverage at equatorial latitudes every six days using a 500 km wide swath. The orbit is sun-synchronous with over-passes at the same local time. The descending equatorial crossing is at 0600, which is a dawn–dusk orbit, meaning that the satellite is rarely in eclipse and is able to acquire data at any time. RADARSAT-2, with a high resolution, multi-polarization SAR, is proposed for launch in 2001, and RADARSAT-3 in 2004.

IRS (Indian Remote Sensing Satellite): The second generation Earth observing satellites, IRS-1C/1D, were launched on the 28th of December 1996 (1C; Russian Molniya launcher) and the 29th of September 1997 (1D; Indian Polar Satellite Launch Vehicle), respectively. The imaging sensor suite on 1C/1D comprise: a multispectral linear imaging self-scanner (LISS-III) in visible, near-IR spectral bands with spatial resolution of around 23 m and a SWIR band with a resolution of around 70 m; a panchromatic camera with a resolution of around 6 m with across track stereo viewing capability; and a wide-field sensor in visible and near-IR region with a spatial resolution of 188 m and a wide swath of around 800 km. Because of the wide swath, the camera provides a repetitive coverage every five days.

Research and Experimental Satellites – Next Generation Instruments

Substantially improved satellite instruments have been under development for the past decade. They address several of the deficiencies found in the older technologies used in the current generation of operational satellites. The sensors typically have a broader spectral range, better spectral resolution, more flexibility in terms of view angles, and much better spatial resolutions. Importantly, they have much better on board calibration systems. Most of the key Earth System variables identified in Table 1 are or will soon be measured or estimated by advanced satellite observing instruments.

The sections that follow describe a representative selection of new-millennium satellite instruments, several of which have recently been launched.

UARS (Upper Atmospheric Research Satellite): atmospheric ozone depletion chemistry, trace gases, water vapor, solar variations. Launched by NASA in 1991, UARS was the first satellite dedicated to increasing understanding of the chemistry and dynamics of the Earth s stratosphere and mesosphere. UARS confirmed the role of CFCs in ozone depletion and clarified chemical processes that cause the Antarctic ozone hole. UARS made the first measurements of several key stratospheric gases: chlorine nitrate ($CLONO_2$), chlorine monoxide (CLO), hydrogen fluoride (HF), hydrogen chloride (HCL), and dinitrogen pentoxide (N_2O_5). These measurements, along with the measurements of nitric oxide (NO), nitrogen dioxide (NO_2), and nitric acid (HNO_3), provided a comprehensive picture of stratospheric photochemical processes involved in ozone depletion. UARS provided the first comprehensive mapping of volcanic aerosol layers and documented the slow increase in aerosol amounts following the eruption of Mt Pinatubo in the Philippines. The satellite also provided the first global picture of atmospheric tides, a clearer understanding of solar UV radiation variations, insight into the relationship between upper tropospheric water vapor and climate, and multiyear information on the transport of trace gases into the stratosphere. UARS was designed to make observations of the upper atmosphere for 18 months. More than seven years after launch, UARS continued to make observations with 8 of 10 instruments and continues to collect data. The UARS instruments include: chemistry: cryogenic limb array etalon spectrometer, halogen occultation experiment, improved stratospheric and mesospheric sounder,

microwave limb sounder (MLS); wind measurements: high resolution doppler imager, wind imaging interferometer; solar measurements: active cavity radiometer irradiance monitor (ACRIM-III), solar/stellar irradiance comparison experiment, solar UV spectral irradiance monitor; energetic particle measurements: particle environment monitor.

TOPEX/Poseidon (Ocean Topography Experiment): sea surface height, winds, waves. Jointly developed by NASA and CNES (France), the satellite, carrying dual and single frequency altimeters, was launched in 1992 to accurately measure the altitude of the satellite above the sea surface, sea surface wind speed and wave energy. The dual-frequency altimeter corrects for ionospheric effects. A GPS receiver is one of the three systems used to precisely track the satellite orbit. A laser retroreflector, used with ground-based lasers, measures satellite position and verifies the satellite altimeter s height measurements. A microwave radiometer measures atmospheric water vapor content and is used to correct altimeter measurements for pulse delay caused by water vapor. Sea surface height is measured to within 4.3 cm. The triple tracking system determines the satellite s location to within 2.8 cm. The distance between the ocean surface and the satellite is measured with an accuracy of 3.2 cm. The follow-on to TOPEX/Poseidon is Jason-1, scheduled for launch in 2001.

SeaWifs (Sea-viewing Wide Field-of-view Sensor): ocean color/biomass and atmospheric aerosols. SeaWifs was launched in 1994 and resumes the measurement of ocean color (phytoplankton) made from 1978 to 1986 by the coastal zone color scanner (CZCS) satellite. Aerosols directly affect the radiative transfer in the atmosphere, and therefore the radiation received by a satellite from the surface of the Earth (land and ocean). When retrieving surface or near surface signals from sensor-measured radiances at satellite altitude, the atmospheric effect must be removed. This atmospheric correction removes more than 90% of the observed radiance at visible wavelengths measured at the top of the atmosphere. The SeaWifs satellite s atmospheric correction algorithm uses radiances measured at two near-IR wavelengths, 765 nm and 865 nm, at which the ocean appears black due to strong absorption by water, to estimate the aerosol optical properties and extrapolate these into the visible. This enables SeaWifs observations to be used to derive global ocean color and ocean bio-optical properties. Aerosol optical properties, particularly optical depth or thickness, is an important byproduct of the SeaWifs atmospheric correction.

TRMM (Tropical Rainfall Measuring Mission): rainfall, clouds, SST, radiation, lightning. In November 1997, TRMM was launched as a collaborative venture between NASA (US) and the National Space Development Agency (NASDA) of Japan, with five instruments: The first spaceborne precipitation radar (PR), the TRMM microwave imager (TMI), a visible and IR scanner (VIRS), a cloud and Earth radiant energy system (CERES), and a lightning imaging sensor. The PR and the microwave radiometer measure the vertical distribution of precipitation over the tropics between $\pm 35^\circ$ in latitude, from the surface to about 20 km; horizontal resolution: 4 km; swath width: 220 km. Rain rates down to about $0.7\,\mathrm{mm\,h^{-1}}$ can be detected. TRMM will reduce the uncertainty in global tropical rainfall estimates to about 10%, an 80% improvement over the current uncertainty of about 50%. The TMI has a full suite of channels ranging from 10.7−85 GHz. and is the first satellite sensor capable of accurately measuring SST through clouds. When rain is not present, attenuation at 10.7 GHz is small and 97% of the sea surface radiation reaches the top of the atmosphere. The high frequency channels (19−37 GHz) can precisely estimate the 3% attenuation due to oxygen, water vapor and clouds. The 37 GHz channels are very sensitive to rain and are used to determine when rain is in the radiometer s field of view. At frequencies below about 12 GHz, microwaves penetrate clouds with little attenuation, providing a clear view of the sea surface under all weather conditions except rain. At these frequencies, aerosols have no effect. The first satellite microwave radiometers operating at such low frequencies were successfully demonstrated on Nimbus-7 and Seasat in 1978, but they were limited by poor calibration systems. The VIRS senses radiation in five spectral regions ranging from the visible to IR (0.63 to 12 μm). It serves as a rainfall indicator, and a transfer standard between TRMM measurements and those made routinely on the operational POES and GOES satellites (*see* TRMM (Tropical Rainfall Measuring Mission), Volume 1).

ACRIM-III: solar irradiance. The ACRIM-III mission (small satellite dedicated mission), called ACRIMsat, launched in 1999, continues the series of satellite data monitoring solar irradiance. Heritage: ACRIM-1 (on NASA s SMM) (solar maximum mission), ACRIM-II (on UARS). ACRIM-III instrument is a miniaturized version of the technology flown successfully on SMM, Spacelab-1, and Atlas missions. The satellite is spin stabilized with the instrument s solar viewing axis aligned with the Sun within 0.25° using magnetic torquers. The Sun is a variable star, and luminosity has been found to vary by about 0.1% over a solar cycle in phase with the level of solar magnetic activity. Sustained change in total solar irradiance (TSI) of as little as a few tenths of 1% per century could be a primary causal factor of climate change. A precision TSI database, with resolution adequate to relate centuries of systematic TSI variation to climate change, must be compiled from the results of many flight experiments. With a nominal lifetime of five years per experiment, their contiguous results must be related with the maximum precision accessible to current technology, on the order of 10 ppm/year (e.g., 0.1% per century). This far exceeds the capabilities of current ambient temperature flight instrumentation to define the absolute uncertainty of

the TSI (>1000 ppm) and even that of cryogenic instrumentation currently under development (>100 ppm). Modeling TSI using ground-based observations of proxy solar emission features is orders of magnitude less precise. The single approach capable of providing the required precision for the long-term TSI database with current measurement technology employs an overlap strategy, in which successive ambient temperature TSI satellite experiments (each with a nominal lifetime of five years) are compared in flight, transferring their operational precision to the data base. The current generation of ambient temperature ACRIM flight instrumentation has demonstrated a capability of providing annual precision of approximately 5 ppm of TSI. A second phase ACRIM instrument is planned for launch in late 2001 to combine the TSI database maintenance function with a new technology development initiative designed to develop a prototype instrument for both total and limited spectral solar monitoring on an operational basis in the National POESS (NPOESS) program.

EOS Satellite Series

NASA s EOS is a series of polar orbiting and mid-inclination satellites specifically developed to monitor nearly all aspects of the Earth System with an unprecedented accuracy, spectral discrimination, and spatial resolution. The first major satellite of the new millennium is EOS-Terra (AM) with a sun-synchronous polar orbit, descending southward across the equator in the morning. The second will be EOS-Aqua (PM) to be launched into a sun-synchronous polar orbit ascending northward across the equator in the afternoon, followed by EOS-CHEM. The key instrument developed to fly on Terra and Aqua is the moderate resolution imaging spectroradiometer (MODIS). MODIS is comprehensive in that it will continue to take measurements in spectral regions that have been and are currently being measured by other satellites, or heritage instruments. Therefore, MODIS will extend the time series of data sets taken by such instruments as AVHRR used for meteorology and monitoring SST, sea ice, and vegetation; and the CZCS used to monitor ocean biomass and ocean circulation patterns (*see* EOS (Earth Observing System), Volume 1).

The EOS satellite sensors have unprecedented onboard calibration systems, enabling a characterization of their performance throughout the lifetime of each satellite s mission, and the correction of errors introduced into the data due to system degradation. Calibration is a set of operations or processes that are used to determine the relationship between satellite instrument output (i.e., digital counts) and corresponding known values of a standard. Pre-flight calibration and characterization includes radiometric and geometric calibration. Radiometric calibration involves determining the relationship between instrument output and radiant input while the instrument views a calibrated radiant source. For the solar spectrum (400–2500 nm), the calibrated radiant source is an integrating sphere that has been calibrated using standards. For thermal IR (above 2500 nm), the calibrated source is a variable temperature blackbody. Pre-flight geometric calibration involves the determination of the detailed spatial response of each instrument band with respect to the nominal instrument telescope pointing direction. Geometric calibration is necessary for converting the instrument radiometric data into images with known relationships to observed Earth targets. Instruments will also be radiometrically and geometrically calibrated on orbit using solar diffusers, blackbodies, space viewports, and in the case of MODIS, a monochromatic source known as the spectroradiometric calibration assembly. EOS and other satellite instruments will also use the Moon as a common, stable, on-orbit radiance reference target source. The accuracy and precision of Earth remote sensing data sets produced by different instruments are only achieved by the consistent use of common on-orbit calibration sources and measurement methodologies. EOS-Terra will perform an on-orbit, pitch-based, calibration attitude maneuver to enable the instruments to view deep space and the Moon. The deep space view provides CERES and ASTER (advanced spaceborne thermal emission and reflection radiometer) an accurate determination of the DC offsets in their thermal bands, and it provides MODIS the opportunity to characterize the dependence of the thermal IR reflectance on the angle of incidence of the scan mirror. The same pitch-based maneuver also provides EOS instruments the opportunity to view the Moon at a lunar phase of 22°. The Moon affords the ability to monitor, among others, radiometric responsivity and stability in the visible, near-IR, and SWIR wavelengths. Validation of satellite measurements is carried out through various means, such as cross-comparing the satellite measurements with aircraft observations.

EOS- Terra: with an AM equatorial crossing, EOS-Terra was launched on December 18th 1999 by NASA. Terra houses five instruments for simultaneous, geolocated measurements and for the intercomparison of new measurement techniques. For example, MODIS s detailed internal calibrations are used, through simultaneous geolocated measurements, to help in the calibration of ASTER. The MODIS and ASTER high-resolution multi-channel observations of clouds are used by the CERES s low resolution radiative flux measurements and by the measurement of pollution in the troposphere (MOPITT) instrument to determine the location of clouds as well as their distribution and properties. The multi-angle imaging spectrometer s (MISR s) multi-angle measurements determine the angular reflectance properties of land surface features, aerosols, and clouds, all of which are used in the data analysis of MODIS, ASTER and CERES. Vegetation properties are derived from both MODIS and MISR data. Aerosol

properties are measured by MODIS using its wide spectral range and 1–2 day single view coverage, and also independently by MISR using its multi-angle data, narrow spectral range, and 2–9 day coverage. Water vapor is derived independently from MODIS measurements of reflected near IR sunlight and emitted terrestrial IR radiation. Emitted smoke particles from biomass burnings and forest fires are observed by MISR and MODIS, and emitted trace gases (carbon monoxide (CO) and CH_4) observed by MOPITT. Terra provides, for the first time, simultaneous measurements of clouds, aerosols, atmospheric trace gases, land and ocean surface properties, as well as Earth radiation budget parameters. The first CERES instrument was flown on TRMM and will also provide continuity to ERBE and pre-ERBE Earth radiation budget measurements. ASTER, developed and built by the Ministry of International Trade and Industry (MITI) of Japan, has 14 spectral bands in the visible, near-IR, SWIR and thermal IR wavelengths, and spatial resolutions ranging from about 15–90 m. MISSR (multi-angle imaging spectroradiometer), a new instrument, views the Earth in four color bands (blue: 446 nm; green: 558 nm; red: 672 nm; and near-IR: 866 nm) and from nine view angles with nine cameras pointed in different directions. MODIS views the Earth every 1–2 days, making observations in 36 co-registered spectral bands at moderate resolution (0.25–1 km). MOPITT, developed at the University of Toronto, Canada, employs gas correlation spectroscopy to measure upwelling and reflected radiation in three absorption bands of CO and CH_4. EOS-Terra instruments are individually described in more detail in the following sections to provide the reader with a sense for the latest available technology in satellite Earth observing technology. With a development time of approximately 10 years, the EOS series of NASA s satellites represents an unprecedented effort in space-based remote sensing of the Earth System as a whole. It is noteworthy that NASA s EOS has involved a large number of partnerships between NASA and the space agencies of many different countries. The enterprise represents a significant achievement in international collaboration. The selection of the EOS series for expanded description in this paper should not detract the reader from important developments in other countries that launch Earth observing satellites. They are also mentioned in this paper, even though not elaborated on.

EOS- Terra/CERES. CERES is based on NASA s ERBE, which used three satellites to provide global energy budget measurements from 1984–1990. The first CERES instrument was flown on TRMM. CERES provides continuity to ERBE and pre-ERBE measurements. CERES is a broadband scanning thermistor bolometer package with extremely high radiometric measurement precision and accuracy. Terra/CERES carries two identical instruments: one operating in a cross-track mode and the other in a biaxial scan mode. The cross-track mode essentially continues the measurements of the ERBE and TRMM missions, while the biaxial mode provides new angular flux information that improves the accuracy of angular models used to derive the Earth s radiation balance. Each CERES instrument has three channels – a shortwave channel for measuring reflected sunlight, a longwave channel for measuring Earth emitted thermal radiation in the 8–12 μm window region, and a total channel for total radiation. On board, calibration hardware includes a solar diffuser, a tungsten lamp system with a stability monitor, and a pair of blackbody sources. Cold space and internal calibration looks are performed during each normal Earth scan. Both CERES scanners operate continuously throughout the day and night portions of an orbit. In the cross-track scan mode, calibration occurs biweekly. In the biaxial mode calibrations also occur biweekly, and sun-avoidance short scans occur twice per orbit. CERES will be used to: study cloud radiative forcings and feedbacks; develop an observational baseline for clear-sky radiative fluxes; determine radiant input to atmospheric and oceanic energetics models; validate general circulation models; and enhance extended-range weather predictions.

EOS- Terra/MODIS (Moderate-resolution Imaging Spectroradiometer): land and ocean surface temperature, primary productivity, land surface cover (including vegetation), ocean color (sediment, phytoplankton), clouds, aerosols, water vapor, temperature profiles, and fire. MODIS views the entire Earth s surface every 1–2 days, making observations in 36 co-registered spectral bands at moderate resolution (0.25–1 km). MODIS is a whiskbroom scanning imaging radiometer consisting of a cross-track scan mirror, collecting optics, and a set of linear arrays with spectral interference filters located in four focal planes. With a viewing swath width of 2330 km (the field of view sweeps $\pm 55^\circ$ cross-track) MODIS provides high radiometric resolution images of daylight-reflected solar radiation and day/night thermal emissions over all regions of the globe. Spatial resolution varies from 0.25–1 km at nadir: 250 m (2 bands), 500 m (5 bands), 100 m (29 bands) at nadir. The broad spectral coverage of the instrument (0.4–14.4 μm) is divided into 36 bands of various bandwidths optimized for imaging specific surface and atmospheric features: 21 bands within 0.4–3.0 μm; 15 within 3–14.5 μm. Polarization sensitivity: 2% from 0.43–2.2 μm and $\pm 45^\circ$ scan. Absolute irradiance accuracy: 5% for <3 μm and 1% for >3 μm. The observational requirements also lead to a need for very high radiometric sensitivity, precise spectral band and geometric registration, and high calibration accuracy and precision. The MODIS instrument has one of the most comprehensive onboard calibration subsystems ever flown on a remote sensing instrument. Calibration hardware includes a solar diffuser stability monitor, a spectroradiometric calibration assembly, a plate-type black body, and a space view port.

EOS- Terra/ASTER: spectral radiances and reflectances of the Earth s surface; surface temperatures and emissivities; digital elevation from stereo images; surface composition and vegetation; cloud, sea ice, and polar ice; volcanoes and other natural hazards. Developed and built by MITI-Japan, ASTER has a broad spectral coverage and high spectral resolution with 14 spectral bands covering visible and near-IR (VNIR), SWIR and thermal IR (TIR) wavelengths. Spatial resolution is high, ranging from about 15–90 m. ASTER, with three distinct telescope subsystems, is a high spatial, spectral, and radiometric resolution, 14-band, imaging radiometer. Spectral separation is accomplished through discrete bandpass filters and dichroics. The VNIR subsystem operates in three visible and near IR bands with 15 m resolution and 60 km swath width. It consists of two telescopes, one that looks backward (along track) and one that looks at nadir, which together produce same-orbit stereo images. The telescope pair is pointable cross-track over a $\pm 24^{\circ}$ angle to increase the revisit frequency of any given Earth location. Light from either of two onboard halogen lamps will be used periodically for calibration. The SWIR subsystem operates in six SWIR channels with a 30 m resolution and 60 km swath width. It contains a pointing mirror that can point $\pm 8.54^{\circ}$ from nadir to allow coverage of any point over the spacecraft s 16 day cycle. The mirror is periodically used to direct light from either of two onboard calibration lamps into the subsystem s fixed, aspheric, refracting telescope. The TIR subsystem operates in five TIR channels with 90 m resolution and 60 km swath width. It contains a scan mirror used for both scanning and pointing up to $\pm 8.54^{\circ}$ from nadir. As with the SWIR, this mirror is also used periodically to view the onboard blackbody for calibration. Light from the TIR scan mirror is reflected into a Newtonian catadioptric telescope system with an aspheric primary mirror and lens for aberration correction. ASTER instruments operate for a limited time during the day and night portions of an orbit. The full configuration (all bands plus stereo) collects data for an average of eight minutes per orbit. Reduced configurations (limited bands, different gains, etc.) can be implemented as requested by investigators. ASTER is the highest spatial resolution instrument on EOS-Terra, and the only one that does not acquire data continuously. Monitoring applications products include: active volcanoes, crops and crop stress, cloud morphology and physical properties, wetlands evaluations, thermal pollution, coral reef degradation, and surface heat balance.

EOS- Terra/MISSR: albedo, clouds, aerosols, land surface vegetation structure, land cover. MISSR is a new instrument on board EOS-Tera which views the Earth in each of four color bands (446 nm – blue, 558 nm – green, 672 nm – red and 866 nm – near-IR) and from nine view angles with nine cameras pointed in different directions. Spatial resolution is about 0.275–1.1 km, with swaths of 360 km. The nine angles are: 70.5, 60.0, 45.6, 26.1° in the forward and aft directions, and 0.0°. MISSR is the first instrument to carry instruments making simultaneous observations at different angles from the same platform. Different combinations of look angles and spectral band are optimized to meet different scientific objectives. Over a period of seven minutes, a 360 km wide swath of the Earth comes into view at all nine angles. Highly accurate absolute and relative radiometric calibration is achieved onboard using deployable solar diffuser plates and several types of photodiodes. Onboard calibration is complemented by *in situ* field instruments (such as PARABOLA-III), which automatically scan the sky and ground at many different angles, and a multi-angle aircraft camera (AirMISR). Global coverage is acquired every nine days at the equator. MISSR will monitor the monthly, seasonal and long-term trends in the amount and type of atmospheric aerosol particles (natural and human produced); amount, type and heights of clouds; and the distribution of land surface cover, including vegetation canopy structure.

EOS-Terra/MOPITT: CO and CH_4 profiles. MOPITT, developed at the University of Toronto, Canada, is a scanning radiometer employing gas correlation spectroscopy to measure upwelling and reflected IR radiance in three absorption bands of CO and CH_4. The instrument modulates sample gas density by changing the length or the pressure of the gas sample in the optical path of the instrument, with detectors at 2.3, 2.4, and 4.7 μm. CO concentrations are obtained using pressure and length modulation with three independent pieces of information represented by values on seven pressure levels as well as CO and CH_4 columns. Spatial resolution: 22 km at nadir. Swath width: 640 km. MOPITT operates continuously, providing data on both day and night portions of an orbit. Calibration using onboard blackbodies and a space look occurs monthly and provides calibration at an elevated blackbody temperature. MOPITT data is used to: measure and model CO and CH_4 in the troposphere; obtain CO profiles with a resolution of 22 km horizontally and 3 km vertically, with an accuracy of 10%; measure the CH_4 column in the troposphere with a resolution of 22 km and a precision of better than 1%; and generate global maps of CO and CH_4 distribution, and provide increased knowledge of tropospheric chemistry. Heritage: AVHRR, HIRS, Landsat TM, Nimbus-7 Color Scanner.

EOS- Aqua (PM crossing): scheduled for launch in July 2001, Aqua will monitor the Earth System at a PM equatorial crossing time, complimenting EOS-Terra (AM crossing). Aqua will measure: clouds and aerosols; land surface temperature (visible conditions); SST (all weather); atmospheric temperature and humidity; snow cover and sea ice; global biological productivity; and atmosphere–land–ocean interaction. The instrument suite on board Aqua includes: MODIS and CERES (also on Terra), The advanced scanning microwave radiometer (AMSR-E), atmospheric IR sounder

(AIRS), AMSU-A, a humidity sounder for Brazil (HSB). MODIS and CERES on Aqua provide complementary and higher diurnal time resolution with the identical instruments on Terra (AM crossing). AIRS will fly on Aqua with two operational microwave sounders, the AMSU and HSB. The AMSU and HSB measurements will be analyzed jointly to filter out the effects of clouds from the IR data in order to derive clear column air temperature profiles with very high vertical resolution and accuracy, plus high accuracy SSTs. The HSB microwave radiometer is being developed by Brazil.

EOS- Aqua/AMSR-E - NASDA/Japan and NASA: rain, clouds, water vapor, SST, surface winds, snow/ice, soil wetness. The AMSR, developed by NASDA, Japan, and NASA, will measure rain rates over both land and ocean, as well as cloud water, water vapor, sea surface winds, SST, ice, snow, and soil moisture (surface wetness). Of particular importance is an external calibration design, which has proved suitable in other satellite microwave instrumentation for the long-term monitoring of subtle changes in temperature and other variables. AMSR-E will have an offset reflector, 1.6 m in diameter, and rotating drum at 40 rotations per minute. Multiple feedhorns (six) will cover six bands from 6.9–89 Ghz with 0.3–1.1 K radiometric sensitivity; vertical and horizontal polarization. Accuracy: 1 K or better. Swath: 1445 km. Resolution: 6×4 km (89.0 Ghz), 14×8 km (36.5 Ghz), 32×18 km (23.8 Ghz), 27×16 km (18.7 Ghz), 51×29 km (10.65 Ghz), 75×43 km (6.925 Ghz). Over the ocean, AMSR-E microwave frequencies can probe through smaller cloud particles to measure the microwave emissions from larger raindrops; sensitivity to ocean rainfall rates as high as $50\,\mathrm{mm\,h^{-1}}$ will be possible. Over the ocean, AMSR-E will also produce SST through most types of cloud cover, supplementing IR measurements of SST that are restricted to cloud free areas. The marked contrast between the microwave emissions of sea ice and water will be used to obtain observations of ice concentration in both polar regions. Over land, AMSR-E can measure the scattering effects of large ice particles that later melt to form raindrops. Though less direct, these measurements can be converted to rainfall rates using cloud models. Low frequency microwave (6.925 Ghz) will be used to measure soil wetness in areas where not too much vegetation is present. AMSR-E will provide the most useful data yet to assess how well low frequency microwave observations can measure surface soil wetness.

EOS- Aqua/AIRS (AMSU-A, HSB): temperature/humidity profiles, clouds, day and night land/ocean surface skin temperature and outgoing longwave radiation flux. NASA s AIRS will fly on Aqua with two operational microwave sounders: AMSU-A and HSB. AMSU-A and HSB measurements will be analyzed jointly to filter out the effects of clouds from the IR data in order to derive clear column air temperature profiles with very high vertical resolution and accuracy, plus high accuracy surface temperatures. Together these instruments constitute an advanced sounding system relative to the HIRS/MSU system currently operating on NOAA satellites. AIRS was designed to meet the NOAA requirement of a HIRS to fly on future operational weather satellites. The AIRS IR sounder measures the Earth s outgoing radiation at 0.4–1.0 μm and 3.7–15.4 μm, measuring simultaneously in over 2300 spectral channels. The high spectral resolution enables the separation of the contribution of unwanted spectral emissions and, in particular, provides spectrally clean super windows, which are ideal for surface observations. The AMSU-A microwave radiometer provides atmospheric temperature measurements from the surface to 40 km. Its primary objective is to obtain profiles of stratospheric temperature and to provide a cloud filtering capability for tropospheric observations. The HSB microwave radiometer, developed by the Brazilian National Institute for Space Studies, is designed to obtain profiles of atmospheric water vapor/humidity and to detect precipitation under clouds with 15 km (nadir) resolution. The AMSU-A and HSB have a total of 19 channels; 15 are assigned to AMSU-A, each having a 3.3° beamwidth, and four are assigned to HSB each having a 1.1° beamwidth. Channels 3–14 on AMSU-A are situated on the low frequency side of the oxygen resonance band (50–60 Ghz) and are used for temperature soundings. Successive channels in this band are situated at frequencies with increasing opacity, therefore responding to radiation from increasing altitude. Channel one, located on the first (weak) water vapor resonance line, is used to obtain estimates of total column water vapor in the atmosphere. Channel two, at 31 Ghz, is used to indicate the presence of rain. Channel 15 on AMSU-A, at 89 Ghz, is used to indicate precipitation using the fact that at 89 Ghz, ice more strongly scatters radiation than it absorbs or emits. Channels 16–19 are located on the wings of the strongly opaque water vapor resonance lines at 183.3 Ghz. Successive channels in this group have decreasing opacity and consequently their data correspond to humidities at decreasing altitudes.

EOS-Aura (Previously called CHEM): atmospheric chemical composition. Scheduled for launch in June 2003, Aura will comprehensively measure atmospheric chemistry. Instruments include the MLS, and the high resolution dynamic limb sounder (HRDLS). MLS measures lower stratospheric temperature and concentrations of water, ozone, ClO, bromine oxide, HCl, OH, HNO_3, hydrogen cyanide, and nitrous oxide (N_2O) for their effects on (and diagnosis of) ozone depletion, transformation of greenhouse gases, and radiative forcing of climate change. HRDLS is an IR limb sounder to sound the upper troposphere, stratosphere, and mesosphere to determine: temperature; concentrations of ozone, water, CH_4, N_2O, NO_2, HNO_3, N_2O_5,

CFC11, CFC12, $ClONO_2$; aerosols; and polar stratospheric clouds and cloud tops.

Various other specialized satellites are also planned under NASA s Earth Science Enterprise (ESE) program, and the counterpart programs of Europe, Japan, and other countries. NASA/ESE examples include: the Vegetation Canopy Lidar (VCL) to measure heights of the vegetation canopy, the EOS–Ice Sheet Altimetry Mission (ICESat), the Solar Radiation and Climate Experiment, CloudSat to understand the role of optically thick clouds on the Earth s radiation budget (jointly with Canada), PCASSO-CENA (jointly with France) to measure the vertical distribution of clouds and aerosols. The descriptions of some of these follow.

EOS- ICESat (rst precision altimetry mission): the ice, cloud and land elevation satellite; measurement of changes in topography and mass balance of polar ice sheets. Scheduled for launch in December 2001, the EOS-ICES will carry the geoscience laser altimetry system and a GPS orbit determination system, to measure along-track ice sheet and land topography to an absolute accuracy of 10 cm or better, within a footprint of 70 m or less. The mission will also provide cloud profile information with reduced vertical information. A repeat mission, focused on the primary science goal of measuring changes in the topography and mass balance of polar ice sheets is in planning for the 2010 time frame.

SeaWinds (surface winds and wind stress over the ocean surface): scheduled for launch on Japan s ADEOS-II in November 2001, SeaWinds builds on the heritage of the NASA Scatterometer (NSCAT) instrument flown aboard the Japanese ADEOS-I (Advanced Earth Observing Satellite) in 1996–1997. As an interim measure, NASA flew QuickScat in June 1999, to further improve and test the active scatterometer technique. SeaWinds is a dual, conically scanning pencil-beam radar operating at 13.4 Ghz. SeaWinds vector wind measurements are obtained with a 25 km resolution across nearly the entire swath of about 1800 km, and cover more than 90% of the global, ice-free oceans daily. Significant ground processing is required to extract backscatter cross-section and vector wind measurements from raw SeaWinds radar measurements. Concurrently, the US Navy is preparing an experimental satellite mission (CORIOLIS) to test the passive microwave polarimetry-radiometer technique for vector wind finding applications.

VCL: the full realization of the scientific potential from instruments on board EOS-Terra and EOS-Aqua as regards land cover/global productivity, short-term climate modeling, and natural hazards studies, will require global topography at digital terrain elevation data Level-2 resolution (30 m spatial, and 16 m vertical). Interferometric SAR data or the conventional photogrammetric data sets are only relative in their measurement of surface elevation. Direct measurements are essential to control the vertical dimension of the topographic image. The shuttle radar topographic mission has been flown to address some of these needs, in particular for accurately mapping the Arctic and the Antarctic ice surfaces. The multi-beam laser altimeter (MBLA) instrument on board the VCL will provide a common global reference frame that is a direct measurement rather than one that is inferred. Within the waveform from MBLA, the first return above a threshold represents the top of the canopy, and the last return represents the ground return. Canopy height is calculated from the difference between the two. VCL is scheduled to be launched in the 2004 or later time frame.

International Developments in Satellite Observing Technology

The Earth Observing System satellites developed by Japan is an example of the development of satellite technology internationally. The ADEOS-II, scheduled for launch around 2001 will replace ADEOS-1, launched in August 1996. The ADEOS satellite series were designed with a comprehensive suite of instruments to monitor the whole Earth System. They include: an ocean color and temperature scanner, developed by NASDA to obtain ocean color and SST data; an advanced visible and near-IR radiometer, developed by NASDA, an optical sensor for the observation of the solar light reflected by the land and coastal zones in the visible and near-IR regions (field of view: 80 km). The instrument will also be useful to monitor deforestation, desertification, and for land use and resource exploration; an improved limb atmospheric spectrometer developed by the Environment Agency (EA) of Japan to monitor high altitude stratospheric ozone layer above the Earth; a retroreflector in space, developed by EA (Japan), is used for Earth–satellite–Earth laser long-path absorption measurements. Ozone, CFC-12, CO_2, CH_4 and others will be measured using pulsed visible and IR lasers; an interferometric monitor for greenhouse gases, developed by the MITI, to monitor the density profile of greenhouse gases such as CO_2, water vapor, CH_4, nitrogen monoxide, and ozone; NSCAT, to measure wind speed and direction over the ocean without being affected by weather conditions. NSCAT data will include backscatter maps, ocean wind vectors, spatially averaged wind field maps, and temporally averaged wind field maps; polarization and directionality of the Earth s reflectances, developed by the CNES of France, to observe the polarization and directional/spectral characteristics of solar light reflected by clouds, oceans, land surface, etc. ADEOS-I successfully operated for about one year before encountering problems with its solar array power supply – it ceased operation on 30 June 1997.

Programs are also planned by the ESA for the next generation of environmental satellites (ENVISAT) that will expand the capabilities of the ERS series of satellites. ENVISAT-1, will carry an advanced SAR, a medium resolution imaging spectrometer, a Michelson interferometer for passive atmospheric soundings, a global ozone

monitoring by occultation of stars instrument, a scanning imaging absorption spectrometer for atmospheric chartography, a radar altimeter (RA-2), a K-band passive microwave radiometer, an advanced along-track scanning radiometer, a doppler orbitography and radio positioning integrated by satellite system, and a laser retro-reflector.

Similarly, the Indian Space Research Organization plans to expand the capabilities of the IRS series of satellites. Future IRS satellites planned include, among others: IRS-P4 OCEANSAT-1, with an ocean color monitor (OCM) with eight narrow spectral bands with a 350 m resolution and a 1500 km swath, and a multi-frequency scanning microwave radiometer operating in four frequencies to provide valuable ocean–surface related observation capability; and the IRS-P5 (CARTOSAT-1) with an OCM with eight narrow spectral bands, 350 m resolution, and a 1500 km swath. Details on other satellite programs are generally accessible through the Internet.

CONCLUSION

Earth observing in the future is likely to be a seamless blend of surface-based, *in situ*, and space-based systems and networks, each with its own unique and characteristic merits and demerits. Some parameters will be measured by both systems, while others will rely exclusively on one or the other to maximize performance of the sensors used while recognizing their physical limits. More and more, the sharp differences between raw observations and analysis are disappearing through computer models of the Earth System (or its components) that are used for data assimilation. They produce data fields needed for the initialization of prediction models as well as retrospective analyses. Importantly, they produce quantitative information for a range of parameters and products that can either not be observed directly or are derived from more than one observation. Energy, momentum, heat, and moisture exchange fluxes belong in this category. There are certain drawbacks that need to be recognized in applying model-dependent data assimilation systems to observed data. The resulting data or analysis field is no longer a direct measurement of an Earth System parameter, but rather has a component that depends on the mathematical or numerical model used at the time. That is, the observation could be prone to unknown model dependent analysis error, especially for the detection of change over time. To minimize the risk arising from such a procedure, it would be necessary to maintain the raw observations, especially those directly measuring a parameter, so that observing systems may be considered baseline or reference systems. Such a concept has been initiated for climate through the definition, identification, and initial implementation of climate reference networks. It would be useful to have counterpart space-based reference observational sensors. In the case of satellites, this would entail carrying a specified set of instruments on all future satellites that would provide continuity to older measurements alongside new sensors with improved technology and accuracy and calibration.

Another emerging concept is that of a sensor web. The sensor web, proposed as one of the centerpieces of a new NASA vision of the future for Earth System science, could consist of a reconfigurable, smart constellation of microsatellites that would adjust their data collection based on emerging events on Earth. Such a web of satellites could affordably provide the robustness that an operational system requires by allowing several small, separate platforms working together to accomplish what was formerly thought to need large, multi-instrument platforms. Scientists and other users could, in principle, have access to any on-orbit sensor(s) and be able to direct and control those sensors in the same manner as we access information on the Internet today. Such a constellation of smart satellites could, in principle, be able, on command, to provide the high-resolution data needed to cover energetically active events, especially hurricanes, volcanic eruptions, large forest fires, and floods, among others, and provide the information required for the mitigation of the impact of natural disasters. The concept will be tested in the EOS-Era. The EOS Landsat, Terra, Aqua, and Aura satellites will be flown in tandem with Cloudsat, and PCASSO in two separate constellations to create an *observatorium*, in the words of Ghassem Asrar, associate administrator for NASA s ESE. Future satellite systems are also likely to use new technologies such as: micro-electromechanical systems including micro-gyroscopes; sub-millimeter solid thrusters, measuring millimeters in diameter, to maintain attitude control for microsatellites; optical communications devices using laser transmitters to beam data at rates exceeding 1 Gigabit sec^{-1}; monolithic microwave integrated circuits; miniature digital active pixel sensors; and diffractive optics.

The Global Temperature Record

PHILIP D JONES

University of East Anglia, Norwich, UK

Global mean surface temperature is the most commonly used measure of the state of the climate system. Periods in the past are generally named according to their relative global mean temperature, e.g., the ice ages in relation to past and present interglacials. Variations of global mean temperature are also the measure against which we assess the sensitivity of the climate system to external factors thought to be of importance, such as changes in greenhouse gases, sulphate aerosols, solar output and the frequency of explosive volcanic eruptions. One of the main foci of climatology is quantifying the response of the climate system, as measured by global mean temperature, to all possible external forcings. Studies of this kind are essential if we are to predict future climatic change.

Local surface temperatures are one of the most important environmental indicators. Together with precipitation, seasonal variations determine the characteristic oral and faunal variability over terrestrial areas. All human life resides at the surface and the air temperature (AT) can determine events and moods, through the changes of temperature that occur in response to the seasons.

The record of past variations in surface temperature is extensive but of variable quality. Most is known about the instrumental era (1850 onwards), but even here, measuring sites are irregularly spaced, so that even now about 15- 20% of the surface is not being monitored. Measuring temperature in a consistent manner is harder than it may appear. Changes in thermometers, their housing and location, the time of day that readings are taken, and the environment around the instrument can all impair the record. All measuring seeks homogeneous values that are solely caused by the vagaries of weather and climate.

This article addresses the quality of the available records and what they tell us about the last 150 years. Since 1850, the global surface temperature average has risen by about 0.6°C, with the four warmest years of the record occurring in the 1990s: 1998 (0.57°C above the 1961- 1990 average), 1997 (0.43), 1995 (0.39) and 1990 (0.35). Recent record global averages may have caught the headlines, but the individual station and marine records tell us about the spatial patterns of the changes, the relative warming of night compared with daytime values, all factors that need explanation, either through modeling or empirical studies. Successful prediction, through general circulation models (GCMs), requires that we must also be able to adequately explain the spatial and temporal patterns of the last 150 years.

With both current assessments and modeling explanations we must realize that the last 150 years is a relatively short period in Earth's history. To place the period in a longer-term context we must resort to less well de ned (proxy) measures of past temperature change, from information held in written historical archives or in natural archives such as tree rings, ice cores, corals and varves (lake sediments). Proxy measures are both less reliable and less complete, most natural archives being biased somewhat to the growing season rather than the calendar year, and restricted spatially in some regions. The last 1000 years is the most relevant to the last 150 years and to the next century. Proxy evidence is becoming more extensive and analyses of this resource for the last 1000 years indicate that the 20th century was the warmest and the 17th the coldest. Individually, 1998 was the warmest year, with 1601 the coldest, being about 1.0°C colder than the 1961- 1990 average.

QUALITY OF BASIC TEMPERATURE DATA

In searching for trends or changes in observational data, it is essential that all series be as internally consistent, or homogeneous, as possible. In climatology, a temperature time series is homogeneous if the variations exhibited by the series are solely the result of the vagaries of the weather and climate. Numerous non-climatic factors can influence

the basic data, causing erroneous conclusions to be drawn concerning the course of temperature change. Before any analyses can be undertaken, it is vital, therefore, that all data are tested for homogeneity. Causes of inhomogeneity are varied and sometimes surprising. For temperature data measured at the Earth s surface, they are best discussed by dividing the data into its two components, land-based and marine records.

Land

Observations made at weather or climate stations are subject to inhomogeneities due to:

- changes in instrumentation, exposure and measurement technique;
- changes in station location (both position and elevation);
- changes in observation times and the method used to calculate monthly averages;
- changes in the environment of the station, particularly with regard to urbanization, that might affect the representativeness of local temperature records.

Few temperature series have followed the same protocols for their entire history. Since the late 19th century, the accepted exposure of thermometers has been in louvred (Stevenson) screens so that the sensors are not affected by direct sunlight. All measurements prior to the use of screens must be treated with caution. The common practice before screens was to attach the thermometer to a wall or building away from direct sunlight (e.g., north facing in the Northern Hemisphere) but direct sunlight can strike such exposed thermometers in summer, particularly in more poleward locations. Overhanging eaves are also a problem as are potential heat sources from inside the building.

In the last 20 years, automation has led to the use of electrical resistance as opposed to mercury or alcohol thermometers, thereby introducing different response times. Simultaneous measurements of the new and old systems are essential for calibration, but these are rarely adequately carried out. It is also important to note that technological improvements may be introduced for many reasons but they do not always lead to more accurate or more homogeneous measurements.

Few observation sites have remained exactly the same over time. Many sites were moved to airport locations in the 1940s and 1950s and were then regularly moved as the airport developed. Again, parallel measurements are essential to correct early readings to the new locations. Station history information is vital, but details of moves may have been lost or not been recorded because it was not considered important at the time.

Over the course of the last 150 years, many schools of thought have existed about when to take measurements and how to calculate the average daily temperature and hence the monthly and annual averages. Practices now vary between and within countries and have varied over time at almost all sites. In the early 20th century, efforts were made to measure the true daily mean temperature (the average of readings every hour) by a combination of a few (generally three or four) readings at fixed and convenient times. In most English speaking countries, the accepted method for the daily temperature average became the mean of the daily maximum and minimum temperature, the development of a thermometer to achieve these two measurements coming around 1860. Most other regions generally used measurements made at fixed hours. With hindsight, it would have been best for all sites to have maintained the same observation times and practices. Changes in specified observation times, the switch in many countries to the use of the simpler maximum and minimum method, and changes to the times of reading the maximum and minimum thermometers have all led to inhomogeneities in the records. All can be overcome with care and with good station history information. For many sites, however, this information is lacking or was not considered important enough to record.

The final problem, changes in the station environment, is generally beyond the control of the observer. Sites which were small towns in the 19th century are now large cities and the measured temperatures are likely to be warmer than without the urban growth. The problem is a real change in climate, although not all urban sites are affected. Some, because of locations in parks or on coasts, are not significantly affected. Urbanization is considered an inhomogeneity in the sense that the measured temperatures from affected sites are now only representative of very localized areas. This problem is the most serious of the four because environmental changes most often produce gradual warming (irrigation of agricultural fields or creation of a golf course are examples that can create cooling), whereas the other three generally induce abrupt jumps in station time series.

Correction of the temperature time series for available stations (about 2500 series are available, digitally, in total, varying in length from between 200+ and 40 years) is a necessary but laborious task, often made difficult or near impossible by the lack of adequate information. Numerous subjective and relatively objective criteria have been developed for testing monthly average data (see recent review by Peterson *et al.*, 1998a). All rely on intercomparison of neighbouring time series, assuming that the closer the sites, the more the records should agree. The urbanization question can be addressed only if suitable rural stations are available. If all sites are cities/large towns, their records may be similarly affected. While there is no definitive basis for establishing accuracy, all the necessary adjustments are made according to station

history information and experience and so are not arbitrary. Adjustments are generally applied on a monthly basis and must be considered only first approximations if daily data are used.

Marine

Historical temperature data over marine regions are largely derived from *in situ* measurements of sea surface temperature (SST) and marine air temperature (MAT) taken by ships and buoys (*see* Sea Surface Temperature, Volume 1). To be of use, each measurement must be accompanied by a location value. Incorrectly located data must be discarded. Up to 15% of the data have been found to be mislocated (e.g., SST/MAT values occurring over land) and can be easily discarded. The major problem arises with the data located in the wrong ocean, generally from coding mistakes with hemispheres (north for south, etc.). Homogeneity problems relate to changes in instrumentation, exposure and measurement technique. For SST data, the changes in the sampling method from uninsulated canvas buckets (generally prior to the early 1940s) to engine intake measurements (early 1940s onwards) causes a rise in SST values of 0.3–0.7 °C. For MAT data, the average height of ships decks above the ocean surface has increased during the 20th century, but the more serious problem is the contamination of daytime MAT through solar heating of the ships infrastructure, rendering only the nighttime MAT (NMAT) data of value.

In combining marine data with land-based surface temperatures to provide a more complete coverage of the Earth s surface, SST anomalies are used in preference to NMAT because they are considered more reliable, principally because there are at least twice as many observations due to the rejection of all daytime MAT values. The basic assumption in their use is that, on monthly and longer timescales, an anomaly value of SST will be approximately equal to that of the air above.

Correction of the SST data for the change from canvas buckets to engine intakes is achieved using a physical-empirical model to estimate the amount of cooling of sea water that occurs in buckets of various designs, depending upon the time between sampling and measurement and the ambient weather conditions (Folland and Parker, 1995). Correction factors for the bucket SST values for all years before 1942 have been estimated using this model. Corrections, which are greater in winter, are tuned using an additional assumption that SST annual cycle amplitudes have not experienced a long-term trend. This gives a sampling time of 3–4 minutes approximately what is generally believed to have occurred.

Since the marine and land components are independent, the two records can be used to evaluate each other after correcting both. The components have been shown to agree well with one another on an hemispheric basis by Parker *et al.* (1994) and using island and coastal data (Folland and Salinger, 1995).

AGGREGATION OF THE HOMOGENEOUS DATA

The basic homogeneous data are irregularly located over the Earth s surface. For ease of use they must be combined into a regular grid, generally based on latitude and longitude. The land and marine components are first developed separately and then amalgamated.

Land

Due to differing station elevations and national practices with regard to the calculations of monthly mean temperatures, interpolation to a regular grid is much more easily achieved by converting all the monthly data to anomalies or departures from a common period. The period with the best available data is 1961–1990. Many station series are not complete, even for this period, so, in practice, each station is required to have 20 years of data in this period to be included in compilations (see Jones, 1994 for more discussion).

The station anomaly values are then simply averaged together within each $5 \times 5^{\circ}$ grid-box. Resulting grid-box time series will thus differ in the number of stations used, both between grid boxes and through time. Individual grid-box time series may, therefore, have differences in variance with time due to changes in station numbers. The implications of this may affect some analyses and will be highlighted later. Several different variants of this basic approach to aggregation have been introduced. Although the results differ slightly, differences in the estimated trends of global averages over the 1880–1990 period differ by only a few hundredths of a $^{\circ}$C 100 years^{-1} (Peterson *et al.*, 1998b).

Marine

For SST, the raw data must be aggregated in a different manner. First, an average field for the 1961–1990 period is derived for each $1 \times 1^{\circ}$ square of ocean for each five day period (pentad) and day of the year. This background climatology is then smoothed spatially and across pentads/days to reduce errors in regions with few observations during the 30 years. Additionally, satellite estimates of SST from 1979 onwards are used to help infill data voids and very poorly sampled (by *in situ* measurements) regions. Grid-box anomalies, from the daily climatology, for each month from 1856 are produced by trimmed averaging of all 1° anomalies for each of the pentads that make up each month. The trimming reduces the effect of outliers. The

final dataset is checked for outliers by comparing neighbouring 5° grid-box values.

Combining the Land and Marine Components

After processing, both components are available on the same 5° grid-box basis. The two data-sets are merged in the simplest manner. Anomaly values are taken where available from each component. For grid boxes where both components are available, the combined value is a weighted one, the weights determined by the fractions of land and ocean in the box. Since the land component for oceanic islands is potentially more reliable than a few surrounding SST values, the land fraction is assumed to be at least 25% for each of the island and coastal boxes. A corresponding condition is applied to the ocean fraction of boxes where this is less than 25%.

Hemispheric and Global Anomaly Time Series

Calculation of hemispheric average values is achieved by weighting all available grid boxes for each month. With latitude/longitude grid boxes, the weights used are normally the cosine values of the mid-point latitude value of each grid box to account for the convergence of longitude lines with latitude. Improvements in coverage mean that estimates improve in accuracy through time (see the following section on the accuracy of hemispheric and global series).

Figure 1 shows the two hemispheric time series by season and year. The global annual series exhibits a warming of 0.57 °C over the 1861–1997 period. Table 1 gives monthly linear trend values, estimated by least squares, for each hemisphere and for the globe calculated over the 1861–1997 and 1901–1997 periods. The extreme warm years of 1998 (and 1999) are omitted in the calculation of trends. Calculation of temperature trends by least squares regression is just one means of estimation. All methods have some shortcomings as the series shown in Figure 1 are only poorly approximated by a linear trend. Warming is slightly, but not significantly greater in the Southern Hemisphere (SH) compared with the Northern Hemisphere (NH). Warming in all months for all three regions is highly statistically significant (better than the 99% significance level), even allowing for the greater uncertainties earlier in the series (see the following section on the accuracy of hemispheric and global series). Warming is least in the NH summer months, perhaps because the warmth of the 1860s and 1870s may reflect exposure problems of thermometers

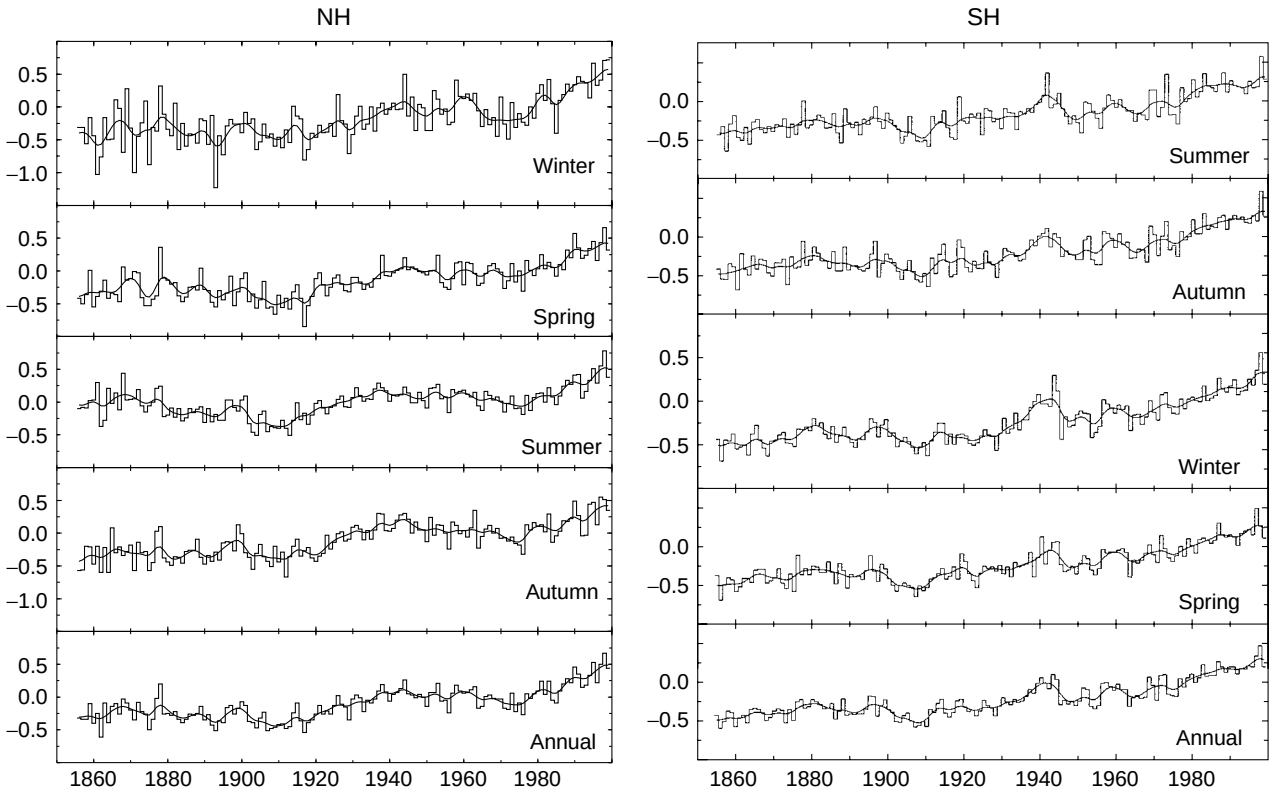

Figure 1 Hemispheric temperature averages by season and year for the period 1856–1999, relative to 1961–1990. Seasons are those routinely used in climatology, winter is the December, January and February average in the NH and the June, July and August average in the SH. The smooth line on these and subsequent time series in this section is a data adaptive filter (10 year Gaussian) that highlights variations on the decadal timescale

Table 1 Temperature change (°C) explained by the linear trend over two periods

	1861–1997			1901–1997		
	NH	SH	GL	NH	SH	GL
January	0.94	0.32	0.63	0.61	0.42	0.52
February	0.92	0.37	0.65	1.01	0.41	0.71
March	1.04	0.39	0.71	0.90	0.44	0.67

November	1.07	0.35	0.71	0.52	0.59	0.55
December	1.05	0.25	0.65	0.82	0.51	0.66
Year	0.71	0.41	0.56	0.63	0.49	0.56

in mid- to high-latitude land areas (see earlier section on homogeneity over land).

Differences between the seasons are much greater in the NH compared with the SH. The NH also shows greater year to year variability in winter than in summer. The greater variability in all seasons in both hemispheres before 1881 is principally due to the sparser data available during these years and represents greater uncertainty in the combined data set. This feature is more marked in the NH and occurs predominantly over land areas.

The seasonal and annual hemispheric series show extremely warm and cool years relative to the underlying trend (the smooth curve). Many of these anomalously warm and cool years are coincident between hemispheres suggesting a response to common forcing. Warm years are generally related to El Niño events and the cold years to La Niña events or to the effects of major explosive volcanic eruptions. The effects of volcanoes tend to give the NH series a slight negative skew in the year to year variability about the smoothed line.

Both hemispheres clearly show two periods of warming, 1920–1940 especially in the NH and since the mid-1970s. Slight cooling occurred between the two periods, albeit barely perceptible in the SH. In the global annual series (Figure 2), 12 of the 14 warmest years occured between 1986 and 1999. The warmest year of the entire series on a global basis occurred in 1998, 0.57°C above the 1961–1990 average. The four warmest years of the series occured in the 1990s with 1997 the second warmest (0.43), 1995 (0.39) and 1990 (0.35), the third and fourth.

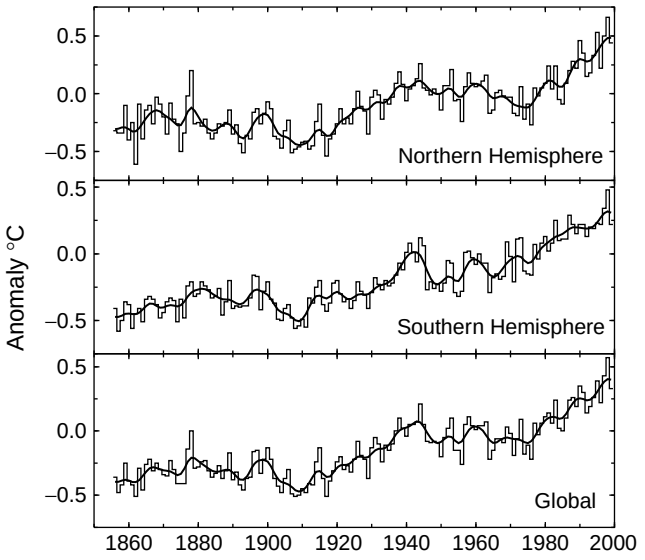

Figure 2 Anomalies of hemispheric and global temperature averages on the annual timescale, relative to 1961–1990

Accuracy of Hemispheric and Global Series

The series in Figures 1 and 2 and the underlying individual grid boxes are subject to two sources of errors: bad measurements and most importantly, changes in the availability and density of the raw data. Errors of the latter type are referred to as sampling errors. For the whole time period, data from the land and marine components have been evaluated for measurement errors. Extreme values exceeding three standard deviations from the 1961–1990 statistics are all checked for spatial consistency. Despite these checks, it is likely that erroneous values slip through, though any effect is considered to be essentially random and will be totally insignificant in the large-scale averages.

Sampling errors are much more important and occur because the availability and density of the data used in the compilation of the surface temperature field are ever changing. For most of the post-1860 period, apart from the two World Wars and since about 1980, the changes should have led to an improvement in the accuracy of

large-scale averages through the use of more complete data fields. Estimates of accuracy need to take into account both changes in the available network of data through time and the areas (particularly the higher latitude Southern Oceans) that are always missing.

Standard errors of regional and hemispheric estimates depend upon two factors: the locations and the standard errors (SE) of grid boxes with data. In the most comprehensive study of the issue, Jones *et al.* (1997) show that the errors are a function of four factors, the temporal variability of each grid-box temperature series, the spatial variability of temperature within each grid box, the number of stations available in each grid box, and the variability of temperature between grid boxes.

Temperature is more variable from one year to the next over continental interiors and polar regions compared with oceanic and coastal regions. To achieve the same accuracy in a grid-box average over Siberia requires more station series than the same sized box over, for example, Ireland. Spatial variability between station time series is also greater in continental and polar regions compared with oceanic and coastal areas. The fourth factor relates to the lack of statistical independence between neighbouring grid-box time series. This interdependence between the time series leads to the concept of the effective number of independent series. This is referred to in statistical terms as the effective number of spatial degrees of freedom. Since the 1950s, about 80% of the 2592 5° grid boxes have anomaly data, yet the number of independent values are only of the order 40–60 for annual averages (i.e., only this number are statistically independent of each other).

All of the factors, except the number of stations per grid box, depend upon timescale, so must be estimated for the time period over which the estimates of accuracy are required. The first two factors are relatively smooth variables when mapped, so this property can be used to estimate the values of these variables in unsampled regions (Jones *et al.*, 1997).

Figure 3 shows SEs calculated on the decadal time scale for hemispheric and global temperature time series. The greater percentage of missing regions in the SH gives higher SEs. Values decrease with time since 1860, with typical values after 1951 for the globe of 0.048 °C when calculating decadal averages. Values are only slightly larger for the interannual timescale (0.054 °C). Standard errors are about twice the post-1950 values for the two hemispheres during the 1860s and 1870s. The larger errors in the 19th century and particularly before 1881 are reflected in the greater variability of the seasonal series in Figure 1.

Standard errors on the interannual timescale may be used to determine whether one year is different in a statistically significant sense from another year. The year 1998, for example, was so extreme that it can be said with high statistical confidence to be significantly warmer than the next warmest year of 1997. The year 1998 also broke most of the monthly records with the first eight months of the year being the warmest such months in the global series.

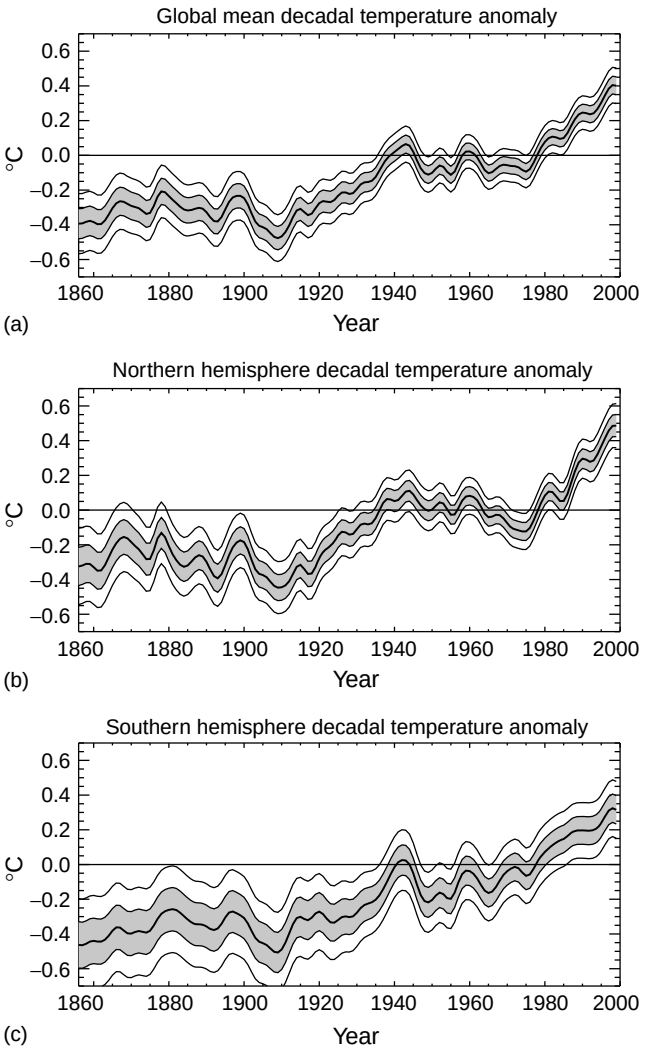

Figure 3 One and two SEs on the hemispheric and global temperature series for the decadal timescale. The shaded areas highlight ±1 SE

Consideration of these errors in the calculation of trends given in Table 1 enables these additional uncertainties to be added to the statistical uncertainties from estimating a linear trend. Combined, the effect of both types of errors creates uncertainties that are less than ±0•05 °C (monthly) and ±0•03 °C (annual) for the temperature changes given in Table 1.

ANALYSES OF THE SURFACE TEMPERATURE RECORD

The record of surface temperature has been extensively analyzed, particularly over the past 10–15 years, in review

papers and international reviews (e.g., those for the Intergovernmental Panel on Climate Change (IPCC) (see for e.g., Folland *et al.*, 1990, 1992; and Nicholls *et al.*, 1996 and earlier references therein). In this section, the following aspects will be addressed:

- patterns of recent warming;
- trends in areas affected by monthly extremes of temperature;
- trends in continental scale temperatures;
- trends in maximum and minimum temperatures;
- daily temperature extremes in long European series;
- the last 150 years in the context of the second millennium.

Global scale temperatures have recently also been calculated for the lower part of the troposphere. Although we might, *a priori*, expect some differences with surface values, much has been written about the comparisons made.

Patterns of Recent Warming

Figures 1–3 clearly indicate that most of the warming this century occurred in two distinct periods. The periods differ slightly between the hemispheres and among the seasons, but the periods from about 1920–1945 and since 1975 stand out. Figure 4 shows the trend of temperature change (calculated by linear trends for each grid box), by season and annually, for the two 20 year periods, 1925–1944 (a) and 1978–1997 (b). The annual global temperature increases during the two periods were 0.37 and 0.32 °C, respectively, with the second period 0.27 °C warmer than the first. Despite these periods exhibiting strong warming in the global series, not every region warms. Statistically significant cooling (not shown) occurs in a few areas in some seasons. There are marked seasonal patterns and the term *global warming* should only be used to refer to warming in the global average. It clearly does not mean warming everywhere on the globe.

In both periods, the regions with the greatest warmings and coolings occur over the northern continents, and, with the exception of a few isolated grid boxes, during the December January February (DJF), March April May (MAM) and September October November (SON) seasons. The largest warmings/coolings may not always be the most statistically significant because of the high year to year variability of continental areas. Small trends over some oceanic areas are significant because of low variability from year to year. Warming clearly dominates and the greatest magnitude values during the DJF and MAM seasons are over the high latitudes of the northern continents.

The 1978–1997 period, despite a lower warming in the global average, has a much larger area with statistically significant warming compared with 1925–1944. Some of this is related to better coverage recently, especially in the tropics. The improvements in coverage between the two periods are apparent, with shipping routes surrounded by data voids in the 1925–1944 period. The pattern of recent warming (1978–1997) is strongest over northern Asia, especially northern Siberia. Warming is also evident over much of the Pacific basin, western parts of the USA, western Europe, southeastern Brazil and parts of southern Africa. Seasonally, the annual pattern is dominated by the DJF and MAM seasons, especially north of 30 °N. Despite this, the season with the greatest spatially significant warming is June July August (JJA), because of lower levels of year to year variability. The area with greatest cooling occurs in SON along the Rocky mountain chain.

The 1925–1944 warming was strongest over northern North America and is clearly evident over the northern Atlantic, parts of the western Pacific and central Asia. The largest coolings occur over northern Asia in SON and much of Europe in DJF. This latter area highlights a problem with trends over a short period of time such as 20 years. European winters were anomalously cold during the early 1940s. Changing the period from 1925–1944 to 1921–1940 would change the slight cooling in this region to slight warming.

Both sets of maps illustrate large differences in trends between apparently close regions. This high degree of spatial variability is partly real, but part of it is likely due to data problems. Measurement errors and inadequacies with homogeneity are factors, but the main problems relate to regions with a few missing years. Grid boxes required 10 of the 20 years to calculate a trend and each season (year) required 2 (8) months of data present.

The choice of the two periods may be somewhat arbitrary, but all other choices would have similar failings. Mapping longer trends over the whole century would have placed great emphasis on the decision of how many years are necessary to constitute a trend, creating situations in which maps would have sparser coverage than for 1925–1944. The best way to view the data is to look at running trends as part of a video sequence, considering 10- or 20-year averaging intervals.

Trends in Areas Affected by Monthly Extremes of Temperature

The previous section showed that regions with the strongest temperature trends are not always those which are the most statistically significant. A more useful measure of temperature change, from an impact point of view, would be one that treats all areas equally by removing the effects of different magnitudes of year to year variability. Taking this approach, the rarity of extreme monthly temperatures can be directly compared between regions. An appropriate transformation uses the gamma distribution (in simple terms

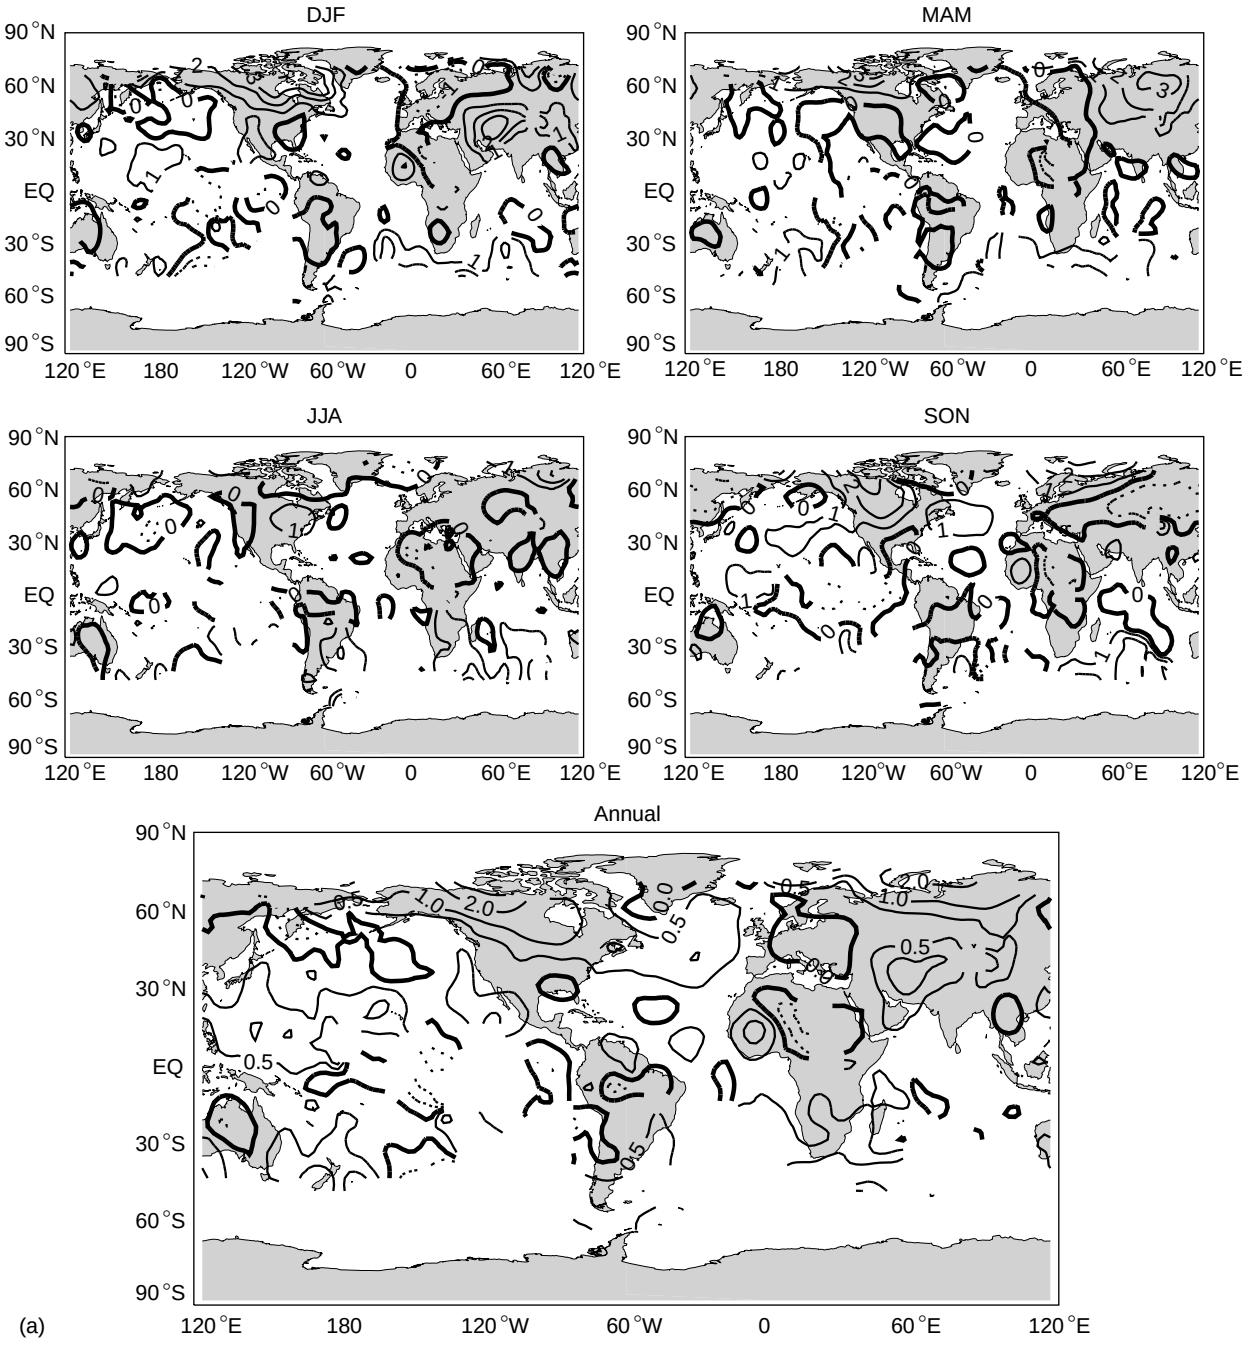

Figure 4 Trend of temperature on a seasonal and annual basis for two 20 year periods, (a) 1925–1944 and (b) 1978–1997. Regions with significant warming and cooling are shown in Jones *et al.* (1999)

this can be considered as a skewed version of a normal distribution). Each grid-box time series, on a monthly basis, is transformed from one based on anomalies with respect to 1961–1990 to one based on percentiles with respect to the same period (see for e.g., Jones *et al.*, 1998a). Using a normal distribution (i.e., simply dividing the grid-box anomaly values by the standard deviation calculated over the 1961–1990 period) works almost as well, but a gamma distribution gives a better representation because monthly temperatures are significantly negatively skewed in many regions of the world.

Figure 5(a) compares the anomaly and percentile method for displaying annual temperatures for 1998. The zero anomaly and the 50% contour are essentially the same in

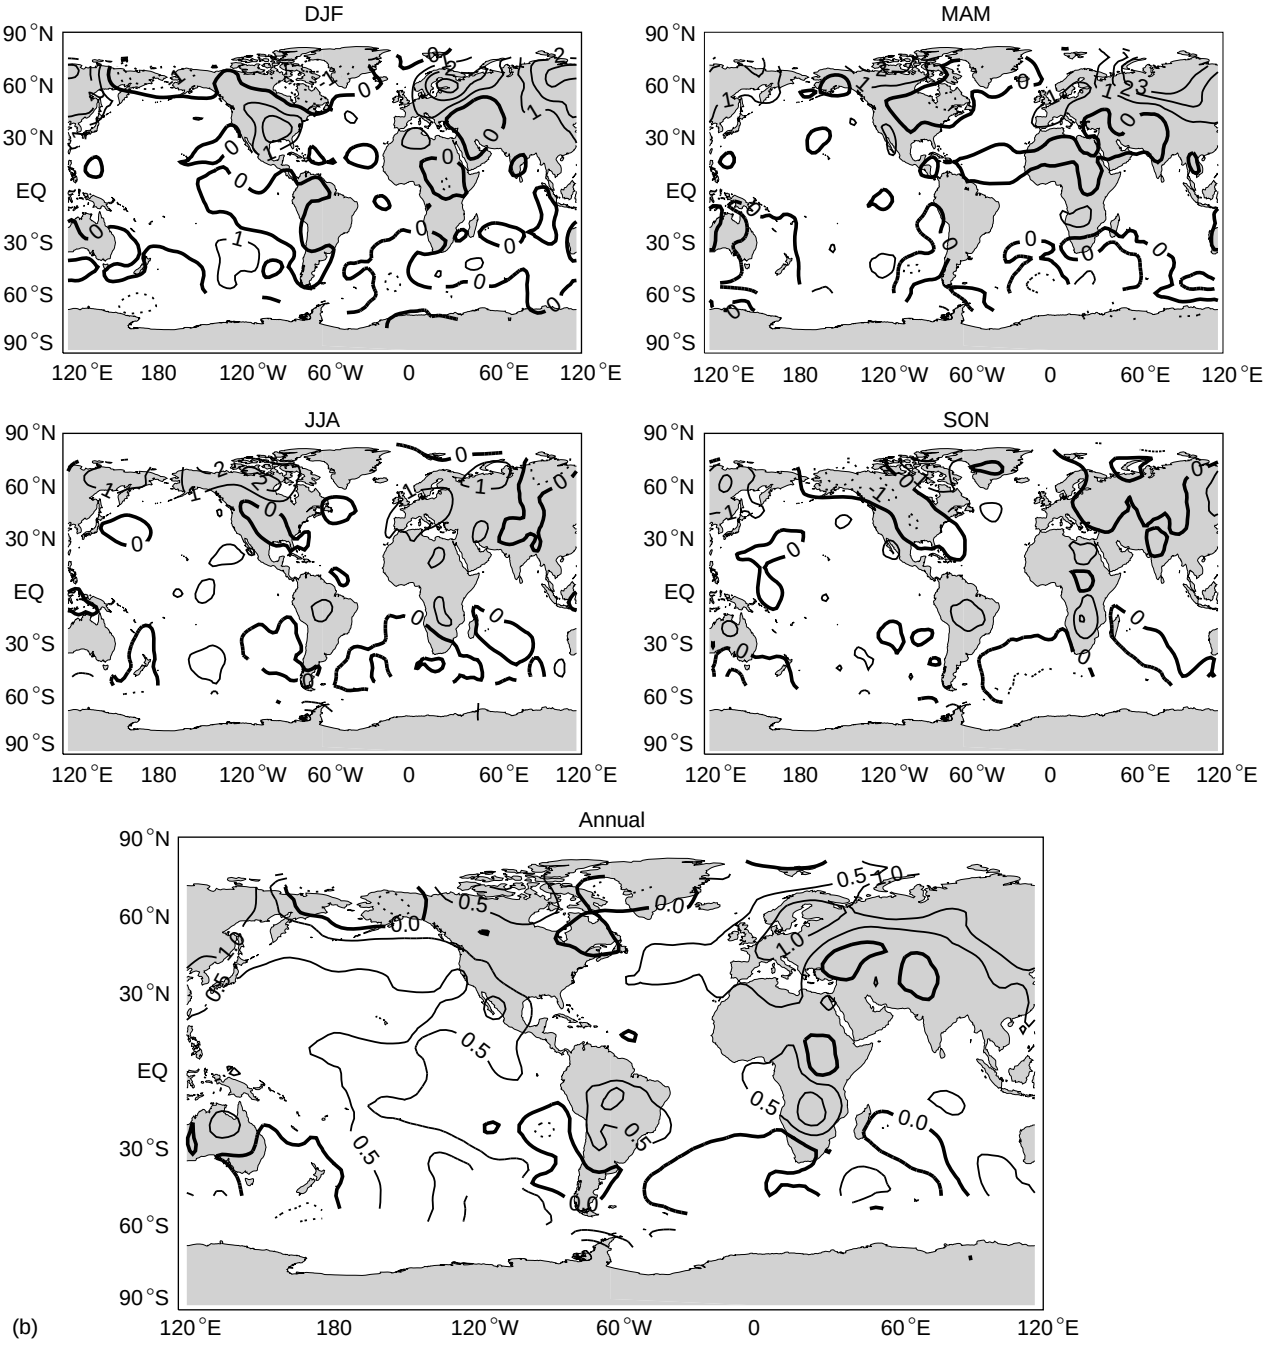

Figure 4 (*Continued*)

both plots. The percentile map indicates extreme annual temperatures over many tropical and oceanic regions that might not warrant a second glance in anomaly form.

For this year, the area in excess of the 90th percentile covers a large proportion of the globe. Figure 5(b) shows the percentage of the analyzed area of the globe with annual temperatures greater than the 90th and less than the 10th percentile since 1900. An increase in the percentage of the analyzed area with warm extremes is evident, but by far the greatest change is a reduction in the percentage of the analyzed area with cold extremes. Some caution should, however, be exercised when interpreting these results. Large changes in coverage have occurred over the 20th century (see Figure 4a) so some of the changes may be due to areas entering the analysis through time. This same problem affects the hemispheric and global anomaly

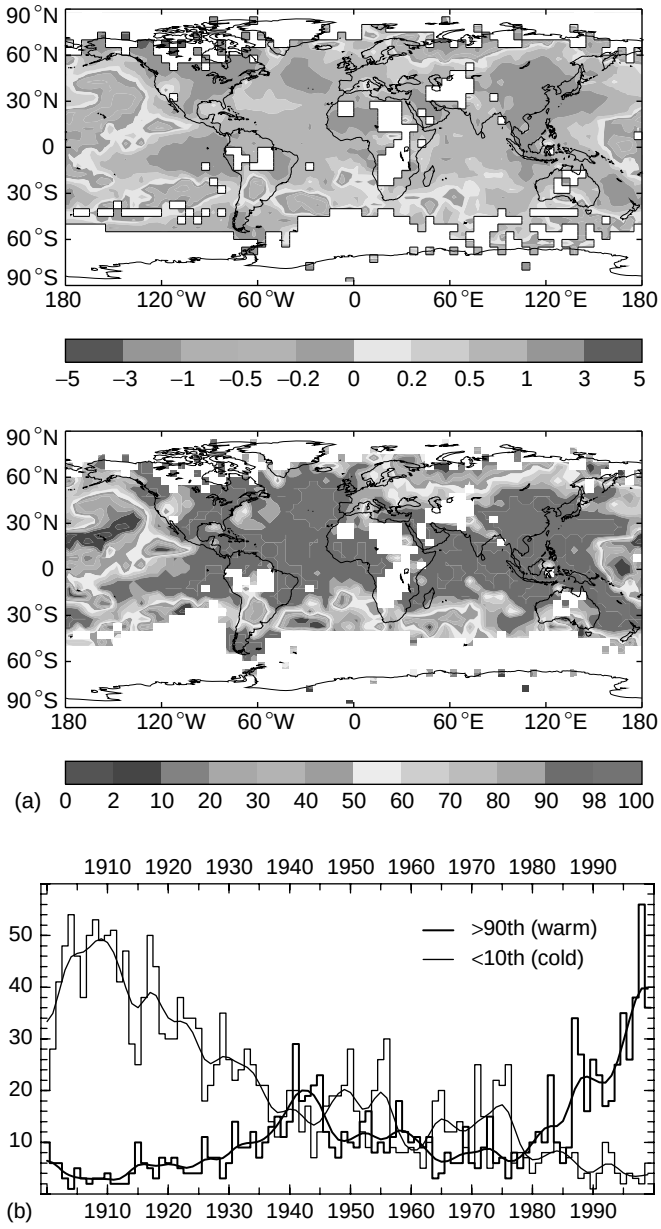

Figure 5 (a) Surface temperatures for 1998, relative to the 1961–1990 average, expressed as anomalies and as percentiles. The percentiles were defined by fitting gamma distributions to the 1961–1990 annual deviations relative to the 1961–1990 average, for all $5 \times 5^{\circ}$ boxes with at least 21 years of annual data in this period. (b) Percentage of the monitored area of the globe, for each year 1900–1999, with annual surface temperatures above the 90th percentile and below the 10th percentile

series in Figures 1 and 2, where the implicit assumption is made that the average of the unsampled regions is the same as the average of the sampled regions. Coverage changes are minimal since 1951 and reanalysis, using only those regions with data for the whole century, produces similar trends to those seen in Figure 5(b). Another problem is that during the early decades of this century grid-box values were based on fewer stations or few individual SST observations, possibly producing more extreme values in the percentile sense. Again, however, changes in the density of observations per grid box are minimal since 1951.

Trends in Continental Scale Temperatures

Another way of looking at grid-box temperature data is to derive continental-scale time series. Figure 6 shows eight regions on an annual basis, each plotted as anomalies from the 1961–1990 period. Each series has been calculated using all $5 \times 5^{\circ}$ land grid boxes in the areas defined in the plots. All eight series show long-term warming but by varying amounts. Europe and South America show a gradual warming over the 20th century, with North America, Africa and the Arctic indicating a strong warming during the first part of the century, cooling over the 1940–1975 period, followed by renewed warming. Asia and Australia show warming principally over the last 25 years. In some regions, temperatures during the 1980s and 1990s are about $1\,^{\circ}$C warmer than those prevailing during the 19th century. Only in Asia and Africa, however, are the extreme individual years clearly evident during the late 1980s and 1990s.

The series also show marked differences in year to year variability. This is partly a function of region size, but also reflects the underlying spatial variability of year to year temperatures. Greater spatial variability is evident over the polar regions and the interior parts of North America and Eurasia. Some regions (the Arctic, Africa and South America) show increased variability during the 19th century. This is not real, but due to the sparser availability of data during these years.

Trends in Maximum and Minimum Temperatures

Up to now, all the surface temperature analyses have used monthly-mean temperatures. This situation principally arises from the widespread availability of this variable. Recently, more extensive data-sets of monthly-mean maximum and minimum temperatures and their difference, the diurnal temperature range (DTR) have become available. The most extensive analysis has been undertaken by Easterling *et al.* (1997) using over 3000 station time series that encompass 54% of the world s land areas, covering the period 1950–1993. Despite the number of stations, the area covered is less than for mean temperatures. Homogeneity problems were assessed but they are more difficult to address with this type of data, requiring much more station history information than is generally available. This study confirmed some earlier analyses and showed that over the 44 years, minimum temperatures warmed by $0.79\,^{\circ}$C (linear

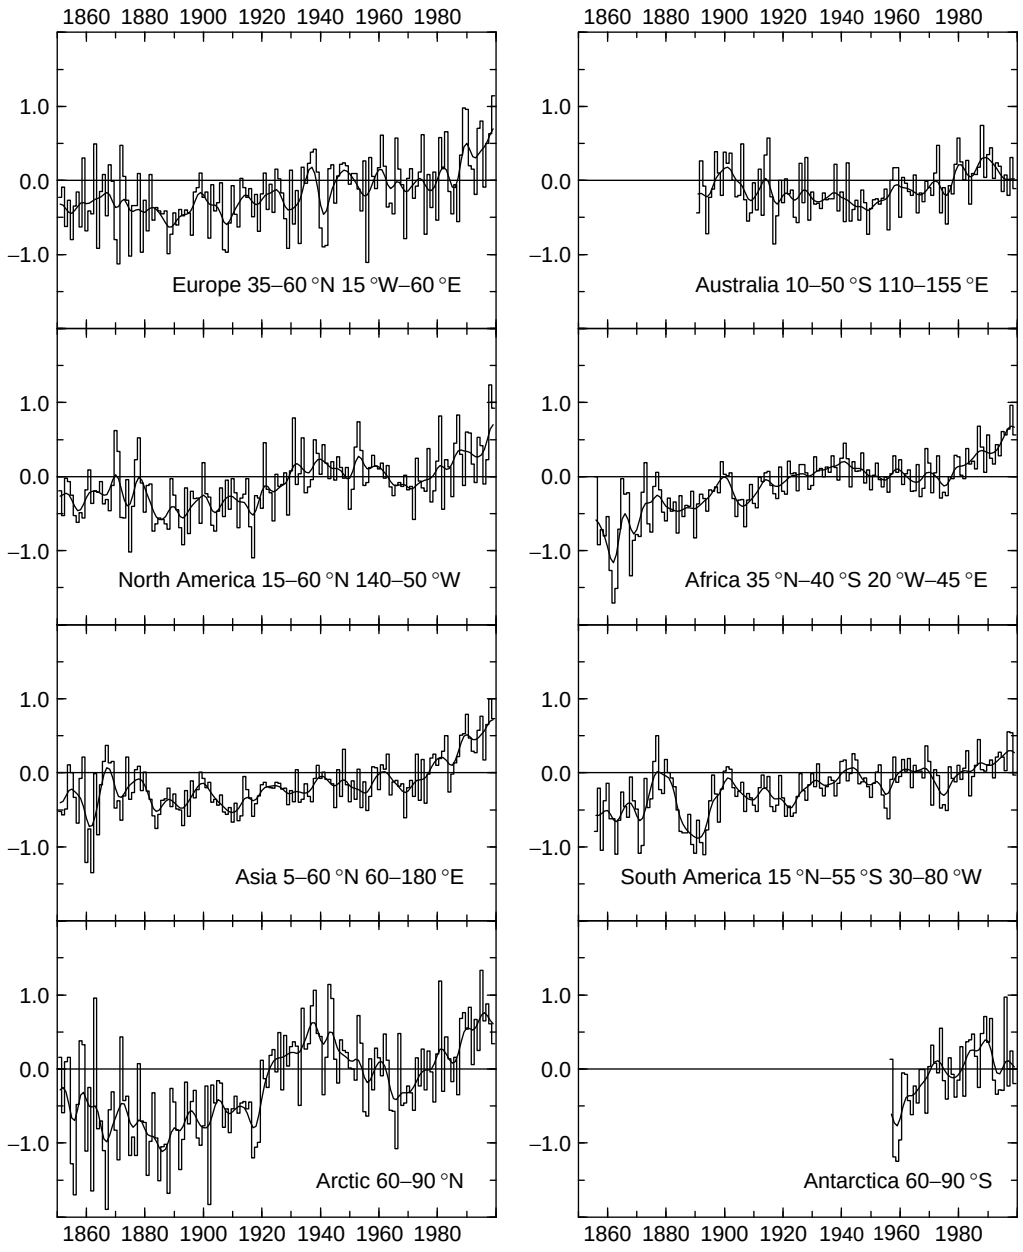

Figure 6 Continental scale temperature anomaly series on an annual basis relative to 1961–1990. The continents are defined in each of the plots. The series have been produced using only land data from the $5 \times 5^{\circ}$ grid-box dataset

trend calculated using the average global series), maximums warmed by 0.35 °C and the DTR decreased by 0.35 °C. The study also attempted to eliminate any possible influence of urbanization effects by using only non-urban stations in the analysis. Whether these trends are part of longer term changes is open to question. Longer series, back to the turn of the century, are only readily available for the United States. Analyses there shows little change over the first half of the 20th century.

Figure 7 shows the annual trends for each 5° grid box for 1950–1993, expressing the trends as °C per century. Minimum temperatures decrease in only a few areas while maximums show decreases over large areas, notably eastern Canada, southern United States, parts of Europe and much of China and Japan. The DTR shows decreases almost everywhere except Arctic Canada and some Pacific Islands. As with Figure 4, there are again large differences between neighbouring grid boxes which reflect both the short period of analysis, some missing years, and more probably, some errant station values in a few series where an individual grid-box series may be made up from a single station. This problem would be reduced if the trends were estimated from

the percentile values of the previous section, but the units would no longer be the easily understood °C.

Daily Temperature Extremes in Long European Series

The last two sections considered extremes on a monthly basis, but the public perception of climate change is often gleaned from daily extremes. A few extreme cold days in a row in a region might lead to questioning of the long-term warming, whereas a heat wave might produce the opposite reaction. In the context of the global warming issue, daily data should be relatively unimportant as detection of change and attribution to human influences is primarily focussed on underlying trends on decadal timescales. In the public and political worlds, however, changes in the frequencies of extremes are how global warming is often perceived.

In examining these data, daily temperature series present greater problems with respect to homogeneity than monthly data. Many of the homogeneity issues discussed earlier have a much greater influence on daily than on monthly values. Site and observation time changes are particularly important and may not be correctable in all cases. Few

long daily series are, therefore, totally homogeneous and the availability of series in digital form is generally restricted to the last 50 years. The longest daily series are available in Europe and a few have had extensive homogeneity analyses undertaken, enabling some confidence to be placed in derived results. The longest currently available daily record (1772 to the present) is that for Central England, which represents the average temperature for three sites (Parker *et al.*, 1992).

The public perception of extremes might be cold winter days or hot summer days, but this definition only considers the extreme seasons and necessitates a somewhat arbitrary definition of a threshold for cold and hot. A cold day threshold of 0 °C clearly has important consequences, but a warm day threshold would clearly be somewhat arbitrary. A better and universally applicable means of defining extremes is to let the data decide the threshold (Jones *et al.*, 1998a). Here an annual cycle of temperature on a daily basis is defined for the period 1961–1990.

With the smooth curve defined, the daily temperature anomalies for the 30 January 1st s for 1961–1990 are fitted to a gamma distribution, as described earlier. The gamma distribution is used because these daily anomalies also have a tendency to be negatively skewed. This distribution enables each January 1st value for the whole series to be transformed to a percentile value. Similar analyses are undertaken for the other days of the year. It is now a simple matter to count the number of days above the 90th (warm) and below the 10th (cold) percentile in a calendar year or in a season.

Figure 8 shows the annual counts of warm and cold days for the Central England series for 1772–1998. As would be expected, there is a strong correlation with annual mean temperatures. The counts show an increase in warm days over the present century, but the largest trend is in the reduction of cold days. The method is insensitive to the choice of base period in that another choice would produce similar trends, but centered around a different base value. Analyses for other long daily series in Europe (St. Petersburg, Stockholm, Uppsala, Brussels, Milan, Padua and Cadiz) show similar trends to the Central England series.

The last three sections have all looked at extremes in different ways, but all yield similar conclusions. The warming of the present century is mostly manifest, not by increases in warm extremes, but by reductions in cold extremes. These sorts of extremes often pass by unnoticed by the public. Only in sectors where cold temperatures are important have their effects been noticed. For example, pesticide use has increased because insect killing frosts are less severe, the skiing season is shorter, and freeze-up periods of some major rivers are reduced.

The Last 150 years in the Context of the Present Millennium

The global average surface temperature has clearly risen over the last 150 years (Figure 2 and Table 1), but what significance does this have when compared with changes over longer periods of time? The last 1000 years is the pre-instrumental period about which we know the most, although it must be remembered that such knowledge is of considerably poorer quality than for the post-1850 period. The last 500–1000 years is also the most important when

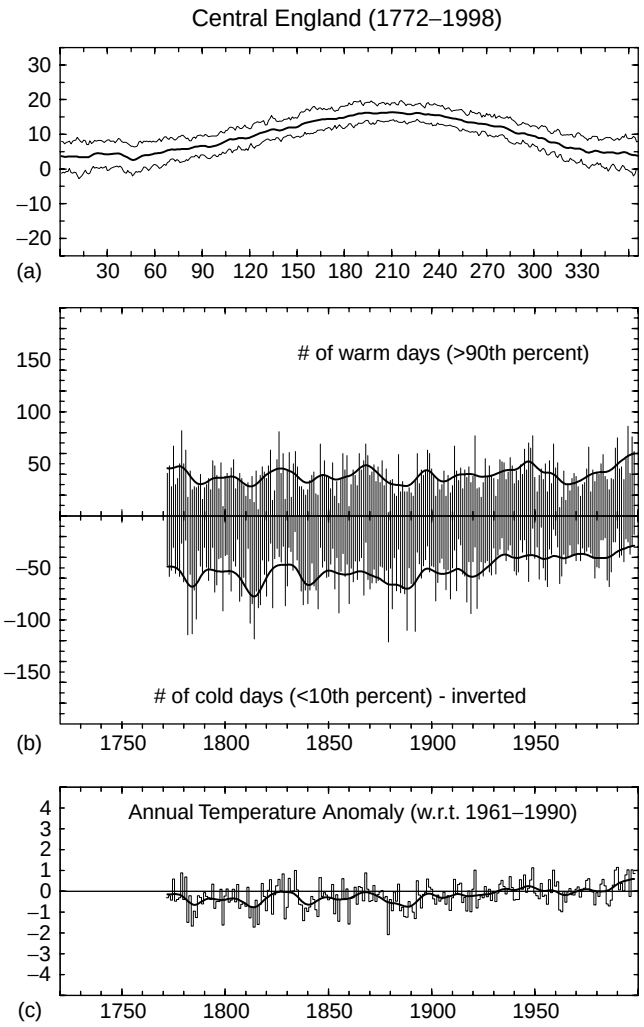

Figure 8 (a) Annual cycle of daily Central England temperatures (CET), 1961–1990. The two outer thinner lines represent the 90th (warm) and 10th (cold) percentiles. (b) Counts of days each year, 1772–1998 in CET above/below the 90th/10th percentile thresholds. (c) Annual temperature anomalies from the 1961–1990 base

considering attribution of recent changes to human influences. Earlier millennia are less important because they are known to have been influenced by changes in solar irradiance caused by changes in the Earth s orbit around the Sun (the Milankovitch effect, *see* Orbital Variations, Volume 1).

Information about the millennium comes from a variety of high-frequency proxy climatic sources (early instrumental records back to the late 17th century, written historical records, tree-ring densities and widths, ice cores, corals and some highly resolved lake and marine sediments). All these sources are discussed in other sections (but see also Jones *et al.*, 1998b and Mann *et al.*, 1998; Natural Records of Climate Change, Volume 1). Uncertainties in

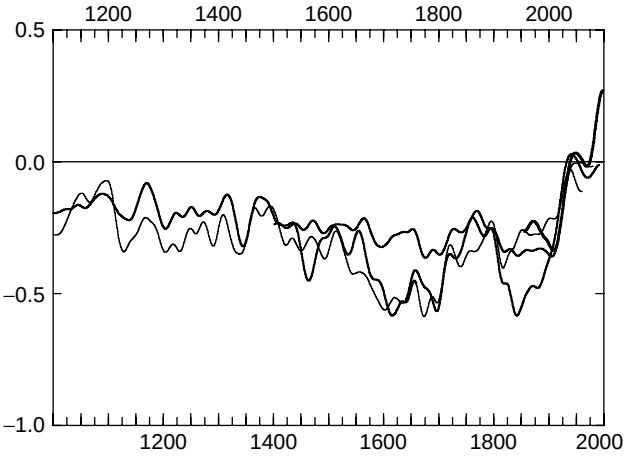

Figure 9 NH temperature reconstructions from palaeoclimatic sources. The three series are Mann *et al.* (1998) (thick), Briffa (2000) (medium) and Jones *et al.* (1998b) (thin). All three annual resolved reconstructions have been smoothed with a 50-year Gaussian filter. The fourth (thickest) line is the short annual instrumental record also smoothed in a similar manner. All series are plotted as departures from the 1961–1990 average

this information are considerably greater because evidence is restricted to limited areas where these written and natural archives survive, and more importantly, all proxy records are only imperfect records of past temperature change.

During the last five years, the number of regions from which records have been developed has dramatically increased. Figure 9 compares three different reconstructions of NH temperatures for part of the last millennium. The reconstructions are all of different seasons, so on the basis of the instrumental record would be expected to differ. The source details are given in the figure caption and the annual instrumental record is superimposed. The most striking feature of the multiproxy averages is the warming over the 20th century, for both its magnitude and duration. The agreement with the instrumental records over the last 150 years should be taken as real in that all three have, to some extent, been calibrated against instrumental data, either locally or as a whole. Agreement is poorer during the 19th century, accentuated partly by the instrumental series being annual and two of the compilations being most responsive to summer conditions. If the proxy records have any validity, then the 20th century is both the warmest of the millennium and the warming during it has been unprecedented. Four recent years (1998, 1997, 1995 and 1990) are the warmest in the instrumental series and are the warmest since 1400 and probably since 1000. The coolest year of the millennium was 1601, about 1.0 °C below the 1961–1990 average. If SEs could be assigned to these series, as was done for the instrumental series, they would be considerably larger, so it is probably very prudent to consider only the longer (decadal and century) timescale changes.

Numerous palaeoclimatic studies have considered the last millennium and two unusual periods, the *Little Ice Age* (*see* Little Ice Age, Volume 1) and the *Medieval Warm Period* (*see* Medieval Climatic Optimum, Volume 1) are often discussed. The three curves in Figure 9 all raise questions about whether, on hemispheric scales, these two periods were universally colder and warmer, respectively, than the present. This questioning arises from the significant advances in palaeoclimatology that have been made over the past 15–20 years. The series used in Figure 9 contain from ten to several hundred diverse proxy climatic series, considerably more than previously analyzed. The coldest century of the millennium, the 17th was on average only 0.5–0.8 °C below the 1961–1990 base. Centuries in the first half of the millennium were milder but still cooler than the 20th century. The differences between these later studies and earlier work is that they are based on considerable amounts of diverse (both in terms of variety and location) proxy data than used earlier. Earlier studies were restricted in location, the terms themselves being defined by early European/North Atlantic analyses, and often used more slowly responding proxies (such as glacial advances and tree lines), where the influence of temperature was generally inferential and qualitative rather than of the quantitative nature recently achieved.

ABSOLUTE VERSUS ANOMALY TEMPERATURES

Up to now, all analyses have been quoted as °C with respect to the period 1961–1990. Analyses with respect to other base periods would be expected simply to change the reference level, offsetting the results by the difference between 1961–1990 and the new period. Random differences would be expected because of missing values in both reference periods but the course of change on the decadal timescale would be unchanged. The use of anomaly values overcomes problems of using absolute temperatures discussed earlier, i.e., elevation, observation times, the varying methods used to calculate monthly-mean temperatures and screen design. Although anomaly values are all that are required, the question often asked is what is the absolute temperature of the surface of the Earth?

Recent advances in data availability and interpolation methods now enable this question to be answered. The means by which this has been achieved are given in detail in Jones *et al.* (1999). Separate analyses are undertaken for four regions:

- land areas except Antarctica;
- ocean areas except the Arctic;
- the Arctic north of 60 °N;
- the Antarctic south of 60 °S.

Land Areas Except Antarctica

For these regions, New *et al.* (1999) have developed a climatology for the period 1961–1990 using 12 092 station estimates of mean temperature. To attempt to minimize problems with the definition of mean temperature, the average of 1961–1990 values of average maximum and minimum temperatures were used wherever possible. These station averages were then interpolated as a function of latitude, longitude and elevation. The use of elevation as an explicit variable enables inclusion of the effect of spatially varying temperature lapse rates in different mountainous regions. The accuracy of interpolation was evaluated by omitting a subset of the data and comparing the results interpolated to these locations. Errors of estimation, even in data sparse regions, were between 0.5 and 1.0 °C. Values for every 1° square containing any land were then calculated using elevation data from a five minute digital elevation model (DEM). The value for each 1° square was the average of all of the 120 five-minute pixels that are land.

Ocean Areas Except the Arctic

In the anomaly dataset, SST anomalies were used because of their superior accuracy compared with MAT data. For the climatology, however, it is preferable to use MAT values as these will combine much better with the land temperatures around coasts and islands than an SST climatology. The MAT climatology, however, will be seriously affected by the solar heating on board ships (see earlier). To overcome this, an air minus sea temperature difference climatology was used, also for 1961–1990, developed using only NMAT and SST values from one hour before sunset to one hour after local sunrise. The AT climatology is the sum of the air-sea and the SST climatology.

Arctic North of 60 °N

This region is treated separately because of the lack of measurements over the sea ice regions. From the late 1930s, measurements have been made on ice islands (principally Russian), these being augmented dramatically since 1979 by automated measurements from the International Arctic Buoy Program. Although much of the buoy data comes from the 1979 to 1997 period, the network provides an extensive array from which to derive a climatology for 1979–1997. The early Russian data are particularly useful in assessing the quality (and adjusting) the buoy data during summers, when there are serious homogeneity problems with thermister housing due to the effects of direct solar radiation. The climatology for the Arctic was an amalgamation of the buoy data with poleward extensions of the land and ocean components already discussed. This aspect of the work presents challenging problems for analysts in

deriving consistent values and is discussed in detail in Jones *et al.* (1999).

Antarctica South of 60°S

This aspect of the climatology is the weakest in terms of accuracy simply because of the lack of data availability. There are less than 30 stations on the continent recording enough temperature data to derive 1961–1990 averages. These are not well located in that over half are located on the Antarctic Peninsula and five of these on one island, King George V Island. Away from the land, there are no measurements made over the sea ice regions and oceanic data are virtually negligible south of 60°S. Automatic weather station (AWS) data augment manned station records in some regions, but record lengths are short. The climatology developed for this region is, therefore, speculative with large amounts of extrapolation. It is, however, the best that can be done with available data.

Combination of the Four Climatologies

Combining the areas produces an average global annual temperature of 14.0°C for the 1961–1990 period, with the NH warmer than the SH (14.6 versus 13.4°C). Due to the problems of developing values over the Antarctic and Arctic, it is difficult to estimate a SE for these values. The 14.0°C global average is believed to be within ±0•5°C of the true value (Jones *et al.*, 1999). The magnitude of the hemispheric seasonal cycle is 13.1°C in the NH and 5.7°C in the SH. In the NH, the warmest and coldest months are July and January as expected. In the SH, January is warmest but August rather than July is the coldest. As would be expected, the global seasonal cycle is dominated by the NH.

With improvements in satellite technology, climatologies for all four areas will be improved. Over both the Arctic and, especially the Antarctic, improvements are necessary but at the present, consistent long-term monitoring of surface temperatures over snow and ice are several years away. It will then take several years to develop a new climatology.

EXPECTED IMPROVEMENTS IN THE NEXT DECADE

Improvements in both the quality and numbers of surface station data are constantly being sought. Only a small fraction (~10%) of surface data measured over land is internationally exchanged. Concerted international efforts are currently underway to improve both the land and marine components. Over land, nearly 1000 sites have been designated as the Global Climate Observing System (GCOS) Surface Network (GSN). Most National Hydrometeorological Services (NHMSs) (through The World Meteorological Organization, WMO) have agreed to attempt to maintain these stations and, where possible, the environments around them, well into the 21st century. The selection of sites aimed to utilize the best stations, improving spatial coverage in recent years, but acceding to Members who have budgetary constraints. Once the network is fully operational, it will improve the quality of the data, particularly for recent years. At present, all climatic data are essentially second-hand weather data in that most NHMSs are only interested in weather forecasting and climate is a minor consideration. GCOS aims to rectify this, bringing the importance of the data for climatic purposes to the fore. If successful, GCOS will provide a network of good stations, enabling researchers in the future to concentrate more on what the data is telling us, rather than worrying about long-term homogeneity.

Improvements are also being undertaken over marine areas. Efforts are underway to digitize much of the ships log material that are known to be available in some regions, principally for the two World War periods and the 19th century (*see* GCOS (Global Climate Observing System), Volume 1). Once available, the new data should significantly improve analyses over much of the Pacific before and during World War II and in the SH.

Since 1979, satellite estimates of SST can be used to infill gaps in shipborne measurements. Absolute values measured from space differ by 1–2°C from ship measurements, but the patterns of variation between the two observing systems agree well. Combining the two involves blending complete satellite patterns to ship measurements using the latter as the anchor for the absolute values. Modifications of this basic technique are undergoing trials for land regions. Results are encouraging for all land surfaces except snow. The challenge for the future will be to blend satellite and surface data over snow and sea ice surfaces.

The past should also not be ignored. Dramatic improvements in our understanding of the last 1000 years have recently been made. These have been achieved through both basic government funding for science and by the increased collaboration of scientists working in different palaeoclimatic disciplines. The National Geophysical Data Center in Boulder, CO, serves as a repository for much of the paleoclimatic data.

Models of the Earth System

MICHAEL C MacCRACKEN

Lawrence Livermore National Laboratory, Livermore, CA, USA

In Earth system sciences, the term model refers, broadly interpreted, to any conceptualization of an object or system, whether mechanical or mental, physical or theoretical. Thus, a model can be a reduced-size replica of a river system, or it can be a conceptual model of the origin and evolution of the universe; it can be a representation of future climatic conditions based on analogues drawn from the past, or it can be a mathematical representation of all the processes that govern how the atmosphere, oceans (e.g., radiation or convection), and land surface work. Models are often used to connect together what is known about a system and to gain insight about how a system has worked in the past, is working now, or may work in the future. What is most important in choosing a type (or types) of model to use to gain insight is to make sure that it is well-suited to the issue being investigated: models that are too simple can leave out important processes that may only come into play over long periods, whereas models that are too complex can prevent the gaining of insight, or even provide misleading insights, because they hide key interactions in a milieu of extraneous detail.

For understanding the Earth system, a variety of types of models are being used, ranging from insights gained from study of past climates to computer-based models that represent the Earth system in terms of numbers (hence the term numerical models). Because of the scope and complexity of the Earth system and the need to represent the wide range of Earth system components and processes, a hierarchy of numerical models has been developed. Such numerical models have become so pervasive that they are often simply referred to as models. Some of these models focus on particular processes in the atmosphere and oceans (e.g., radiation or convection), some models focus on particular components of the system (e.g., the atmosphere or oceans), some models focus on particular sets of interactions within the Earth system (e.g., the carbon cycle or atmospheric chemistry), and some models focus on the overall climate system. By selecting carefully, and cross-checking across models of varying sophistication and comprehensiveness, signi cant insights have been gained about the workings of the Earth system.

INTRODUCTION

For a scientist seeking to understand the workings of the very large, complex, and intercoupled Earth system, finding a way to represent the system and its behavior using a model of that system can provide many benefits. Among the reasons models are constructed are to accomplish the following.

- *Diagnosis of prevailing conditions and empirical (experiment-based) prediction*: Models are used to provide a framework for organizing and inter-relating observations of the Earth system. As an example, databases that are constructed to store the diverse sets of observations of winds, temperatures and humidity taken at the surface, by balloons and by satellites, serve as a record for how the atmosphere is behaving. By analyzing the time evolution of such records, diagnostic studies can provide insights about how, for example, changes in particular places relate to changes over larger spatial scales. Relationships derived from this type of study, which uses the time and space history of system behavior as the model, benefit the public every day, for example, in the weather forecasts of what will happen at particular locations.
- *Explanation of causal connections*: Having available a representation of the Earth system, whether as a physical or mathematical model, allows investigation of how particular outcomes or events are caused. Although it is possible to find correlations in observational data sets, determining if there is a connecting mechanism is essential to the gaining of understanding and the development of predictive capability. For example, ocean sediment records indicate that the growth and decay of continental ice sheets over many tens of thousands of years correlate well with variations in the amount of solar radiation reaching high latitudes of the Northern

Hemisphere that are caused by cyclic variations in the Earth s orbit around the Sun. Models are being used to determine how such seemingly small solar variations over hundred-thousand year periods can cause ice-age cycling when seemingly larger variations in solar radiation over tens of thousands of years are apparently not causing such large climatic shifts. Without a model, there is no way of testing what mechanisms might explain such apparent paradoxes.

- *Prediction and projection of future conditions*: While we might want to know what the future brings, there is no way to run the full Earth forward in time – one can only live what is happening. At least some types of models, however, can be used to explore what the future might bring. Weather forecast models start with present observations and, based various on experience and mathematics, attempt to foretell how the existing weather will evolve. Other types of models, checked for relative validity against past behavior, can be used to try to look ahead months to centuries, being careful to recognize the limits of the results. Without models, whether simple or complex, the future would just come as a complete surprise.
- *Management and policy analysis*: Now that human activities have become significant enough to affect the Earth system (or at least parts of it), models can be used to explore what the consequences of various actions might be. Often, a range of possible future conditions is investigated by considering a range of scenarios for the future (*see* Prediction in the Earth Sciences, Volume 1). Such if-then experiments with these models thereby allow consideration of the potential costs and benefits of particular choices and policies, and what changes in their intensity or timing might mean, all without having to actually impose the policies or experience the outcomes. Of course, it always must be remembered that the experiments are being done using models rather than evolving in the real world, a situation that emphasizes the importance of making good choices in the selection, testing, and use of models.

With this perspective on the purposes of having models, the following sections explore the possible types of models, the approaches to numerical modeling (which is a particularly flexible and useful way of constructing models), and approaches to testing models. In that the results of models are described throughout this encyclopedia, the detailed discussion of models, their testing, and their application are treated in other articles.

GENERAL APPROACHES TO CREATING A MODEL OF THE EARTH SYSTEM

There are a variety of possible approaches to creating a model of the Earth system, each relying on creating a particular framework for encapsulating and representing what we do and do not understand about the system. Some of the approaches are physical and others mathematical; some are focused on particular processes and others on the entire Earth system. Wide ranges of factors are important to consider in selecting among the various approaches. For example, a key aspect in choosing a modeling approach is not only to create a model that can be observed, but also to create a model that can be manipulated to see how it might respond to various types of changes. For some types of models, a physical change, such as warmer temperatures, can actually be imposed; for other types of models, thought (or *gedanken*) experiments must be conducted by investigating the potential effects of a hypothetical change using mathematical or theoretical approaches. A model must also be practical, a constraint that introduces consideration of issues of size and type of problem and the resources required to use the model into the selection process. A model must also be understandable (meaning we must be able to use the model to investigate cause–effect relationships). Models are simply approximations of the real world, and so it is vital that a model be able to provide insights into how things are working in ways that can be applied to understanding not just the model, but the real world.

A number of possible ways of constructing models, broadly conceived, have been used to help provide insights about the Earth system. While each of these approaches has its strengths and shortcomings, by choosing an approach best suited to the problem being investigated, scientists have been able to use these models in actual and *gedanken* experiments to better understand how the Earth system actually works. Such experiments generally consider the present world as the control – or baseline state – and then use the various types of situations, whether past states of the system or experimentally altered states, as the perturbed situation to be compared to the control situation. For this to work, of course, there must be either the possibility of changing the conditions of the model, or having available a historical record of how conditions have changed in the past.

With this brief context, a brief overview of approaches that have been used to create models of the Earth system, or at least of some of its parts.

Laboratory Models and Field Experiments

A traditional approach to trying to understand a problem is to construct a replica, to some scale, of the process or system of interest. The Earth sciences are rich with examples of such laboratory models, ranging from chambers in which the absorption of radiation by various gases can be measured or clouds can be created, to rotating containers of fluids designed to look at how heating creates the large scale circulation of the atmosphere. A particularly interesting example has been Biosphere 2, located in Oracle,

AZ, which is one of the largest enclosed laboratories in the world. Covering about 1.27 hectares and enclosing a volume of about 200 000 m^3, Biosphere 2 is being used to study the response of several different biomes to controlled changes in atmospheric composition, temperature, and other variables.

Moving out of the laboratory, instrumentation of the atmosphere or ocean as part of field experiments has provided extensive data sets of how parts of the Earth system behave, thus using a part of the system as a model of how processes function throughout the whole system. For example, the wind drag of the surface and the effects of clouds on radiation can be studied by instrumenting a relatively small set of representative areas and then extrapolating to the world. Alternatively, the whole atmosphere at one time can be used to draw inferences about how the system will work at other times or with other conditions (e.g., global scale observations of the evolution of the weather have provided insights about warm and cold fronts, storms and droughts).

Special events also provide interesting opportunities. For example, how global average temperature changes after solar radiation is reduced by a volcanic eruption gives an indication of how the climate might respond to a change in the amount of available energy, and an eclipse of the Sun, which blocks out solar radiation reaching the stratospheric ozone layer, provides an opportunity to record the dependence of stratospheric chemistry on ultraviolet (UV) radiation. Indeed, so much can be learned from studying special locations and situations that there are major international cooperative programs of many types aimed at understanding the Earth s water cycle, atmospheric chemistry, and much more.

Although much can be learned from such approaches, the Earth system is so complex, with scales of processes extending from the microscopic, when dealing with the physics of clouds and aerosols, to the global, when dealing with the circulation of the oceans and atmosphere, that scientists have been unable to construct a sufficiently comprehensive model (or set of field experiments) that can be manipulated in appropriate ways to determine how human activities might affect the future. Thus, such models have important limitations when trying to understand the functioning of the entire Earth system, although they do provide a very useful approach for understanding particular processes or places.

Earth System History as a Model

One way to overcome the limitation of present conditions not providing enough of a range of examples for study is to use the Earth s past behavior as the model. In that the Earth is some 4.6 billion years old and geological records indicate that the Earth has experienced a wide range of climates, it can be argued that the Earth has experienced virtually all of the imaginable conditions that can occur (*see* Earth System History, Volume 1). The key shortcoming, of course, is that scientists were not there to keep accurate records of what did occur (and, most importantly, why the changes occurred). The challenge accepted by paleoclimatologists, acting as forensic scientists for the planet, has been to use the evidence of past conditions that remains in order to figure out what did happen, and why, because if we don t know why, it is hard to understand whether such events might occur in the future and it is difficult to infer what lessons they have to offer (*see* Natural Records of Climate Change, Volume 1).

All kinds of evidence have been found and are being used to generate information on past changes. Cores drilled in ice cores have found layers of ice and trapped air that are over 400 000 years old, providing a very useful record of past temperatures and atmospheric composition. The widths of tree rings are being used to get a sense of climatic conditions during the growing season (and even through the year), and scientists have now been able to overlap from tree to tree in a number of locations and reconstruct climatic conditions back several thousand years. The variations of the Earth s magnetic field captured as molten lava solidified are used to date the movement of the continents and their past latitudinal positions. The types of minerals deposited are being used to indicate where they were formed and, for example, the intensity of volcanic activity, characteristics of atmospheric composition, and, by use of radioactive isotopes, the age of the sample. The skeletons of very small animals in the oceans accumulate on the ocean floors, and their type and location, are providing information about the temperatures of the upper and deep ocean environments where they lived. An immense and growing number of such proxy indicators are being employed to gain insights into the Earth s past (*see* Natural Records of Climate Change, Volume 1).

In these ways and more, paleoclimatic science has been able to document the rich history of changes, from periods when the Earth was extensively glaciated to times when the polar regions were apparently warm enough for palm trees to grow. What we now have, albeit with many gaps and blurred images, is a rich tapestry of inferences about the types of conditions that occurred in the past. What has also become clear, however, is that the types of modifications that human activities are now forcing on the Earth system are quite unlike, in magnitude and rate, any transitions that have occurred in the past. As a consequence, while very useful for improving the Earth system, the paleoclimatic record provides only a limited basis for constructing analogues about how the future may evolve (see US/USSR, 1990 and Climate Analogues, Volume 1).

Other Celestial Bodies as Models

While the Earth is, to the best of our knowledge, unique, the rich diversity of other celestial bodies provides a very diverse set of examples of how planetary environments work and function. For example, we have learned that the surface of Venus is much hotter than the Earth. While this might not seem surprising because Venus is closer to the Sun than the Earth, this is actually not the main reason why the surface of Venus is so hot. What observations indicate is that, because of its bright clouds (which is why Venus is so visible in the night sky), Venus actually absorbs less solar energy per unit area than the Earth. Instead, Venus is warm because its atmosphere creates a greenhouse effect that is many times stronger than the Earth s. Looking at Mars, observations indicate that its surface is colder than the Earth s, again not surprising in that Mars is farther from the Sun. However, because the atmosphere of Mars contains many times more carbon dioxide than the Earth s atmosphere, the study of Mars makes clearer how important water vapor is as a greenhouse gas for the Earth.

Of even more relevance have been the lessons learned about how stars behave. Not having a long record of measurements of how solar output may have varied, astrophysicists have used information about sun-like stars to get a sense of the evolution of stars and how the intensity of the Sun s energy output has likely varied over the Earth s history. It is such studies, using other stars as models, that have provided indications that our Sun is becoming brighter over time, and was a considerably dimmer in much earlier times (raising a question about whether the Earth was ever ice-covered, and, if not, why).

The Recent Past as a Model for the Future

The similarity of the weather from one day to the next and of the climate from one year to the next can lead to a notion that the recent past might be a very good model for the future. For example, those living in tropical and subtropical areas often advertise the persistence of their weather as a reason to come vacation and walk along their beaches. Indeed, an important test of the skill of weather forecast models has been to determine if they can show more skill than persistence, and if predictions of seasonal climate fluctuations are skillful relative to climatology, which is simply the average of the past.

For the case of climate change, using the recent past as a model might suggest using the trend that has been observed over the 20th century as a basis for predictions that the next century will experience the same amount of change. When actually trying to use the past as a model for the future, a number of problems arise, however. First, how far back into the past should be used to generate a trend line? That we have warm winters and cold winters intermittently, and seemingly at random, suggests that we need to go back at least a couple of decades to try to get a smooth trend. But once we go back a few decades, we start to find that there have also been multi-decadal fluctuations, with warm conditions in the 1940s followed by cooler conditions in the 1960s (at least in the Northern Hemisphere) and then warmer conditions thereafter. If we go back further, we start to find multi-centennial fluctuations and then, even further back, we find cycles of glacial advance and retreat. In addition, it is virtually certain that human activities that affect atmospheric composition will be changing in the future, rapidly creating new types of conditions.

While surely important to consider as one means of gaining insight about the future, extrapolating from the past into the future raises a great many complications, and ignores the insights that can be gained by understanding how the Earth system works – whether of the cold front approaching on a spring day or the warming likely to be caused by the changing of atmospheric composition.

Mathematical Analysis

In addition to direct experimentation, a traditional approach to understanding the workings of a system is to formulate a set of mathematical equations (e.g., algebraic or differential equations) that describe its behavior, and then to simply solve the equations for the unknown term as a function of other terms that are known or can be measured. For example, measurements led to development of the Stefan-Boltzman law, which uses a proportionality constant (conventionally termed sigma) to relate the amount of infrared heat radiated by a body (such as the Earth) to the fourth power of the average temperature (T) of the body. Because the amount of heat radiated by the Earth equals the amount absorbed, assuming conditions have prevailed long enough for the climate to reach a stable state, the equations can be used to determine the Earth s average temperature if the amount of solar energy absorbed is known. The amount of solar energy absorbed is quite well established to be the intensity of solar radiation ($S \cdot 1368\,W\,m^{\cdot 2}$) divided by four to spread it around the sphere and multiplied by the co-albedo (which is the fraction absorbed, being 1 minus the amount reflected, which is about 30%). Solving for the temperature and filling in the values gives an average planetary radiating temperature of 255 K (or about $\cdot 18\,^{\circ}C$). This temperature is not the temperature at the surface, but is instead the average temperature about 5–6 km above the surface, which is the altitude that, because of the greenhouse gases, is the average height from which radiation is emitted to space (*see* Energy Balance and Climate, Volume 1). This analysis also starts to hint at the difficulty of this approach; namely that, while much can be learned from mathematical analyses of some aspects of the Earth system, there are in reality so many equations and relationships that

it is not possible to solve them analytically except for very special limiting cases. Hence, this mathematical approach is useful for gaining broad insights, but not adequate for understanding the full system without introducing significant complexities.

Numerical Models

To overcome the difficulty of not being able to make a physical model of the system in the laboratory, and the difficulty of not being able to solve the sets of equations representing the global system, resort is often made to creating a model designed to simulate (or represent) the Earth using a computer. In these models, the spatial domain is divided into grid cells that, like tiles, cover the domain (e.g., cover the Earth). Grid cells are then stacked up to represent the various layers of the atmosphere or ocean. Numbers are then used to represent conditions at particular points, and equations are used to represent how the values of various parameters in each grid cell change with time. Because the equations are often set up for a finite grid of cells, and exchanges between these grid cells are based on differences in their conditions, the resulting numerical models are also sometimes called finite difference models. In addition, because the total set of equations often numbers in the thousands to millions, such models are also often referred to as computer models because only a powerful computer can keep track of all the numbers and relationships.

One of the first efforts to actually construct such a model of the atmosphere was made by Lewis Fry Richardson. Lacking a computer, but having much time while serving as an ambulance driver during World War I, he tried to actually demonstrate that a numerical model of the European weather could be constructed by doing all the calculations himself by hand. While the effort failed to yield a successful forecast, it did set the stage for improved approaches several decades later. For further information on this effort (*see* Richardson, Lewis Fry, Volume 1).

With these sets of equations representing conditions in many grid cells over a wide domain, one does not really try to solve the equations in an algebraic sense to derive a parametric relationship that can be evaluated by just filling in the numbers. Rather, with equations defining relationships for particular parts of the system, these numerical models seek to use the equations and the numbers representing the system with the expectation that the modeled system will evolve in essentially the same way that the real system evolves. That is, an equation is not solved that gives, for example, the strength of the jet stream in an analytic sense; instead the numerical model calculates or simulates the changes that lead to the evolution of the atmosphere (and jet stream) in a series of small time steps. The key point is that features like the jet stream emerge from the calculations just as they emerge from the motions of the real atmosphere; such features are not imposed explicitly or independently in the model s structure. The sequence of the computed atmospheric changes, if the model is a good one, will evolve in a manner that cannot be distinguished, in a statistical sense, from how the jet stream (and everything else) is changing in the real world.

Numerical models now exist for a wide variety of systems, from chemistry in the atmosphere to how the oceans and atmosphere move and interact. These models are designed to incorporate the quantitative relationships that we know are applicable, and as such, they potentially provide an objective, quantitative representation of all that we know. What is of most value about numerical models is that experiments can be done with them by simply changing numbers or relationships – not having to actually change the Earth or atmosphere.

Although a wide range of types of models have been developed and tested, as highlighted more extensively in the next section, there are also limits to the utility of numerical models. These arise, for example, because the Earth is an exceedingly complex system. As a result, models cannot represent every possible process that plays a role (from the microscopic to the planetary). In addition, even the largest computers are too limited at present to allow representation of all scales that are recognized to be important. In addition, the Earth system is not a fully deterministic system; just as for the real world, there is a range of possible outcomes from a model (*see* Chaos and Predictability, Volume 1). Thus, while models can provide very useful indications about how the system works and, of particular importance, how the Earth may be affected by changes in various conditions such as atmospheric composition, such models are not really the Earth, and so there are necessarily uncertainties involved in applying them and interpreting their results (e.g., *see* Model Simulations of Present and Historical Climates, Volume 1).

APPROACHES TO NUMERICAL MODELING OF THE EARTH SYSTEM

While the development of numerical models of the Earth system provides an important tool that can be probed and experimented with to learn about how the system functions, having available only a model as complex as the entire Earth system would simply provide a new challenge to understanding in that all the same complexities would be present. Although we would be able to make changes, such as in atmospheric composition, that we could not make in the real world, and this would help give a better sense of the sensitivity of the Earth system to changes and perturbations, the complexity of the Earth system would still be present, and would likely cloud our ability to deduce the most important couplings and relationships. Thus, just as in many other fields, the key to enhancing understanding is best

promoted by having available an array of approaches, each suitable to particular issues or parts of the problem.

In the field of Earth system studies, this is accomplished by construction of a hierarchy of numerical models for simulating the processes critical to particular issues. The hierarchy is such that it ranges from simple, conceptual models to fully comprehensive models based, for example, on the choice of the number of spatial dimensions treated, the detail of the time calculation, and the complexity and comprehensiveness of the processes that are represented. In seeking to understand a particular process or aspect of the Earth system, looking at how a process works in a simple model can lay the basis for understanding how the process may play a role when intercoupled with other processes, and finding an unexplained variation in a comprehensive model can be explored using simple models to determine which factors are playing a dominant role.

Throughout this Encyclopedia and throughout the field of Earth system studies, the term model is used in many ways, sometimes rather seamlessly moving across the following hierarchy of numerical models. The examples below provide a sampling of the various possibilities along the way.

Zero-dimension Models

For some questions about the Earth system, what is most important is not the spatial variation, but the detailed interactions happening at a particular location or within a particular parcel of air, land, or ocean. A good example is the investigation of basic mechanisms relating to stratospheric chemistry. The air in the stratosphere is quite layered because temperature increases with height in the stratosphere, creating quite stable conditions where chemistry can act in the absence of major influences by transport from other layers of the atmosphere. In addition, for each layer, north–south transport is relatively slow compared to the rate of chemical reactions. Thus, it is useful to assume that air within a given layer at a particular place reacts chemically without mixing significantly. Under such circumstances, and for certain types of questions, a model can be constructed that devotes attention to the hundreds of chemical reactions that are occurring, while assuming that there will not be significant influences from transport of air from outside the box being looked at. It was in this way that some of the initial studies were done about how various chemicals called chlorofluorocarbons (CFCs) (like Freon) might catalyze the depletion of stratospheric ozone (*see* Depletion of Stratospheric Ozone, Volume 1). While providing much useful insight, an obvious limitation is that over time the air does actually mix, and changes in ozone at different levels of the atmosphere will obviously affect the amount of solar UV radiation getting through to that layer. Thus, for more integrated estimates, additional aspects of the Earth system must be considered.

Other examples of zero-dimension models include: (a) early models of photochemical smog, which treated an appropriate set of chemical reactions in a volume of air moving from the city center to outlying areas; (b) models of areas of land on which various plants and trees develop; and (c) models of cloud microphysics in which vapor condenses and droplets combine to create cloudy air and then precipitation. For all such models, focusing on the details of mechanisms while ignoring the effects of how the environment is affected by spatial variations and transport of materials allows inquiry without unnecessary complexity.

Vertical-dimension Models

The thickness of the Earth s atmosphere – at least that part of it critical to the climate system – extends upward for only about 50 km. While the surface climate might be roughly the same for two locations about 50 km apart, the differences in conditions going by this distance from the surface are very dramatic, with temperature, composition, and pressure changing most markedly. For this reason, it is very useful to use vertical models to study certain aspects of the Earth system. There have been three major types of such models, each of which provides particular types of insight.

Radiation Transport Models

Radiation transport models are used to study the fluxes of solar and infrared radiation through the atmosphere. These models are designed to treat the penetration, reflection, and absorption of solar radiation as it enters the atmosphere, strikes clouds, is partially absorbed by atmospheric water vapor and other gases and aerosols, reaches the surface, and is reflected to space. The energy absorbed is then radiated as infrared radiation upward from the surface and upward and downward from the atmospheric gases and clouds. Svante Arrhenius did a mathematical analysis of this type in 1896 (*see* Arrhenius, Svante, Volume 1), in which he calculated the climate s response to a hypothetical doubling of the atmospheric carbon dioxide (CO_2) concentration. The calculation indicated that the global average surface temperature would rise by 4–6 °C. Since that time, very detailed radiation transport models have been developed that treat in detail the spectral dependencies of the various gases (*see* Infrared Radiation, Volume 1). When detailed information is used to define temperatures and gas composition based on observations at a particular location, the model results can be carefully checked against observations. Such models can also be tested against laboratory experiments where radiation at particular wavelengths is passed through a gas of a given concentration. Thus, such models can be carefully validated, and they provide significant information about the relative roles of various greenhouse gases in the

energy balance of the atmosphere (Ellingson and Fouquart, 1991). Simplified versions can also be constructed that can be used as components in other models that represent more processes and simultaneously treat more locations.

Radiative–Convective Models (RCMs)

Radiative–convective models are models of the Earth s temperature that start at the surface and extend up into the stratosphere. These models start from the radiation models just described (note that Regional Climate Models also, confusingly, have the same acronym). However, because the radiation models do not account for all of the necessary processes controlling the addition and removal of energy and its movement up and down through the atmosphere, they cannot be used to calculate temperature change. To account for the warming of the surface and then the upward movement of energy, a representation is included in RCMs of the process of convection that accounts for vertical motions of the air and causes, for example, the formation of clouds. Although convection is often represented in a somewhat *ad hoc* fashion, the effect of convection is to redistribute energy upward through the troposphere. This has the effect of creating and sustaining the observed atmospheric lapse rate (which is the vertical decrease in temperature with altitude, and is observed to be about $\bullet$ 6$\bullet$5 $^{\circ}$C km$^{\bullet 1}$). The first of these models was developed by Syukuro Manabe and Richard Wetherald at the NOAA Geophysical Fluid Dynamics Laboratory (*see* Manabe, Syukuro, Volume 1). The model was used in 1967 to simulate the vertical variation of atmospheric temperature. Through its representation of convective adjustment, the model quite accurately represented surface, tropospheric, and stratospheric temperatures (Manabe and Wetherald, 1967). The model was readily solved via computer, and could be used for many types of experiments. For example, with this model, a doubling of the atmospheric CO_2 concentrations was calculated to cause a global average warming of about 2.4 $^{\circ}$C.

Another well-known application of such models was to estimate the response of surface temperature if a major nuclear war were to inject very large amounts of smoke into the upper troposphere (Turco *et al.*, 1983). These simulations made clear that if solar radiation was absorbed in the atmospheric layers above the greenhouse gases (particularly at levels above the atmospheric water vapor), the greenhouse effect would be disrupted. As a result, for a global smoke cover, the land surface temperature would drop toward the radiating temperature of the Earth (so toward $\bullet$ 18 $^{\circ}$C), which would freeze the entire surface of the Earth. While an interesting insight, what quickly became obvious was that the model was treating neither the large heat capacity of the oceans (which it would take a long time to cool) nor the many areas of the Earth that would not be covered with smoke were a postulated war to take place. Thus, while a starting point, more needed to be done to get a handle on that issue (see Pittock *et al.*, 1986).

Overall, the strength of RCMs is that they can quite accurately represent atmospheric radiation. The key shortcomings are that such atmospheric features as clouds have to be very simply represented (even specified) and that there is no representation of the horizontal distribution of climate from north to south or east to west.

Atmospheric Chemistry Models

Atmospheric chemistry models that treat only the vertical variations in atmospheric composition have also proven to be very useful. These models add chemistry to the set of processes treated in RCMs. While about 99% of the atmosphere is made up of nitrogen and oxygen molecules, the rest of the atmosphere is made up of hundreds of other species. Although present in very low concentrations, these species can be highly reactive. The chemistry that goes on controls, for example, how much ozone is present (e.g., *see* Stratosphere, Chemistry, Volume 1). This in turn affects other parts of the system, because when present in the stratosphere, ozone protects the surface from high-energy UV radiation, and, when present in the boundary layer, ozone contributes to air pollution and affects the chemistry of the rain that falls (so controlling acid deposition and deposition of various nutrients). These models have been used, for example, to study the effects of various human activities on the stratospheric ozone layer, including the effects of CFCs, nuclear war, rocket launches, and so on (e.g., *see* Depletion of Stratospheric Ozone, Volume 1). Such models are very useful at getting a first estimate of how important various perturbations might be, but must be complemented by studies that can also treat the variations with latitude of the solar radiation and temperatures that strongly affect chemical reaction rates.

Horizontal-dimension Models

In contrast to models that focus on variations in the vertical dimension, a class of models, most notably those referred to as energy balance models, focuses on representing the processes that create variations across the surface of the Earth in the horizontal dimension. These models represent and attempt to explain, for example, the geographic variations in surface temperature. Such models thus seek to include the processes that make the equatorial regions warm and polar regions cold. While at least some of the processes creating these differences do depend on the vertical structure of the atmosphere, these models represent (or parameterize) the effects of the complexities of atmospheric processes in highly simplified ways as a way of reducing the computational burden, thereby allowing the models to run for very long periods of time. This ability to simulate very long periods in turn allows study of problems dealing with the long-term variation of the climate in response

to perturbations (e.g., the slow increase in the output of the Sun over the Earth s history, the effect of changing the intensity of the greenhouse effect, etc.). There are two main variants of such energy balance models: energy balance models that consider only latitudinal variation, and energy balance models that also treat the longitudinal dimension.

Energy Balance Models

Energy balance models that treat only the latitudinal variation were first developed independently in the late 1960s by Mikhail Budyko (*see* Budyko, Mikhail Ivanovich, Volume 1) and by William Sellers. This type of model is based on the physical requirement that energy be conserved (that is, sources minus sinks of energy determine the amount of energy accumulated at any given point). In implementing this fundamental conservation law, the early models calculated the surface temperature for various latitude bands based on the influences of solar and infrared radiation, evaporation, heat transport to the air, and a parameterization of the effects of the north–south transport of energy. Energy transport, including both sensible heat (i.e., transport of warm or cool air) and latent heat (i.e., transport of water vapor that could condense and give off heat in the process of precipitation) was represented in a combined way using an approximation drawn from the treatment of heat in a solid – namely a diffusion based algorithm with the diffusion coefficient determined based on fitting the model results to observations. The models typically included specifications for cloud cover, related infrared radiation to temperature in a parametric way, and accounted for the albedo effect of snow and other factors by changing surface reflectivity based on temperature. A surface heat capacity was created to account for the effects of oceanic and subsurface heat storage. Among the most interesting studies with these energy balance models are studies of whether glaciation exceeding a certain amount (i.e., reaching equatorward of a certain latitude) might trigger a transition to a snow-covered Earth and whether, if this occurred, such a situation would be stable and the Earth would remain frozen. That this might be possible was one of the spurs to development and application of models that represented the various controlling processes in more detail. For example, Hyde *et al.* (2000) extend this work with higher dimensional models (*see* Earth System History, Volume 1).

Over the past several decades, representation of the processes in energy balance models has continued to improve (e.g., including the effects of ocean currents and ocean overturning) (*see* Energy Balance Climate Models, Volume 1). Because it is very computer intensive to simulate the climatic effects of every emissions scenario that is suggested, such energy balance models are now used by the Intergovernmental Panel on Climate Change (IPCC, 2001) for this purpose. In using the models in this way, the parameters of the energy balance model are first calibrated to the set of simulations carried out with the full global models described below, and then the energy balance models are used, in essence, as smart interpolation tools to calculate the effects on the climate of a much wider set of emission scenarios than can be treated by the full global models (IPCC, 2001). In addition, because these models can be run in minutes on computers, they can be used for a wide variety of studies of the effects of various changes in factors that may affect the climate.

Two-dimensional Energy Balance Models

Latitude–longitude energy balance models represent not only the large horizontal temperature gradients from pole to equator, but also the significant variations in climate in the east–west direction caused by the land–ocean distribution. These models still greatly simplify the representation of processes in the vertical dimension, but do attempt to represent the time-averaged effects of atmospheric and oceanic processes that transport heat and water vapor north–south and east–west. These transports have been approximated in various ways, in some models by using an eddy diffusion approximation and in other models using an approach based on the wave patterns evident in the global atmospheric circulation. Among the interesting studies with these two-dimensional energy balance models have been investigations of how variations and fluctuations in the transport of energy (e.g., based on observed fluctuations in the atmosphere) might affect the global distribution of temperature, and study of how the distribution of continents and other large-scale features of the Earth might have contributed to past changes in the climate. More recently, models of this general type have been used with some success to forecast the evolution of the El Niño/Southern Oscillation (ENSO).

While horizontal dimension models are generally able to represent the broad scale horizontal distribution of climate (which is to be expected in that they are fundamentally calibrated to do so), what becomes apparent is that it is very difficult to build confidence in highly simplified representations of many of the processes occurring in the vertical. Therefore, while very useful for many exploratory studies, studies with energy balance models need to be complemented with studies using models that more fully represent various processes determining the vertical structure of the atmosphere and oceans.

Land Surface Models

Land surface models are another type of horizontal dimension model. These models have been developed to represent the processes determining vegetation, water resources, and other features of the land surface. In these models, atmospheric conditions, including temperature and precipitation, are imposed based on observations or outputs from other models. Representations of various landscape types,

from forests to deserts, are included to varying degrees of complexity. Some biogeographic models use empirically derived relationships about the type of vegetation typically present within certain temperature and precipitation ranges while others use parameterizations that actually follow the biological and biochemical growth of plants of various types. Biochemical processes are often treated in order to address such issues as carbon storage and the effects of atmospheric deposition. Such models often treat hydrologic processes, including flow of waters, accumulation and melting of snow, soil moisture, runoff, and other factors controlling the timing and amount of water resources. Conditions leading to fires and other disturbances can also be calculated. Comparisons among these types of models have been undertaken as a means of gaining insight about the various simulations of the potential consequences of climate change. A number of groups report significant progress in representing continental scale vegetation distributions (e.g., see Vegetation/Ecosystem Modeling and Analysis Project Members, 1995; Neilson *et al.*, 1998).

Zonal Models

As a step toward modeling the full system, zonal models represent both altitude and the north–south dimension (roughly equivalent to representing the complexity of an orange by treating one section). Such models are able to represent the variation and complexity of processes in the vertical from the surface to, typically, the stratosphere (with a vertical resolution of one to a few kilometers), and to represent latitudinal variations from the poles to the equator (with a resolution, typically, of about 10° of latitude, or about 1100 km). In constructing such models, the conservation laws for mass (of air, species, water, etc.) and of energy are generally quite well represented, whereas the processes determining the wind fields and their effects are parameterized based on observations, or simplifications of the laws for fluid flow and conservation of momentum. Such models have been constructed for both the climate system (atmosphere, oceans, land surface) and to represent stratospheric chemistry in that both, to a large degree, vary to first order primarily with latitude and height rather than with longitude.

Zonal Climate Models

Zonal climate models were first developed in the late 1960s and used to study issues ranging from the causes of ice ages to the potential effects of volcanoes, changes in atmospheric composition, and smoke from nuclear war on the climate (MacCracken and Ghan, 1988). These models have generally focused most on treatment of atmospheric radiation and the factors that affect it (including changes in atmospheric composition), and on surface processes that affect the storage of energy and surface temperature. Because this type of model does not fully calculate atmospheric and oceanic circulation, these models can typically be used to simulate periods from decades to many thousands of years. Present uses for such models, which typically take tens to hundreds of hours of computer time, include study of glacial–interglacial cycling (*see* Climate Model Simulations of the Geological Past, Volume 1) and simulating the potential consequences of changes in atmospheric composition (e.g., Prinn *et al.*, 1999).

Zonal Chemistry Models

Zonal chemistry models have proven very useful tools for studying atmospheric chemistry since first being developed in the early 1980s. This type of model typically extends from the surface up about 40–50 km and represents the global scale chemistry of both the stratosphere and troposphere. Large sets of species and chemical interactions are also included in these models. Such models have been used, for example, to simulate the effects of CFCs on the stratospheric ozone layer (*see* Depletion of Stratospheric Ozone, Volume 1), the processes governing the Antarctic ozone hole, and the effects of volcanic eruptions on stratospheric chemistry. Prinn *et al.* (1999) also describe how zonal chemistry and climate models are being coupled to models of the global economy.

Although zonal climate and chemistry models represent many important processes in impressive detail, they are unable to represent the geographical distribution of the climate, which is essential for many types of studies about potential climate impacts. In addition, the simplified treatments of horizontal transport processes, which are likely to be affected by the very perturbations that these models are often used to study, create uncertainties about the latitudinal details of the simulations.

Three-dimensional Global Models

While it might seem obvious that it is essential to treat the full three-dimensional complexity of the atmosphere–ocean–land system, this has proven to be a very significant challenge in practice because the world is so extensive and involves so many different processes. To represent the full range of processes and domains, a grid is created that covers the Earth from deep in the ocean to the surface and then well up into the stratosphere. In the atmosphere, for example, a grid resolution of 4° of latitude by 5° of longitude (which would provide, on average, information every 400 km around the Earth, or roughly one point of information for an area the size of the state of Colorado in the US) requires a total of over 3200 grid cells spread out to cover the Earth s surface. To adequately resolve the variations in temperature, clouds, and chemistry in the vertical typically requires a resolution

of 2–3 km up to an altitude of about 50 km, so a total of about 20 levels, creating a total of roughly 64 000 grid cells in the atmosphere. To represent the more detailed aspects of the weather such as storm fronts and regional variations in mountainous regions, much finer resolution is needed, thereby requiring use of many times this number of grid boxes.

The conditions in each of the grid boxes and the exchanges between the grid boxes are calculated using approximations of the fundamental conservation laws of mass, energy, and momentum (or motion). As an example, for each grid box in the atmosphere, these equations include terms to treat a wide range of processes and characteristics (*see* Climate Feedbacks, Volume 1; Earth System Processes, Volume 1), including, for example:

- solar radiation (with an appropriate set of spectral intervals covering UV, visible, and near infrared wavelengths and a range of absorbers and scatterers of radiation including gases, aerosols, and clouds);
- infrared radiation (with an appropriate set of spectral intervals to allow treatment of the various absorbing gases such as water vapor, CO_2, ozone, etc.);
- vertical transport (with treatments of both large-scale upward motions and the smaller scale convective motions in thermals and clouds, which can themselves create clouds);
- horizontal transport (with treatments of both the large scale features and the disruptions caused by the presence of mountain ranges);
- hydrologic interactions (with treatments of the processes governing the sources, movement, and removal of water and its transition from vapor to liquid to solid form);
- composition and chemistry (with treatments of processes that add, move, transform, and remove substances including ozone, carbon dioxide, aerosols, and, to adequately treat chemistry and climate feedbacks, many other species);
- land surface exchanges and processes (with treatments of reflection, absorption and emission of radiation, evaporation, thermal heating of the atmosphere, emission and deposition of various chemical species, land-ocean differences, mountain ranges, etc.).

Treatment of the oceans requires a similar set of grid boxes and processes. Because oceans are more layered than the atmosphere, layers must be thinner; also because oceanic eddies and motions (like the Gulf Stream) are smaller than in the atmosphere, horizontal resolution must be finer. Oceanic processes also introduce new types of terms, including salinity, biochemical processes, sea ice formation, and more.

For the land surface, spatial resolution is a particularly important consideration. While it may be adequate for grid cells in the atmosphere to be the size of a US state (e.g., Colorado in the early global models), this is generally insufficiently fine scale to represent surface conditions (e.g., in Colorado from the edge of the Great Plains to the middle of the Rocky Mountains and all the vegetation and climatic zones in between). Were the number of grid points not a limitation, the desired resolution for the surface might be 10 km or less. In practice, however, the best resolution being achieved in global climate models that can be run in reasonable time on available supercomputers is typically 10–30 times this size. Treatment of the land grid points also requires treatment of additional processes, including soil moisture, runoff, snow and ice build-up and retreat, growth and decay of vegetation, uptake, release, and transformation of various chemicals, etc.

An additional challenge is to represent the evolution of all of the processes and domains for times from days to millennia. This requires keeping close track of the fluxes of substance, energy, and momentum from one grid box to another at each increment in time. Because the time step must be such that transport of a quantity from one box to another does not pass through a box before being recorded (e.g., for the wind to carry moisture in one side of a grid box and out the other), time steps for the calculations must be limited. This has typically meant that the time steps of the calculations can only be fractions of an hour, even with approximations that filter out sound waves and other high velocity waves that are solutions to the set of flow equations, but not important in determining the climate. This can mean that models must take a few tens of thousands of time steps each year, or a few million time steps to simulate a century.

As a result of this computational burden, approximations have to be made, even when using the fastest supercomputers in the world. Given available computer resources and the urgency of the calculation, each modeling group has made what it deems to be the optimal approximations and simplifications regarding spatial resolution, the set of processes, and the lengths of the simulations. So that simulations can be completed in reasonable times, the choice of approximations is usually such that the models run of order a few hundred to a few thousand times as fast as real time. Thus, a few century simulation might take a few months of time to complete.

Several types of models have emerged, each aimed at addressing various types of problems.

General Circulation Models (GCMs)

General circulation models have been constructed that focus on the dynamics and movement of the atmosphere GCMs (AGCMs) or the ocean GCMs (OGCMs); see Nihoul (1985), Washington and Parkinson (1986), Schlesinger (1988), Mote and O Neill (2000); and www-pcmdi.llnl.gov, and General Circulation Models (GCMs), Volume 1. For

the atmosphere, simplified models of this type (called quasi-geostrophic models) were first developed in the late 1940s and early 1950s and were used in early attempts to forecast the weather. These models were followed in the early 1960s by AGCMs that were able to simulate weather-like features over periods of seasons to years and, when initialized by observed weather conditions, were used to forecast the evolution of the weather out to a few days. Over the past several decades, significant improvements have been made and AGCMs are now used to assimilate the variety of atmospheric observations taken at the surface, aloft, and from satellites and to forecast the weather out to approximately a week with useful skill. Because AGCMs used for weather forecasting typically only have to simulate for weeks of time, computer resources are typically used to refine resolution and to run ensembles of simulations (in an attempt to overcome the chaotic nature of the weather). For climate studies, however, AGCMs are typically used to simulate periods of many decades to many centuries. Initial studies in the 1970s, for example, evaluated the effects of the climate of a doubling of the atmospheric CO_2 concentration. AGCMs, now more fully developed, serve as the atmospheric component of Earth system models (ESMs) (see section on ESMs herein).

Similarly, OGCMs have evolved from their initial development in the 1960s and are now able to simulate many of ocean currents and features of the global ocean. Because forecasting of changes in the oceans requires having knowledge of the current state of the oceans, extensive efforts are being made using buoys, satellites, and other means to develop data sets on the conditions of the ocean surface and deeper waters. These models now also serve as the oceanic component of ESMs (see section on ESMs herein).

Global Chemical Models

Global chemical (or chemistry) models are sometimes also called global biogeochemical models because they treat the global cycles of various species that interact with the biosphere (*see* Biogeochemical Cycle, Volume 2). These models are developed based on representations of the processes affecting composition of the atmosphere and the oceans and the various cycles of particular compounds such as carbon, ozone, etc. Such models generally focus on treating the atmospheric chemistry and surface processes that emit, transform, or sequester various species and, rather than calculating the wind fields, use wind fields derived from observations or simulations with AGCMs. Global chemical models are typically used to study the build-up of carbon in the atmosphere and its uptake by surface vegetation, the chemistry of the troposphere (*see* Troposphere, Ozone Chemistry, Volume 1; Aerosols, Troposphere, Volume 1; Carbon Cycle, Volume 2), and the characteristics and concentrations of atmospheric aerosols.

Earth System Models (ESMs)

Earth system models are designed to provide full treatment of the Earth system, in a combined and interactive way (Ojima, 1992). These models are often referred to as global climate models (for which, confusingly, GCM is also the acronym). ESMs are just starting to be developed and tested that treat atmospheric dynamics and chemistry, oceanic transport and the carbon cycle, and the land surface with its ecological and snow–ice dynamics. A key challenge is in deciding which processes to include, and whether the set is sufficiently complete for the problem being investigated. For example, an initial study by the Hadley Centre, which is a climate modeling center established by the UK Meteorological Office, has connected atmosphere, ocean, and land/vegetation models and been able to simulate the pre-industrial CO_2 concentration and climate without arbitrarily fixing key parameters (Cox *et al.*, 2000). This model has been used to simulate the effects on climate and vegetation of the human-induced buildup of CO_2 in the atmosphere. Among the interesting features of the simulation is the projected drying up of the Amazon region in the mid-21st century, a change that kills off the Amazon rain forest, adding further CO_2 to the atmosphere and further warming the climate. While a very interesting simulation, the key issue is whether this initial attempt to construct a true Earth system model includes all of the ecological processes that might be involved, including allowing for the various communities of vegetation that might develop.

Regional Models

Because of the limitations of current supercomputers, those developing current versions of global GCMs or ESMs are currently unable to treat spatial resolutions of less than a few hundred kilometers. However, it is quite clear from climate observations that important variations occur over much smaller scales. For example, in some regions along the west coast of the Americas, the terrain goes from ocean to coastal plain to mountain to valley to desert, for example, all in the space of roughly 100 kilometers. For this reason, GCMs and ESMs provide only the coarsest indication of the local climatic conditions and how these conditions may change if the climate changes and regional models have been developed. Regional models, as their name implies, treat only particular regions of the globe, but do so with finer spatial resolution, typically in the tens of kilometers. Such models are of most value in representing regions with very sharp topographic variations (e.g., western North America, the Alps), particular features of the climate system (e.g., large storm systems such as hurricanes and typhoons), or locations where large changes are occurring (e.g., the tropical Pacific Ocean that experiences the ENSO cycle, and the Arctic Ocean with its variable sea ice). In these models, the effects of the rest of the world are typically handled by

imposing boundary conditions that are generally taken from coarser grid global simulations (hence, regional models are sometimes nested within global models). Even by treating only parts of the globe and thereby greatly limiting the number of different locations for which calculations must be done, the increased resolution and necessarily shorter time step generally limit the lengths of the simulated periods in these calculations to days to years rather than centuries.

In spite of the limitations in coverage and length of simulation, regional models have proven to be very useful. In weather forecasting, fine-scale regional models can be driven by coarser-scale global scale weather models and, particularly for intense weather situations, generate much-improved estimates, for example, of rainfall distribution in regions of complex terrain. For climate studies, regional models are starting to be used to study the spatial distribution of changes in precipitation, being able to better represent, for example, the accumulation and melting of snow in mountainous areas (*see* Modeling Regional Climate Change, Volume 1).

APPROACHES TO TESTING THE PERFORMANCE OF ESMs

While models, particularly numerical models, may be quite comprehensive in terms of the set of processes and components that are represented, models are simply representations of the actual Earth system. With the Earth system being governed not only by a complex set of physical and chemical relationships, but also by biological relationships and human participation, the Earth system is arguably the most complex and challenging system under scientific study (particularly if the urgency and relevance of enhancing understanding is included). Therefore, one cannot expect any of the models to be perfect replicas of the system, and an important task is to determine how much confidence can be placed in such models. This is particularly important because models might exhibit unusual, even chaotic, behavior as a result of their own structure, which may not include the full complement of stabilizing processes or may introduce thresholds or nonlinearities not present in the actual Earth system.

While it is easy to suggest that models should be tested (and not be used unless they match some specified set of observations), there are quite a number of complications. First, processes range from the microphysical to global, and span times from less than a second to many millions of years, and all the processes and their interactions need to be treated under a wide range of conditions. Second, we only have the data that we have – while we can use a number of techniques to reconstruct some aspects about what happened in the past, even today, much less a century or a millennium ago, the data sets being collected are quite limited and are not always the data sets that are needed. Third, we have learned from study of chaotic systems (*see* Chaos and Predictability, Volume 1) that the Earth system, or at least major parts of it, is following only one of what could be many paths that would be consistent with the underlying physical laws. It is a little like what happens in considering the history of the world: while the overall growth and advancement of the world population is proceeding (and this is what models of the world would tend to represent as the major course of history), there are many possible paths, some involving major disruptions such as wars, that can alter what happens in particular places and at particular times along the way. For this reason, models can provide general indications, but not detailed predictions (*see* Prediction in the Earth Sciences, Volume 1). Fourth, a key issue is developing confidence in the ability of the models to project into the future rather than to simply reproduce past occurrences. Because humankind is perturbing the Earth in unique ways for which there are no comparable analogues in the past (*see* Climate Analogues, Volume 1 and the Anthropocene, Volume 1), there is no perfectly analogous test case. As the philosopher Karl Popper has noted, the complexity and irreproducibility of the Earth system make it impossible to actually validate a model – about all that can be attempted is to invalidate the model, and then, once this is done, to improve the model and try the process again with an ever widening set of tests. Thus, while success with some tests can add to confidence in the model, there can never be complete assurance that the models will be correct, only that they have not yet been proven wrong.

The types of tests that have been proposed to test global scale models span a wide range of space and time scales, as well as covering a wide set of the processes included in the models (e.g., Schlesinger, 1991). As an example, the following types of tests are typically used to test the ability of ESMs to simulate the climate.

Testing Representations of Individual Processes

To the extent possible, model developers test the representations of each process introduced into the global models against relevant observational and experimental data. For example, radiation modules of global models, which generally approximate the full spectral dependence of radiation in terms of a few to a few dozen wavelength bands, can be tested against laboratory experiments and against detailed spectrally resolved models. Similarly, the treatment of surface drag can be tested against wind flow experiments across lakes and fields, and so on. The particular challenge in global modeling arises because these representations of particular processes must apply across spatial scales of modest-sized US states or even countries. Thus, representing the effects of clouds, which typically have dimensions up to a few kilometers, using variables calculated on grid sizes of hundreds of kilometers requires

a number of simplifying assumptions and approximations (*see* Cloud- Radiation Interactions, Volume 1). While the empirical relationships that have typically been developed are valid under many conditions, there is no guarantee that they will remain valid as the climate changes.

Testing the Model's Ability to Simulate the Weather

Although climate models are designed to represent the time-average conditions that make up the climate, they do so by trying to simulate the evolution of the system in terms of its weather, i.e., the models simulate the development of weather systems and storms, heat waves and snowfalls, and day and night variations. Two types of tests can be done. First, if the atmospheric and surface components of the model are initialized with the observed weather variables, then the model can be used as a weather forecasting model and its skill can be evaluated. For theoretical reasons, relating to the chaotic nature of the atmosphere, forecasting of the precise state of the atmosphere should be expected to diverge from the behavior of the real atmosphere over periods of one to three weeks, or so. Models developed to date show reasonable skill out to several days to a week, depending on scale of motion. While much success has been shown, more should be possible. The second type of test is to compare the weather statistics generated by the model, with the observations describing the real world. The very wide range of weather conditions around the world is a particularly severe test of the performance of model processes; for example, a cloud or convection parameterization must work from the cold of the Arctic to the heat of the equatorial regions. Again, while there is much agreement with the observed evolution of the weather, there are also systematic differences that have been identified and further improvement should be possible.

Testing the Model's Ability to Simulate the Cycle of the Seasons

In that there are very large seasonal variations in the Earth s climate, testing to determine if a model can represent the annual cycle of the seasons poses a stringent test of model parameterizations. Wintertime conditions, for example, test particularly well how the oceans and atmosphere move energy from warm to cold conditions, whereas summertime conditions test how the model stores heat and cools the surface by radiation and convection. As for the other tests, models generally do fairly well (Gates *et al.*, 1999), on average, in simulating the range of seasonal variations and their variation with latitude. However, shortcomings remain. For example, among the features not yet adequately represented is the location of the intertropical convergence zone that determines the position of equatorial rain belts. Again however, improvements are occurring as greater model resolution and improved treatment of processes become possible.

Testing the Model's Ability to Represent Interannual Fluctuations

Although summer is always warmer than winter, not all summers or winters are alike. Thus, an important test of models is their ability to represent the year to year and decade to decade fluctuations of the climate. The largest contributor to these fluctuations is ENSO, which is most evident over the Pacific Ocean, but which has influences across much of the world (*see* El Niño and La Niña: Causes and Global Consequences, Volume 1). The best of the ESMs are starting to be able to simulate El Niño-like features, and the focus is now moving on to test how well models can represent other such variations (e.g., the North Atlantic Oscillation). Major international model intercomparison projects are currently underway to test model performance on these time scales (Gates *et al.*, 1999; Lambert and Boer, 2001; and www-pcmdi.llnl.gov). Again, the indications are that current models have both strengths and weaknesses, but are improving.

Testing the Model's Ability to Represent the Climate of the Recent Past

With the intense interest in projecting potential climate change during the 21st century, an important test of climate models is their ability to simulate the climatic changes and variations over the past 100 years (or more generally over the past 1000 years). A key challenge in attempting such simulations is that we have only limited records of what happened over the recent past (e.g., we have only very limited information about deep ocean temperatures or above ground air temperatures back more than 50 years), and even less about some of the factors that may have caused climate change over this period (e.g., changes in solar radiation, volcanic eruptions, etc.). In spite of these limitations, model simulations are demonstrating some skill at representing variations over these periods, albeit with significant questions remaining (*see* Climate Change, Detection and Attribution, Volume 1; Model Simulations of Present and Historical Climates, Volume 1).

Testing the Model's Ability to Simulate Glacial Cycling

While we expect the future climate to be warmer than at present, determining how well models can simulate climates that are much colder provides important information about how sensitive the climate is to changes in radiation of the type believed to have been the major driver of glacial cycling. However, limitations in the data and limitations in computer resources have limited use of this type of

testing to either simple models that attempt to simulate the actual cycling, or full models that test model simulations against particular periods in the past rather than against the periods of change. For example, results from the Paleoclimatic Model Intercomparison Project also indicates that models show some limited skill in simulating the climatic conditions prevailing 6000 and 20 000 years ago, when the climate was slightly warmer and significantly colder, respectively (see Joussaume and Taylor, 2000). As explained in Climate Model Simulations of the Geological Past, Volume 1, tests with simplified climate models suggest that, in addition to the normal feedback mechanisms treated in most GCMs, additional feedbacks involving isostatic variations, changes in vegetation, and others also seem to be important in determining long-term climatic behavior.

Testing the Model's Ability to Simulate Warm Climates of the Geological Past

One must go back many millions of years to find test-case climatic conditions from the geological past that were as warm as the Earth might become over the next few centuries, if emissions from fossil fuel combustion continue to grow as rapidly as they have in the past. A key limitation in using such conditions as analogues for the future, however, is that they occurred gradually rather than rapidly. Test cases for models include the Pliocene of about 3 million years ago, which was a few degrees warmer than at present, and the Cretaceous of greater than 65 million years ago when dinosaurs roamed the Earth, which was so warm that tropical vegetation was apparently present in near polar latitudes. Attempts to simulate the very warm Cretaceous using models have not yet been successful – basically, the climate models, responsive as they are to changes in greenhouse gas concentrations, are not able to find a way to transport enough heat to high latitudes to make them much warmer while not significantly warming the equatorial regions (a condition suggested by the geological evidence). Indeed, what is particularly troubling about the various paleoclimatic simulations is that virtually all of the model simulations underestimate the response of the climate system, suggesting that the models are still missing amplifying feedback mechanisms that operate over the long-term.

While models have yet to succeed in satisfactorily representing all of these conditions, the numerical models do provide the most rigorous, quantitative basis for understanding the Earth system, keeping track of the myriad of processes that interact around the world and on many different time scales to create the climate that we now experience. Confidence in our understanding arises, for example, from the ability of the models to represent reasonably well the stability of the climate during historical times (i.e., the model climates are roughly stable in the absence of human-induced forcing), but confidence is limited by an apparent conflicting tendency of models to lean toward overestimating climate change during the 20th century while simultaneously leaning toward underestimating the long-term changes in the climate. In coming years, with better data sets for the present, better reconstructions of past climates, improving model representations, and faster computers, significantly better models are likely to emerge as a result of efforts to test the Earth system and model simulations against an even wider set of conditions.

SUMMARY

A diversity of modeling approaches, ranging from physical to numerical, is being used to improve understanding of the behavior of the Earth system, providing a rich appreciation of both the complexity and the sensitivity of the Earth system. This article has provided an overview of the various types of models and how they are tested. Other articles in this volume describe the application of these models to a wide range of ways to explore and encapsulate understanding of the Earth system, to interpret past and project future conditions, and to test scenarios of what could happen and how changes in policies may affect the outcome (e.g., *see* Projection of Future Changes in Climate, Volume 1).

Model Simulations of Present and Historical Climates

CURT COVEY

Lawrence Livermore National Laboratory, Livermore, CA, USA

Theoretical models of climate are used to study the mechanisms of climate change, to help reconstruct climates in the distant past, and to predict future changes in climate such as human-induced global warming. In evaluating the credibility of these models, a natural step is to investigate how well or how poorly they simulate the climate of the present day and the (relatively) well documented climatic record of the recent past. Comparison of model simulations with observations is an ongoing activity that began with development of the first global climate models in the 1970s. Since that time, climate models – like their close relatives, weather prediction models – have slowly but steadily improved.

In the first climate simulations, merely achieving qualitative agreement with the observed large-scale patterns of atmospheric temperature, pressure, rainfall and winds was considered a notable accomplishment. More recent models also simulate clouds, sea ice, ocean circulation and many other climate-relevant phenomena with an increasing degree of fidelity. They also mimic features of observed natural climate variations such as El Niño. Any complex 3-D model of the global climate system will contain simplifications and flaws, so one must ask what level of accuracy is required for a model to be usable. Answering this question (which of course depends on the particular use being made of the model) has proved elusive, but progress has been made in quantifying model errors as well as differences among models.

Evidence of climatic changes over the course of the 20th century implies that the 'present climate' is a moving target. Accordingly, the time evolution as well as the equilibrium state of climate model simulations is studied by comparing it with the observed record. Modern global climate models can reproduce the global mean surface warming of the 20th century – about 0.6°C – provided they include human-produced greenhouse gases (GHGs) and airborne particles (aerosols). The magnitudes of the aerosol effect and other climate forcing factors, however, are highly uncertain. It is thus a matter of controversy how much confidence should be placed in a climate model because of a successful 20th century simulation. An even greater challenge to models is simulation of the pre-20th century climate, in which both the forcing and the observed climate evolution are extremely uncertain.

EVALUATING THE RELIABILITY OF CLIMATE MODELS

A variety of simulation models have been used to investigate factors controlling the climate (*see* **Models of the Earth System**, Volume 1). Some relatively simple models, encoded in as few as 100 lines of computer language and executing quickly on a personal computer, calculate little more than the average temperature of the Earth's surface (*see* **Energy Balance Climate Models**, Volume 1). At the other extreme, 3-D coupled ocean–atmosphere general circulation models (Coupled GCMs) rank among the most demanding users of supercomputer time (*see* **General Circulation Models (GCMs)**, Volume 1; **Projection of Future Changes in Climate**, Volume 1). These models simulate the evolution of global climate including temperature, pressure, clouds and winds throughout the atmosphere; ocean temperature, salinity and circulation; sea ice concentration and thickness; and land surface properties such as snow cover, soil moisture and river runoff. They are the models most often used to investigate human-induced climate changes such as global warming.

Coupled GCMs simulate individual weather systems (as do their close relatives, numerical weather prediction models), producing, for example, day-to-day rainfall and snowfall at thousands of points on the Earth's surface. Such details are believed to be inherently unpredictable beyond a few weeks, so model output is often averaged over each

month of simulated time before it is archived for climate studies. Even so, a modern coupled GCM simulating the development of climate over a century or two can readily produce hundreds of Gigabytes of data encompassing dozens of variables, each recorded at tens of thousands of grid points in 3-D space. Given, for example, assumptions about future increases in atmospheric carbon dioxide (CO_2), such a model will make definite projections of global warming including regional details.

How much of this staggering volume of data is reliable enough to be useful? An obvious first step in answering this question is to ask models to simulate the present-day climate. Success in doing so, while not guaranteeing a model s ability to project future conditions, would seem to be a necessary condition for model credibility. (Even this innocuous-sounding statement begs the question of how to define success, i.e., how much accuracy in a present day simulation is required to accurately simulate future changes in climate.) The present contribution discusses results from model simulations of the present climate and the recent past, recent being defined as extending back in time about 1000 years. Climate model simulation of the more distant past is discussed elsewhere (*see* Climate Model Simulations of the Geological Past, Volume 1).

The emphasis in this contribution will be on coupled GCMs. The extensive output of these models allows a detailed comparison of simulations with observations – so detailed that some discrepancies are inevitable. The question then arises as to what level of agreement between a model and observations is required for the model to be pronounced reliable. The answer, of course, depends on the particular use one contemplates for the model. An error of a degree or two in North Pacific sea surface temperature, for example, could prove disastrous in assessing the state of Alaskan fisheries, but it might not be significant in predicting the globally averaged temperature of the Earth s surface. It must be confessed, however, that even for the latter purpose there is no agreed standard that separates acceptable from unacceptable model performance.

Accordingly, no attempt will be made here to reach a final conclusion about model reliability. The consensus among climate scientists, in the words of one official assessment, is that current models are now able to simulate many aspects of the observed climate with a useful level of skill (Gates *et al.*, 1996). By examining the model-observation comparisons in the following sections, readers can draw their own conclusions.

EQUILIBRIUM CLIMATE STATES

A natural starting point in evaluating a coupled GCMs performance is to examine the long-term average climate it simulates in a control run, with external forcing factors such as the Sun s energy output and the atmospheric concentration of carbon dioxide being kept constant at today s levels. Control run simulations are typically compared to observations of the climate averaged over recent decades. Because the recent observational record includes the response of the climate to both natural perturbations (such as volcanic eruptions and varying solar output) and human-induced effects (most notably the production of GHGs), one cannot expect a model control run to precisely match the observations. Nevertheless, a considerable degree of agreement is expected and achieved.

For example, Figures 1 and 2 compare simulated near-surface temperature and precipitation – taken from one recently developed coupled GCM – with the best available observations. The simulated and observed temperatures are remarkably similar, especially considering that the model uses physical conservation laws without direct knowledge of the observed present day climate. In contrast, conventional wisdom in the early days of climate modeling held that coupled GCMs could not accurately reproduce the observed climate without including observed surface temperatures as input and assuming artificial sources of energy at the Earth s surface to force the models into agreement with the observations. This technique, known euphemistically as flux adjustment or flux correction, is no longer employed in many coupled GCMs.

Of course any model that attempts to simulate global climate in detail will have errors to some degree. From Figures 1 and 2 several discrepancies between the model and observations are apparent. The simulated near-surface temperature is generally too low. The simulated precipitation is more problematic: the global mean error is of the order of 10%, and the spatial pattern over the Earth s surface, while recognizably similar to the observations in many respects, includes several areas of disagreement. One artifact occurs in the central and eastern tropical Pacific Ocean (about $90-180\,^{\circ}$W longitude). Here the simulated precipitation shows a minimum along the Equator, flanked by symmetric maxima at $10\,^{\circ}$N and $10\,^{\circ}$S latitudes. Observations in this region reveal only one precipitation maximum that is oriented east to west, the Intertropical Convergence Zone at $10\,^{\circ}$N. South of the Equator a band of maximum precipitation runs from northwest to southeast in the observations, but this so-called Southwest Pacific Convergence Zone does not appear in the model simulation. Precipitation has been a notoriously stubborn problem in coupled GCMs, especially in the tropics, as one might expect from the large difference between the scales of relevant processes (clouds and convection, ranging from micrometers to kilometers) and the scales explicitly resolved by the atmospheric component of global models (typically in excess of 1 km vertically and 100 km horizontally).

Despite such difficulties, the accuracy of coupled GCM control runs is impressive. Areas of agreement with observations may be found not only near the surface

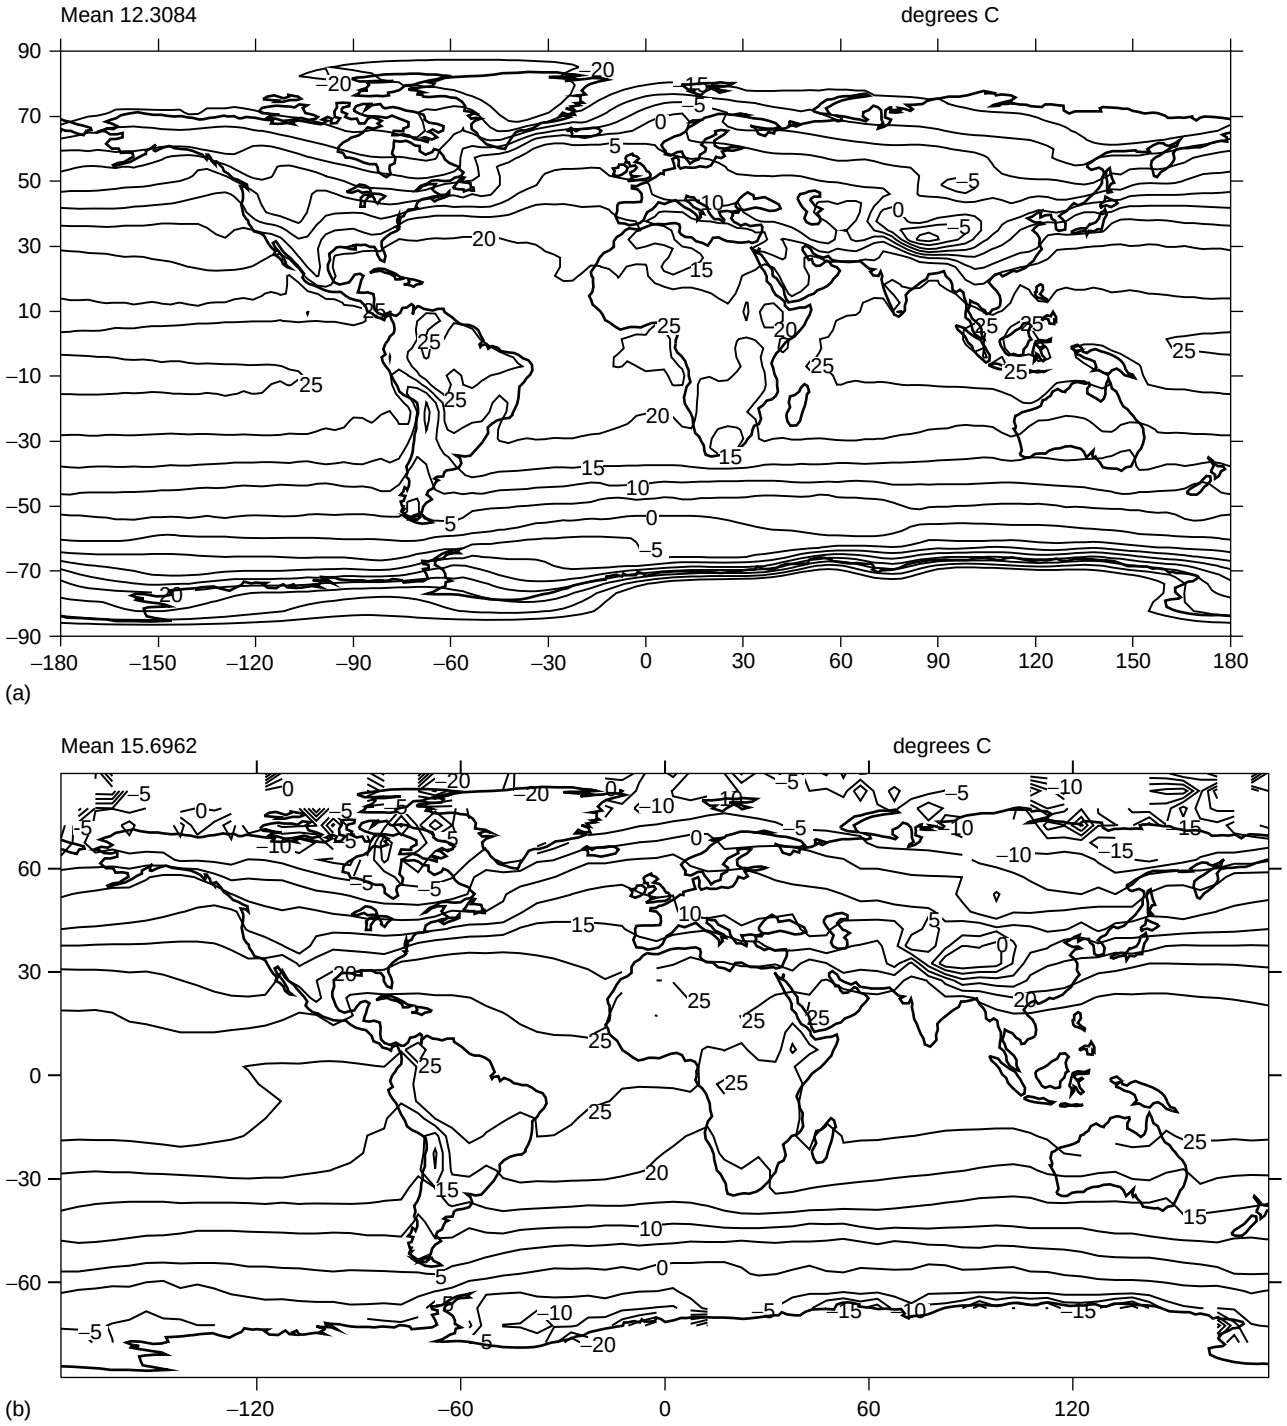

Figure 1 Annual mean near-surface air temperature: (a) as simulated by the Parallel Climate Model (Washington *et al.*, 2000); and (b) as observed by Jones *et al.* (1999). (For this figure, model output was obtained from the Coupled Model Intercomparison Project database (http://www-pcmdi.llnl.gov/cmip) and observed data were obtained from the PCMDI observational data system (http://www-pcmdi.llnl.gov/obs/pods/mo/obs.mo.source.htm))

but also in the overlying atmosphere, in sea ice regions near the poles, and within the ocean. Simulation of mid-atmospheric temperatures and winds is generally the most accurate aspect of GCM performance, presumably due to the primary attention modelers have given to meteorological applications of atmospheric thermodynamics and fluid dynamics. The stratosphere, a more recent focus of GCM development, is not as well simulated. Overly low polar

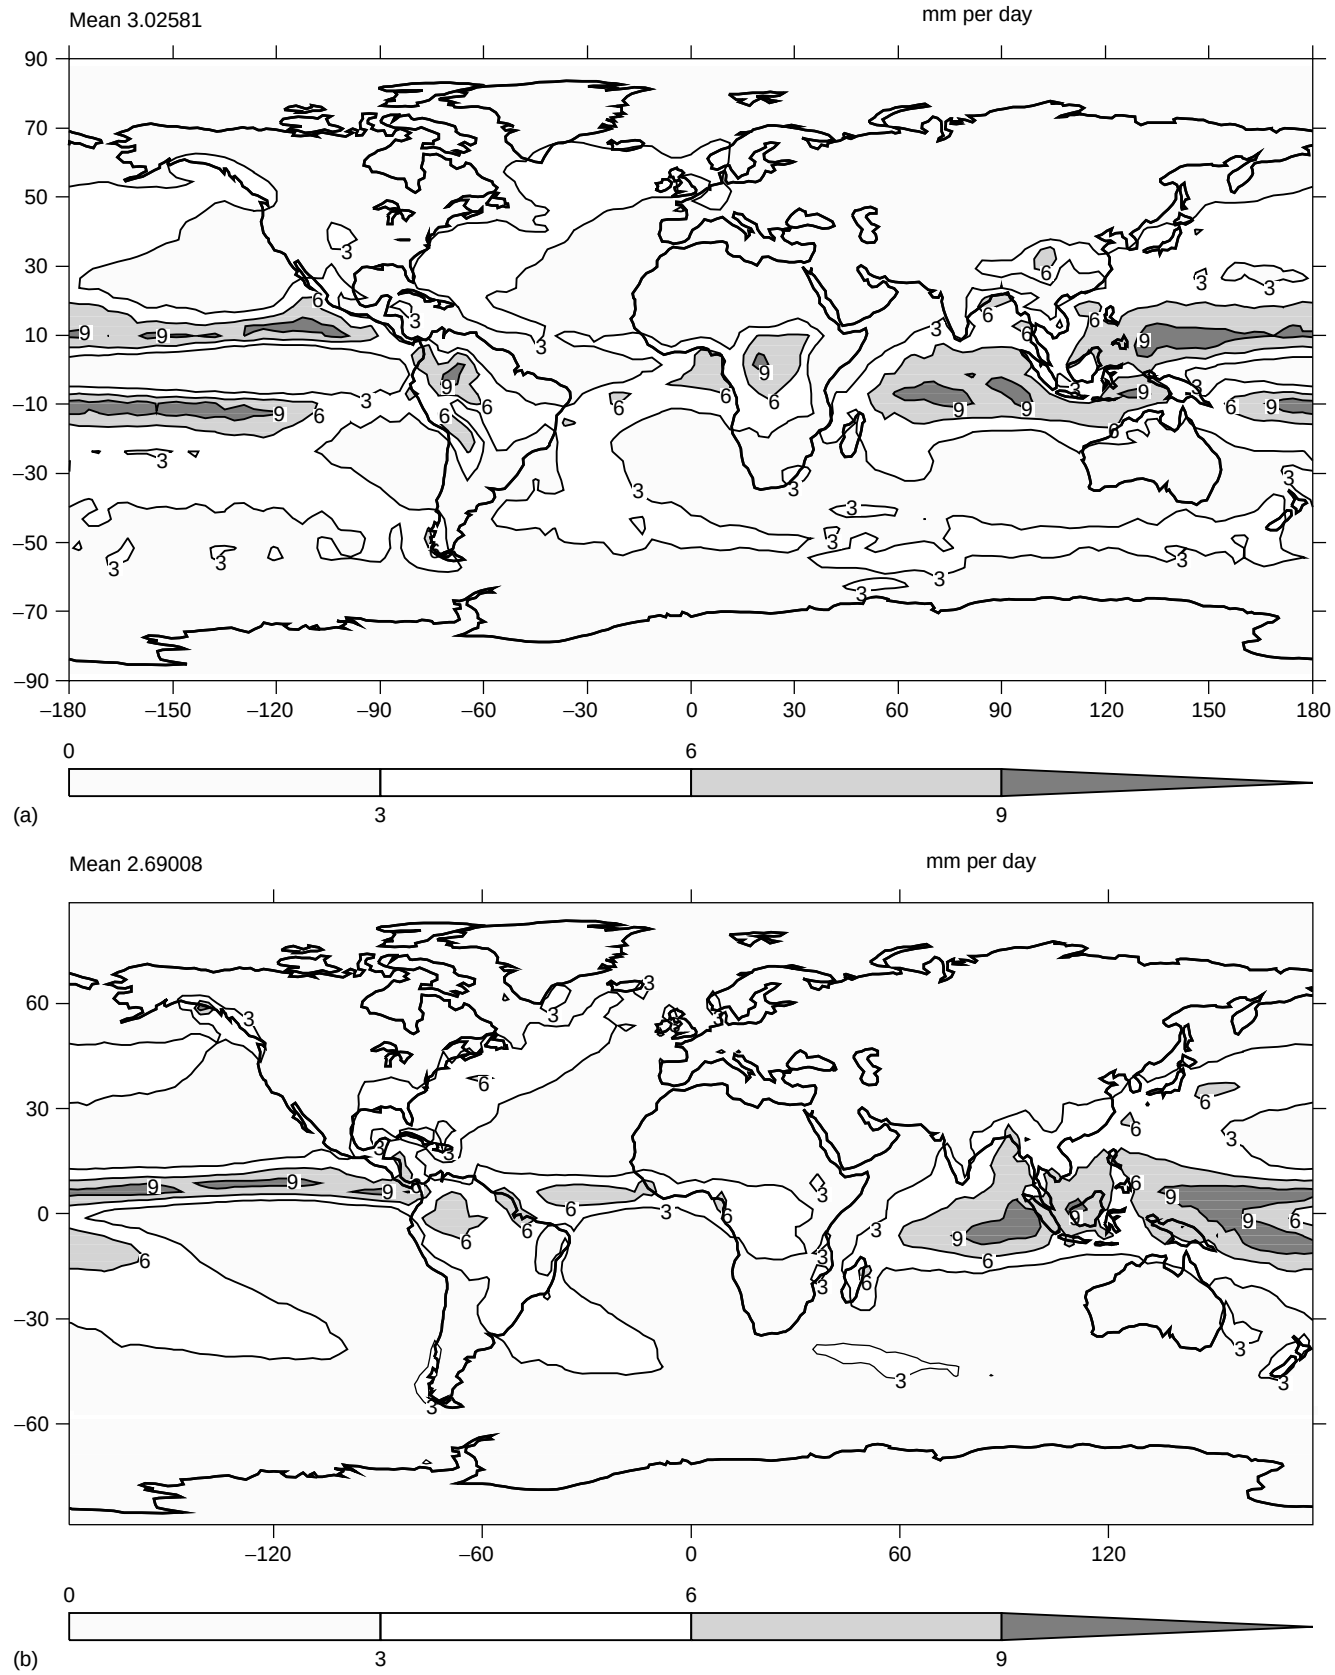

Figure 2 As in Figure 1 for annual mean precipitation (with observations from Xie and Arkin, 1997)

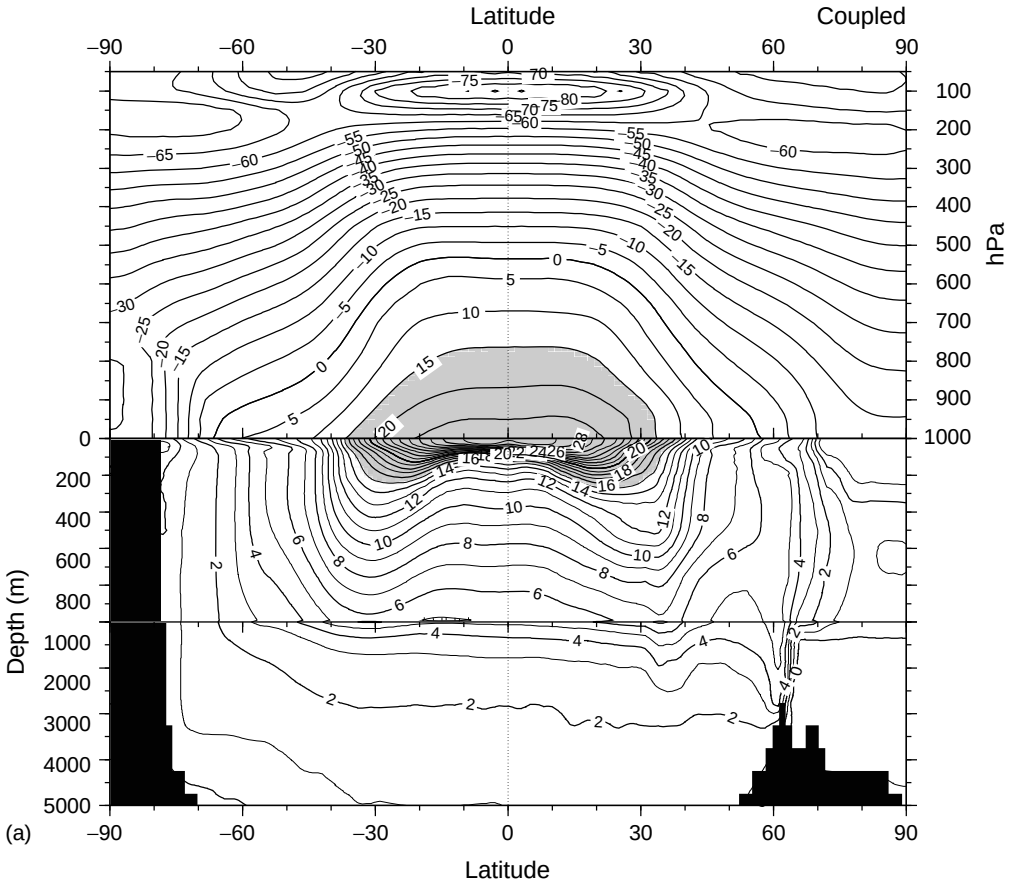

Figure 3 Longitude average (zonal mean) of annual mean temperature simulated in the atmosphere and the ocean by a coupled GCM: (a) after 50 simulated years without flux adjustment and; (b) in its initial state, which was chosen to closely match observations. The vertical coordinate in the atmosphere is pressure in hectopascals, and the vertical coordinate in the ocean is depth in meters. From Guilyardi and Madec (1997). (Reproduced by permission of Springer–Verlag Publishers)

temperatures and misplaced jet stream circulations are common deficiencies in model stratospheres. Nevertheless, GCMs succeed in reproducing the large-scale structure of stratospheric temperature and wind, producing a 3-D pattern of these quantities that is recognizably similar to observations. Analogous comments apply to ocean temperatures, salinity and currents. Modern coupled GCMs simulate temperatures and currents at and below the sea surface with sufficient fidelity to reproduce the observed magnitude and direction of large-scale ocean heat transport. This success, in turn, has reduced the need for flux adjustments at the air-sea interface.

To exemplify the state of both atmospheric and oceanic modeling, Figure 3 shows a cross-section of temperatures from the ocean bottom to the stratosphere, both as observed and as simulated by a recently developed coupled GCM. The similarity between the model and the observations is remarkable, considering that the model was allowed full opportunity to wander away from its observation-based initial conditions for 50 simulated years without flux adjustments. For example, the sharp decline of ocean temperatures in the first 1000 m of depth between latitudes 40 °S and 40 °N (the so-called ocean thermocline) was maintained during the control run. On the other hand, a detailed comparison of the changes during the 50-year simulation reveals a warming of most of the ocean (by 0.5–1 °C) and the atmosphere (by 1–2 °C generally and by 4 °C or more in the Northern Hemisphere stratosphere). This shift of the simulated climate away from observations – often called climate drift – is a continuing problem, particularly with models that do not use flux adjustment.

Climate models simulate the cycle of the seasons as well as the annual mean climate. Figure 4 shows both model simulations and observations of the amplitude of the cycle, which is measured by the difference between July and January values of near-surface air temperature over land. The solid line in the figure represents the average of results from eight coupled GCMs that do not use flux adjustment; dashed lines indicate the range defined by adding and

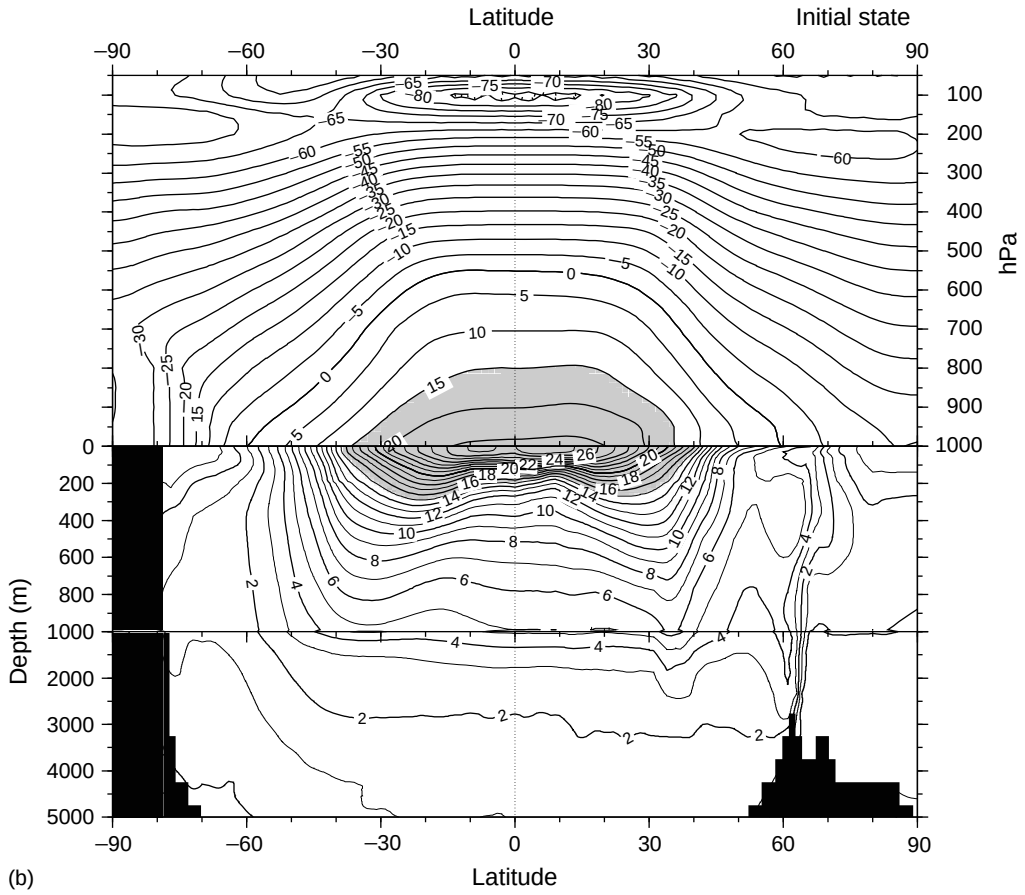

Figure 3 (*Continued*)

subtracting one standard deviation taken over the different model results. At most latitudes the average model simulation nearly coincides with the observational data (shown as points). The standard deviation of model results is typically about 20% of the average value, indicating substantial differences among the models. Nevertheless, the extent to which the models on average match the observations is striking, since the models shown (unlike their flux-adjusted counterparts) make no explicit assumptions designed to force them into agreement with the present day climate.

The most troubling deficiencies in coupled GCMs involve water vapor and clouds, the behavior of which account for most of the uncertainty in predicting climate changes such as human-induced global warming, and air-sea exchanges of heat and momentum, by which the atmosphere and ocean interact to determine the behavior of the climate system. These phenomena have been notoriously difficult to simulate even to a rough degree of accuracy. Examination of several models in the early 1990s, for example, revealed that many underestimated cloud coverage by nearly a factor of two over large parts of the world, and that about half erroneously calculated not only the magnitude but also the direction of large-scale ocean heat transport implied by air-sea exchanges. A few years later, however, the same examination of then-current models showed a noticeable reduction in the most egregious mistakes. The overall picture that emerges from such investigations is one of continuing serious problems but steady incremental improvements in model performance.

The gradual improvement of coupled GCMs is well illustrated by comparison of the model exhibited in Figures 1 and 2 with a much earlier version. The current model (Washington *et al.*, 2000) takes advantage of modern computer technology to simulate the ocean at roughly 50 km horizontal resolution using 32 separate vertical levels, permitting a detailed regional simulation of currents, temperature and salinity. In the earlier version (Washington *et al.*, 1980), the ocean component of the model used only four vertical levels and a horizontal resolution of about 500 km. The developers assessment at that time was that even though many first-order aspects of the climate system are simulated, improvements were still needed. The crude resolution appeared to induce a spurious numerical diffusion of heat in the model ocean, resulting in overly low temperatures in the tropics and overly high temperatures at higher latitudes (a problem typical of coupled GCMs at that time).

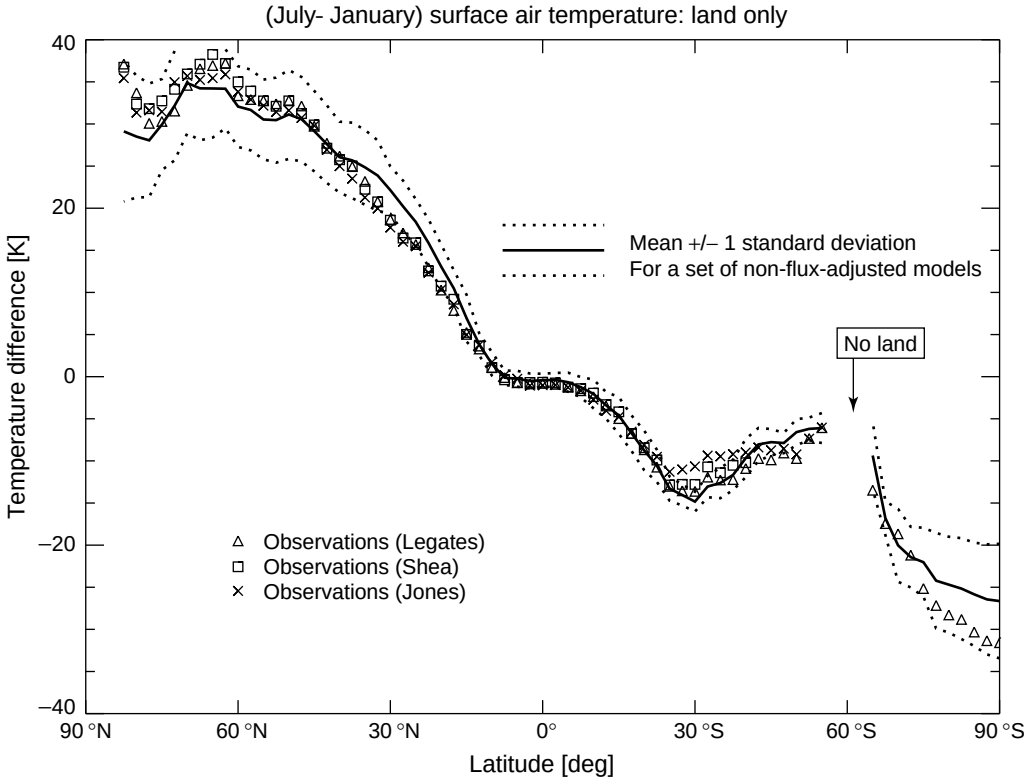

Figure 4 The seasonal cycle of near-surface air temperature over land, averaged over longitude and expressed as the difference between July and January mean temperatures. Points indicate observed values from three different datasets (identified in the graphic). The solid line is an average over results from eight coupled GCMs that do not use flux adjustment, and the dashed lines indicate the range implied by the standard deviation over these eight models. (Data from Figure 6(a) of Covey *et al.*, 2000. Adapted by permission of Springer–Verlag Publishers)

The model s western tropical Pacific warm pool region was too cool by about 5 °C. The absence of key features such as the warm pool in model simulations led many observational specialists to the opinion that detailed model-data comparison would be unproductive. In coupled GCM papers published during this era, evaluations of control run simulations tended to be rather perfunctory and to claim, at best, a qualitative similarity between the model and observations.

In contrast, the control run simulations of modern coupled GCMs are sufficiently Earth-like to compare quantitatively with observations. For example, examining the dozen or so coupled models in current use, one finds that the space-time pattern correlation between simulations and observations is around 50% for precipitation and greater than 95% for near-surface air temperature (on a scale in which 0% indicates no correlation and 100% indicates perfect correlation). The correlation values for precipitation indicate continuing model deficiencies, but even in this case model improvements may be limited by uncertainties in the observations as much as by problems with the models themselves. This conclusion follows from the relatively low (80%) correlations between different observational datasets for precipitation.

NATURAL CLIMATE VARIABILITY

In addition to the long-term mean climate, confidence in models depends on their ability to simulate the natural year-to-year fluctuations that result from the interactions of the ocean and atmosphere (*see* Natural Climate Variability, Volume 1). The most prominent of these inter-annual variations is the El Niño/Southern Oscillation (ENSO) (*see* El Niño/Southern Oscillation (ENSO), Volume 1). ENSO simulations from present versions of global GCMs suffer from a number of deficiencies including, typically, an underestimate of this phenomenon s amplitude and a misplacement of the region of maximum temperature variability. Global GCMs also show only modest skill at best at forecasting the detailed evolution in time of individual ENSO events (Landsea and Knaff, 2000). Despite these problems, the ability of the models to even partly simulate ENSO came as a pleasant surprise in the late 1980s. At that time conventional wisdom held that the models crude horizontal resolution in the tropical Pacific precluded simulation of anything resembling ENSO.

Since then, many coupled GCMs have been designed with enhanced resolution in this region, allowing improved

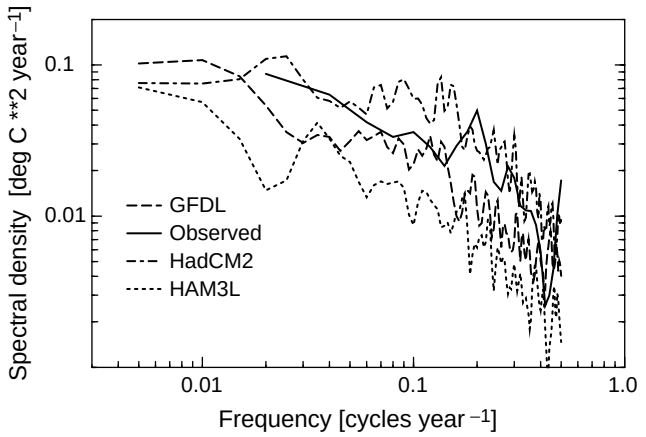

Figure 5 Intensity of global and annual mean near-surface air temperature variations as simulated by three different coupled GCMs (from the Geophysical Fluid Dynamics Laboratory (GFDL) in the US, the Hadley Center for Climate Research and Prediction (HadCM2) in the UK, and the Max Planck Institute for Meteorology in Hamburg, Germany (HAM3L)). The simulated variability is compared with observations by Jones *et al.* (1999). For both models and observations the intensity of variations is plotted as a function of their frequency in time. (From Stouffer *et al.* (2000). Redrawn by permission of the American Meteorological Society)

ENSO simulation. The models have also succeeded in reproducing observed aspects of other modes of climate variability, such as monsoons and the North Atlantic Oscillation. To summarize the state of the art, Figure 5 compares the global near-surface temperature variability of three coupled GCMs with observations over a range of time scales, from frequencies of 0.02–0.5 cycles per year (i.e., periods from 2–50 years). Over this range, the models and the observations have the same magnitude of variations.

Of course a plot that displays global mean results on logarithmic scales can hide a multitude of errors. One indication of the problematic aspects of model-simulated variability is provided by Figure 6, which shows results for land and ocean areas separately. This figure presents the near-surface temperature variability of 16 different coupled GCMs in the form of histograms. It appears that most of the models underestimate variability over the oceans but overestimate it over land. The ocean-area underestimate might be expected from continuing problems with ENSO simulation (although it seems that other factors are involved as well). Over land, the overestimate of variability seems worse in models having less sophisticated parameterizations of land surface processes.

One complication in interpreting the variability of model control runs is that, by assumption, such runs do not include the effects of changing the degree of climate forcing. Changes in forcing can be induced by human activities such as the burning of fossil fuels, which add heat-trapping carbon dioxide to the atmosphere. Changes in forcing can also be induced by purely natural phenomena such as volcanic eruptions or changes in solar brightness. Volcanic eruptions add airborne particles (aerosols) to the upper atmosphere, where they reflect sunlight back to space. Changes in solar brightness affect the amount of solar energy reaching Earth; such changes have been minor (no more than 0.1%) during the few years they have been measured, but they may be greater over time scales of several decades or more. All such phenomena presumably add to the climate variability of the real world. In the following two sections their effect on climate model simulations is considered.

THE 20th CENTURY'S CLIMATE

Globally averaged near-surface air temperature increased over the course of the 20th century by about 0.6 °C (*see* The

Global Temperature Record, Volume 1). This amount, while seemingly tiny, is confirmed by the agreement of independent land-based and ocean-based measurements, and it appears to be much greater than global mean temperature changes over the preceding 900 years. (Note, however, that for estimates of pre-20th century temperatures the margins of error – to the extent they are known at all – are distressingly large.) Climate models are able to simulate the observed increase of global mean surface temperature over the course of the 20th century. They can do so, however, only if they assume changes in climate forcing due to human production of both GHGs (mainly carbon dioxide) and aerosols. Many if not all climate scientists have concluded from these simulations that human activities are altering the climate enough to make a detectable difference in the observational record (*see* Climate Change, Detection and Attribution, Volume 1).

The matter of human-produced aerosols is the most problematic in this tangle of issues (*see* Aerosols, Effects on the Climate, Volume 1). Burning fossil fuels release not only carbon dioxide – which together with water vapor is the main product of the chemical reactions involved in combustion – but also a number of trace pollutants including aerosols. The aerosols include sulfate particles that scatter sunlight more than they absorb it. At the moment the scientific consensus is that the net effect of the aerosols is to cool the Earth by reflecting sunlight back to space, counteracting some, but not all of the greenhouse warming effect of carbon dioxide and related gases. Because of the relatively short lifetime of human-produced aerosols in the atmosphere, their concentration and thus their climate forcing varies substantially over different locations (unlike carbon dioxide, which is relatively long lived and well mixed in the atmosphere). Complicating matters further is the presence of a number of other natural and human-induced perturbations to the climate, including land cover changes, volcanic eruptions, ill-defined changes in solar brightness, ozone depletion, a variety of additional GHGs and aerosols in addition to carbon dioxide and sulfate particles, and above all the possibility of indirect climate forcing by aerosol-induced changes in cloud properties.

Although it seems highly likely that the sum of human-induced greenhouse and aerosol forcing amounts to heating rather than cooling, data on aerosol amounts and properties are not sufficient to accurately determine the amount of heating even in the global average. Model simulations of the climate of the 20th century use plausible values as input and their output shows fair agreement with the observational record. Figure 7 shows a typical set of calculations by a coupled GCM. The global mean near-surface temperature increase simulated by the model over the entire 20th century is a close match to the observed value. In the mid 20th century, however, the observations show a pause in global warming that the model

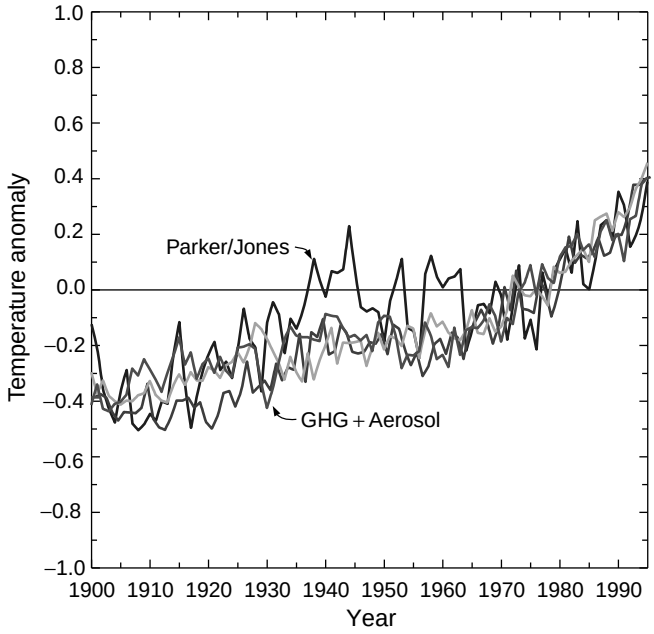

Figure 7 Twentieth century time series of global and annual mean near-surface air temperature, expressed as a deviation from the average temperature around mid-century. The curve marked Parker/Jones gives observations from Jones *et al.* (1999). The remaining (GHG • Aerosol) curves give simulated values from a coupled GCM including anthropogenic GHGs and aerosols; the simulations producing these three curves differed only in the initial conditions supplied to the GCM. (From Boer *et al.* (2000). Reproduced by permission of Springer–Verlag Publishers)

does not reproduce. This discrepancy, which is common in model simulations of 20th century climate, may be due to climate forcing that is present in the real world but missing in the model run, to deficiencies in the model itself, or even to inherent limits to the predictability of the climate system due to chaos. The last possibility is illustrated by the somewhat different results obtained by three model runs begun with slightly different initial conditions (all within the realm of possibility for the climate of the beginning of the 20th century, when the state of the oceans in particular was poorly characterized). An expanded ensemble of model runs might include one simulated temperature curve that matches the observations much better than others. Such a result has occurred for at least one coupled GCM (Delworth and Knutson, 2000). Other models obtain better agreement with early to mid-century global mean temperatures if they include plausible variations in solar energy output (e.g., Stott *et al.*, 2000).

Regardless of the details, model runs including both human-produced GHGs and aerosols tend to give more accurate reproductions of the 20th century climate record than those that omit them. This conclusion follows from

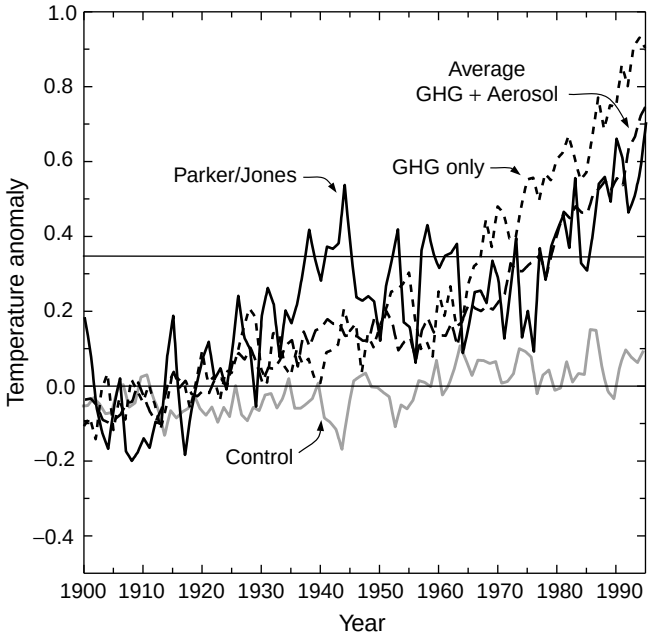

Figure 8 Additional 20th century time series of global and annual mean near-surface air temperature, expressed as a deviation from the average temperature around mid-century. Again the curve marked Parker/Jones gives observations from Jones *et al.* (1999). The long-dashed line (labeled Average GHG • Aerosol) gives the average of the three model-simulated GHG • Aerosol time series shown in Figure 7. The short-dashed line (labeled GHG only) gives results from a simulation in which anthropogenic GHGs were included, but aerosols were not included. The line labeled Control gives results from a model control run in which neither anthropogenic GHGs nor aerosols were included; the thin horizontal line at about 0.35 °C indicates three times the standard deviation of the control run. (From Boer *et al.* (2000). Reproduced by permission of Springer–Verlag Publishers)

Figure 8, which compares the average of the three model runs in Figure 7 with analogous runs in which aerosols are omitted (leaving the GHGs only) and in which no changes in climate forcing at all are included (the control run). For the last third of the 20th century, agreement is excellent between observations and the model simulation that includes both GHGs and aerosols. The control run, in contrast, produces more or less steady temperatures in obvious disagreement with observations, while the run that omits aerosols produces too much warming. Results such as these have been obtained from a variety of climate models and have led many to conclude that a human fingerprint is apparent in the observational record of climate. One cautionary note is that the spatial patterns of simulated global warming (omitted by the global averaging that produces the curves in Figures 7 and 8) are rather sensitive to the details of the assumed climate forcing.

THE PRE-INDUSTRIAL PERIOD

Finally, one may consider the performance of climate models in simulating the history of climate over a period of several centuries. This evaluation is made difficult by the paucity of observational data for both climate forcing and temperature response. In recent years, however, compilations of indirect or proxy data indicative of surface temperature – sometimes referred to as high resolution paleodata – and somewhat more extensive datasets on forcing have provided enough confidence to allow model simulations to begin (*see* Natural Records of Climate Change, Volume 1; Little Ice Age, Volume 1; Medieval Climatic Optimum, Volume 1). Figure 9 shows the results of one such experiment. To save computer time, this study employed a simple energy balance ocean – atmosphere model that was calibrated to have the same response to climate forcing as a typical coupled GCM. Forced by a plausible scenario of pre-industrial natural climate forcing, the model simulates Northern Hemisphere temperatures in agreement with the observed gradual decline over most of the millennium (called the Little Ice Age). When the simulation is extended through the 19th and 20th centuries with forcing similar to that used to produce Figures 7 and 8, results analogous to those obtained with coupled GCMs emerge: a general agreement with the overall temperature rise during the period, but disagreement in detail.

With multi-century climate simulations in their infancy, it is difficult to make firm statements about model performance in such experiments. Future studies will no doubt include coupled GCMs, allowing among other things a more complete assessment of the role of internally generated long-term oscillations of the climate system. The simplified nature of energy balance climate models rules out many of these modes of variability. One conclusion from the study that produced Figure 9 was that about half of climate variability in the pre-industrial period was generated by externally varying natural forcing from the Sun and volcanoes. Given the uncertainty in the forcing, one could imagine a coupled GCM study using less external forcing but achieving equally good agreement with the observed variability.

CONCLUSIONS

Coupled GCMs retain enough problematic features to keep climate scientists busy for the indefinite future, but when viewed over the past few decades they show a steadily improving agreement between their control run simulations and recent observations. Much of this improvement is attributable to higher resolution in the models finite difference grids (or numerical equivalents such as a greater number of basis functions in spectral-space models). Higher resolution is made possible by the tremendous increase in

computer power and storage capacity that has occurred since climate models were first developed. Making productive use of this computer power is a nontrivial task, however, especially in parallel processing machines. The challenge has been met by a variety of research groups, often with the additional benefit of entraining mathematicians and computer scientists into global change research.

An equally praiseworthy accomplishment of model developers has been and continues to be increasingly sophisticated sub-grid scale parameterizations (*see* Sub-grid Processes, Volume 1; Earth System Processes, Volume 1). These are required by even the highest-resolution GCMs in order to account for spatial scales not explicitly resolved by the models. For the atmosphere, parameterizations describing clouds and convection have evolved from simple algorithms – which do little more than prevent unphysical instabilities from persisting – to extremely complex accounting schemes incorporating a wealth of empirical data. An analogous increase in sophistication has occurred in the treatment of land surface processes. Similar progress has also taken place in the oceanic components of coupled models, many of which now employ parameterizations of eddies operating at scales down to a few kilometers (where most of the kinetic energy of ocean circulation resides).

Coupled GCMs, together with simpler energy balance models, are increasingly used not only for purely scientific research but also in the policy-making arena, most notably in deciding what if anything to do about human-induced global warming. Controversy exists about how far the models predictions can be trusted. On occasion the discussion sounds sterile, like an argument over whether a glass of water is half empty or half full, but continued debate is healthy and inevitable considering the stakes involved in adapting or responding to global change. At the same time, both scientists and policy-makers are taking the models seriously. Much of this confidence arises from the fidelity with which the models simulate the present day climate as well as that of the past 100–1000 years.

ACKNOWLEDGMENTS

I thank the editors of this encyclopedia and a large number of additional colleagues, especially my fellow authors in the Intergovernmental Panel on Climate Change (IPCC), for extensive discussions of climate model evaluation. This work was performed under auspices of the US Department of Energy by University of California Lawrence Livermore National Laboratory under contract No. W-7405-Eng-48.

Projection of Future Changes in Climate

JERRY D MAHLMAN AND RONALD J STOUFFER

Princeton University, Princeton, NJ, USA

This article summarizes the basic science of human-caused climate warming, the role of climate data in documenting long-term climate changes, the role of climate models in evaluating climate warming to date, and model projections of expected climate changes over the next century. These projections assume that substantial reductions of fossil fuel use will not have occurred.

Such projections of climate changes include further global-mean surface- air temperature increases of roughly 3.0°C by the year 2100. While regional details are more uncertain, some substantial effects are rather well understood. Land is expected to warm more than ocean. Northern Hemisphere high latitudes are expected to warm more than the lower latitudes. The hydrological cycle is expected to become more intense (more oods and more droughts). Vertical mixing of temperature and trace constituents in the ocean is likely to become more inhibited. Summertime soil moisture in continental interiors is likely to decrease substantially. Summertime heat index in moist subtropical areas is likely to increase by about 50% more than the actual temperature increases. Intense tropical cyclones are expected to become more intense, on the average. Finally, sea level is expected to rise by roughly 15- 70 cm over this century, with steady rises for many centuries thereafter.

AN OVERVIEW OF THE SCIENCE OF HUMAN-CAUSED CLIMATE WARMING

Historical Setting

Much of the material in the first three major sections is adapted from Mahlman (1998). Since the pioneering work of Arrhenius (1896), the possibility of a net warming of the global climate due to an increase in atmospheric carbon dioxide (CO_2) concentration produced by the burning of fossil fuel has been recognized. The subject matured scientifically with the publication by Manabe and Wetherald (1967) of the first fully self-consistent model calculation of this so-called greenhouse warming effect. They used a simple one-dimensional (altitude only) model of the global atmosphere. In the three decades since, a tremendous amount of observational, theoretical, and modeling research worldwide has been directed at the climate system and possible changes in it due to human activity.

Some Fundamental Aspects of Greenhouse Warming Science

The Earth is strongly heated every day by incoming radiation from the Sun. This heating is offset by an equally strong flux of infrared radiation leaving the planet. Interestingly, if Earth were without any atmosphere, and if its surface reflectivity did not change, the global-mean surface–air temperature would be roughly 33°C colder than it is today. This large difference is due to the strong atmospheric absorption of infrared radiation emitted from the Earth s surface, and a portion of this absorbed energy being re-emitted back to the surface. The major gaseous atmospheric infrared absorbers are water vapor, CO_2, and ozone; in popular language, they are called greenhouse gases. This strong infrared absorption and strong downward atmospheric emission effect is extremely robust. It is readily measured in the laboratory and is straightforwardly measured from Earth-orbiting satellites. Simply put, adding CO_2 and other greenhouse gases to the atmosphere adds yet another infrared blanket to the planet and, thus, directly acts to warm the Earth s atmosphere.

The basic story of human-induced greenhouse warming remains simple. Increased infrared absorptivity due to increasing atmospheric concentrations of CO_2 and other greenhouse gases produces a net heating effect at the Earth s surface, due mainly to increased downward infrared radiation. The effect is not dissimilar to the observable suppression of nighttime cooling when there is cloud cover or when the air is very humid.

It is an inescapable scientific conclusion that added CO_2, water vapor, and other greenhouse gases provide a measurable direct addition to the atmospheric trapping of infrared radiation leaving the surface of our planet. However, a naive comparison of the relative greenhouse efficiencies of water

vapor and CO_2 quickly becomes problematic because water vapor exists in the climate system almost exclusively as a feedback gas. That is, the warming due to increased CO_2 concentrations produces a feedback that increases the water vapor amount. All models and observations currently indicate that, as climate warms or cools, the observed and calculated global-mean relative humidity of water vapor remains roughly constant as the climate changes, whereas the water vapor mixing ratio changes considerably. Relative humidity is the ratio (in percentage) of the actual amount of water vapor in the air to the maximum possible amount (saturated). The saturation vapor pressure, determined from the Clausius–Claperon equation of classical thermodynamics, is a strong exponential function of temperature, roughly doubling for each 10 °C increase in temperature. Water vapor mixing ratio is the mass of water vapor of air divided by the mass of dry air; following an air parcel, it is generally conserved for a few days when no condensation is present. As climate warms due to an increasing atmospheric CO_2 concentration, the holding capacity of atmospheric water vapor increases exponentially. Thus, the increase in water vapor provides a powerful positive feedback mechanism – that is, a process that acts to amplify the original warming caused by increasing atmospheric CO_2 levels. With this major positive feedback, the modeled climate sensitivity increases by about a factor of three, to approximately 3 °C warming for a doubling of the atmospheric CO_2 concentration ($2 \times CO_2$) over its preindustrial level.

The term climate sensitivity typically refers to the level of equilibrium global-mean surface–air temperature increase that the climate system would experience in response to a doubling of CO_2 (*see* Climate Sensitivity, Volume 1). Each model has its own climate sensitivity, almost guaranteed to be somewhat different from the unknown value for the real world. Currently, observational evidence remains roughly consistent with the modeling results that project a strong positive water vapor mixing ratio feedback under approximate constancy of relative humidity as the climate changes (Oort and Liu, 1993; Sun and Held, 1996). The long-term quality of water vapor data in the upper troposphere, however, is not particularly good, thus making it difficult to evaluate model calculations of the important water vapor feedback process in that layer of the atmosphere.

An additional, but smaller, positive climate feedback is the relationship between ice and snow (or its absence) at the Earth s surface and its reflectivity (albedo) of solar radiation. In essence, if ice or snow cover melts, the surface left exposed (ground, vegetation, or water) is generally less reflective of incoming solar radiation. This leads to more absorption of the solar radiation, thus more warming, which then leads to less ice or snow, and so on.

Inclusion of these snow and ice albedo feedback processes in mathematical models of the climate further amplifies the calculated warming response of the climate to increased atmospheric concentrations of CO_2 and other infrared absorbing gases; these feedback processes would also amplify any calculated cooling effects. Other kinds of feedbacks, both positive and negative, result from interaction of land surface properties (e.g., changes of vegetation that lead to albedo and evaporation changes) with climate warming/cooling mechanisms or from changes in CO_2 uptake by the biosphere (*see* Climate Feedbacks, Volume 1).

The major source of uncertainty in determining the climatic response to any atmospheric radiative perturbation arises from the impact of clouds on the radiative balance of the climate system. Clouds are effective absorbers and reflectors of solar (visible plus ultraviolet) and infrared radiation. Their net effect is to cool the planet, but the effect is very small relative to the 33 °C atmosphere/no-atmosphere difference noted above. However, for predicting smaller human-caused climate changes, the effect of clouds becomes crucially important. An increase in thick low clouds mainly acts to reflect more solar radiation and thus would provide a negative feedback to global warming. An increase in thin high clouds mainly adds to the absorption of infrared radiation trying to escape the planet and would thus provide a positive feedback. A relatively small change in cloud microphysical and optical properties could make the sign of the cloud feedback go either way. Which of these changes, if any, would dominate in an increasing CO_2 world? We are not sure. Our inability to answer this question with confidence is the major source of uncertainty in today s projections of how the climate would respond to increasing infrared-absorbing gases. Furthermore, it is not likely this cloud–radiation uncertainty will be sharply reduced within the next 10 years (*see* Cloud- Radiation Interactions, Volume 1).

Although shortcomings in the treatment of clouds dominate the climate modeling uncertainty, other key processes are also in need of improved understanding and modeling capability. A key example is the effect on climate response of human-produced airborne particles (aerosols), which are composed mostly of sulfate (produced by oxidation of the sulfur in fossil fuels) and carbon (from open fires) (*see* Aerosols, Troposphere, Volume 1). Sulfate aerosols strongly reflect solar radiation, producing a cooling effect, whereas carbonaceous aerosols strongly absorb solar radiation, producing a net heating effect. Efforts to reduce the current uncertainty of aerosol effects are limited by inadequate measurements. Even more uncertain are the so-called indirect effects of atmospheric aerosols. By indirect effect we mean the uncertain role the presence of these aerosols plays in the determination of cloud amounts and the optical properties of a cloud s water droplets and ice crystals (*see* Aerosols, Effects on the Climate, Volume 1).

Another key uncertainty lies in modeling the response of the ocean to changed atmospheric greenhouse gas

concentrations. Uncertainties in the oceanic heat uptake rate affect the calculated rate of response of the climate on time scales greater than a decade. The uncertain ocean response also includes the possibility of changed ocean circulation, a potential major factor in shaping regional climate changes.

A frequently overlooked aspect of the human-caused greenhouse-warming phenomenon is its fundamentally long time scales. The current rate of adding to the atmospheric CO_2 amount is slightly more than half a percent per year, and total CO_2 emissions are expected to increase over the next half century (*see* Carbon Dioxide, Recent Atmospheric Trends, Volume 1). The time required for atmospheric CO_2 concentrations to approach twice pre-industrial levels ($2 \times CO_2$) is roughly a half-century to a century from now, a process well underway (CO_2 concentrations are now over 30% higher than pre-industrial levels). Because of the large heat capacity of the oceans, the atmospheric temperature is not expected to respond quickly to the higher CO_2 concentrations (*see* Carbon Cycle, Volume 2). This oceanic heat capacity effect can produce delays in the realized warming on time scales ranging from decades to centuries. Moreover, the deep ocean carries over a thousand years of temperature memory. Thus, after CO_2 concentrations stop increasing, it is expected that it will take many centuries for the atmosphere and ocean to stop warming.

This large ocean-induced resistance to changes in the climate is also a big factor at the other end of the problem. What if we have produced a climate regime we do not like and want our normal one back? The current evaluation of the net atmospheric lifetime of fossil fuel-produced CO_2 is about three-quarters of a century. The net CO_2 atmospheric lifetime is expected to become considerably longer as more CO_2 is added, and the fast-removal CO_2 reservoirs (upper ocean and land surface) become increasingly burdened with CO_2 (Houghton *et al.*, 1992). Thus, a natural draw down of the enhanced atmospheric CO_2 concentration is expected to require multiple centuries. Also, the warmed ocean would add an even longer time to give up its accumulated heat after the atmospheric CO_2 concentrations had begun to return toward appreciably lower levels.

THE ROLE OF CLIMATE MODELS

Over the past four decades, a quiet revolution has fundamentally changed the way that much of the research in climate science works. Earlier, the controlling science paradigm was the interchange between theory and observation concerning the structure and behavior of the climate system. Today, much climate research is driven by the interactions among theory, observation, and modeling. Modeling involves computer-based simulations of various phenomena, based on numerical solutions of the known equations governing the phenomena under investigation. This combined approach (theory, observation, modeling) is now widespread in the physical sciences. It is significant that mathematical modeling of weather and climate literally pioneered this now-widespread new approach to scientific research in the 1950s and 1960s.

Mathematical models of climate can range from simple descriptions of simple processes to comprehensive simulations of the entire dauntingly complex climate system (*see* Models of the Earth System, Volume 1). Models of the coupled atmosphere–ocean–ice–land climate system now lie close to the most complex limit of such models. This very complexity can lead to highly divergent human reactions to them, varying from deeply skeptical to totally uncritical. The truth is far from either of these unscientific characterizations.

Newcomers to the greenhouse-warming problem tend to be unaware of the long and rich history of mathematical modeling of the atmosphere and the ocean. In the late 1940s and early 1950s, simple mathematical models were created to attack the weather forecasting problem. More advanced models were built in the late 1950s and early 1960s (Phillips, 1956; Smagorinsky, 1963) because of a strong research interest in understanding and predicting the circulation of the atmosphere. Shortly thereafter, the first model bearing a strong resemblance to today s atmospheric models was created (Smagorinsky *et al.*, 1965) (*see* General Circulation Models (GCMs), Volume 1). That early model, as well as all of today s models, solved the equations of classical physics relevant for the interacting atmosphere–ocean–ice–land system. These equations are conservation of momentum (Newton s second law of motion), conservation of energy (first law of thermodynamics), and conservation of matter (air, water, chemicals, etc., can be blown around by wind or currents, undergo phase changes, transferred across boundaries, or converted chemically, but the number of atoms of each kind remains unchanged).

The modeling approach thus provides high potential for fundamental tests of applications of these theoretical first principles. Such modeling appears deceptively simple. These equations are taught in high school physics. There are some daunting challenges, however. When atmosphere, land, ocean, and ice processes are coupled and applied to moving (and deforming) fluids such as air and water, the model equations form complex systems that are intrinsically nonlinear and can thus exhibit surprisingly counterintuitive behaviors. Moreover, their solution in a climate model requires a reasonably fine-scale grid of computational points all over the atmosphere–ocean–ice–land system, ideally, well more than a million such points. In addition, important small-scale processes such as atmospheric moist convection (e.g., thunderstorms) and turbulent dissipation (smaller-scale mixing of heat, momentum, etc.) remain formidably difficult to incorporate on a first-principles basis. Often, such processes are included statistically (parameterized) through use of field observations.

Finally, no meaningful steady-state (time-independent) solutions of the governing equations can solve directly for the average climate. In effect, the average climate in such a model must be described as a statistical equilibrium state of an unstable system that exhibits important natural variability on time scales of hours (thunderstorms), days (weather systems), weeks to months (planetary-scale waves/jet-stream meanders), years (El Niño), and decades to centuries (ocean circulation variations and glacial ice fluctuations). A complete model must calculate all of these time-varying processes directly. Clearly, models of such a large, complex, and time-varying system are intrinsically computer intensive. Fortunately, today s supercomputers are nearly 10 000 times faster than those of 30 years ago. Because of today s widespread availability of relatively inexpensive computer power, the number of fully coupled atmosphere–ocean–ice–land climate models in the world has increased from a few in the early 1980s to roughly 10 independently conceived models today. Roughly another 20 models are essentially based on these 10 models.

Over the last half century, use of these kinds of physically based mathematical models has resulted in major improvements in the science of weather forecasting. Sharp forecasting skill improvements have been achieved through finding the useful short-term predictability in a fundamentally chaotic system (which means that the details of weather variations become essentially unpredictable after a sufficient lapse of time, say a couple of weeks) (Lorenz, 1963) (*see* Chaos and Predictability, Volume 1).

Recently, it has become clear that slower variations of the coupled atmosphere–ocean–ice–land system provide potential for finding useful predictability on time scales longer than the couple of weeks characteristic of individual weather systems. The most visible example is the realization that El Niño events, which produce warming in the tropical eastern Pacific Ocean, may be partially predictable a year or so in advance under certain circumstances (Cane *et al.*, 1986) (*see* El Niño and La Niña: Causes and Global Consequences, Volume 1). The existence of such a predictable spot of warm eastern Pacific Ocean water provides the basis for a nearby improvement of the prediction of seasonal weather anomalies (e.g., a wetter than normal California winter).

The existence of limited extended-range predictive potential in the climate system leads to obvious questions about such models validity for projecting systematic changes in the statistical equilibrium climate (say a 20-year running average) resulting from the inexorably increasing concentrations of infrared-active gases currently underway. Projections for greenhouse warming scenarios depend on a number of physical processes that are subtle, complex, and not very important to weather prediction. However, people outside the climate field have frequently said that climate models are ill posed and irrelevant because they attempt to forecast climate behavior that is well beyond the limits of deterministic predictability. Thus, they assert that, if one cannot predict weather more than a week or two in advance, the climate change problem is basically impossible. Such a statement is scientifically incorrect. The weather prediction problem is essentially an initial-value problem, in which the predictability of interesting details (i.e., weather) is fundamentally limited by uncertainty in initial conditions, model errors, and instabilities in the atmosphere itself. In contrast, climate change projections are actually time-varying boundary value problems, where the objective is to determine the changes in average conditions (including the average features of the evolution toward the new equilibrium) as the planet is heated or cooled by newly added processes (e.g., increased concentrations of CO_2 or sulfate particles).

The differences between weather and climate models are further instructive when one considers how their strengths and weaknesses are evaluated. Thanks to massive amounts of weather and climate data, both kinds of models can be evaluated by careful comparison with data from the real world. In practice, however, the approaches to improving these superficially similar models are very different. The skill of weather forecasting models is evaluated by comparing model-based forecasts, which are started up from real data on a given day, with what actually happens hours to weeks later. Interestingly, one of the key problems with such weather models is that, in longer-range forecasts (days to weeks), they can easily reject their initial conditions by drifting toward a model climate that is quite different from that of the real data that was used to start up the detailed forecast calculation. In effect, such a drifting weather forecast model is deficient in the climate that it would produce if released from the constraints of its starting data.

In sharp contrast, a climate model has the responsibility of properly simulating the time-averaged climate for today s conditions. In this case, the focus of the scientific inquiry is quite different from weather forecasting. Here, attention is directed toward proper simulation of the statistics of climate, such as the average daily and seasonal temperature cycles forced by the variations in incoming solar radiation, the average number and intensity of extratropical cyclones, the locations of deserts and rainy areas, the strength and location of jet streams and planetary waves, the fidelity of El Niño simulation, the location and characteristics of clouds and water vapor, the strength and location of ocean currents, the average magnitude and location of snow accumulation and snow melt, and, finally, the amplitudes and time scales of the natural variability of all of these on a wide range of time scales (days to centuries) (*see* Model Simulations of Present and Historical Climates, Volume 1).

Achieving all of this in a climate model is a daunting task because of the enormous wealth of phenomena in the climate system, many of which exist on scales smaller than can be resolved by current models. This leads to the need for judicious science-based or *ad hoc* tuning and/or adjustment of various poorly defined processes (such as cloud properties, or the fluxes of heat between atmosphere and ocean) to improve the model s agreement with observed climate statistics. Such tunings and adjustments are widespread, especially for the global-mean radiative balance, and are often done to ensure that the model agrees with the various time-mean features of the climate. If this is not done, a coupled model started up with today s climate conditions will tend to drift toward a less realistic climate.

These practices have been criticized as evidence that climate models have no credibility for addressing the greenhouse-warming problem. Interestingly, such tunings and adjustments (or lack thereof) may have little to do with the ability of a model to reduce its fundamental uncertainty in projecting human-caused climate change. Recall that the key uncertainties highlighted above (water vapor, cloud, and ice-albedo feedbacks) revolve around how such properties might change when greenhouse gases are added to the atmosphere. This is a set of challenging modeling problems that cannot be evaded by judicious model tunings or adjustments. Likely to prove much more fruitful in the long run would be improved fundamental modeling of the key processes that govern the most important climate feedbacks as the atmospheric CO_2 concentration increases (e.g., clouds, water vapor, ice, ocean circulation). Many of these modeling issues are addressed in the major scientific assessments prepared by the Intergovernmental Panel on Climate Change (IPCC) (Houghton *et al.*, 1990, 1995, 2001).

Thus, climate models are imperfect tools for making projections of climate change. Does this mean we should shift our focus to other tools? Definitely not! Unfortunately, there exist no good alternatives. Statistically based models that use historical data are possible alternatives, but they are of marginal validity, mainly because the recent Earth has apparently never experienced the rate of global-mean warming expected to result from the current run up of atmospheric greenhouse gas concentrations. In this sense, the large, but very slow, global-mean climate excursions of the past geological epochs are instructive, but they are far from definitive as guidelines or analogs for the next century.

The above considerations make it clear that there is no competitive alternative to coupled climate models for projecting future climate states and how they might unfold. The physically based climate models have the huge scientific advantage of being fundamentally grounded in known theory that can be evaluated against all available observations. There are indeed reasons to be skeptical of the ability of such models to make quantitatively accurate projections of the future climate states that will result from various hypothesized future greenhouse gas concentration scenarios. Fortunately, the weak points of such climate models can be analyzed, evaluated, and improved with properly focused, process-oriented measurements, complemented by well-posed numerical experiments with various formulations of the climate models. In short, the use of such climate models allows a systematic approach to close the gap between theory and observations of the climate system. No alternative approach comes close.

THE ROLE OF CLIMATE DATA

The availability of climate data in many forms is crucial in the quest to understand, simulate, and predict the behavior of the climate system, how it has changed to date, and how it might change in the future. Such data provide the basics for our characterizations of the time-averaged climate states of various statistics of temperature, pressure, wind, water-vapor amounts, cloudiness, and precipitation as a function of geographical location, time, and altitude. Most importantly, such data provide invaluable information on the natural variability of climate, ranging from seasons to decades.

These data sets have empowered important direct insights on how the climate system works. For example, the observed average daily and seasonal ranges of mean temperature provide important evaluations of our theoretical understanding of how the climate changes in response to changed radiative circumstances (e.g., day to night, summer to winter). On much longer time scales, indirect inferences (or proxy measures such as ice core or tree ring data) provide valuable information on how ice ages and warm epochs appear to depend sensitively on subtle changes to the heating of Earth due to seemingly small variations in the precession of Earth s orientation toward the Sun and in Earth s elliptical orbit around the Sun. Interestingly, the onset of ice ages and their terminations appear to respond more sensitively to these small solar heating changes than are calculated by our current climate models. For example, the ice core records show that ice-age atmospheric CO_2 concentrations decline very slowly as the climate cools, seemingly, a positive ocean–biological feedback effect that is slow enough that we would not expect it to be of significant importance over the next century. Unfortunately, proxy observations of prehistoric climates are still ambiguous enough that they do not justify any confident conclusions that our current climate model projections may be underestimating or overestimating the century-scale global temperature increase due to added greenhouse gases.

Recently, climate data have been the focus of a substantial shift in emphasis. As the climate models have become more mature, we have gained more confidence in their

ability to simulate a future climate change by evaluating their capabilities to diagnose the presence of human-caused climate change already present in the climate record to date. These accelerated efforts have already yielded important insights about how the climate system appears to be responding to added greenhouse gases plus sulfate and carbon particles over the past century or so, as will be discussed later.

Most importantly, however, recent research has revealed important deficiencies in our capability to diagnose such responses accurately. The best models tend to agree in the broadest sense, but can differ substantially when very specific and regional processes are examined. The available data sets have deficiencies that can inhibit the capability to diagnose long-term changes in the climate, particularly so in undersampled regions. Fortunately, our measurements of the global trends in greenhouse gas concentrations and their associated direct infrared radiative effects are very well known. Other potential perturbations of the climate balance, such as effects of sulfate and carbon particles, and changes in heat energy from the Sun, are much more poorly known.

An additional complication arises in our efforts to determine how the climate responds to added greenhouse gases and aerosols. The climate system is naturally noisy, and thus tends to obscure its systematic changes until such changes are larger in magnitude than the background climate noise. By climate noise, we mean the natural fluctuations in, say, the atmospheric temperature even when no external effects are influencing the climate system. For example, the global-mean surface temperature of a climate model or the real world can change by a couple of tenths of a degree Celsius over a 30-year period just due to the interactions between the atmosphere and ocean. If one is looking at a magnitude of expected systematic change of a few tenths of a degree Celsius over a comparable period, it is not surprising that the conclusion can be a bit blurred due to the natural fluctuations. This is why very long climate records are so invaluable in the efforts to understand and diagnose climate change.

Fortunately, careful examination of the characteristics of the systematic changes in climate models, in the presence of their own internally generated climate noise, can also give sharpened insights into how climate change in the real world might be expected to emerge and slowly become ever clearer as time progresses. As the climate-warming signal continues to grow, the interpretive confusion caused by natural climate fluctuations is expected to diminish. In addition, such models can help sharpen our understanding of what capabilities are required to measure and monitor the actual evolving systematic changes in the climate. Without improvements in our current climate measurement systems, our ability to detect climate change and to attribute cause and effect to such changes will remain insufficient.

MODEL HINDCASTS OF THE 20TH CENTURY WARMING

In the previous two sections, we argued that combined use of climate models and climate data is an inseparable requirement for understanding climate change. This strong interdependence is quite evident in the challenge of understanding the climate warming observed over the 20th century.

It is now well known that the global mean surface–air temperature has increased considerably, roughly 0.6 °C over the 20th century, with a substantial amount of that warming occurring over the past couple of decades (Nicholls *et al.*, 1996). Is this observed warming due to natural climate variability, volcanoes, or changes in the Sun s radiant energy? Or is it due to the CO_2 and other greenhouse gases that we have added to the atmosphere? (*see* Climate Change, Detection and Attribution, Volume 1) Why should we be so focused on what has already happened?

The answers to these questions are fundamental to evaluating the credibility of the projections we will present in the next section on expected future climate warming, the warming that we expect to be considerably larger than that measured over the 20th century. An evaluation of the past data from a modeling and theory perspective is the only direct way we currently have of evaluating the skill, or lack thereof, of model-based projections of future climate warming. In recognition of this, the climate community has developed estimates of the past radiative forcings. Because some of the 20th century climate forcings were not directly measured, there is important uncertainty associated with these estimates. Mitchell *et al.* (1995) were the first to perform this type of integration using a physically comprehensive climate model. They used best-available estimates of the greenhouse and sulfate aerosol forcing of climate change. Their experiment has become a standard that a number of groups have followed, including our own Geophysical Fluid Dynamics Laboratory (GFDL) group. This forcing scenario, while highly simplified, captures the essence of much of the known changes in radiative forcing of climate over the past century. This scenario purposely ignored the forcings due to volcanic aerosols, changes in the Sun s luminosity, and ozone depletion. Recently, several groups have made integrations that included some or all of these other forcings (Santer *et al.*, 1996; Tett *et al.*, 1999). However, the message below is not noticeably changed by these presumably more realistic forcing integrations.

For sake of simplicity, we present only the results from the GFDL coupled climate model. Figure 1 shows the Jones *et al.* (1999) compilation of observed global-mean surface–air temperature (solid line) from 1860 through 1999 and an ensemble of six (GFDL) model runs (Delworth and Knutson, 2000; using the Mitchell *et al.*, 1995 scenarios described above). This figure reveals that the apparent magnitudes of the observed natural variability are

comparable with the model-simulated magnitude of natural climate variability. Also, the model captures the run up of global-mean temperatures in the 20th century rather well. Experiment three of the six-member ensemble even captures the observed increase of temperatures from 1915 to 1945. This result suggests that the observed 1915–1945 increase may be attributable to a combination of greenhouse gas increases and to a particular form of natural variability operative during that period, namely, the presence of a natural-variability-induced warming in high northern latitudes in the observations and in ensemble member number three (Knutson *et al.*, 1999). Other factors not included in the model experiments, such as total solar irradiance variations, may also have contributed to the 1915–1945 warming period.

This line of reasoning is quite plausible, although it falls a bit short of the definitive proof about global warming that some would require of the 20th century information. The picture gets a bit fuzzier when one considers the uncertainties in the IPCC greenhouse gas plus sulfate particle scenarios used in these calculations. However, we argue that this retrospective exercise serves as a good test for projections over the next century, when one considers that there is still a complete lack of a viable natural-variability-only hypothesis to explain the observed 20th century warming.

We further argue that the additional model results of 20th century warming from Mitchell *et al.* (1995) and Haywood *et al.* (1997) provide a further check on the credibility of these models for use in projections of future climates. It must be cautioned, however, that these 20th century tests

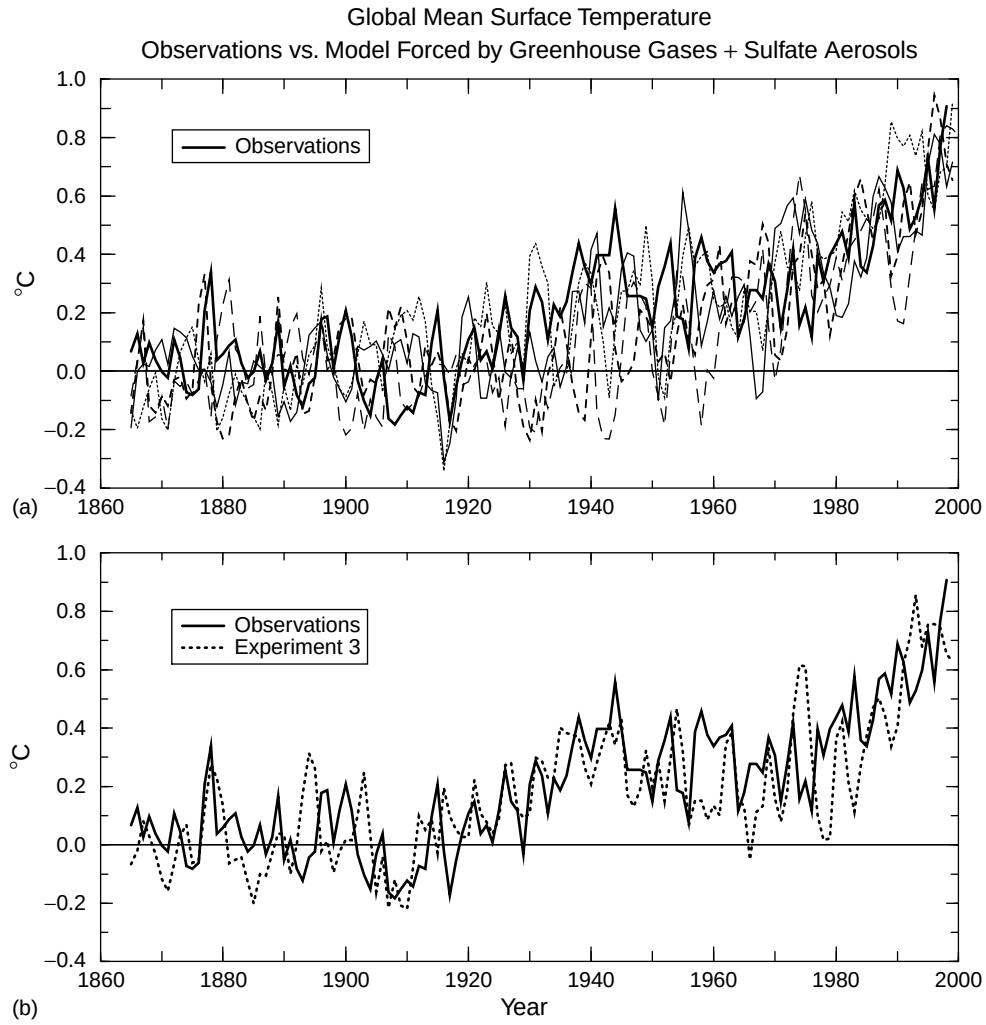

Figure 1 Time series of global mean surface temperature, 1865 to present day. The thick line in both panels are the observations. The thin lines are the various members of five model integrations. Four model integrations are shown in (a). The time series from experiment 3 is shown in (b). Over land, surface–air temperature is used to compute the global mean. Over the oceans, sea surface temperature is used. Units are deviations from the 1880–1920 average. In constructing the global averages, the model output is sampled only at times and locations where observations are available

do not tightly constrain model projections of future climate warming. It is still possible, for example, to imagine that the world s best model-based evaluations of the expected 3 °C global-mean climate warming due to $2 \times CO_2$ could be high or low by as much as 1.5 °C. We do estimate, however, that the likelihood of model errors of this magnitude is now less than 10% (Mahlman, 1997). The main basis for this assertion is that we currently lack either observational insights or published self-consistent theoretical arguments that can produce departures of the models warming levels as much as 1.5 °C from the average warming levels obtained by the most tested and evaluated models.

We thus assert that future climate change projections using such models are likely to yield results that will resemble what will happen in the real world with sufficient credibility, that the global warming issue will eventually be taken very seriously.

MODEL PROJECTIONS FOR THE 21ST CENTURY

To project changes in climate over the 21st century, we need to project both the changes in the radiative forcing of the planet and the climate response to those changes. The changes in the future radiative forcing are controlled by the emissions of greenhouse gases, sulfate aerosols, and other radiatively active substances. The future emissions of these substances depend on global population growth, technological developments, CO_2 emissions mitigation decisions, economic changes, and a host of other societal decisions. These factors all have a great deal of uncertainty associated with them. In 1992, the IPCC developed a set of emission scenarios by considering reasonable estimates of many of these factors. Of the 1992 emission scenarios, the IS92a scenario (Houghton *et al.*, 1992) has become a *de-facto* standard used by the modeling community to investigate future climate changes. In 2000, the IPCC developed a new set of emission scenarios, published in the so-called Special Report on Emission Scenarios (SRES) scenarios (Nakicenovic *et al.*, 2000). The SRES scenarios are grouped into four families where each family has an associated story line for the various assumed factors that affect the emission rates. The IS92a scenario, and many of the new SRES scenarios, produce increases in radiative forcing during the 21st century that lie between those of an effective 1% $year^{-1}$ atmospheric CO_2 increase and an effective 0.5% $year^{-1}$ CO_2 increase.

In the discussion below, the model projections shown are based on models forced using either the IPCC SRES A2 or B2 scenarios, or an idealized 1% $year^{-1}$ scenario leading to doubling ($2 \times CO_2$) or quadrupling ($4 \times CO_2$) of the atmospheric CO_2 concentration relative to pre-industrial levels, then held constant thereafter. For the remainder of this section, we purposely ignore the uncertainty associated with the forcing. Although the uncertainty in the future radiative forcing remains substantial for longer time scales, alternative forcing scenarios can be usefully explored by interpolating global-average changes logarithmically between the $2 \times CO_2$ and $4 \times CO_2$ model experiments. The time-dependent model response uncertainty for a given scenario arises from uncertainties associated with estimates of the actual climate response, which are mainly related to the changes in radiative properties associated with clouds (both in their distribution and changes in their direct radiative properties), and with uncertainties associated with the oceanic heat uptake rate.

Oceanic heat uptake rate is important for determining the climate changes during the time when the radiative forcing is changing. After the radiative forcing becomes steady and as the ocean temperature comes progressively nearer to equilibrium with that forcing, the oceanic heat uptake rate becomes less and less important in determining the final climate change. During the time when the radiative forcing is changing in time, a model with a relatively large (small) oceanic heat uptake rate will have a smaller (larger) surface–air temperature response and a larger (smaller) amount of sea level rise (considering only thermal expansion) in comparison with the typical climate model, all other factors being equal. Because of their large heat capacity, the oceans tend to delay the surface–air warming caused by the increases in the radiative forcing. In addition, the strength of the various feedbacks (water vapor, snow–ice albedo, etc.) is dependent on the magnitude of the surface temperature changes (Hansen *et al.*, 1984). Therefore, the still uncertain oceanic heat uptake rate will play an important role in determining the magnitude of the time evolving climate warming over the 21st century.

As the climate responds to the increasing atmospheric concentrations of greenhouse gases, different parts of the climate system warm at different rates. This is due to the differing thermal heat capacities characterizing the climate system. The land surface and atmosphere have a relatively small heat capacity and a response time scale of about 1 month. The uppermost part of the ocean (the so-called oceanic mixed layer) has a moderate heat capacity and a response time scale of about 10 years, while in the deepest parts of the ocean, the full warming response requires roughly 1000 years.

To illustrate the various responses of the climate system to increasing greenhouse gases, we will show only the surface–air temperature response and the sea-level response. The initial surface–air temperature response has a time scale of about 10 years, indicating that it is closely related to the response time of the upper part of the ocean (mixed layer).

In the model simulations, the calculated global-mean surface–air temperature rises by about 2.25 °C between the years 2000 and 2100 when using the SRES B2 scenario

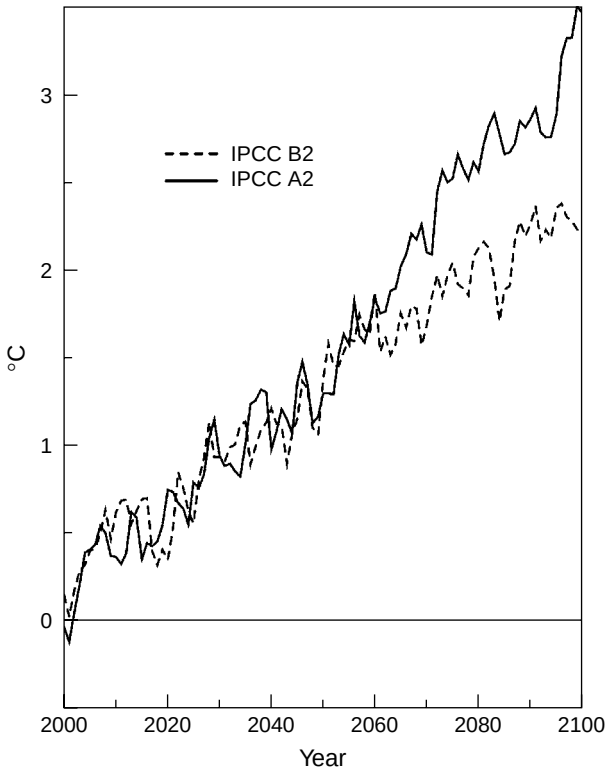

Figure 2 GFDL model calculations of global mean surface–air temperatures for two IPCC SRES radiative forcing scenarios: A2, an essentially business as usual scenario and B2, a middle of the road CO_2 emissions mitigation scenario. Temperatures are expressed as a departure from the temperature typical for the period around the year 2000

in the GFDL medium-resolution R30 (2.25° latitude by 3.75° longitude) coupled model; the calculated 21st century warming is 3.5 °C for the A2 scenario (Figure 2). The magnitude of this response is similar to that found in other coupled models (Houghton *et al.*, 2001). This calculated future warming is much larger than the roughly 0.6 °C warming observed and calculated for the past century (see the previous section). Figure 3 indicates that the higher Northern Hemisphere latitudes warm more than the lower latitudes. The land areas warm more than the adjacent oceans. There are minima in the warming in the North Atlantic Ocean near Greenland/Iceland and in the Circum-Antarctic Ocean. These general characteristics can be found in both the SRES A2 and B2 distributions (Figure 3).

The exact details (i.e., the specific amount) of the expected warming remain rather uncertain. Over the continents, the surface–air temperature warming is influenced by local changes of aerosol emissions, clouds, vegetation, etc. However, the gross patterns, as noted in the preceding paragraph, are not as uncertain and tend to be more related to changes in the global-mean surface–air temperature rather than the local differences in the forcings.

As the climate warms, an intensified hydrological cycle results, i.e., there is more global-mean precipitation and evaporation. This is the result of the warmer atmosphere being able to hold more water vapor. More water vapor in the atmosphere results in increased poleward water vapor transport, so that high-latitude precipitation increases substantially. Over most mid-continental areas, the warmer temperatures cause the soil to become drier in the summer, while the soil becomes wetter in winter due to increased precipitation.

The warming of the atmosphere makes the modeled oceans more stable at all latitudes. In low latitudes, the ocean is made more stable due to the strong heating of the upper layers. In high latitudes, where much of the vertical mixing in the ocean takes place, the precipitation-caused increase in lower-density fresh water at the ocean s surface also makes the ocean more stable. This increased stability in the world s ocean further inhibits vertical mixing, which can act to change the ocean circulation. The warming of the atmosphere and sea surface also allows more latent-heat energy to be available in smaller-scale storms. Studies have indicated that, in the warmer world, the strongest hurricanes and typhoons would tend to get even stronger (Knutson *et al.*, 1998). Finally, surface–air temperatures are expected to warm more during nighttime than in daytime (Houghton *et al.*, 1995).

These changes in the physical climate system will lead to changes in other systems as well. For example, the modeled heat index (the apparent temperature due to a combination of sensible temperature and moisture felt by the human body) greatly increases in the warm, humid regions of the planet (Delworth *et al.*, 1999). The combination of heat and moisture increases makes the summertime heat index increases in the moister climate roughly 50% larger than for just the sensible temperature increases.

The final part of this discussion centers on how the climate may be expected to change over the 21st century and centuries beyond. Due to the long response times in the deep ocean, the warming climate is still well short of equilibrium with today s radiative forcing. This means that, without any further increase in the radiative forcing, Earth s climate would continue to warm over the next few centuries as the entire ocean slowly warms to reach equilibrium with the warmer atmosphere. This illustrative calculation of future warming, which assumes a situation that is effectively impossible because it would allow for no changes from today s radiative forcing due to added greenhouse gases and aerosols, is defined here as the absolute future warming commitment beyond the 0.6 °C that has already been experienced. There are corresponding future commitments for all other climate variables as well. Hansen *et al.* (1984) concluded that the magnitude of the absolute future warming commitment beyond 1984 is about 1 °C. This is significantly larger than the

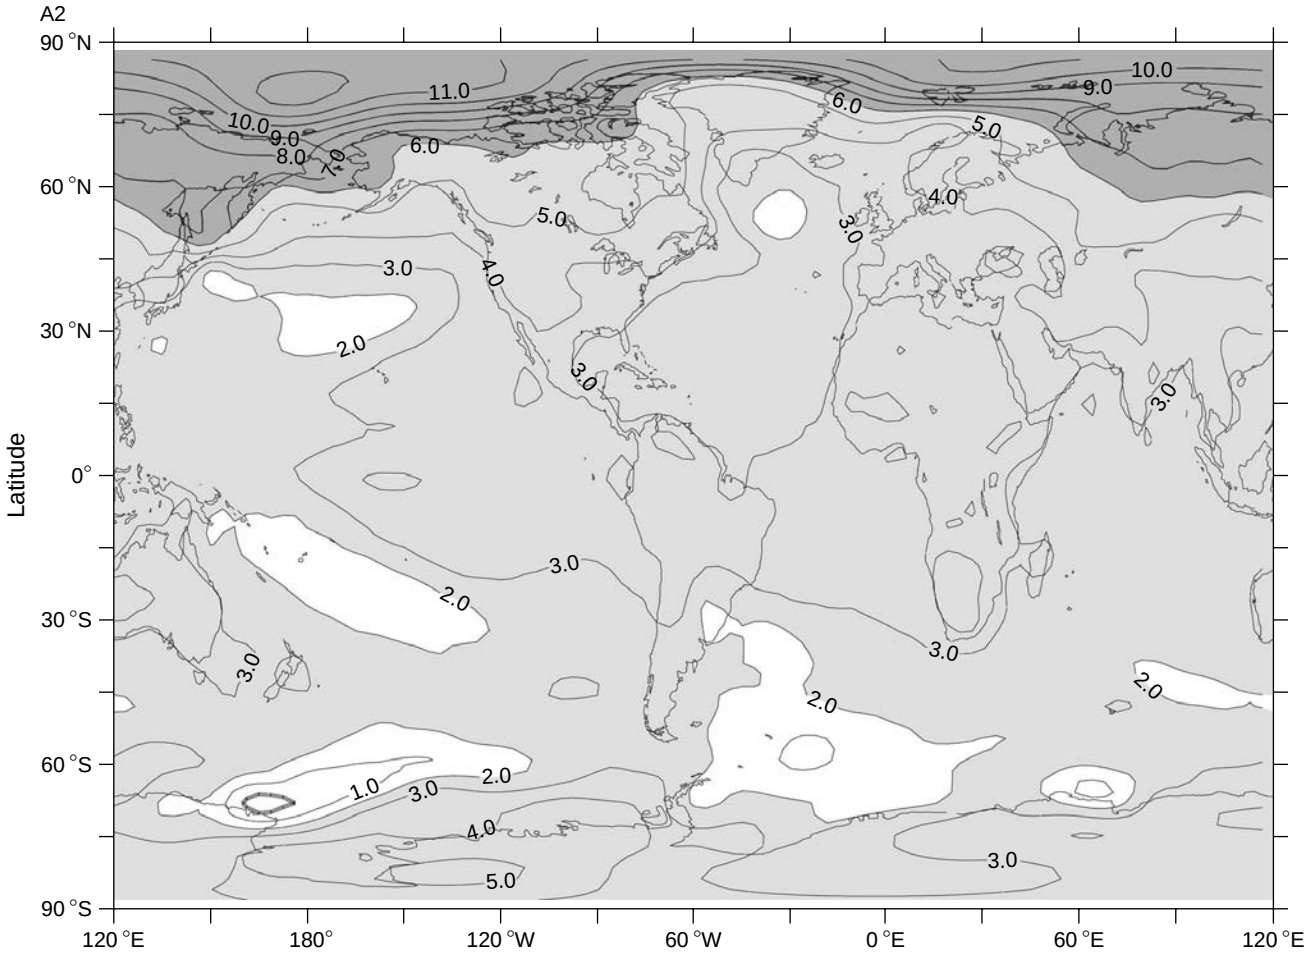

Figure 3 GFDL model-calculated regional distribution of surface–air temperature changes over the 21st century using the IPCC SR A2 and B2 scenarios described in Figure 2. The light shading range is from 2 to 6 °C. The dark shading covers areas greater than 6 °C. The contour interval is 1 °C

observed warming during the 20th century, roughly 0.6 °C. Remember that these absolute future warming commitment calculations implicitly assume very small future emissions, a nearly impossible scenario, but they serve to illustrate the major societal challenges required to keep future warming amounts from being much larger than the Earth has experienced to date.

As mentioned earlier, sea level rise has a very long response time scale due to its close relationship to the deep-ocean temperature. During the 21st century, sea level is projected to rise by 9–88 cm, due mainly to the thermal expansion of the sea water as it slowly warms (Houghton *et al.*, 2001) (see also Figure 4). Generally for a given mass of water, warmer water occupies a larger volume than colder water. This thermal expansion of sea water will probably be the largest contributor to sea level rise over the next century, but we cannot discount the possibility that melting land ice could also contribute substantially (*see* Sea Level, Volume 1).

It is unclear what the net effect on sea level will be from changes in the large Antarctic and Greenland ice sheets. The general warming may cause parts of the ice sheets to melt at the lower elevations. However, most of the ice sheet is well above sea level, where the initial likely effect of the warming may be to increase snowfall. Therefore, the net effect of changes in Antarctic and Greenland ice volume on sea level could be small over the 21st century. Beyond 2100, however, the story begins to change. At some point in the future, if the climate continues to warm, substantial parts of these great ice sheets could melt. The magnitude of the sea level rise estimated from melting all of the Greenland ice sheet is about 7 m, while the West Antarctic ice sheet would contribute about 4–5 m.

Finally, it is useful to ask what happens to the climate after the radiative forcing becomes constant (i.e., after atmospheric concentrations of human-produced radiatively active substances stop changing). Typically, in stabilization

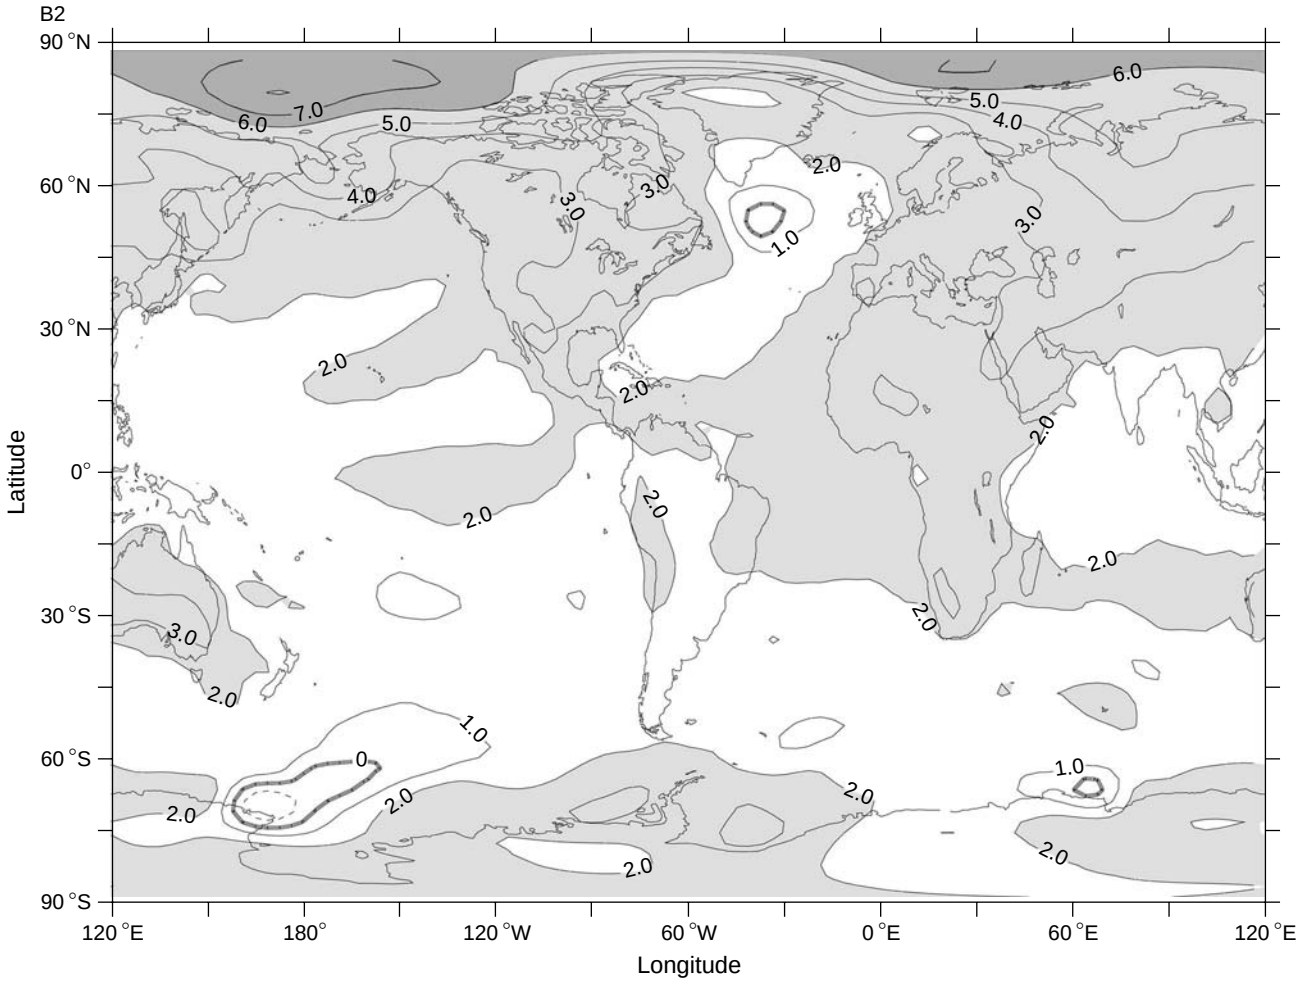

Figure 3 (*Continued*)

integrations, the atmospheric CO_2 concentration increases up to a certain value (e.g., $2 \times CO_2$) and then is hypothesized to remain constant for the remainder of the integration. Because this type of integration involves integrating the model for very long time periods (at least several centuries), only a few integrations have been performed using coupled climate models. Furthermore, no standard emission scenarios have been used for forcing these model runs and most have used idealized stabilization values ($2 \times CO_2$, $3 \times CO_2$, or $4 \times CO_2$, for example). In these integrations, simple CO_2 changes are used to represent the radiative forcing changes of all of the greenhouse gases and their aerosol offsets (equivalent CO_2). Model experiments, where the coupled system is allowed time to reach equilibrium with the radiative forcing, clearly show the response times of its various components (Manabe and Stouffer, 1994).

Even after the radiative forcing becomes constant, the calculated surface–air temperatures continue to increase for many centuries (Figure 4). The rate of warming after stabilization is relatively small (• 0•3 °C century^{-1}). However, the total warming after the radiative forcing stabilizes can be significant (• 1 °C) because the warming continues for many centuries.

The slow rate of surface–air temperature increase occurs as the heat anomaly slowly penetrates to depth in the ocean. The rate of penetration is dependent on a model s simulation of ocean overturning and treatment of small-scale vertical mixing processes. It appears that much of the modeled difference in the oceanic heat uptake are due to differing treatments of ocean mixing, thus explaining much of the difference in the modeled rates of surface warming.

In these stabilization experiments, sea level continues to rise for more than 1000 years after the radiative forcing becomes constant (just due to thermal expansion of sea water). The total sea level rise computed in this and other models is quite large, nearly 2 m for $2 \times CO_2$ and nearly 4 m for $4 \times CO_2$. The potentially large additional effects of melting ice sheets have not been included here because of the large uncertainty in their modeled simulations.

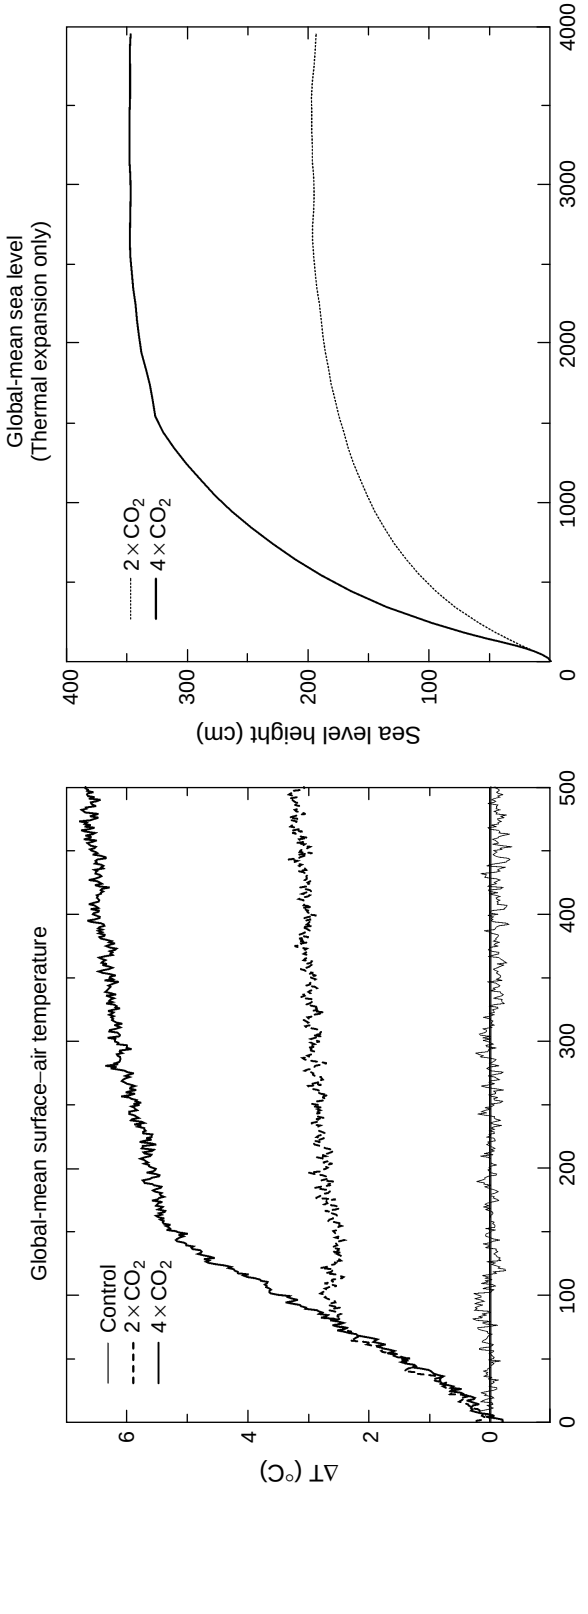

Figure 4 Three GFDL model experiments using idealized forcings. The first (thin solid line) assumes no forcing changes for a model that is in equilibrium. The second (dotted lines) assumes a 1% per year increase of atmospheric CO_2 up to a doubling over pre-industrial levels. The third (thick solid lines) assumes a 1% per year increase of CO_2 up to a quadrupling of atmospheric CO_2. (a) Global-mean surface–air temperature. (b) Global-mean sea level (assuming sea level rise is due to thermal expansion only)

The totality of all the observations of the climate system, the variety of coupled climate models used, and the still-notable lack of viable alternative hypotheses to the model calculations, all lead to a simple conclusion. The warming of the climate due to human-emitted greenhouse gases and aerosols is a very real phenomenon that will not go away. The specific details of the expected climate changes remain elusive. However, the major ways that the climate is expected to change are rather well framed out. A significant amount of climate warming is already committed in the 20th and 21st centuries. Very large climate changes can still be prevented if global society does eventually decide to reduce emissions of CO_2 and other greenhouse gases substantially. Such decisions are fundamentally social and political, thus lying well beyond the realm of the climate-change science presented here.

ACKNOWLEDGMENTS

The authors are indebted to Syukuro Manabe because of his inspirational leadership and mentoring to both of us on this still daunting challenge of climate change. We are grateful to Anthony Broccoli, Steven Carson, Thomas Knutson, Michael MacCracken, Ted Munn, John Perry, and Betty Williams for their valuable improvements to the manuscript.

Depletion of Stratospheric Ozone

DONALD J WUEBBLES

University of Illinois at Urbana-Champaign, Urbana, IL, USA

Human activities have had a devastating effect on the concentration and distribution of stratospheric ozone over the last few decades. The distribution of ozone that is naturally formed in the stratosphere is often referred to as the ozone layer. This layer protects life on Earth from harmful levels of solar ultraviolet (UV) radiation. Therefore, a decrease in the amount of ozone would allow an increase in the amount of the UV radiation from the Sun to reach the Earth's surface. Atmospheric measurements have shown that the depleted levels of ozone have indeed increased the amount of UV radiation at the surface. Corresponding to this increase in UV radiation are projected signi cant impacts on ecosystems and human health, including increases in incidences of skin cancer, eye cataracts, damage to genetic DNA, and suppression of the ef ciency of the immune system. It is the concerns about increased biologically harmful levels of UV from the decreasing levels of ozone that have largely been the driver for policy actions to protect the ozone layer.

The amounts of ozone in the stratosphere vary naturally throughout the year as a result of production and destruction processes, and as a result of winds and other transport processes that move the ozone molecules around the planet. In addition, changes in ozone occur associated with changes in the solar radiation reaching the Earth during the 11-year solar cycle and with various events such as large explosive volcanic eruptions. However, natural causes cannot explain the large observed decrease in ozone over recent decades. The signi cant global decrease in stratospheric ozone since the 1970s is well correlated with increasing amounts of chlorine (Cl) and bromine (Br) in the stratosphere. The sources of this Cl and Br are chloro uorocarbons (CFCs) and other halocarbons produced industrially for a variety of uses such as refrigerants in refrigerators, air conditioners and large chillers, as propellants for aerosol cans, as blowing agents for making plastic foams, and as solvents for dry-cleaning and for degreasing of materials. Atmospheric measurements have clearly corroborated theoretical studies showing that the Cl and Br released from the destruction of these halocarbons in the stratosphere are reacting to destroy ozone.

Ozone is also a greenhouse gas, having a large infrared absorption band in the atmospheric window at 9.6 μm. It is the balance between the solar and infrared radiative processes that determines the net effect of ozone on climate. Decreases in ozone in the stratosphere above about 30 km (roughly 18 miles above the Earth's surface) tend to increase the surface temperature as a result of the increased absorption of solar radiation, effectively increasing the solar energy that warms the Earth's surface. Below about 30 km, decreases in ozone tend to cool the surface temperature, because the infrared greenhouse effect dominates in this region. Scienti c analyses have shown that the decrease in ozone over recent decades has had a cooling effect, counteracting a fraction of the warming effect over this time from increasing concentrations of carbon dioxide and other greenhouse gases.

Over coming decades, the stratospheric ozone layer should gradually recover as a result of international actions taken to control the production and use of CFCs and other halocarbons under the Montreal Protocol. While ozone concentrations slowly recover, scientists and policymakers will need to work together to ensure that new problems do not develop as a result of the introduction of new chemicals into the atmosphere. Attention will also need to be devoted to interactions with industry and governments to ensure that the potential introduction of commercial supersonic aircraft, which will have cruise altitudes in the stratosphere, does not have a signi cant impact on ozone. Deeper understanding is also needed about the potential effects on the ozone layer of various natural events, such as volcanic eruptions and solar events, and possible human activities, including nuclear explosions.

FORMATION AND DESTRUCTION OF OZONE

The stratospheric ozone layer is an important natural feature of the atmosphere. For example, the formation of the ozone layer is generally believed to have played an important role in the development of life on land. The accumulation of oxygen molecules in the atmosphere as a result of the emergence of life in the ocean allowed for the production of ozone. Gradually the increasing levels of ozone led to the formation of the stratosphere, a region of the upper atmosphere where temperature increases with altitude largely as a result of the absorption of solar radiation by ozone. The resulting screening of lethal levels of solar UV radiation by the ozone layer is thought to have been important to allowing life to migrate from the oceans onto land.

Ozone (O_3) is composed of three oxygen atoms and is a gas at atmospheric pressures and temperatures. Although only about 15% of the atmospheric mass is in the stratosphere, approximately 90% of the atmospheric ozone is in the stratosphere. Most of the remaining ozone is in the troposphere, the lower region of the atmosphere extending from the Earth s surface up to roughly 10 km at mid-latitudes and 16 km in the tropics. Figure 1 shows a typical vertical ozone distribution for mid-latitudes. At these latitudes, the peak concentration of ozone occurs at altitudes between 20 and 30 km. At high latitudes, the peak occurs at lower altitudes, largely as the result of atmospheric transport processes and the lower height of the tropopause (the transition region between the troposphere and stratosphere).

How is Stratospheric Ozone Produced?

Without human intervention, the stratospheric ozone layer would be produced and destroyed through natural processes. In 1930, Sydney Chapman of Oxford University developed a photochemical theory for the formation and destruction of ozone based on a scheme involving only oxygen. Various experiments since then have verified that the production of ozone occurs as a result of the chemical reactions in his basic scheme.

Production of ozone in the stratosphere results primarily from photodissociation of oxygen (O_2) molecules (*see* Photochemical Reactions, Volume 1). The breaking of the molecular bond by high-energy solar photons at wavelengths less than 242 nm results in oxygen atoms that generally react rapidly with an oxygen molecule to form ozone. The sequence of reactions to form ozone is represented as:

$$O_2 + h\nu \ (\lambda < 242\,\text{nm}) \longrightarrow O + O \quad (1)$$

$$O + O_2 + M \longrightarrow O_3 + M \quad (2)$$

where $h\nu$ represents a photon, λ is wavelength, and M is a third body, normally a nitrogen (N_2) or oxygen (O_2) molecule, the primary components of air (*see* Stratosphere, Chemistry, Volume 1).

Because the atmosphere is uniformly filled with oxygen molecules, most of the ozone is generated where there is a balance between the decreasing atmospheric density with altitude and where there is available UV solar radiation in the wavelength region less than 242 nm. This primarily occurs in the upper stratosphere.

The high-energy solar radiation needed to produce ozone is largely absorbed in the stratosphere, resulting in the production of the ozone layer. Too little UV radiation reaches the troposphere for it to be a major cause of ozone production in this region. In contrast, the smaller amount of ozone in the troposphere is largely formed through a series of chemical reactions, generally referred to as smog reactions. The transport of stratospheric ozone down into the troposphere is also important to the budget of tropospheric ozone.

Although the primary production of ozone occurs in the tropics and primarily above 30 km altitude, the largest concentrations of ozone occur at lower altitudes, as shown in Figure 1, and at higher latitudes. The combined importance of chemical and transport processes in determining the ozone distribution is demonstrated in Figure 2, which shows the vertically-integrated total column of ozone as a function of latitude and season, based on ground-based and satellite observations. The minimum in total ozone actually occurs in the tropics, while the maximum amounts in total ozone occur in late winter and early spring in both hemispheres. The ozone peak is closer to the pole in the Northern Hemisphere than the peak in the Southern Hemisphere, largely due to the differences in winds and other processes affecting the transport of ozone within the two hemispheres. Also seen in the Antarctic region is the large ozone destruction in their springtime, termed the *Antarctic ozone hole*, to be discussed later. Variations in total ozone with longitude are generally small in comparison with variations with latitude; however, recent decreases in ozone during the Northern Hemisphere winter and early spring associated with ozone hole type processes have occurred at specific longitudes where the polar winter vortex was occurring in that hemisphere.

The total column amount of ozone in Figure 2 is reported in Dobson units, which were named after George Dobson of Oxford University, a pioneer in measuring atmospheric ozone. One Dobson unit equals one milliatmosphere–cm. The average amount of ozone around the globe is 300 Dobson units. Although ozone plays a vital role in the atmosphere, the molecules of ozone are exceedingly rare, accounting for fewer than 10 of every million molecules of air. If all of the ozone in the troposphere

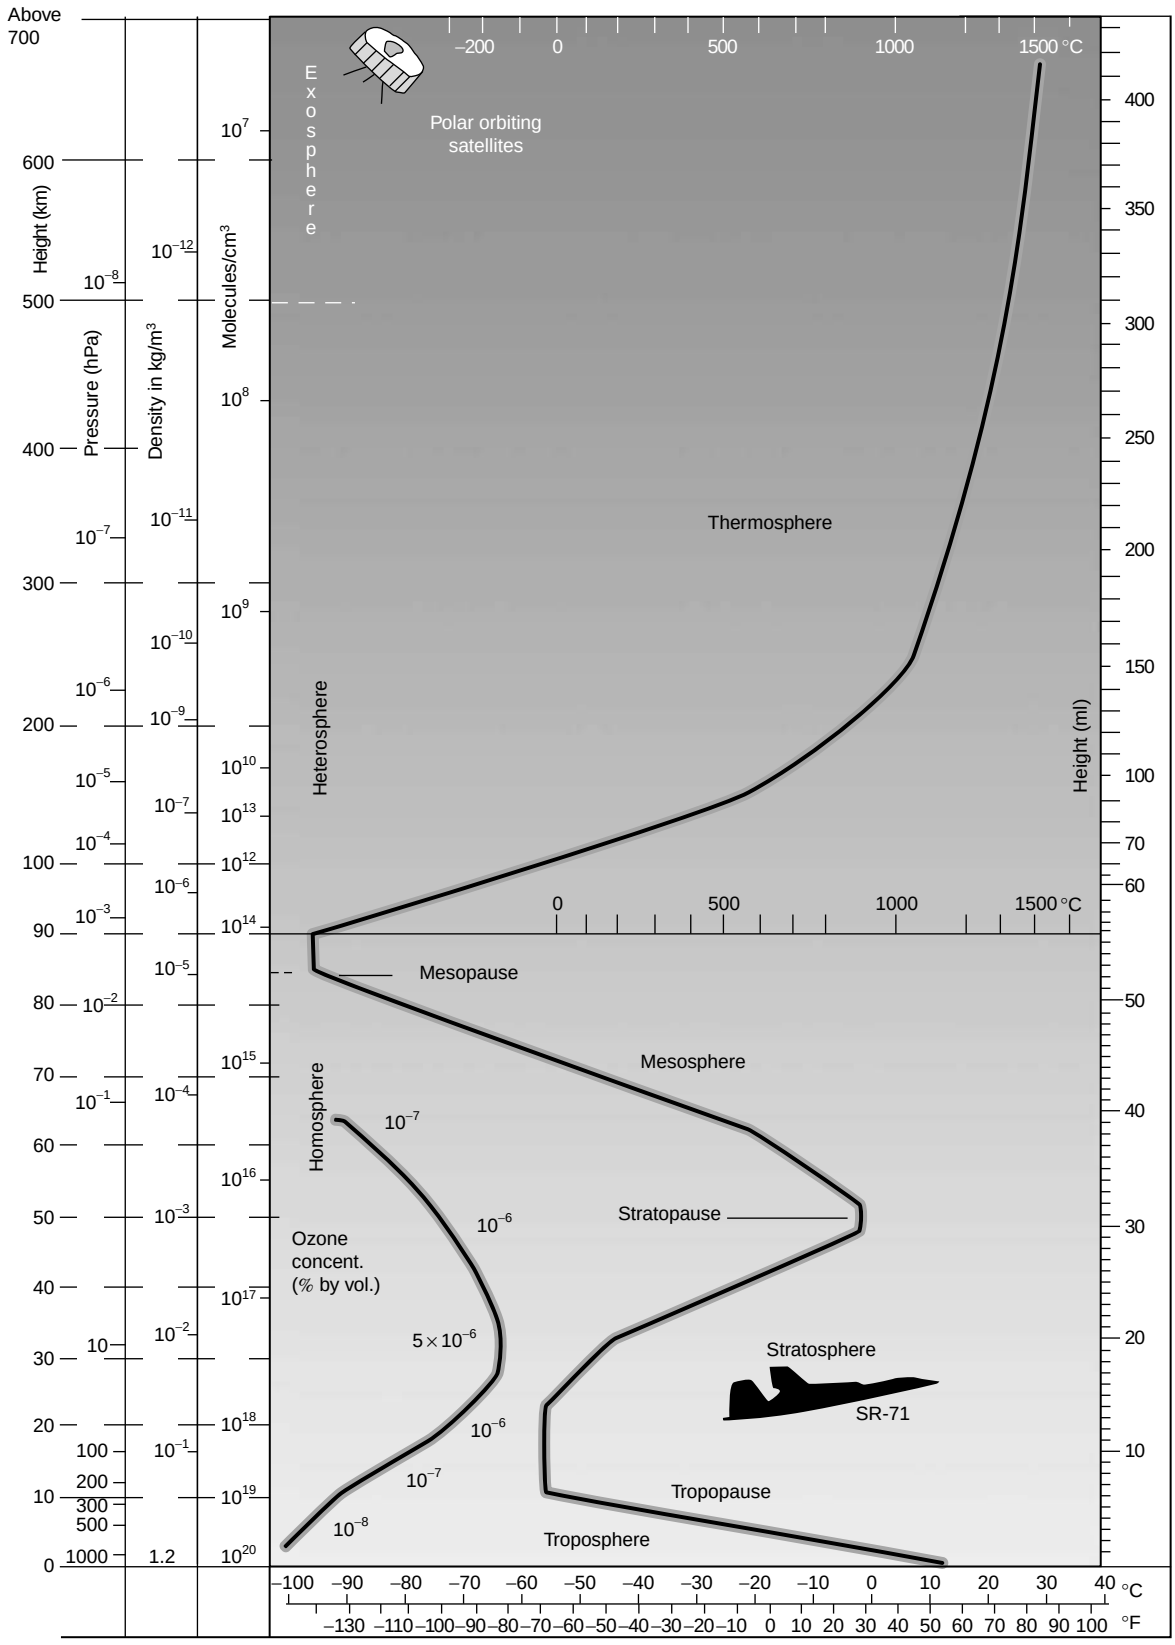

Figure 1 The typical variation in temperature and concentration of ozone with altitude in the troposphere and stratosphere over mid-latitudes in the Northern Hemisphere

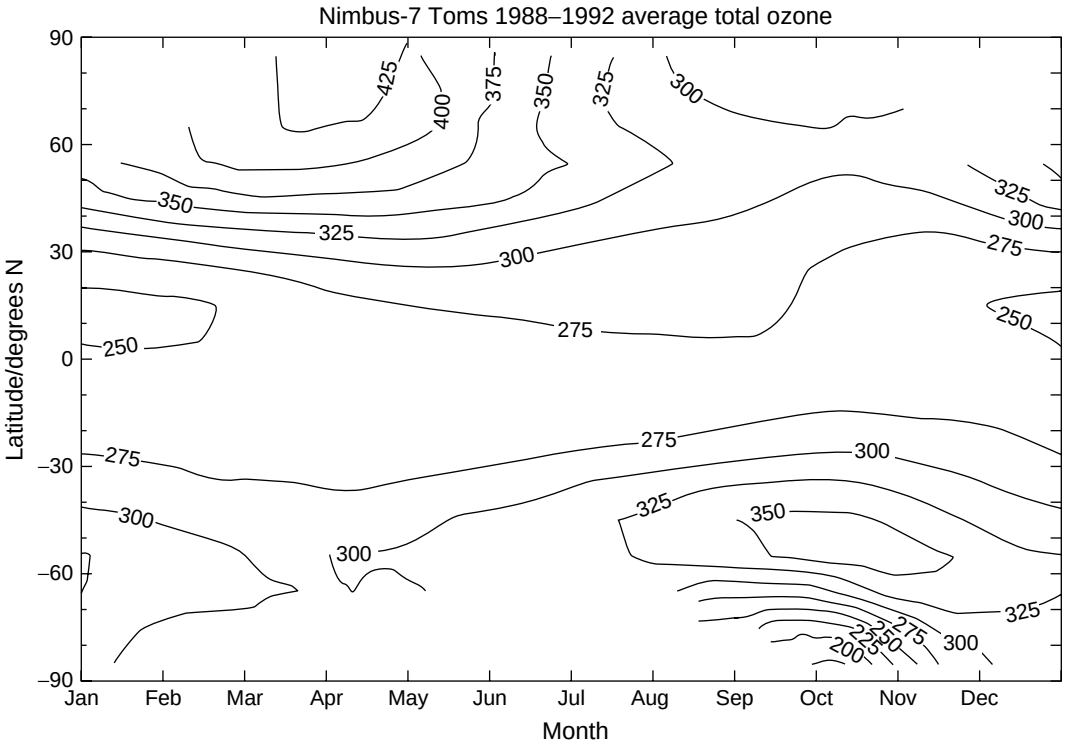

Figure 2 Integrated column amount of ozone, referred to as the total ozone column, in Dobson units, as a function of latitude and season, based on observations taken by the total ozone mapping spectrometer (TOMS) satellite (McPeters *et al.*, 1996)

and stratosphere were brought to sea level and spread evenly around the globe, it would fit in a layer only about 3 mm thick.

How is Ozone Destroyed?

Without natural ozone destruction, most of the oxygen in the stratosphere, and perhaps throughout the atmosphere, would eventually be converted to ozone. Such concentrations of ozone would be intolerable to many forms of life on Earth, both because of the direct toxicity of ozone and because no UV radiation would reach the Earth s surface.

Although Chapman s oxygen-based chemical scheme did not capture the reactions actually responsible for the primary destruction of ozone, he did recognize that ozone and atomic oxygen rapidly interchange with each other, while the sum of the two is linked to much slower chemical processes. This led to the conceptual picture of thinking of ozone destruction in terms of destruction of the odd-oxygen.

Ozone photodissociates at UV and visible wavelengths to produce O and O_2. However, because the oxygen atom will generally react to reform ozone, this mechanism produces no net change in the amount of odd-oxygen.

The destruction of ozone and odd-oxygen in the stratosphere occurs mainly through catalytic reactions with other gases. In the stratosphere, important catalysts for ozone destruction include nitric oxide (NO), hydroxyl (OH), chlorine (Cl) and bromine (Br). Such gases can be directly substituted for X in the following catalytic mechanism:

$$X + O_3 \longrightarrow XO + O_2 \quad (3)$$

$$XO + O \longrightarrow X + O_2 \quad (4)$$

These reactions result in the net reaction of $O + O_3$ being converted to two oxygen molecules. Because gas X is recycled through these reactions, it continues to destroy ozone until some other reaction converts X to a less reactive form, such as nitric acid or hydrogen chloride. In this way, a single Cl atom can lead to the net destruction of thousands of ozone molecules before it becomes tied up. Because of such cyclic reaction mechanisms, relatively small concentrations of reactive Cl and other catalytic species in the stratosphere can have a significant impact on the amount and distribution of stratospheric ozone (*see* Stratosphere, Chemistry, Volume 1).

In addition to the mechanism described by Equations (3) and (4), there are a number of other catalytic mechanisms also affecting ozone. These must all be considered in evaluating the effects of human-related emissions on ozone. In addition, some gases, like iodine (I), that are not present in significant amounts in the current atmosphere, are now known to react catalytically with ozone,

and require careful analysis to prevent future ozone destruction if chemicals containing these atoms are considered for use.

The total amount of ozone in the stratosphere would remain fairly constant (relative to well-recognized seasonal variations) were there no change in the destruction rate and the transport of ozone out of the stratosphere. However, increasing inputs of Cl and Br into the stratosphere over the past few decades have changed the balance. As an analogy, the production and destruction of ozone is akin to the faucet and drain in a tub of water. As long as the destruction is constant (i.e., the size of the drain remains the same), the ozone amount (i.e., the level of the water in the tub) will remain relatively constant. However, the increasing amount of Cl and Br act, in effect, to increase the size of the drain in the tub. As a result, the water level, or the amount of ozone, will decrease.

ATMOSPHERIC GASES AFFECTING OZONE

Without human intervention, concentrations of gases important to concerns about stratospheric ozone would be expected to change slowly, as indicated by ice core measurements of gases like methane (CH_4) for concentrations prior to the 20th century. These same ice cores show that there were very low amounts, if any at all, of the Cl-containing CFCs and Br-containing halons in the atmosphere before the 20th century. Since the beginning of the industrial age, however, emissions associated with human activities have risen rapidly. Agriculture, industry, waste disposal, deforestation, and fossil fuel use have been producing increasing amounts of carbon dioxide (CO_2), CH_4, nitrous oxide (N_2O), CFCs and other important gases. Due to increasing emissions, atmospheric levels of these gases have been increasing at an unprecedented rate, raising concerns regarding the impacts of these gases on ozone and climate. While all of these gases have had some impact on stratospheric ozone, some like the CFCs and other halocarbons have been particularly effective at depleting ozone.

The Growth in Halocarbon Concentrations

Several halocarbons have been largely responsible for stratospheric ozone loss over recent decades. Halocarbons containing Cl and/or Br are of particular concern with regard to destruction of stratospheric ozone (*see* Halocarbons, Volume 1). Amongst the most potent halocarbons in the current atmosphere are the CFCs CFC-11 ($CFCl_3$) and CFC-12 (CF_2Cl_2) (*see* Chloro uorocarbons (CFCs), Volume 1). Because of their additional importance as greenhouse gases that can affect climate, a number of halocarbons are of particular concern. With the exception of the naturally occurring fractions of methyl chloride (CH_3Cl) and methyl bromide (CH_3Br), all of the halocarbons in the atmosphere are thought to be a result of human activities. Their inertness and long lifetimes in the atmosphere have made them attractive chemicals for use as propellants, refrigerants, fire retardants, and other industrial applications.

All of the CFCs, halons and other halocarbons that affect stratospheric concentrations of Cl and Br have the common feature of not being soluble to any significant degree in water. On the other hand, sea salt and other Cl-containing emissions at the Earth s surface, such as the emissions of Cl gas from swimming pools or HCl from a variety of sources, are generally water-soluble; this Cl tends to be rapidly removed from the atmosphere by precipitation. Atmospheric measurements have confirmed that concentrations of the water-soluble chlorides decrease rapidly with altitude in the troposphere. Volcanic eruptions sometimes contain Cl, generally as HCl, that could be directly injected into the stratosphere; however, it appears that this Cl is removed before it reaches the stratosphere by processes associated with such eruptions. Sulfur emissions in explosive volcanic eruptions can and do affect ozone through heterogeneous reactions that occur on the resulting sulfuric aerosols.

All of the fully halogenated CFCs have long atmospheric lifetimes. The lifetime of CFC-11 is about 50 years, while the lifetime of CFC-12 is about 102 years. The long atmospheric lifetimes of the CFCs help make these compounds of particular concern to ozone. As first pointed out by F Sherwood Rowland and Mario Molina of the University of California at Irvine (*see* Molina, Mario J, Volume 1; Rowland, F Sherwood, Volume 1), the long lifetimes of CFCs mean that these molecules will not be destroyed until they reach the stratosphere, generally by photodissociation, thus releasing their Cl right where it can most readily affect the ozone concentration.

Measurements of CFCs and other compounds by the US National Oceanic and Atmospheric Administration s (NOAA) Climate Monitoring Diagnostic Laboratory at sites throughout the world are shown in Figure 3. CFC-11 and CFC-12 have the highest atmospheric concentrations, at 0.26 and 0.53 parts per billion by volume (ppbv), i.e., the number of molecules per one billion molecules of air, respectively. The tropospheric concentrations of both of these gases were increasing at about 4% year^{-1} in the early 1990s, but the rates have now slowed appreciably. The concentrations of CFC-11 and several other halocarbons controlled under the Montreal Protocol have already started to decline. The use of these compounds has diminished greatly, with all but essential applications being banned by the beginning of 1996. The atmospheric concentrations of several other halocarbons have, until recently, been growing at even faster rates than CFC-11 and CFC-12. For example, the concentration of CFC-113 ($C_2F_3Cl_3$) was increasing about 10% year^{-1} in the early 1990s, but its rate of rise

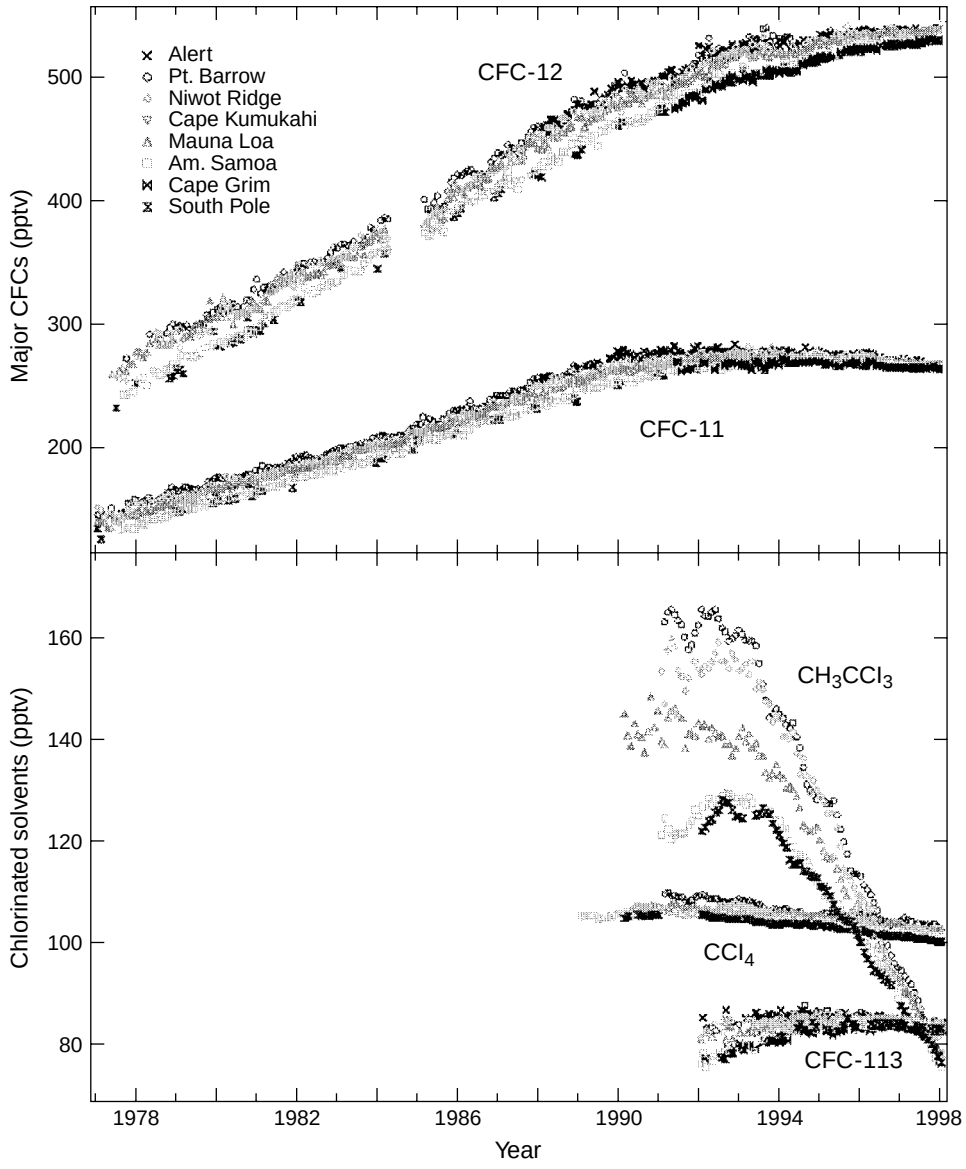

Figure 3 Changes over time of measured CFC concentrations (in parts per trillion by volume, pptv), showing a sharp rise over last few decades, and then the beginning of a decline in recent years. Measurements were taken by the NOAA Climate Monitoring and Diagnostics Laboratory (J Elkins, private communication, 2000)

has also slowed greatly; its current concentration is about 0.08 ppbv.

Abundances of the compound methyl chloroform (i.e., 1,1,1-trichloroethane (CH_3CCl_3)) have declined appreciably. Although its five year lifetime is much shorter than the lifetimes of CFCs, methyl chloroform has been controlled under the Montreal Protocol because the large amounts of this compound being used as a solvent and cleaning agent still resulted in a significant contribution to the stratospheric Cl concentration.

The atmospheric lifetimes of the hydrochlorofluorocarbons (HCFCs), hydrofluorocarbons (HFCs), and other halocarbons containing hydrogen tend to be much shorter than the CFCs. Several of these compounds are being used as replacements for CFCs and halons in a variety of uses. A few were already in use before the controls on CFCs were put into place. Due to their shorter lifetimes, smaller amounts of these replacement compounds are reaching the stratosphere and, as a result, their Cl and Br have less effect on ozone than the CFCs. HCFC-22 (CHF_2Cl), a refrigerant often found in home air conditioners, has gained increased use as a replacement for CFCs and its concentration has been increasing at about 5–6% $year^{-1}$ since 1995. The measured concentrations of several other replacement compounds are also increasing.

Br is more effective at destroying ozone than Cl. Studies suggest that its overall effectiveness in the stratosphere is roughly 50 times that of Cl. Therefore, rapid increases in atmospheric concentrations of Br-containing halons, most notably Halon-1301 (CF_3Br) and Halon-1211 (CF_2ClBr), have caused concern. Despite their control under the Montreal Protocol, the concentrations of several halons, including H-1211 and H-1301, continue to increase. Primary destruction of these compounds occurs through photolysis, resulting in long atmospheric lifetimes (65 years for Ha-1301; 20 years for Ha-1211). These compounds, however, currently have small atmospheric concentrations, about 4 pptv (parts per trillion by volume) or less. As a result, the impact of Br on the current atmosphere is smaller than that of Cl.

Largely as a result of the dissociation of CFCs, halons, and human-related emissions of other halocarbons, there are now over 3.5 ppbv of reactive Cl and over 20 pptv of reactive Br in the stratosphere as compared to less than 1 ppbv of reactive Cl and less than 7 pptv of reactive Br estimated as being in the pre-industrial stratosphere. The increase in stratospheric Cl during the 1980s and 1990s has been measured directly by instruments on satellites, balloons and aircraft, and has been shown to directly correlate to what would have been expected from the corresponding increase in concentrations of CFCs and other halocarbons at the ground.

HUMAN-RELATED EFFECTS ON OZONE

A Historical Perspective

Before examining the changes in ozone concentrations over recent decades, it is useful to consider how the understanding of the atmosphere has changed over the last 50 years. Through the work of George Dobson and others, the annual variation in the distribution of ozone for selected latitudes was beginning to be understood by the early 1950s. This knowledge was largely gained through the use of the Dobson spectrophotometer, an instrument still in use, which measures the total ozone column based on the extent of UV radiation absorbed at selected wavelengths. The measurements of solar spectra clearly indicated that ozone was important to life on Earth because of its absorption of UV light. However, the understanding of the chemistry affecting stratospheric ozone in the 1950s had not evolved from the oxygen-only hypothesis of Sydney Chapman in 1930.

By 1950, measurements of several major gases, including CO_2, water (H_2O), CH_4, and N_2O, were being made. The roles of these gases in atmospheric chemistry and climate, however, were not very well understood. Also, the presence of CFCs and other halocarbons in the atmosphere remained unknown until the first measurements of their concentration were made by a medical doctor from the UK, James Lovelock, in the early 1970s (*see* Lovelock, James, Volume 1). Until the 1970s, CFCs were thought to be chemically inert in the atmosphere.

In the 1950s, it began to be recognized that hydrogen oxides likely play a role in the destruction of ozone. Then in 1970, Paul Crutzen (*see* Crutzen, Paul J, Volume 1) suggested that nitrogen oxides were important in the destruction of ozone. Through this and many later studies, scientists were discovering that the stratosphere, and the atmosphere in general, was strongly affected by atmospheric chemical processes. A few years after Crutzen s landmark paper, Richard Stolarski and Ralph Cicerone, then at the University of Michigan, suggested that the Cl catalytic cycle could be important to ozone if a sufficient source of Cl in the stratosphere could be found. In 1974, Rowland and Molina determined that CFCs could provide the source of Cl. Soon after, it was determined that Br could also catalytically destroy ozone. In 1986, Susan Solomon, Rolando Garcia, F Sherwood Rowland and Donald Wuebbles suggested that heterogeneous reactions of Cl molecules on particles could be important to the chemistry affecting ozone. Since then it has been discovered that heterogenous reactions have had a significant effect on the observed trends in stratospheric ozone over recent decades.

In 1967, the first space-based spectral measurements of ozone were made by the Orbiting Geophysical Observatory (IV). Since the initial success of this satellite, numerous satellites have been launched for the purpose of observing the distribution of ozone around the globe and its changing concentration over time. Some of these satellite instruments, like the TOMS, measure total column ozone, while others, like the Solar Backscatter UV instrument and several instruments on the upper atmosphere research satellite (UARS), measure the vertical distribution of ozone. The UARS satellite also has been providing important measurements of the solar flux and many of the gases and particles affecting stratospheric ozone since it was launched in 1991.

To understand the underlying importance of the chemical and physical processes affecting ozone, the measurements from ground-based, aircraft, balloon and satellite instruments are coupled with and compared to analyses from computer-based models of the relevant atmospheric processes. These models attempt to derive the changing distributions of the gases and aerosols affecting ozone. Such models generally represent over 50 chemical species and more than 150 chemical reactions that have affected or can affect ozone. These models allow scientists to better understand the complex interactions that control past, present, and future concentrations of stratospheric ozone.

In the late 1970s and early 1980s, scientists projected that stratospheric ozone would decline gradually as a result of the increasing atmospheric burden of CFCs and other halocarbons. The discovery of the Antarctic ozone hole in 1985 demonstrated that the decrease in ozone was actually

occurring at a much faster rate than the earlier studies had projected.

Stratospheric Ozone Trends

As mentioned earlier, the connection between potential environmental effects on ozone and manmade CFCs was first pointed out by Molina and Rowland in 1974, when they suggested that Cl from these compounds could destroy stratospheric ozone. Research findings since then have continued to support the projections of the effects of these compounds on the global distribution of ozone. In addition, it is recognized that other gases containing Cl and Br, which is even more reactive with O_3 than Cl, are also affecting ozone. To a lesser extent, increasing concentrations of other gases like CO_2, CH_4, and N_2O, are also involved in chemical reactions that are affecting stratospheric ozone.

Measurements of ozone by satellite and ground-based measurements over the last several decades indicate that stratospheric ozone levels have decreased (*see* Stratosphere, Ozone Trends, Volume 1). Atmospheric ozone has decreased globally by more than 5% since 1970. Figure 4 shows satellite and ground-based measurements of the change in total ozone column from 60 °S to 60 °N (the latitude extent is limited primarily by the amount of satellite data available at higher latitudes, particularly in the winter). Detailed satellite measurements began in late 1978, while a reasonably representative global network of ground-based stations has been in operation since the late 1960s. Seasonal variations and the effects of the variations in the solar flux due to a 11-year solar cycle, which produce about a 1.2–1.5% variation from solar minimum to solar maximum, have been removed from the data shown. The ground-based data in Figure 4 show a decrease in ozone of over 4% since 1978. Model calculations extending the estimated ozone amounts back to the late 1960s indicate there has likely been an additional 1% decrease in total column ozone. Because the largest changes in ozone have occurred at higher latitudes as a result of the ozone hole heterogeneous chemistry

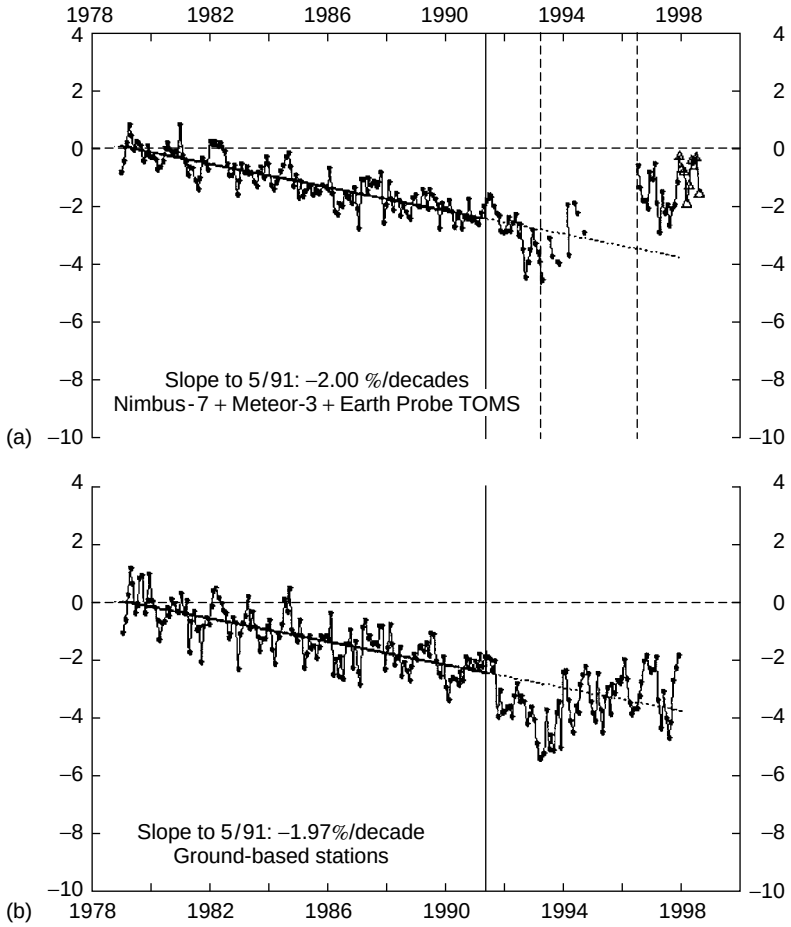

Figure 4 Deviations in total ozone with time relative to January 1979 from various ground-based (b) and satellite measurements (a). The data are area weighted over 60 °South to 60 °North. (Based on World Meteorological Organization, 1999)

(to be discussed later) the decrease in ozone in Figure 4 would be larger yet if the change in ozone at higher latitudes of both hemispheres were also included.

The trends in total column ozone in Figure 4 from the satellite data agree well with the trends determined from the ground-based measurements through the mid-1990s. However, the satellite data in the late-1990s show much smaller changes in ozone. This discrepancy appears to result from difficulties in calibrating the satellite data in the late-1990s after there was a change in the satellite being used to take the measurements. More recent analyses, using improved calibration of the irradiances measured by the satellite instrument, are now in better agreement with the ground-based measurements.

The decrease in ozone in Figure 4 appears to reach its maximum decrease in the early 1990s. However, the large decrease during the early 1990s was in part a response of ozone to the large amount of sulfate aerosols in the stratosphere resulting from the Mt Pinatubo volcanic eruption in June 1991 (*see* Volcanic Eruption, Mt. Pinatubo, Volume 1). These aerosols acted as heterogeneous reaction sites for reactions involving nitrogen, Cl and Br in the stratosphere, allowing for larger destruction of ozone than would be expected in the stratosphere with normal levels of sulfate aerosols. With the removal of the Pinatubo-induced sulfate aerosols from the stratosphere through transport processes, there has been a slight recovery of stratospheric ozone since the mid-1990s. However, the total column ozone from 60 °S to 60 °N is still less than it was pre-Pinatubo. Data for 1999 and early 2000 not shown in Figure 4 continue to show further decline in total column ozone, suggesting that the most significant decrease in ozone may not yet have been reached.

Figure 5 shows the seasonal variations of the trends in total ozone since 1979 (to January 1998) as a function of latitude. The changes in ozone are shown as a percentage per decade. The data in Figure 5 show generally good agreement between ground-based measurements and satellite measurements from the TOMS instrument, although some differences exist in the Southern Hemisphere, particularly at latitudes where there are few ground-based measurement sites. Significant decreases in total ozone are found in both the Northern and the Southern Hemisphere at the middle and high latitudes, with no significant change in the equatorial region.

Surface measurements indicate that the total ozone column at mid-latitudes in the Northern Hemisphere has decreased by 1.3% decade^{-1} in the summer months and 2.7% decade^{-1} in the winter months from 1969 to 1999. Much larger decreases in total ozone are found at latitudes greater than 60°, particularly in the Southern Hemisphere. The largest changes in total column ozone at high latitudes are found in the springtime of each hemisphere.

Satellite and ozonesonde (i.e., made by balloon) data sets indicate that ozone is decreasing particularly rapidly in the lower stratosphere, accounting for a major fraction of the trend in total ozone, although there is also significant ozone destruction occurring in the upper stratosphere. Figure 6 shows the annually averaged change in ozone with latitude and altitude for 1979 through 1996 from the Stratospheric Aerosol and Gas Experiment (SAGE) satellite observations. Available ground-based and balloon-based measurements show similar trends. Large percentage decreases in ozone, approaching 1% year^{-1}, are found in the upper stratosphere. The data at these altitudes are well described as a linear decline modulated by the 11-year solar cycle variation that has been subtracted from the analysis shown in Figure 6. The maximum annual decline of $-0.8 \pm 0.2\%$ year^{-1} (or about 8% decade^{-1}) occurs at 40 km altitude, with strong symmetry between the Northern and Southern Hemispheres. Measurements of relevant atmospheric gases as well as studies modeling the chemistry and physics of the stratosphere indicate that the long-term changes in ozone in the upper stratosphere are well explained by the effects of the gas-phase Cl catalytic cycles discussed earlier.

However, there is much less ozone in the upper stratosphere than in the lower stratosphere, where smaller percentage changes actually imply larger numbers of molecules destroyed. Maximum decreases in lower stratospheric ozone occur at about 15 km altitude, reaching $7.3 \pm 4.6\%$ decade^{-1} at mid-latitudes. However, there is strong variability with location. For the balloon-borne ozonesonde instrument data, 10 stations from 36 °N to 59 °N show maximum annual trends in ozone of -2 to -12% per decade for 15 to 20 km altitude. The largest decreases in ozone tend to be found in the winter and early springtime.

For mid-latitudes, between the two areas of peak change in the lower and upper stratosphere, the minimum trend is $-2 \pm 1.8\%$ decade^{-1} at 30 km, which is just statistically significant at the 95% confidence level. Thus, at northern mid-latitudes, a statistically significant negative trend in ozone exists at all altitudes between 12 and 45 km.

The Antarctic Ozone Hole

Beginning in the late 1970s, a special phenomenon began to occur in the springtime over Antarctica, referred to as the Antarctic ozone hole. A large decrease in total ozone, now over 60% relative to pre-hole levels, has been observed in the springtime (September to November) over Antarctica. Joseph Farman and colleagues first documented this rapid springtime decrease in Antarctic ozone over their British Antarctic Survey station at Halley Bay, Antarctica. These analyses attracted the attention of the scientific community, which soon found that decreases in the total ozone column were greater than 50% compared with historical values observed by both ground-based and satellite techniques.

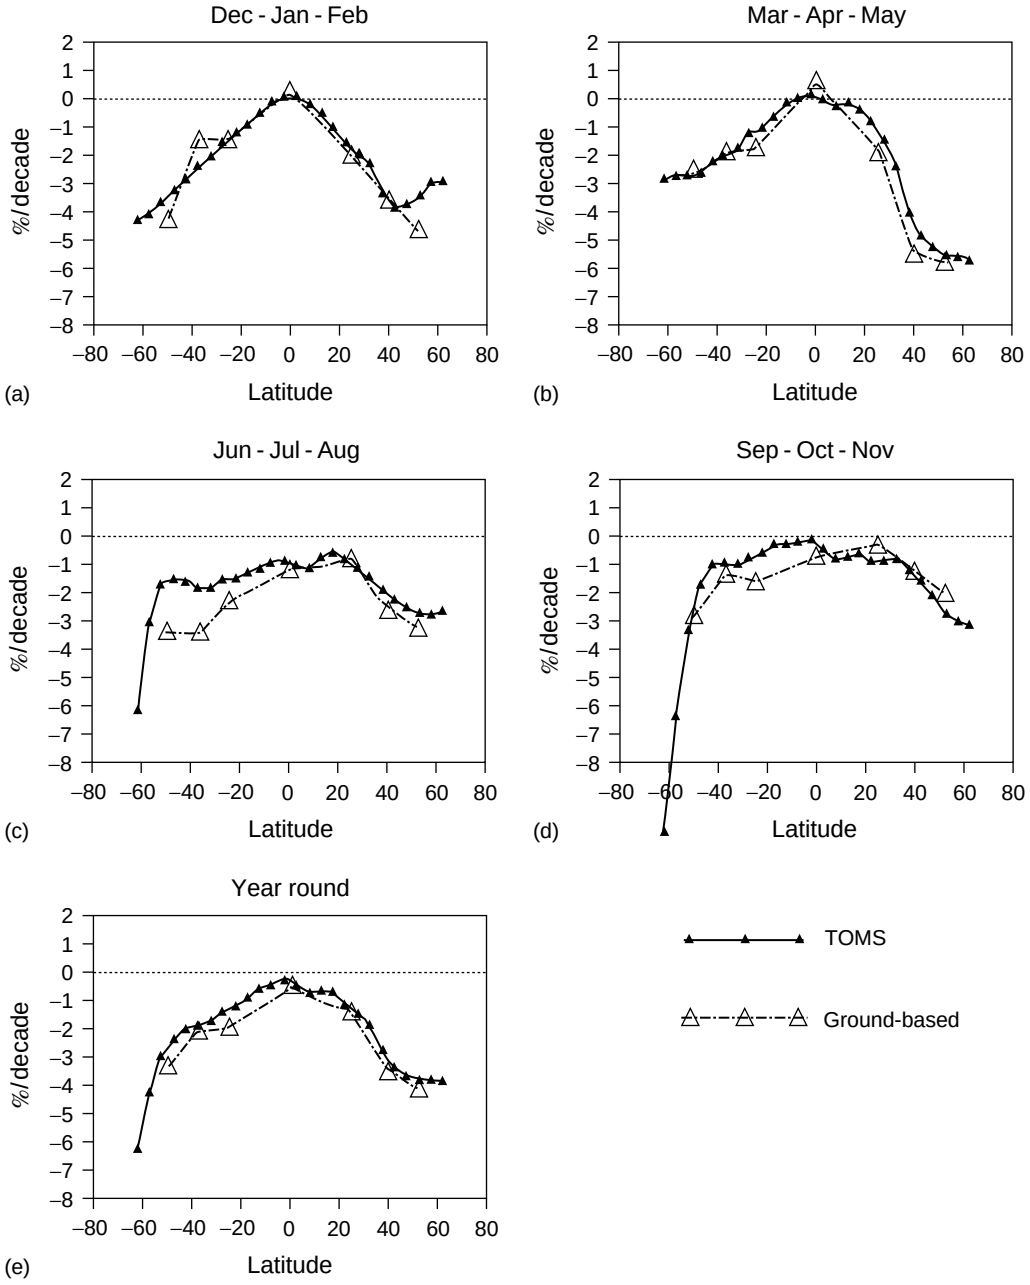

Figure 5 Change in total ozone with latitude (negative is Southern Hemisphere, positive is Northern Hemisphere) and season from January 1979 to January 1998 for satellite TOMS measurements and to May 1997 for ground-based Dobson measurements. (Based on the World Meteorological Organization, 1999)

Measurements made in 1987 indicated that more than 95% of the ozone over Antarctica at altitudes from 13–22 km had disappeared during September and October. More recent measurements have found 60–90% decreases in monthly average ozone amounts between 12 and 20 km for the September to November time period, relative to pre-ozone-hole levels, with essentially all the ozone destroyed at times. Since 1992, the Antarctic ozone holes have been the biggest (in areal extent) and the deepest (in terms of minimum amounts of ozone overhead), with ozone being locally depleted by more than 99% between about 14–19 km in October. There is no indication, as of mid-2000, that the magnitude of the Antarctic ozone hole has peaked or begun to decline.

At the time of the original 1985 paper by Farman and colleagues, there was no expectation that such a phenomenon was occurring. The traditional gas-phase approach to analyzing the expected ozone destruction from CFCs and other

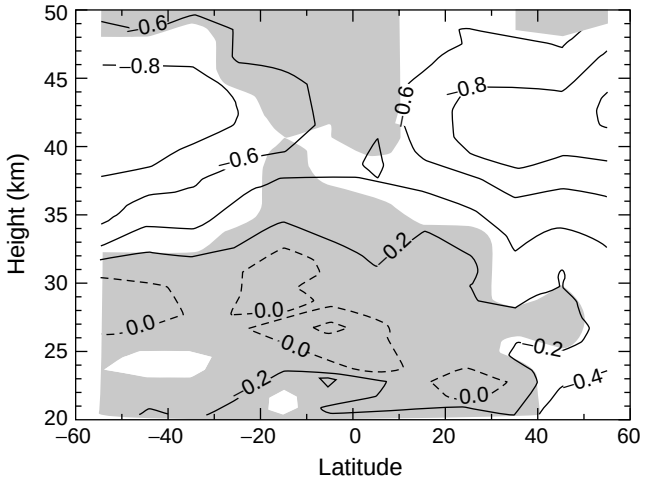

Figure 6 Annually-averaged change in O_3 with latitude and altitude from SAGE satellite observations (1979–1996). The shaded areas indicate where the trends do not differ from zero within the 95% confidence limits. (Based on World Meteorological Organization, 1999)

halocarbon emissions of Cl and Br projected ozone destruction in the upper stratosphere, but suggested little response of ozone levels in the lower stratosphere. As a result of the Farman paper, a number of hypotheses arose, each attempting to explain the large ozone destruction in the springtime over Antarctica. The Farman paper had proposed that the Cl catalytic cycle might explain the observed ozone decrease, but this did not match the expected ozone decrease possible from the reactive Cl available at the high latitudes. Other hypotheses suggested that a change in atmospheric downward transport processes in the polar region or a cyclic variation in natural production of nitrogen oxides might explain the ozone decrease. However, later measurements over Antarctica demonstrated that the concepts proposed in the 1986 paper by Susan Solomon of the NOAA in Boulder, CO, and co-authors, Rolando Garcia of the National Center for Atmospheric Research, also in Boulder, F Sherwood Rowland of the University of California, Irvine, and Donald Wuebbles of Lawrence Livermore National Laboratory, provided the basic explanation for the observed ozone decrease. An expedition organized by several US agencies to Antarctica in 1987, led by Susan Solomon, was able to take sufficient measurements to substantiate the basic premise and demonstrate the clear connection of Cl chemistry in explaining the observed ozone destruction.

According to this explanation, the air over the Antarctic becomes extremely cold during the winter as a result of the lack of sunlight over the polar region and because of greatly reduced mixing of the lower stratospheric air in the south polar region with warmer air outside this region. During the winter, a circumpolar vortex, also called the polar winter vortex, forms, which isolates the air in the polar region from that outside of the region as a result of a stratospheric jet of wind circulating around the world between approximately 50 °S and 65 °S. The extremely cold temperatures inside the vortex lead to the formation of clouds in the lower stratosphere (from roughly 12–22 km), called polar stratospheric clouds. The Solomon *et al.*, paper proposed that heterogeneous reactions occur on these particles that convert less reactive forms of Cl to much more reactive ones. When daylight starts to occur over Antarctica in the early spring, this Cl is available to react with and destroy ozone. Br compounds and nitrogen oxides can also react heterogeneously on the particles of these clouds. The ozone destruction continues until the polar vortex breaks up, usually in November. While further analyses have substantiated the basic concepts of the Solomon hypothesis, laboratory and atmospheric measurements have further refined understanding of the nature of the particles in the polar stratospheric clouds and their reactive properties and of the Cl and Br chemistry that leads to the ozone destruction.

Arctic Ozone Hole?

In the late 1980s, it was generally thought that the Arctic lower stratosphere did not get cold enough to lead to decreases in ozone during the winter and spring like those found in the Antarctic. This was because the polar vortex is not generally as strong in the Northern Hemisphere, and, although polar stratospheric clouds would form, they would be unlikely to last long enough for extensive decreases in ozone to occur. However, as of mid-2000, extremely low ozone concentrations have been found in the Arctic polar vortex in the late winter/spring during eight of the last 11 years. Ozone losses average about 100 Dobson units, with extremes exceeding about 200 Dobson units below the 1964–1976 average total ozone column amounts. Lower-stratospheric temperatures in the Arctic vortex have been sufficiently low during those years to lead to ozone destruction processes similar to those found in the Antarctic ozone hole. As with Antarctica, large increases in concentrations in Cl and O have been measured in the regions where the large ozone destruction is occurring.

Explaining the Observed Ozone Trends

Atmospheric measurements of relevant stratospheric gases that react with ozone have confirmed the role being played by increasing concentrations of Cl and Br. Further, computer-based models of atmospheric chemical and physical processes are able to largely explain the globally observed trends in ozone over the last few decades. Although the increase in Cl and Br largely explain the observed decrease in ozone, the trends could not be fully explained without also accounting for the natural effects of

volcanic eruptions and solar flux variations and the changes in climate affecting stratospheric chemistry and transport processes.

The modeling studies have clearly confirmed the original hypothesis put forth in 1974 that emissions of CFCs would lead to a significant reduction of upper stratospheric ozone, with the maximum decline due to gas phase Cl chemistry expected near 40 km latitude. There is good agreement between the observed and modeled long-term trends in ozone at this altitude. The models reveal a long-term decline in ozone throughout the upper stratosphere that is driven by the accumulation of human-related Cl. In addition, modeled and measured increases in upper stratospheric HCl and hydrogen fluoride (HF) are in excellent agreement with the increases expected as a result of the increases in atmospheric concentrations of CFCs and other halocarbons.

Modeling studies can also largely explain the observed changes in ozone in the lower stratosphere, demonstrating the effects of heterogeneous chemistry involving reactions on sulfate particles outside the polar winter vortices, and the importance of heterogeneous reactions on polar stratospheric cloud particles within the polar winter vortex in each hemisphere. However, some uncertainties remain in fully explaining the observed trends in lower stratospheric ozone.

CONSEQUENCES OF OZONE DEPLETION

UV and Ozone

While the ozone in the troposphere and stratosphere is chemically identical, the ozone in each region has very different effects on life at the Earth s surface. Stratospheric ozone plays a beneficial role by absorbing solar UV radiation, preventing biologically harmful levels of UV radiation from reaching the Earth s surface (*see* Ultraviolet Radiation, Volume 1). Concern about increased UV radiation from ozone loss has been the driver for policy actions to protect the ozone layer. On the other hand, direct contact with ozone is toxic to many life forms on Earth. Surface air pollution, which is often associated with high levels of ozone, and transport of stratospheric air to the ground, with associated stratospheric levels of ozone, have been known to have negative impacts on human health, animals and plants, including some agricultural crops.

Ozone and molecular oxygen ensure that little UV at wavelengths less than 280 nm reaches the Earth s surface. Molecular oxygen absorbs effectively at wavelengths less than 240 nm while ozone absorbs well from 240 nm to wavelengths greater than 300 nm. With normal ozone levels, by the time solar radiation at 278 nm reaches the ground, its intensity has been reduced by a factor of about 10^{17} relative to its intensity at the top of the atmosphere. At 300 nm, the intensity at the ground is about 1% of its value at the top of the atmosphere.

While most life on the Earth s surface co-exists with the existence of UV radiation (in fact, some is needed for the production of vitamin D in humans), too much radiation can be damaging. However, not all of the radiation is equally damaging. Longer wavelengths of solar radiation in the UV, at wavelengths from 315–400 nm, called UV-A, can cause some biological damage. However, UV-A also stimulates repair mechanisms, so that effects in most people are minimal as long as changes in UV-A are not large. UV-A is only weakly absorbed by ozone. In contrast, solar radiation at shorter wavelengths, termed UV-B (280–315 nm) and UV-C (100–280 nm), can cause severe biological damage at sufficient exposure. The large concern about decreases in the amount of stratospheric ozone is because of the resulting increase in UV-B radiation.

Ground-based spectrophotometer measurements of total ozone actually measure the UV solar radiation reaching the ground at selected wavelengths. Therefore, the measured decrease in ozone at many of the stations around the world is a direct indication that there has also been a corresponding increase in the UV radiation reaching the ground. In addition, special instruments that measure either the integrated change in UV-B or the response with wavelength throughout the UV spectrum are being used at a number of locations around the globe. These instruments show that the inverse relationship between changes in ozone and UV-B radiation is well established by both theoretical analyses and observations. Figure 7 shows this inverse relationship in measurements from several sites. As an example, an instrument in Melbourne, Australia measured a sharp increase in UV-B at the same time as a 10% decrease in ozone was being measured. Longer-term increases in UV-B have also clearly occurred over the last decade at clean air sites in the Swiss Alps.

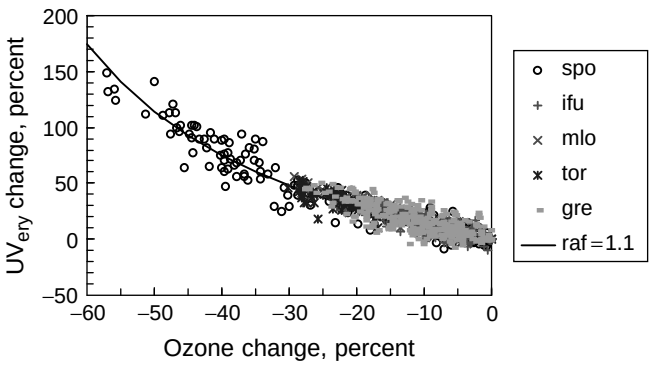

Figure 7 Dependence of erythemal UV radiation at the Earth's surface on stratospheric ozone, measured on cloud-free days at various locations, at fixed solar zenith angles. Legend: South Pole (spo); Lauder, New Zealand (ifu); Mauna Loa, Hawaii (mlo); Toronto, Canada (tor) and Garmisch, Germany (gre). Solid curve (raf) shows predicted relationship from a radiative transfer model of the atmosphere. (Based on Madronich *et al.*, 1998)

A number of studies have shown that sufficient exposure to UV-B, even at pre-ozone destruction levels, can lead to increased incidences of skin cancers and eye disorders, and a reduction in disease immunity, in humans, as well as damage to plants and animals. These effects can be exacerbated by the increase in UV-B at the ground resulting from ozone depletion.

As with other organisms, the human skin has developed various defense mechanisms to deal with exposure to sunlight. The skin adapts to UV exposure by thickening the outer layer, the epidermis, and by developing pigmentation that serves to protect the deeper, more vulnerable, residing dividing cells. Molecular damage is dealt with in the body through repair or replacement. When these natural safeguards are overcome or fail, which can happen with sufficient UV exposure, then serious problems can result. Because such safeguards do not protect the human eye as well, it is particularly sensitive to exposure. Various eye problems, such as the formation of cataracts (a clouding of the lens of the eye) can result. A 10% increase in UV-B is projected to cause a 6–8% increase in the incidence of cataracts. In the US, cataracts are the third largest cause of blindness, and there are about one million cataract operations in the US each year.

Amongst the most serious concerns from UV exposure are several types of skin cancer. Scientific consensus indicates that UV helps cause two types of non-melanoma skin cancer (squamous-cell carcinoma and basal-cell carcinoma) and may be linked through epidemiological evidence to some forms of malignant melanoma. The available data suggest that the incidence of non-melanoma skin cancers increase about 2% for every 1% loss in average stratospheric ozone concentration. In the US, with ozone down as much as 7% in the summertime compared to 30 years ago, there is expected to be a steady increase in squamous and basal cell cancers in the ensuing years, leading eventually to as many as 100 000 extra cases per year compared to the 1960s (there were about 700 000 reported cases in the US in 1994). The largest impacts are expected to occur at the lower latitudes and where there is a high incidence of sunny days. The largest incidence tends to occur amongst fair-skinned people of European origin. While these cancers are treatable, the added medical expenses are still large.

Malignant melanoma is a relatively rare but frequently lethal form of skin cancer. In the US, there are roughly 30 000 cases of melanomas diagnosed each year, with roughly 20% associated fatalities of all cases diagnosed. The link between UV exposure and malignant melanoma is more tenuous than for the non-melanoma skin cancers. Epidemiological evidence suggests that melanoma may be related to a history of sporadic over-exposure of UV radiation. Light skinned persons are 7–10 times more likely to contract malignant melanomas compared to dark-skinned people. A 10% increase in UV-B radiation is projected to cause a 3.5–9% increase in cases of malignant melanoma. At the current rate of increase of incidence of such cases in the US, it has been projected that about 10% of all cancer deaths in the US will be due to melanoma by 2010.

Experimental evidence also suggests that increased exposure to UV-B decreases the effectiveness of the immune system and can aggravate the spread of infectious diseases. There is also concern that UV-B radiation may lower the effectiveness of preventive vaccinations, such as that used against tetanus. There is little known about the current effects on human immunology from the decrease in stratospheric ozone.

Plants and animals are also affected by increases in UV-B. However, knowledge on the effects of increasing UV-B on ecosystems is quite limited. The most studied have been the effects of UV-B exposure on agricultural crops. Soybeans appear to be quite sensitive to increased levels of UV-B. In one study, the equivalent increase in UV-B to a 25% decrease in ozone reduced yields of soybeans by 25%. Marine life, such as zooplankton, phytoplankton and fish larvae are also quite sensitive to increased levels of UV-B. One study estimated that a 25% reduction in ozone would lead to a 35% reduction in primary productivity of phytoplankton near the water surface and a 10% reduction throughout the upper layer of the ocean.

Effects on Climate

A change in the distribution of ozone can affect climate in several ways. The importance of ozone as an absorber of solar radiation, particularly at UV wavelengths, results in a reduction in the amount of solar radiation reaching the Earth s surface. In addition, ozone absorbs solar radiation at visible wavelengths. Ozone is also a greenhouse gas, with several infrared absorption bands in the atmospheric window, where greenhouse gases other than water vapor can have their largest effect on climate. Ozone has a particularly large band at 9.6 μm in the infrared. It is the balance between the solar and infrared radiative processes that determines the net effect of ozone on climate.

The increase in temperature with altitude in the stratosphere, as seen in Figure 1, is explained by the absorption of solar radiation by ozone. The peak absorption defines the top of the stratosphere. In terms of the solar absorption by ozone, this is the altitude at which there is the right balance between the decreasing pressure and density of the atmosphere with altitude and the large concentration of ozone found in the stratosphere. As the available UV radiation decreases with altitude, so does the temperature, even though the amount of ozone remains large throughout the stratosphere.

Increases in stratospheric ozone above 30 km tend to decrease the Earth s surface temperature as a result of the increased absorption of solar radiation, effectively decreasing the solar energy that would otherwise warm the Earth s

surface. Below 30 km, increases in ozone tend to increase the surface temperature, and the infrared greenhouse effect dominates in this region. The large decrease in stratospheric ozone, particularly in the lower stratosphere, over the last several decades has resulted in a net cooling influence on climate, counteracting some of the warming trend over that time period from increasing concentration of CO_2, CH_4, and other greenhouse gases. While ozone has not been a driver of climate change in the way that the change in concentration of CO_2 has been, it is still an important contributor.

Policy Considerations to Protect Ozone

The recognition of the harmful effects of Cl and Br on ozone spawned international action to restrict the production and use of CFCs and halons in order to protect stratospheric ozone. These actions included the 1987 Montreal Protocol on Substances that Deplete the Ozone Layer, the subsequent 1990 London Amendment, the 1992 Copenhagen Amendment, and the 1997 Montreal Amendment. In the Montreal Protocol and its amendments, there is a distinction made between control measures to be taken in developed and developing countries. These agreements initially called for reduction of CFC consumption in developed countries. A November 1992 meeting called by the United Nations Environment Programme and held in Copenhagen resulted in substantial modifications to the protocol because of the large observed decrease in ozone. The Amendment called for the phase-out of CFCs, carbon tetrachloride (CCl_4), and methyl chloroform (CH_3CCl_3) by 1996 in developed countries. As a result of this Amendment, for example, the US, through the Clean Air Act, halted production and import of these chemicals. Production of these compounds is to be totally phased out in developing countries by 2006, while production of halons in developed countries was stopped in 1994. Human-related production and emissions of methyl bromide were not to increase after 1994 in developed countries, and are supposed to slowly decline, with total elimination by 2005. Production and emissions of HCFCs, many of which have been used as replacements for the CFCs but which still contain Cl that can destroy ozone, are to be phased out in the developed countries by 2030.

One of the criteria for the acceptability or unacceptability of a chemical under the Montreal Protocol and the US Clean Air Act is its ozone depletion potential (ODP), a concept developed by Donald Wuebbles, then of Lawrence Livermore National Laboratory of the University of California. This concept provides a relative measure of the effect on ozone from emission of a chemical per unit mass emitted relative to the effect on ozone from the same mass of CFC-11, one of the chemicals of most concern to ozone. By definition, CFC-11 has an ODP of 1.0. Based on their effects on ozone other CFCs also have large ODPs. Most of the compounds being eliminated have ODPs greater than 0.1, although compounds are now being regulated with ODPs smaller than this.

Further policy considerations to protect stratospheric ozone are likely to be primarily aimed at examining potential replacement compounds for CFCs, halons, and HCFCs. A number of the new generation of replacement compounds still contain Cl and/or Br, and in some cases, iodine (I), and could therefore still impact ozone. However, these chemicals are also being chosen in part because they have short atmospheric lifetimes as well as characteristics that make them desirable for a given application. The short atmospheric lifetimes result in more destruction of the chemical in the lower troposphere and therefore a smaller amount of the Cl, Br, or I reaches the stratosphere. As a result, these short-lived chemicals generally have smaller ODPs, making them less likely to affect ozone and more acceptable in terms of their environmental damage.

THE FUTURE OF STRATOSPHERIC OZONE CONCENTRATIONS

Projected Trends in Ozone

Worldwide compliance with the international agreements to protect ozone is resulting in significant reductions in the emissions of the CFCs, halons, and other halocarbons having the largest effects on ozone, As a result, levels of stratospheric ozone should slowly begin to recover over the coming decades as the reactive Cl and Br in the stratosphere declines. This recovery will be gradual, primarily because of the long time it takes for CFCs and halons to be removed from the atmosphere.

Projected changes in globally averaged total ozone based on several different assumptions about future emissions of CFCs, halons and their replacements are shown in Figure 8. These analyses are based on the Cl and Br available to affect ozone, and do not account for other factors that may affect future trends in ozone, as discussed below. With the original Montreal Protocol provisions, the ozone reduction would have continued to grow, although not as rapidly as if there had been no protocol. It is important to note that only under the London and Copenhagen Amendments provisions, calling for the complete phase-out of CFCs, halons and other halocarbons, is the ozone reduction trend reversed. The largest ozone reductions are predicted to have been reached in about 1998–2000. After this, the ozone layer is predicted to gradually recover, although it is not until about 2040 (Copenhagen Amendments) and about 2050 (London Amendments) that the 1980 level is again obtained. Thus, it will be roughly the middle of this century before the Cl and Br in the stratosphere return to levels corresponding to the beginning of the Antarctic ozone hole. Without any control measures, and assuming

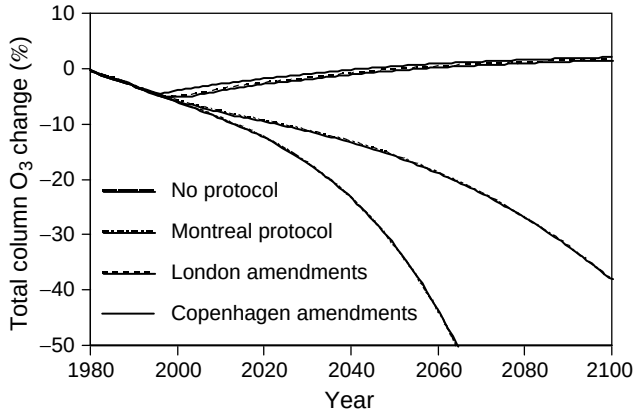

Figure 8 Estimated total column ozone change for the No Protocol, Montreal Protocol, London Amendment and Copenhagen Amendment scenarios. Based on analyses by D Wuebbles and A Jain using their model for equivalent Cl loading at the University of Illinois. Similar analyses can be found in the World Meteorological Organization (1999)

unfettered growth, the global mean total column of ozone would have decreased by about 30% by 2050, and would have continued to decrease with time.

The black line in Figure 8 corresponds to the observed changes in ozone relative to 1980 up to the mid-1990s, and follows the changes in ozone expected if the latest version of the Montreal Protocol is adhered to. However, uncertainty about other changes occurring in the background atmosphere could affect the timing of the return to natural ozone levels, possibly increasing the time by several decades.

Recent studies with complex computer-based models of the global atmosphere suggest that the ozone recovery will likely be slower than the analyses based on the Cl and Br loading in the stratosphere. These studies show that the future behavior and recovery of stratospheric ozone will also be affected by changes in the concentrations of other atmospheric gases like CO_2, CH_4, NO_2, and sulfate aerosols. Changes in the Earth s climate, as projected to result from the effects of increasing concentrations of greenhouse gases, are also likely to affect the recovery of ozone by changing the winds and other transport processes controlling the movement of ozone and other constituents in the stratosphere, by affecting the amount of tropospheric water vapor transported to the stratosphere, and by potentially affecting the tropopause, which is the transition region and barrier for transport between the stratosphere and troposphere. The expected cooling of the stratosphere, due to increasing concentrations of CO_2, could also lead to increased amounts of polar stratospheric clouds and extension of the effectiveness of ozone hole type processes in both the Arctic and Antarctic.

These additional factors, in combination with possible changes in atmospheric variability, suggest that the exact timing of the recovery of ozone, or even knowing when the recovery will begin, is thus uncertain. Some modeling studies suggest that the recovery of ozone could take several decades longer than the simpler scaling presented in Figure 8 (e.g., see the international assessment of ozone published by the World Meteorological Organization, 1998). Other studies are suggesting that the recovery could extend beyond 2100, without the ozone layer ever really returning to the distribution of ozone that existed before human intervention.

THE POTENTIAL FOR NEW IMPACTS ON OZONE

As mentioned above, the projected changes in climate could result in important impacts on stratospheric ozone during the 21st century. The increasing temperatures in the troposphere could change the processes influencing the transport of ozone and constituents in the stratosphere. In addition, changes in the transport of air across the tropopause could result in increased water vapor in the stratosphere, which, in turn, could change the chemistry controlling ozone in the stratosphere. The projected increase in the concentration of CO_2 has a radiative cooling effect on the stratosphere. The resulting cooler temperatures have direct effects on the temperature dependence of the chemistry affecting ozone in the stratosphere, and indirect effects through the increased probability for sufficiently cool temperatures to form polar stratospheric clouds and resulting ozone hole effects on ozone. Projected increases in emissions and atmospheric concentrations of CH_4 and NO_2, also important as greenhouse gases, could affect the balance of ozone destruction from hydrogen oxides and nitrogen oxides in the stratosphere.

Variations in the radiation from the Sun can also affect ozone concentrations. The integrated ozone column varies by about 1.2−1.5% during the 11-year cycle due to solar effects on the photodissociation of oxygen and resulting production of ozone in the stratosphere. Longer-term changes in the solar flux can also occur and could affect future levels of ozone. The current limitations in understanding the processes affecting the output of the Sun limit our ability to predict future changes in the solar flux.

As demonstrated by the 1991 eruption of Mt Pinatubo, large explosive volcanic eruptions can emit significant amounts of sulfur into the stratosphere. This sulfur is rapidly transformed to sulfuric acid aerosols, which can then serve as sites for heterogeneous reactions. Such reactions can convert nitrogen oxides to less reactive nitric acid and convert less reactive hydrochloric acid (HCl) and Cl nitrate ($ClONO_2$) to more reactive forms of Cl. For a few years, until transport processes from the stratosphere remove the sulfuric particles, there can be increased destruction of stratospheric ozone. Such eruptions are likely in the future, and could create further uncertainities in prediction of future changes in ozone resulting from human activities.

The exhaust of solid-fuel rockets can emit gaseous HCl and aluminum oxide particles directly into the stratosphere, leading to potentially large destruction of stratospheric ozone. However, current projections of the frequency of space shuttle flights and other solid-fuel rockets, such as the Titan IV and the Ariane, do not suggest any significant problem with respect to ozone depletion.

A large fraction of the jet aircraft in the current worldwide commercial fleet spend a significant amount of their time at the cruise phase of their flights in the upper troposphere and lower levels of the stratosphere. Projected increases in the number of subsonic aircraft and the tendency towards larger aircraft will mean more of these aircraft will be spending a significant amount of flight time in the lower stratosphere. In addition, there are continuing discussions about the eventual development of a fleet of commercial aircraft that would fly at supersonic speeds (only a few of the existing Concorde supersonic aircraft, which flies at Mach 1.6, were ever built). Emissions of nitrogen oxides and water vapor from aircraft are of particular concern with respect to ozone depletion. Current aircraft fleets are large enough to have a small effect on stratospheric ozone, and research groups continue to evaluate the potential effects of projected fleets of aircraft on ozone over the coming decades. Of particular concern are potential fleets of supersonic aircraft that would fly at higher altitudes, closer to the peak levels of stratospheric ozone. In addition, assessments are being carried out to quantify possible climatic effects created by aircraft emissions (IPCC, 1999).

Atmospheric nuclear explosions dissociate N_2 gas, leading to the production of nitrogen oxides that can destroy ozone. Nuclear explosions near the ground with an explosive power larger than about 1 megaton can loft these nitrogen oxides directly into the stratosphere. Atmospheric nuclear tests in the early 1960s appear to have affected ozone during that period, but such tests are now largely banned under international agreements. However, the devastating effects of a nuclear war would be further exacerbated by the potential for a substantial decrease in the protective ozone layer.

CONCLUSIONS

Human activities have seriously affected levels of stratospheric ozone over the last few decades. The effects that have occurred are now largely understood, and international policy has been put in place to correct the impacts on ozone caused by CFCs, halons and other halocarbons. However, there is the potential for significant perturbations to continue into the future. As a result, the need for research to understand the processes influencing stratospheric ozone and to measure the changes occurring in the atmosphere continues to be an important priority to the benefit of the life on our planet.

International Organizations in the Earth Sciences

JOHN S PERRY
Alexandria, VA, USA

By their very nature, environmental changes are often regional or global in their genesis and impact. Yet, human affairs are primarily organized in terms of political jurisdictions from counties to nations that have little relation to the processes of nature. Sulfur emissions from a power plant in Britain do not stop at the English Channel, or at the Swedish border.

Moreover, the branches of human knowledge and activity that may be brought to bear on environmental problems are similarly divided within traditional boundaries that do not correspond readily to real world problems. Universities maintain chemistry departments and law schools; governments have ministries of commerce and transportation; but there is no Department of Acid Rain.

International and interdisciplinary organizations have therefore become ever more essential, and have in fact become ever more effective in advancing our understanding of the global environment and developing sound policies for its protection. For these reasons, the increasing prominence of global-scale environmental issues has motivated increasing emphasis on activities that transcend political and disciplinary boundaries. Depletion of stratospheric ozone was a scienti c problem too large for a college chemistry department; controlling it by worldwide limits on chloro uorocarbon production was a problem too large for any individual nation. Yet effective global action was somehow agreed and acted upon through an international process based on an interdisciplinary scienti c consensus.

In volumes four and ve of this Encyclopedia, the social, political and policy dimensions of international organization for environmental issues will be addressed. Here, we will focus on the nuts and bolts of international organizations involved in encouraging and summarizing global environmental research.

INTRODUCTION

International endeavors in science have a long and highly productive history. Scientists from Aristotle to Einstein have developed many means to communicate observations, theories, insights, and hypotheses among themselves. In the 18th century, to gain large-scale benefit from the collective results of the many individual scientists, learned societies such as the Royal Society in Britain took on roles as national and to a growing extent international clearinghouses for scientific information. In addition, in the 19th century practical applications such as weather forecasting produced further demands for international exchange of data, and organized networks for weather observations were set up. In the late 19th century, growing interest in polar exploration led to organization of the First International Polar Year of coordinated observation and research in 1882–1883. In the 20th century, the advance of global communications and commerce led to the formation of operationally oriented international organizations such as the International Meteorological Organization.

DEVELOPMENT OF INTERNATIONAL ORGANIZATION

The emerging pattern of international cooperation in environmental science was cruelly shattered by World War II. As the planet emerged from that conflict, new tensions and new opportunities arose. The international schism between East and West loomed as a barrier to addressing global scale problems. But at the same time, satellites presented an opportunity to observe the whole Earth for the first time without regard to national boundaries or conflicts. These considerations led in 1958–1959 to the International Geophysical Year (IGY) (*see* IGY (International Geophysical Year), Volume 1), an ambitious attempt to transcend national boundaries and conflicts to study the whole Earth using all available resources of human intellect and technology.

Universally judged to be a resounding success, the IGY provided inspiration for US President John F Kennedy to call upon the United Nations (UN) to utilize the resources of space technology to address the problems of weather and

climate. The resulting Global Atmospheric Research Program (GARP) (*see* GARP (Global Atmospheric Research Program), Volume 1) built upon the organizational pattern of the IGY, again with great success, and laid the foundation for today s organized international activities in weather, climate, and global environmental change.

How are such enterprises conceived, organized, managed, and executed in today s world? Anyone seeking to understand the international framework is confronted with a bewildering smorgasbord of programs, projects, and institutions, each identified by an acronym apparently chosen more for euphony than for meaning. The quest for understanding should start with recognition of what international organizations can reasonably be expected to do. One taxonomy of functions has been presented by Kay and Jacobson (1984):

1. identifying problems;
2. coordinating monitoring and evaluation activities;
3. data gathering and information collection;
4. risk estimation and impact assessment;
5. information exchange and dissemination;
6. facilitation and coordination of national and international programs;
7. normative pronouncements;
8. standard setting and rule making;
9. supervision of norms, standards, and rules;
10. direct operational activity.

In recent years, there has in addition been increased emphasis on capacity building, i.e., enhancing the human and technological resources of countries to address their own environmental problems and to participate in regional and global activities.

INTERGOVERNMENTAL ORGANIZATIONS

The activities behind the acronyms may usefully be classified along several dimensions. The primary distinction is between intergovernmental and non-governmental organizations. The former group is epitomized by the organizations of the UN family; the UN and its institutional bodies, and the specialized agencies that work under its aegis. These organizations are primarily funded by dues, contributions, and project funds from national governments; governed by standing groups of governmental representatives from their constituent nations; and supported by permanent secretariats staffed by international civil servants. For example, the programs of the World Meteorological Organization (WMO) are overseen by the World Meteorological Congress, an assembly of some 185 nations that meets every four years, and an Executive Council that meets annually. WMO s activities are carried out by a couple of hundred staff members based in Geneva, Switzerland (*see* WMO (World Meteorological Organization), Volume 1).

Many of these organizations are closely linked with kindred agencies within their constituent nations. Thus, for example, the Food and Agriculture Organization communicates with and responds to the agriculture ministries of its member nations. Others, such as the United Nations Educational, Scientific, and Cultural Organization (UNESCO), have extremely broad mandates that do not correspond to single bureaucracies in member nations (*see* UNESCO (United Nations Educational Scienti c and Cultural Organization) and the Environment, Volume 4). Moreover, organization within individual nations for various environmental areas sometimes reflects unique political and historical patterns. For example, meteorology is found in departments of environment, agriculture, transportation, and defense in various countries, and is sometimes split between operational and pure research bodies in an unpredictable and confusing pattern. Nevertheless, it is helpful to think of the intergovernmental international bodies as extensions of, and creatures of, their corresponding national agencies.

The intergovernmental organizations carry out an exceedingly broad and diverse array of activities far too numerous to inventory in a brief encyclopedia entry. They convene workshops and symposia to exchange information. They recommend standards to the nations for weather observations, allocation of radio frequencies, protection of intellectual property, and coordination of a host of other topics. They often provide the secretariats for international agreements. On occasion, they perform very significant operational roles ranging from control of locust eruptions to provision of equipment and training. Perhaps their most important functions, however, are simply their ability to place issues of global importance on the agendas of all their constituent nations, and to give voice to the concerns of all nations, large and small, rich or poor. The international organizations have little or no power to command action by sovereign nations, but they have a highly potent power to command attention from their governmental bureaucracies.

A relatively new species of *ad hoc* international organization has arisen in recent years. The prime example is the Intergovernmental Panel on Climate Change (IPCC) (*see* Intergovernmental Panel on Climate Change (IPCC): an Historical Review, Volume 4), which was established under the aegis of the WMO and United Nations Environmental Programme (UNEP) to provide coordinated, authoritative assessments of human influence on global climate. These assessments are prepared in order to inform the work of the intergovernmental Framework Convention on Climate Change (*see* United Nations Framework Convention on Climate Change and Kyoto Protocol, Volume 4). Although consisting of scientists nominated by governments, the IPCC nevertheless operates independently to provide unbiased assessments of current scientific understanding of human impacts on global climate.

NON-GOVERNMENTAL ORGANIZATIONS

The second principal stream of international activity is led by non-governmental organizations. These diverse organizations carry out the day to day work of scientific communication and exchange that makes science (particularly environmental science) an efficient and productive global endeavor.

Loose associations of scientists in different countries have existed for many years. Beginning in the 19th century, national academies of science or their equivalents were formed, and formal societies or unions began to develop in various disciplines, as scientists began to realize the benefits of exchanging data and ideas. In 1931, this growing structure was brought together in the International Council of Scientific Unions (ICSU), now renamed the International Council for Science (*see* ICSU (International Council for Science), Volume 4). Currently, this comprises 98 national member organizations (academies of science or the equivalent), 26 disciplinary scientific unions, and 28 associated scientific organizations. Although the boundary between governmental and non-governmental science is blurred in many countries, the key feature of ICSU and its family of activities is its governance by scientists acting in their individual capacities rather than representatives of political bodies. This independence gives ICSU a unique degree of freedom, independence, and authority.

Among the unions operating under the aegis of ICSU, the International Union of Geodesy and Geophysics (IUGG) is particularly relevant to global environmental change. The IUGG comprises a family of semi-autonomous international associations whose fields of activity span the Earth sciences:

1. the International Association of Geodesy (IAG);
2. the International Association of Geomagnetism and Aeronomy (IAGA);
3. the International Association of Hydrological Sciences (IAHS) (*see* IAHS (International Association of Hydrological Sciences), Volume 1);
4. the International Association of Meteorology and Atmospheric Sciences (IAMAS) (*see* IAMAS (International Association of Meteorology and Atmospheric Sciences), Volume 1);
5. the International Association for the Physical Sciences of the Ocean (IAPSO) (*see* IAPSO (International Association for the Physical Sciences of the Oceans), Volume 1);
6. the International Association of Seismology and Physics of the Earth s Interior (IASPEI);
7. the International Association of Volcanology and Chemistry of the Earth s Interior (IAVCEI).

Each of these maintains a substructure of specialized committees or commissions, convenes dozens of international symposia and workshops each year, and holds periodic international assemblies of the association as a whole. For example, IAMAS has commissions focusing on atmospheric chemistry and global pollution, climate, and ozone among its 10 specialized commissions.

Much of ICSU s work is carried out through a network of interdisciplinary scientific and special committees focused on important topics that transcend disciplinary specialities. Among the most relevant to global environmental change are:

1. Scientific Committee on Antarctic Research (SCAR);
2. Programme on Capacity Building in Science (PCBS);
3. Committee on Data for Science and Technology (CODATA);
4. Scientific Committee on Problem of the Environment (SCOPE) (*see* SCOPE (Scienti c Committee on Problems of the Environment), Volume 4);
5. Scientific Committee for the International Geosphere–Biosphere Programme (SC–IGBP) (*see* IGBP (International Geosphere- Biosphere Programme), Volume 2);
6. Special Committee for the International Decade for Natural Disaster Reduction (SC-IDNDR) (*see* IDNDR (The International Decade for Natural Disaster Reduction), Volume 4);
7. Scientific Committee on Oceanic Research (SCOR) (*see* SCOR (Scienti c Committee on Oceanic Research), Volume 1);
8. Scientific Committee on Solar–Terrestrial Physics (SCOSTEP);
9. Committee on Space Research (COSPAR);
10. Scientific Committee on Water Research (SCOWAR).

Other important projects are carried out jointly with intergovernmental or non-governmental bodies, e.g., the World Climate Research Programme (WCRP), which is implemented jointly with the WMO and the Intergovernmental Oceanographic Commission (IOC) of UNESCO (*see* WCRP (World Climate Research Programme), Volume 1). The very broadly interdisciplinary IGBP, which works closely with the WCRP, the International Human Dimensions Programme (IHDP), the SCOR, and the Global Change System for Analysis Research and Training (START) regional networking system, has focused on developing detailed plans for the conduct of science in its eleven component program elements. These are composed of eight broadly discipline oriented projects, covering such topics as atmospheric science, terrestrial ecology, oceanography, hydrology, and links between the natural and the social sciences. Three framework activities on data, modeling, and regional research, facilitate incorporating scientific results into a holistic picture.

ICSU also provides a home for important international data acquisition, management, and archiving services relating to such parameters as sea level, glaciers, Earth rotation,

and so on. Typically, secretariats or project offices for these activities are established under the aegis of some host institution, often with major support from the host country. For example, the IPCC secretariat is housed by the WMO; ICSU s IGBP occupies a floor of the Royal Swedish Academy of Sciences; and ICSU itself inhabits a gracious townhouse in Paris provided by France.

Focused projects organized and coordinated through international organizations play an especially important role in environmental science. The observational data required to study phenomena such as the El Niño or pollutant transport cannot be gathered by one nation alone. Moreover, the attendant data processing, archiving, and research often demand resources greatly exceeding those of any single nation. It has therefore become common for dozens of nations to collaborate very actively over extended periods in scientific programs. During one 4-month field experiment of the Tropical Ocean Global Atmosphere (TOGA) program (*see* TOGA (Tropical Ocean Global Atmosphere), Volume 1), for example, nearly 1200 people from more than 20 nations conducted more than 700 days of ship operations, launched nearly 12 000 rawinsondes, completed 125 aircraft flights, and maintained continuous operation of 30 moored instrument systems. The International Satellite Cloud Climatology Program currently collects data from European, Japanese, and US satellites, calibrates the data in France, and analyses and archives it in the US (*see* ISCCP (International Satellite Cloud Climatology Project), Volume 1). In global scale environmental science, international organization is neither a luxury nor an afterthought; it is becoming the primary mode of performing effective research.

Numerous other international bodies relevant to environmental issues, many of which are scientific associates of ICSU, merit mention. For example, the International Institute for Applied Systems Analysis (IIASA) in Austria, governed and funded through member organizations in a group of countries, carries out significant innovative interdisciplinary research in demographics, energy systems and environmental impacts (*see* IIASA (International Institute for Applied Systems Analysis), Volume 4). The Third World Academy of Sciences (TWAS) supports scientific excellence and research in developing countries. The World Wildlife Fund (WWF) has a diverse constituency of both governmental and non-governmental partners, and carries out a broad range of conservation activities worldwide.

A full inventory of international organizations of all kinds relevant to global environmental change would require an encyclopedia of its own. Indeed, the complex and often overlapping networks of institutions, organizations, and programs are better suited to the hypertext of the World Wide Web than to the printed page. This complexity is, however, neither accidental nor perverse. Rather, it reflects the very real complexity and interconnection of both the natural and human worlds, and the need to balance disciplinary depth and rigor against the challenge of real world problems. Indeed, a former president of ICSU, Sir John Kendrew, once remarked that the distinguishing characteristic of 20th century science was the willingness to address messy, poorly defined (but important) problems that do not fall neatly within national or disciplinary boundaries. The overarching problem of global environmental change is the archetype of such problems.

See also: Scienti c Responses in an Era of Global Environmental Change, Volume 4).

ACCOMPLISHMENTS

The international organizations dealing with the environment should therefore be assessed in terms of their effectiveness in meeting these challenges, not in terms of any preconceived notions of bureaucratic neatness. From this standpoint, the international organizations have many successes to their credit. A very few examples drawn from their rich array of achievements are illustrative:

1. UNEP s orchestration of international agreements to reduce pollution of the Mediterranean.
2. The Global Atmospheric Research Programme of WMO, ICSU, and IOC that made today s long-range weather prediction possible.
3. The TOGA program, again a WMO/ICSU/IOC effort that elucidated the El Niño/Southern Oscillation phenomenon and developed seasonal/interannual forecasting capabilities.
4. The international assessments of ozone depletion that laid the foundation for control of ozone depleting chemicals, and thus averted what might well have been a global environmental disaster.
5. The comprehensive and authoritative interdisciplinary syntheses, assessments, and studies of natural and human made environmental changes and the effects of these changes on people carried out by ISCU s SCOPE.
6. The IPCC that is similarly laying a firm foundation for international efforts to limit and cope with damaging human impacts on global climate.

CONCLUSION

Ultimately, the work of the world is carried out by individual scientists and citizens, with resources primarily mobilized by the governments and corporations that levy taxes and render bills. However, the legal, political, and disciplinary boundaries that permit scientists and citizens to focus effectively on their individual tasks can at the same time hinder coordinated global action on problems of importance to humanity as a whole. International organizations of all kinds play a vital role in fostering communication and coordination across

these barriers, in providing a framework for planning and executing collaborative activities, and in providing a common agreed base of understanding on which the nations can build sound policies for securing humanity s future on our precious and unique planet.

Abrupt Climate Change

see Cloud–Radiation Interactions (**Volume 1**)

Acoustic Thermometry

Acoustic thermometry is a method for measuring the average ocean temperature over large areas. This is particularly appropriate when trying to see if the climate is changing. The method is based on the fact that sound travels faster in warm water than in cold water. Thus, the travel time of an acoustic pulse can be used to determine the mean temperature of the intervening water between source and receiver. For a typical measurement designed to be taken over a distance of several thousand kilometers, there are many tens of possible transmission paths, and associated arrival times, for a single emitted sound pulse. Early arrival times indicate travel of the sound along steep rays oscillating between the surface and the bottom of the ocean, such that their travel time is affected by the temperature profile in the entire water column. Late arrival times indicate sound paths that hug a sound axis that exists typically in cold waters at 1 km depth. Thus, each path of a sound pulse weights the water column in a different way. The set of arrival times can be analyzed to estimate the vertical temperature profile and the horizontally averaged heat content between source and receiver. The basin-scale averages suppress the relatively large fluctuations associated with ocean weather that can hide the slowly changing climate signal.

This technique has proven useful in polar regions that are ice covered during winter. A 3000 km transmission path across the North Pole shows a 0.4 °C warming relative to average conditions over the past few decades. An experiment in the western Mediterranean has given accurate measurements of seasonal heat content. Transmissions in the western Pacific from a source on Pioneer Seamount off California to various sensor arrays near Hawaii and Christmas Island have been compared to seasonal and year-to-year changes in sea level (which is also affected by ocean temperatures) determined by satellite altimetry, and it has been shown that these two methods together lead to accurate estimates of heat storage in the ocean.

ACSYS (Arctic Climate System Study)

ACSYS, a component of the World Climate Research Programme, concentrates on the understanding of Arctic Ocean variability and change including sea ice processes. It will be expanded into the Climate and Cryosphere Initiative (CLIC) investigating the role of the entire cryosphere for global climate and as an early indicator of change.

The scientific goal of ACSYS is to ascertain the role of the Arctic in global climate:

- global consequences of natural or man-made change in the Arctic climate system;
- sensitivity of the Arctic climate system to increased greenhouse gases.

The project includes several subprograms.

ARCTIC OCEAN CIRCULATION PROGRAM

This provides the information necessary to realistically represent the role of the Arctic Ocean in the global climate

system in models of global climate. The Arctic Ocean Hydrographic Survey collects high-quality hydrographic data on physical and chemical properties of the Arctic Ocean. Arctic Ocean Shelf Studies are aimed at understanding shelf processes. The Arctic Ocean Variability Project assesses the variability of the circulation and density structure of the Arctic Ocean. The historical Arctic Ocean Climate Database Project builds a digital hydrographic database for the Arctic Ocean.

ARCTIC SEA ICE PROGRAM

Arctic Ocean pack ice has dramatic effects on the physical characteristics of the ocean surface, and plays a role in the global heat balance and thermohaline circulation. The program seeks to assemble a climatological archive of pack ice in both the Arctic and Antarctic seas, and to study the interaction of polar pack ice with other elements of the global climate system.

ARCTIC ATMOSPHERE PROGRAM

This program includes field campaigns, re-analysis of data, polar clouds and radiation research, *in situ* and satellite measurements, and improved modeling.

HYDROLOGICAL CYCLE IN THE ARCTIC REGION

This program includes compilation of an Arctic hydrological database, development of hydrological models, and subprojects on solid precipitation and development of an Arctic precipitation data archive.

ACSYS MODELING PROGRAM

Models will be optimized for the Arctic region, parameterizations will be developed, and numerical experiments performed.

DATA MANAGEMENT AND INFORMATION PANEL

This group develops a strategic approach to data management and information in ACSYS.

Information is available from the International ACSYS/CLIC Project Office, The Polar Environmental Center, N-9296 Troms , Norway.

Aerosols, Effects on the Climate

Joyce E Penner
University of Michigan, Ann Arbor, MI, USA

Aerosols are small particles suspended in the atmosphere. While technically the term can refer to both particles and cloud droplets, it is common to use this term to only refer to particles which are smaller than about 10 μm*. Aerosols are important because they are able to alter climate in two important ways. First, they scatter and absorb radiation in the atmosphere and, second, they change the microphysical structure and possibly the lifetime and extent of clouds within the atmosphere. Radiation in the atmosphere is divided into solar and thermal radiation. The former has wavelengths ranging from 0 to* ∼*4* μm*, while the latter has wavelengths ranging from 4- 20* μm*. Because most aerosols are smaller than 10* μm *and because aerosol particles interact most strongly with wavelengths near their size, most of the scattering and absorption of radiation by aerosols takes place in the solar spectrum. An exception to this rule applies to particles with diameters greater than about 2* μm *which consist primarily of dust particles and sea salt particles as well as compounds which condense onto or react with these aerosols. The scattering of solar radiation acts to cool the planet, while absorption of solar radiation by aerosols warms the air directly instead of allowing sunlight to be absorbed by the surface of the Earth. When sunlight is absorbed by the Earth's surface, the heat is then transferred back to the atmosphere either in the form of thermal (heat) radiation, by conduction of heat, or by evaporation of water which, when it condenses, releases the heat back to the atmosphere. Large particles in the troposphere (diameter (d)* $>$ *2* μm*) will absorb the thermal radiation. Absorption of this radiation by these particles tends to warm the planet.*

As a result of their abundance and size, cloud droplets both scatter solar radiation and absorb thermal radiation. Warm liquid water clouds at low altitudes tend to mainly scatter solar radiation, while ice clouds at high altitude mainly absorb thermal radiation. Thus, increases in the former act to mainly cool the planet while increases in the latter tend to warm it. Aerosols can impact clouds by acting as cloud condensation nuclei (CCN) (i.e., the particles on which water vapor condenses as cloud drops form). Increases in aerosols will tend to increase the number concentrations of warm liquid water cloud droplets (and decrease their size). Because increases in the number concentration of cloud droplets in warm clouds may greatly increase their scattering of solar radiation (while having little effect on their interaction with thermal radiation as

long as the total amount of water in the cloud remains constant), the primary effect of increases in aerosols is to tend to cool the planet. Little is known about how aerosols may impact ice clouds.

A secondary effect of increases in aerosols might occur if changes in droplet concentrations alter the lifetime and extent of clouds. Cloud lifetime might be increased because smaller droplets may require longer times to develop into precipitating clouds, resulting in more extensive cloud cover and/or deeper clouds. The issue is complex because the absorption of solar radiation by clouds may lead to dynamical responses in a cloud that either extend its vertical structure and lifetime or reduce it.

Changes in aerosol concentrations over time have the potential to greatly impact the radiation balance and therefore climate. Because aerosols primarily tend to cool the climate, if aerosol emissions decrease (as, for example, if controls limit future emissions of SO_2), warming by greenhouse gases may be expected to accelerate.

SOURCES OF AEROSOLS

Particles in the atmosphere are most often composed of sulfate, nitrate, ammonium, organics, silicates and other compounds associated with soils and dust, sea salt and compounds associated with the sea salt aerosol, soot or black carbon and trace metals (the total trace metal mass is small and is therefore not described here due to its very small climatic influence). The sources of these aerosol components vary significantly with region and time of year. This, together with the fact that the aerosol lifetime is relatively short (about five days), implies that the concentrations of the components also vary significantly with location and time.

Aerosol sources may be divided into gas phase sources and primary particulate sources (*see* Aerosols, Troposphere, Volume 1). *Gas phase sources* may either directly condense to the particulate phase, or they may be oxidized in the atmosphere through photochemical reactions to produce gases that may condense to the particulate phase. An example of the former is ammonia (NH_3) while the latter includes sulfur dioxide (SO_2) or dimethylsulfide (DMS), which may oxidize to form sulfate (H_2SO_4) (*see* Dimethylsul de (DMS), Volume 1) and nitrogen oxides (NO_x), which is converted to nitric acid (HNO_3). H_2SO_4 has low volatility and will partition almost wholly to the particulate phase while NH_3 and HNO_3 are both semi-volatile and their partitioning into the particle phase depends on local conditions. Organic gases can also oxidize to form either semi-volatile compounds or compounds with low volatility. The sources of gas phase precursors are summarized in Table 1.

Primary particulate sources are emitted as particles at or near the source. They include smoke from fires, dust uplifted by wind, sea salt from direct injection and bursting of bubbles, and biogenic particles (fungi, spores, epicuticular plant waxes etc.). Fires mainly originate from anthropogenic activity (burning for agriculture, to clear land, burning of fossil fuels). Dust outbreaks have also been associated with anthropogenic activity, since agricultural processing of the land can lead to more frequent dust outbreaks and because some desertification is associated with land use changes (*see* Dust, Volume 1). Tegen and Fung (1995) estimated that about 50% of their total dust source strength was associated with land use changes.

Table 2 presents NH and SH average sources for primary particulates according to aerosol size ($d < 2\,\mu m$ and $2 < d < 20\,\mu m$). The fine particle fraction of the atmospheric aerosol (defined as that portion with diameter less than $2\,\mu m$) has been studied the most because it generally contains the largest number fraction and is generally the most important fraction for determining the direct radiative forcing. The composition and number concentration of the sub-micron fraction is also important for determining the indirect effects of aerosols. However, because both the small and large fractions act both as available surfaces for the reaction of gas-phase aerosol precursors and as condensation sites for aerosol precursors, sources for the entire aerosol size spectrum must be quantified in order to quantify the sub-micron component. Also, in some circumstances, the available surface area for large particles can control the supersaturation maximum reached within an updraft as clouds form so that the abundance of large, highly soluble aerosols such as sea salt can partly determine droplet cloud droplet concentrations in clouds. Furthermore, in regions with high concentrations of dust and sea salt particles, the large particle component can be important to direct forcing. Thus, the budget for all sizes of aerosols needs quantification in order to determine the magnitude of the forcing of aerosols on climate.

If one assumes that the airborne portion of HNO_3 is in equilibrium with the sulfate aerosol and NH_3 concentrations, one can derive estimates of the total aerosol source strength from the gas phase aerosol precursor emissions in Table 1. These are presented in Table 3.

EFFECTS OF AEROSOLS ON CLIMATE

Because the sources of anthropogenic aerosols are a relatively large fraction of the total source strength, it is important to try to understand the possible impact of these recently increasing aerosol concentrations on past and future climate change (*see* Climate Change, Detection and Attribution, Volume 1). One method for estimating their possible climate impact is to estimate the radiative forcing associated with the anthropogenic fraction of aerosol. *Radiative forcing* is the change in net incoming radiation

Table 1 Annual source strength for emissions of gas phase aerosol precursors (Tg N or S or C year^{-1})

	NH	SH	Global	Range

Anthropogenic	1.04	9	109	70–150
Terpenes	67	60	127	90–180

[a] Volcanic emissions are annually averaged emissions to the troposphere. Explosive volcanoes may emit much larger amounts to the stratosphere.
NH, Northern Hemispheric; SH, Southern Hemispheric.

at the top of the troposphere caused by a specific change in composition (*see* Radiative Forcing, Volume 1). It gives a first-order measure of the long-term steady state response of the climate because the global average change in surface temperature is approximately linearly related to the radiative forcing. Thus,

$$\Delta T_s \approx \lambda \Delta F \quad (1)$$

where λ is defined as the climate sensitivity (K (W m^{-2})$^{-1}$) and ΔF is the radiative forcing. The climate sensitivity depends primarily on the long-term changes in water vapor (the main greenhouse gas in the atmosphere), clouds, sea-ice cover and snow. The magnitude of λ has been estimated from climate models to range from 0.2 to 1.1 K (W m^{-2})$^{-1}$. This range of variability results from different representations of physical processes within climate models.

It is important to note that radiative forcing is only an approximate measure of climate effects. It relies on the concept that the surface temperature change is effectively communicated throughout the troposphere by convective and radiative processes. However, because emissions into specific regions can alter the vertical profile of local temperature as well as the local cloud fraction and water concentrations, the concept is only approximately valid. Nevertheless, it provides a first-order estimate of the relative impacts of different emissions. Radiative forcing by aerosols may be compared to the forcing from greenhouse gases and from changes in solar radiation over the past 100 years. These latter forcings were estimated as $\sim 2.5\,\mathrm{W\,m^{-2}}$ and $-0.3\,\mathrm{W\,m^{-2}}$, respectively, in the recent Intergovernmental Panel on Climate Change scientific assessments (IPCC, 1996, 2001).

DIRECT EFFECTS OF ANTHROPOGENIC AEROSOLS

Recent estimates for the direct forcing by anthropogenic aerosols are between -0.3 to $-0.9\,\mathrm{W\,m^{-2}}$ for sulfate aerosols, between -0.15 and $-0.25\,\mathrm{W\,m^{-2}}$ for biomass

Table 2 Primary particle emissions (Tg year^{-1})

	NH	SH	Global	Low	High

aerosols (from biomass fuel use and land clearing), and between $+0.15$ and $+0.2\,W\,m^{-2}$ for fossil fuel and industrial sources of organic and black carbon aerosols. Figure 1 shows the spatial distribution of the estimated forcing of anthopogenic sulfur and carbonaceous aerosols (Penner *et al.*, 1998). Estimates of climate forcing from anthropogenic nitrates and anthropogenic ammonia are small compared to forcing by sulfates. Anthropogenic sources of dust aerosols are estimated to have a global forcing of $+0.09\,W\,m^{-2}$ according to Tegen *et al.* (1996). Sea salt, while considered natural, appears to be the most important aerosol component with a total radiative effect of up to about $-1.0\,W\,m^{-2}$. The climate forcing associated with anthropogenic aerosols could offset a substantial fraction of the warming associated with greenhouse gases. If the ratio of aerosol emissions to greenhouse gas emissions remains constant, however, these impacts should decrease in the future, because aerosols have a lifetime in the atmosphere of order five days so that their concentrations do not increase as rapidly as those of most greenhouse gases (many of whom have lifetimes that are much longer). In addition, it should be noted that if SO_2 emissions are controlled in the future, more rapid warming should occur.

EFFECTS OF AEROSOLS ON CLOUDS

While estimates of climate forcing by aerosols associated with the direct reflection and absorption of radiation are

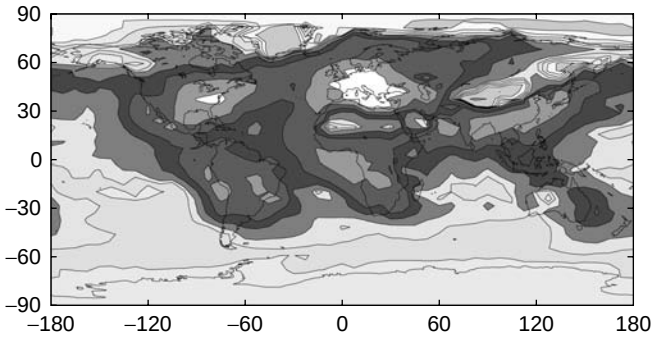

Figure 1 The sum of direct forcing by anthropogenic sulfate aerosols, biomass aerosols and organic matter and black carbon from fossil fuels. (Reprinted with permission from Penner *et al.*, 1998, © Springer-Verlag)

reasonably straightforward, estimates of the indirect effects of aerosols on clouds are much more difficult. This is mainly because the indirect effect of aerosols depends on knowing the natural as well as anthropogenic sources, the state of mixing of the different aerosol compounds, the fate of gas phase precursors which may either nucleate to form new particles that grow to a size range that would act as a CCN or condense on pre-existing aerosols, and the response of clouds (i.e., their droplet concentration and their vertical and horizontal extent) to changes in aerosols and droplet concentrations.

The state of mixing of aerosol has been shown to lead to uncertainties ranging from $-0.4\,\mathrm{W\,m^{-2}}$ to $-1.5\,\mathrm{W\,m^{-2}}$ in forcing by sulfate aerosols associated with changes in drop size distributions (see Chuang *et al.*, 1997). Changes in droplet concentrations due to carbonaceous aerosols from biomass burning and fossil fuel/industry lead to estimates of forcing that range from -1.2 to $-1.6\,\mathrm{W\,m^{-2}}$ depending on the magnitude of natural organics assumed in the calculation (Penner *et al.*, 1999). Changes in the magnitude of natural sources of dust and sea salt could change this estimate by a factor of 2. The estimates by Chuang and co-workers as well as those by Penner *et al.* (1999), assume that the total lifetime and extent of clouds remain constant. If this constraint is relaxed, then models have shown that the total forcing can more than double. Thus, the total indirect forcing by anthropogenic aerosols may range from about -0.3 to $-3.0\,\mathrm{W\,m^{-2}}$. It is not clear yet whether the upper range of these estimates for indirect forcing are far too large, but if they are correct, then our understanding of recent climate changes and the consistency of the historical record of temperature change with the record of radiation forcing would need to be altered.

As noted above, increases in high cirrus clouds may act to warm the climate. Aerosols from aircraft have been associated with observed increases in cirrus clouds that have occurred since the early 1970s (Fahey *et al.*, 1999). However, these increases may also be associated with surface level emissions, or they may be associated with other, natural cycles. Thus, there is not yet an estimate for the impact of aircraft exhaust on cirrus cloudiness and the associated radiative forcing.

FUTURE EFFECTS OF AEROSOLS

Scenarios for future emissions of SO_2 and other aerosols are highly uncertain. Some scenarios have SO_2 emissions increasing along with industrial emissions of CO_2. In these scenarios, the impact of aerosols on radiative forcing does not keep pace with the radiative forcing associated with CO_2 because the aerosols are removed from the atmosphere far more quickly than is CO_2. In other scenarios, SO_2 emissions are controlled (as they are now controlled in much of the developed world). These scenarios imply more rapid warming than scenarios which allow SO_2 emissions to grow as the overall industrial activity grows. However, additional effects must also be considered. For example, the aerosols from so-called natural sources may change. This is because the aerosols associated with sea salt, dust and DMS generation are dependent on wind speed and also on soil moisture in the case of dust. Aerosols from natural terpene emissions depend on temperature and light levels as well as changes in soil moisture. Thus, changes in environmental conditions associated with climate change itself can alter emissions of aerosols. Initial estimates of the possible changes in the emissions of DMS (*see* Dimethylsul de (DMS), Volume 1), terpenes, and dust aerosols by the year 2100 indicate that increases in DMS emissions may be relatively small, while both dust and terpene emissions may increase by about 10 and 20% on an annual average basis, respectively. Sea salt emissions may increase by 75% in the year 2100. Such changes could lead to an additional negative forcing of up to approximately $-1\,\mathrm{W\,m^{-2}}$ from direct forcing and an additional -1 to $-2\,\mathrm{W\,m^{-2}}$ from indirect forcing. Future climate models must consider both the projected changes in anthropogenic aerosols as well as the changes in natural aerosols and aerosol precursors associated with climate change.

Aerosols, Polar Stratospheric Cloud

Giovanni Pitari
Università L'Aquila, L'Aquila, Italy

Polar stratospheric cloud (PSC) aerosols are one of the most important types of particles present in the middle atmosphere. They are normally made of nitric acid hydrates or pure water ice and may only be formed at very cold temperatures (below about 200 K) in the wintertime polar vortices. These polar particles are regarded as one of the major factors responsible for the formation of the Antarctic ozone hole and for the presently detected negative trends of ozone in the Northern Hemisphere. Ef cient heterogeneous chemical reactions may in fact take place on the surface of these particles, producing large increases of reactive chlorine and bromine in the polar vortices with simultaneous presence of sunlight. Future increases of stratospheric water vapor and nitric acid, coupled to extensive stratospheric cooling caused by increasing burdens of greenhouse gases, are believed to be potentially capable of enhancing PSC formation (IPCC, 1999), thus delaying the future recovery of stratospheric ozone.

Sulfuric and Polar stratospheric cloud (PSC) particles are regarded as the most important aerosols in the stratosphere. They alter the ozone s chemical budget and may then affect the amount of ultraviolet radiation reaching the ground surface (*see* Stratosphere, Chemistry, Volume 1). Heterogeneous chemical reactions (see Table 1) may take place on the surface of these particles, and represent an important sink of reactive nitrogen at mid-high latitudes. In turn, a decrease of odd nitrogen makes chlorine and bromine catalytic cycles for ozone destruction faster than in a pure gas phase chemistry atmosphere. Reactions involving chlorine nitrate ($ClONO_2$) and hydrochloric acid (HCl) are very efficient on PSC particles and many scientific investigations have pointed out their role in the formation of the Antarctic springtime ozone hole. In the presence of sunlight, the temporary reservoir species formed by these reactions (Cl_2, HOCl, $ClNO_2$) are readily photodissociated, forming reactive chlorine. Aircraft data collected in the 1992 Arctic winter show dramatic losses of HCl and $ClONO_2$ with corresponding build-up of ClO when entering the polar vortex from the mid-latitudes (World Meteorological Organization (WMO), 1995).

PSC aerosols are complex particles made essentially by condensation of nitric acid and water vapor on preexisting nuclei (mostly sulfuric aerosols). However, while sulfuric acid condensation may occur everywhere in the middle atmosphere below about 35 km, nitric acid and water vapor condensation take place only at very cold temperatures in the wintertime polar vortices ($\approx$10–25 km altitude), forming particles of typical sizes of 1–10 μm radius. This implies that PSC particles may interact with the chemistry of the middle atmosphere, not only via heterogeneous chemistry, but also by irreversibly removing reactive nitrogen and water vapor via gravitational sedimentation, which may prolong ozone depletion (WMO, 1999). Denitrification and dehydration are the terms usually employed to refer to these kinds of irreversible loss of nitrogen and water. De-NO_x-ification, on the other hand, is the NO_x loss process associated with heterogeneous reactions that produce a net conversion of NO_x temporary reservoirs (N_2O_5, $ClONO_2$, $BrONO_2$) into nitric acid.

Chlorine activation, denitrification and de-NO_x-ification result in a perturbed stratospheric composition that is more favorable to ozone destruction (National Aeronautics and Space Administration, 1992). In fact, because of low levels

Table 1 Heterogeneous reactions on PSC and sulfuric aerosols relevant to atmospheric chemistry

$N_2O_5 + H_2O$	$\longrightarrow 2HNO_3$
$BrONO_2 + H_2O$	$\longrightarrow HOBr + HNO_3$
$ClONO_2 + H_2O$	$\longrightarrow HOCl + HNO_3$
$ClONO_2 + HCl$	$\longrightarrow Cl_2 + HNO_3$
$HOCl + HCl$	$\longrightarrow Cl_2 + H_2O$
$HOBr + HCl$	$\longrightarrow BrCl + H_2O$
$N_2O_5 + HCl$	$\longrightarrow ClNO_2 + HNO_3$

of NO_x and chlorine nitrate, some chlorine activation will tend to persist even after PSC particles disappear in the vortex. Horizontal mixing of air from mid-latitudes is the competitive process limiting the time extent of these low NO_x conditions. Pure H_2O ice particles are extensively observed only in the Antarctic polar vortex as winter progresses and upper air layers cool down below the frost point of water vapor in the polar stratosphere (≈187 K). These are normally coarse particles that are efficiently removed by gravitational sedimentation, with the net effect of dehydrating the south polar lower stratosphere (Kelly *et al.*, 1989). The observed dehydration and denitrification of the Antarctic winter stratosphere also have the effect of reducing the frequency of cloud formation at a specific temperature threshold.

Some properties of PSC particles have been defined by a decade of satellite observations (SAM II) from 1979 to 1989 (McCormick *et al.*, 1982; McCormick and Trepte, 1986; McCormick and Trepte, 1987). PSC frequency of observation peaks in August over the Antarctic region (60% PSC detection in the 18–20 km layer) and in the second half of January–first half of February over the Arctic region (10% PSC detection in the 18–22 km layer) (WMO, 1992). The observed optical depth at 1 μm wavelength is about 0.01 during the austral winter months over Antarctica (excluding the years perturbed by volcanic eruptions). Another class of upper atmospheric polar H_2O cloud particles is normally referred to as noctilucent clouds, but while PSC aerosols are found in the polar lower stratosphere, noctilucent cloud particles reside in the mesosphere at more than 80 km above the ground.

Future increases of stratospheric water vapor and nitric acid, coupled to extensive stratospheric cooling caused by increasing burdens of carbon dioxide and other greenhouse gases (methane and N_2O in particular), might enhance PSC formation over wider regions of the polar stratosphere and for longer periods of time. These atmospheric composition changes may then slow down the recovery rate of stratospheric ozone in the next few decades, as expected following the Montreal protocol compliance for chlorofluorocarbons and halons (WMO, 1999). Future trends of water vapor may also be a consequence of climate changes: in particular a warming/cooling of the tropical tropopause may be a key climate factor determining the distribution of stratospheric H_2O. In fact, the most important mechanisms for producing H_2O in the stratosphere are methane oxidation and upward transport in the lower stratospheric tropical pipe (i.e., the upper extension of the Hadley circulation). Future climate changes may affect the temperature of the tropical tropopause and then the saturation water vapor pressure in this critical region, from where the whole stratosphere is dynamically fed.

High-flying supersonic aircraft might be another potential cause of a future increase of frequency of PSC occurrence. Only a few studies, applying detailed PSC microphysical schemes, have been made to investigate the effects of stratospheric aircraft emissions on PSC properties (Peter *et al.*, 1991; Pitari *et al.*, 1993). A thorough review of the effects on PSC surface area densities, applying a selection of state-of-the-art atmospheric models with varying degrees of microphysical complexity, has been provided by IPCC (1999). It is shown by the International Panel on Climate Change (IPCC) that *in situ* aircraft emissions of NO_x and H_2O in the lower stratosphere may create more favorable conditions for nitric acid and water vapor condensation into PSC particles.

Common to most modeling studies (Pitari *et al.*, 1993, as an example) is the assumption of the existence of two types of solid phase PSC particles, forming at certain threshold temperatures (e.g., the nitric acid trihydrate (NAT) condensation temperature and the ice frost point). Subsequent research has revealed the existence of at least three PSC particle types, showing complicated transition processes between liquid and solid type particles, that depend on the temperature histories of individual particles (Larsen, 2000).

The most important physico-chemical processes involved in our current understanding of PSC formation and growth are the evolution of liquid PSC and the mechanisms of liquid-to-solid and solid-to-liquid transitions. The background stratospheric aerosol particles are mostly supercooled sulfuric acid/H_2O liquid droplets. Their composition is strongly dependent on temperature: as temperature falls, they absorb water vapor. Below 200 K the uptake of HNO_3 becomes important, and these droplets change in composition and grow in volume (Carslaw *et al.*, 1994). If local temperature falls below the ice frost point, these particles freeze, forming a mixture of ice and solid hydrates of the acids.

Several mechanisms have been suggested for the formation of solid phase particles at temperatures above the ice frost point. Koop *et al.* (1995) have argued that the $HNO_3/H_2SO_4/H_2O$ particles do not freeze above the ice freezing temperatures, if the HNO_3 and H_2SO_4 weight fractions are close to their equilibrium values. On the other hand, when the $HNO_3/H_2SO_4/H_2O$ droplets evolve away from the thermodynamic equilibrium (i.e., during fast cooling and heating events), the $HNO_3/H_2SO_4/H_2O$ particles could become similar to HNO_3/H_2O pure solution droplets: these can freeze a few degrees above the ice freezing temperatures (between 190 K and 193 K), forming solid NAT (Meilinger *et al.*, 1995). Cooling/heating events associated with orographically generated gravity waves are an important driving mechanism for the formation of these solid particles. Other theories are based on freezing nucleation mechanisms (Jensen *et al.*, 1991; Luo *et al.*, 1994).

Aerosols, Stratosphere

Giovanni Pitari

Università L'Aquila, L'Aquila, Italy

A variety of aerosol particles can be found in the middle atmosphere, with sulfate and polar stratospheric cloud (PSC) particles being the most important for the chemical budget of the stratosphere and for their potential impact on climate. Other aerosol types detectable in the stratosphere are meteoritic dust and carbonaceous particles. The latter can be injected in situ by aircraft engines and can also be transported into the lower stratosphere by deep convective storms. This vertical mixing mechanism moves upward black carbon soot and organic particles produced at the surface by fossil fuel and biomass burning, forest res and terpene oxidation.

The main process responsible for stratospheric aerosol production (other than transport from the troposphere or from space) is gas condensation on pre-existing nuclei or on molecular clusters formed through homogeneous nucleation mechanisms. Sulphuric acid condensation may occur everywhere in the middle atmosphere below about 35 km, producing the observed size distribution of sulfate aerosols. Nitric acid and water vapour condensation takes place only at very cold temperatures in the wintertime polar vortices, forming PSC particles. In situ injection from aircraft plumes is another important production mechanism for sulfate aerosols: future supersonic high- ying aircraft will greatly increase the particle number and surface area density (SAD) in the mid-stratosphere (IPCC, 1999).

Stratospheric sulfate aerosols (SSA) may be formed *in situ* following ultraviolet (UV) photolysis of carbonyl sulfide (OCS), forming sulfur dioxide (SO_2), and also through oxidation of SO_2 penetrating the tropical tropopause. SO_2 is oxidized in a three-body reaction with OH forming sulphuric acid (H_2SO_4) as the final product of a reaction chain. Sulphuric acid and water vapour condensation takes place on pre-existing nuclei: these are Aitken particles coming from the tropical tropopause (mainly carbonaceous) that are first coated by H_2O/H_2SO_4, and also ultrafine sulfate particles formed by homogeneous nucleation immediately below the tropical tropopause (Weisenstein *et al.*, 1997).

The particle size distribution at a given location is determined by simultaneous microphysical processes (heterogeneous and homogeneous nucleation, condensation growth, evaporation, coagulation) and by large-scale transport and gravitational sedimentation.

Background sulfate aerosols are those photochemically produced in steady-state conditions of stratospheric sulfur abundance. These background sulfate particles are often perturbed by new aerosol formation starting from SO_2 or H_2S injected *in situ* by explosive volcanic eruptions. In the case of large eruptions, the aerosol optical thickness may increase by orders of magnitude.

Removal of stratospheric aerosols is produced by large-scale downward transport at mid–high latitudes, which moves the particles down into the troposphere where they are washed out or deposited at the surface.

Gravitational sedimentation is another important removal mechanism, although the lower stratospheric settling deposition is faster than advective downward motion only for particles with radius larger than 1 μm. This process, however, is important in determining the aerosol vertical profile in the mid-stratosphere.

Sulfate and PSC aerosols (*see* Aerosols, Polar Stratospheric Cloud, Volume 1) are of primary importance for the chemical budget of the middle atmosphere: heterogeneous reactions taking place on the surface of these particles represent an important sink of reactive nitrogen at mid–high latitudes. In turn, a decrease of odd nitrogen makes chlorine and bromine catalytic cycles for ozone destruction faster with respect to a pure gas phase chemistry atmosphere. Chlorine activation and de-NO_x-ification result in a perturbed stratospheric composition that is more favourable to ozone destruction (NASA, 1992). Sporadic sulfur injection in the stratosphere produced by large volcanic eruptions may produce catastrophic ozone losses (Prather, 1992).

Stratospheric aerosols have been sampled using balloons and high-altitude aircraft (Hofmann and Rosen, 1981; Rosen *et al.*, 1975) and from ground-based lidar measurements (pioneering observations were those by Fiocco and Grams, 1964). The most extensive coverage of stratospheric aerosols has been made by the SAGE satellite: these satellite data have provided information on the three-dimensional global-scale distribution of several aerosol properties, as extinction, optical thickness, mass density and SAD, acidity, and size distribution (McCormick *et al.*, 1979; Kent and McCormick, 1984; Yue *et al.*, 1986; Yue *et al.*, 1994). The range of typical non-volcanic values is summarized in Table 1.

Table 1 Summary of background stratospheric aerosol properties

Extinction at 1.0 μm (10^{-5} km^{-1})	1–100
Mass density (μgm^{-3})	0.01–0.5
SAD (μm^2 cm^{-3})	0.1–2
H_2SO_4 weight fraction	0.4–0.9
Number density of optically active particles ($r > 0.15$ μm) (part mg^{-1} air^{-1})	1–10
Stratospheric optical depth at 1.0 μm	5×10^{-4}–2×10^{-3}
Log-normal mode radius (μm)	About 0.07
Log-normal dispersion (μm)	About 1.8
Mass burden (Tg-S)	About 0.14

Stratospheric sulfate aerosols (SSA) play a key role in the chemical budget of the stratosphere. Several chemical reactions may efficiently take place on the surface of these particles (JPL, 1997): these heterogeneous reactions include hydrolysis of N_2O_5, $BrONO_2$, $ClONO_2$ and others involving hydrochloric acid (reacting with $ClONO_2$, HOCl, HOBr; see Table 2) (*see* Stratosphere, Chemistry, Volume 1). Reaction probabilities are normally highly dependent on particle acidity, with the important exception of $N_2O_5 + H_2O$: in this case the sticking coefficient is rather insensitive to temperature and humidity conditions. Many laboratory studies have been made on the efficiency of heterogeneous reactions involving Cl/Br species, due to their potential importance in polar ozone depletion (Hanson and Ravishankara, 1991; Hanson and Ravishankara, 1995; Hanson *et al.*, 1994; Hanson *et al.*, 1996).

The net effect of these heterogeneous reactions on SSA surfaces is to lower the NO_x to NO_y ratio (Fahey *et al.*, 1993), where NO_x is the sum of reactive nitrogen and temporary reservoirs ($NO + NO_2 + NO_3 + HNO_4 + N_2O_5 + ClONO_2 + BrONO_2$), while NO_y is the sum of NO_x and nitric acid (HNO_3). Heterogeneous reactions on SSA are in fact the most important loss mechanisms for NO_x in the lower stratospheric mid–high latitudes, along with the three-body reaction of NO_2 with OH forming nitric acid. This NO_x removal ends up in a ClO, BrO increase due to the decreased amount of chlorine and bromine nitrates, thus making Cl/Br catalytic cycles for ozone destruction dominant at about 50 hPa (Weisenstein *et al.*, 1991).

The 1991/92 mid-latitude observations collected by Fahey *et al.* (1993) clearly show the effect of the additional Pinatubo aerosols on the stratospheric chemistry: NO_x/NO_y at about 20 km and 45 °N falls from about 0.12 with a SAD of 0.5 μm^2 cm^{-3} (typical background value) to 0.09 with

Table 2 Heterogeneous reactions on SSA relevant to atmospheric chemistry

$N_2O_5 + H_2O$	$\longrightarrow 2HNO_3$
$BrONO_2 + H_2O$	$\longrightarrow HOBr + HNO_3$
$ClONO_2 + H_2O$	$\longrightarrow HOCl + HNO_3$
$ClONO_2 + HCl$	$\longrightarrow Cl_2 + HNO_3$
$HOCl + HCl$	$\longrightarrow Cl_2 + H_2O$
$HOBr + HCl$	$\longrightarrow BrCl + H_2O$

SAD = 4 μm^2 cm^{-3} and to 0.07 with SAD = 20 μm^2 cm^{-3} (during March 1992, with substantial Mt. Pinatubo aerosol penetration into the Northern Hemisphere, *see* Volcanic Eruption, Mt. Pinatubo, Volume 1).

The corresponding reactive chlorine fraction increases in the total chlorine budget (Cl_y): ClO/Cl_y ranges between 0.02–0.03 with SAD < 4 μm^2 cm^{-3} and between 0.04–0.06 with SAD = 20 μm^2 cm^{-3}. On the other hand, model calculations assuming pure gas phase chemistry give a much higher NO_x/NO_y ratio (0.19). The role of aerosol variations in anthropogenic ozone depletion at northern mid-latitudes in the last two decades has been shown by Solomon *et al.* (1996). A time-dependent model exercise carried out for the ozone assessment of the World Meteorological Organization (WMO) has shown that the photochemical perturbation produced by the Pinatubo aerosols during 1992/93 can explain to a large extent the total ozone depletion observed by the total ozone mapping spectrometer (TOMS) (WMO, 1999). Additional radiation scattering and absorption by volcanic particles may also perturb the ozone distribution through photolysis rates and circulation changes in the stratosphere (Pitari and Rizi, 1993; Kinne *et al.*, 1992).

Future trends of anthropogenic SO_2 emissions may significantly perturb mass and surface area densities of SSA. This is because not only will the total emission change, according to IPCC (2000) future scenarios, but also because large regional changes will occur with decreasing emission in western industrialized countries and large increases over the Middle East, China, India, Africa, and Central and South America. Enhanced SO_2 release in the tropics may significantly perturb the net amount of sulfur dioxide reaching the tropical tropopause and then entering the stratosphere.

Assuming as a reference case the IPCC (2000) A2 scenario, SO_2 emissions should peak around the year 2030, with a 60% increase with respect to present time; an increase of lower stratospheric SSA SAD associated to this larger tropospheric influx could affect the rate of recovery of stratospheric ozone. A faster heterogeneous chemical production of reactive Cl/Br may also be expected as a consequence of future supersonic aircraft emissions of ultrafine sulfate particles (IPCC, 1999).

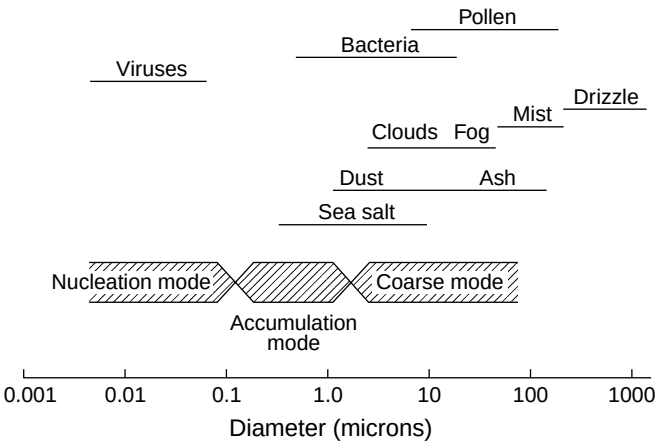

Figure 1 Sizes of some typical aerosols

Aerosols, Troposphere

Peter Brimblecombe
University of East Anglia, Norwich, UK

Aerosols are popularly seen as the products of spray cans. This misconception is understandable given the scienti c dif culties in de ning a term that was coined at the end of World War I to describe arsenical smokes. Aerosol has come to mean a suspension of solids or liquid droplets in air and can be regarded as an analogue of a hydrosol, the suspension of solid particles in water. The broadest de nition of aerosol embraces earlier terms such as: dusts, smokes, fogs, mists, fumes. The troposphere is lled with such aerosols, exhibiting a wide range of sizes due to their various sources and having a range of consequences. The study of aerosols has coped with treating both the individual particles and the bulk properties of the clouds they form.

It is size that most broadly characterizes aerosols and is critically important for their properties. There is an upper limit on the size that can remain suspended for any period of time. Occasionally very large particles are found in the atmosphere, perhaps 100 microns (μm) across. These are short lived, but include droplets, mists and volcanic particles. In general aerosol particles that are most often collected are about 20 microns or less in diameter. Figure 1 shows typical sizes of aerosols from a range of sources. The size of particles often reflects the processes responsible for their production. Those less than 0.1 microns are freshly formed by condensation or produced from reactions in the gas phase. This size range is known as the *nucleation mode*. Such small particles soon grow by coagulation or further condensation and lead to particles belonging to the *accumulation mode*. The largest particles (*coarse mode*) are usually formed by disaggregative processes, such as grinding or shattering after impacts at the surface of the Earth.

The very small size of aerosol particles has often made individual particle studies very difficult. Their properties may be studied optically, but bulk collection is perhaps the most common approach. Typically aerosols are collected onto filters of fibrous cellulose or quartz, or membranes of polycarbonate or Teflon. Membranes have the advantage of retaining particles on the surface, so they can later be examined by microscopy. The filters thus collected can later be weighed or analyzed. Collectors are often designed to admit particles in specific size ranges relevant to the planned study.

Size can be difficult to define because not all aerosols have regular shapes. This means that descriptions of aerosols have to define exactly what is meant by the size or diameter. Sometimes particles are assumed to be spheres with their volume treated as if it were spread within a sphere of a given diameter (*equivalent diameter*). When particles are observed under optical microscopy, the maximum edge to edge distance can be gauged (*Feret's diameter*). The rate at which fine particles fall in air (*settling velocity*) is dependent on their size. It provides another method of measuring particle size, so some studies express size as an *aerodynamic diameter*. This is defined as the diameter of a sphere of unit density (i.e., $1\,\mathrm{g\,cm^{-3}}$) that attains the same terminal velocity as the particle in question.

The aerosols found in the atmosphere have sizes that are often close to the wavelength of light. This enables them to interact with light and cause a wide range of optical phenomena. The reddish glow in the sky at sunrise and sunset is enhanced when large fires or volcanic eruptions have forced large quantities of particulate material into the atmosphere. This glow is produced as small particles scatter blue light and allow red to penetrate. It was first treated theoretically by Rayleigh late last century, but it has become apparent that the scattering process he described was restricted to

particles smaller than 30 nm (0.03 microns). In the present century a more complete description has been developed to describe what is called *Mie scattering*. It accounts for scattering taking place with particles close to the wavelength of light that could not be handled by the Rayleigh theory. These theories describe the optical properties of spherical particles, typically droplets, but are more difficult to apply to ice crystals, for example. More complex optical phenomena arise from particles of particular shape. Perhaps the best known of those originating from non-spherical particles, including phenomena such as the sun pillars (vertical shafts of light extending upward or downward from the sun).

SOURCES OF AEROSOLS

Although size reflects the process of aerosol production, composition is potentially a more informative indicator. *Primary particles* are those generated directly by their sources, as is seen clearly with wind blown dusts. The composition of dust particles is very similar to that of the soil from whence they came, so such particles include much silicon, calcium, aluminum, iron, etc. (*see* Dust, Volume 1). Although dust composition changes slightly over time, as particles age, much of the material is relatively insoluble and resistant to weathering.

The oceans are also a source of aerosols. Breaking waves produce sea spray, which can dry and yield salt particles in the atmosphere. However, salt particles from spray tend to be fairly large and short-lived. The minute bubbles that burst at the ocean surface, however, are more significant sources of sea salt particles. As this happens, the film from the cap of the bubble shatters, giving minute droplets, 6–30 microns in diameter that dry to form salt particles 1.5–8 microns across. Additionally, as the cavity left by the void that replaces the bubble collapses, a small jet pushes further droplets into the atmosphere; these are larger and produce salt particles of some 25 microns across. Although these droplets are mostly sea salt (sodium chloride with traces of other salts), there is the potential for other substances to be incorporated as the bubble forms. The surface of the sea is sometimes covered with a thin organic film that can interact with metals present in seawater and enhance their concentration in bubble caps. As bubbles burst, these metals are incorporated into the droplets released to the atmosphere, so we can find some elements enriched in the marine aerosol.

Volcanic particles contain rock fragments, but are often associated with sulfuric, hydrofluoric and hydrochloric acids from the hot vented gases. The high temperature production process gives the potential for the relocation of moderately volatile materials onto finer particles. These include metallic compounds or oxides, such as boron oxide, which can be found as boric acid in aerosols.

Biological activities are also an important source of particles, relevant to human health, as hay fever suffers well know. Bio-aerosols can be associated with the transmission of infectious diseases. The dispersal of pollen and spores are necessary for the propagation of plants. There are both viable and non-viable particles of primary origin. Non-viable particles include plant fragments, insect parts, feces, dander, etc. The seasonal distribution of biological particles is quite distinctive. In the spring, there is an important dominance of pollen grains that lie in the 10–30 micron range. In the autumn and winter, smaller biological particles dominate as bacterial aerosols arise from the decay processes.

Many of the particles discussed above are *primary particles* produced directly by processes such as combustion or weathering at the Earth s surface and carried aloft. Although this seems a very obvious source, it is not necessarily the most important. Much of the particulate material in the atmosphere, especially in the smaller size ranges, is produced by chemical reactions in the atmosphere. Such particles are called *secondary aerosols*. Typically atmospheric aerosols contain a significant proportion of sulfate (Figure 2). Much of this comes from the oxidation of atmospheric sulfur dioxide or sulfides that produce sulfuric acid. Sulfuric acid has an extremely strong affinity for water and, once formed, rapidly becomes incorporated in minute droplets. This acid can often enhance the uptake of alkaline ammonia from the atmosphere, such that fine particles are frequently found to be ammonium sulfate or bisulfate. Nitric acid is also produced in the atmosphere and can lead to the presence of an ammonium nitrate fraction within atmospheric aerosols. Thus, we have a situation where the soluble component of fine particles might be imagined as a $H^+/NH_4^+/SO_4^{2-}/NO_3^-$ system. Over the oceans, coarse

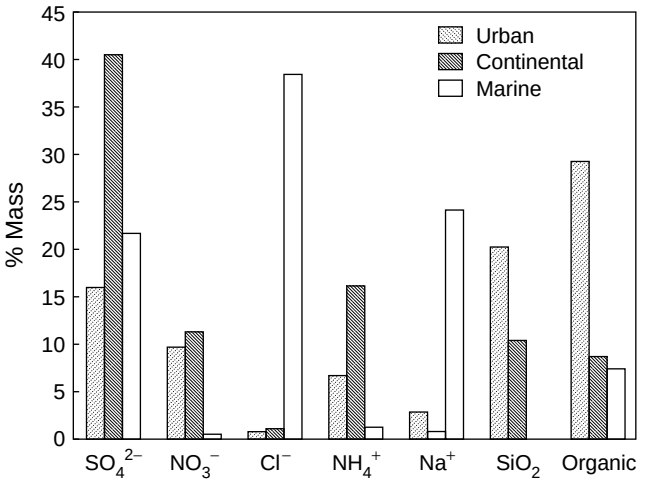

Figure 2 Percentage mass of various fractions in a typical urban, marine and continental aerosol (data from Colbeck, 1998)

sea salt particles of mostly Na^+/Cl^- are found together with this finer fraction. By contrast the finer continental aerosol, far from the oceans, is mostly produced from reactions in the atmosphere and will often be present with a coarser primary fraction composed of soil-derived dusts.

In addition to these inorganic materials, there is an organic component, that has not been as well studied. This typically includes acids or aldehydes, because they are so readily produced through the oxidation of volatile organic compounds (VOCs) in the atmosphere. Simple acids such as formic acid and acetic acid are abundant; they can only be removed (by conversion to droplets) if there is a significant amount of liquid water, as in clouds. Less volatile acids, and notably the dicarboxylic acid, oxalic acid, have a low volatility and high solubility and so become associated with aerosols in most conditions. Volatile hydrocarbons from plants include a wide range of terpenes. A common terpene, such as alpha-pinene, is released in large quantities by forests. It is readily oxidized in the atmosphere to a range of compounds, which include pinonic and pinic acids (derivatives of cyclobutane). These have been identified as components of forest aerosols.

Agriculture is one of the most natural human activities. However, it stirs up dust, and the pesticides that are in use also become part of the atmospheric aerosol loading. Fires that are so often a part of our agricultural endeavor are a further important source of atmospheric aerosols. Mention should also be made of widespread forest fires that are also a result of human activities, most notably in tropical South America (1970s and 1980s) and Southeast Asia (1990s). There has been much discussion that the impacts these fires, often set to clear land of vegetation, have on human health and regional air chemistry, including raising ozone concentrations. Biomass burning yields many millions of tonnes of soot every year. The soot has a graphitic structure, but there are some oxidized organic and hydrocarbon entities associated with it. Potassium and zinc are also likely to be found in the particles from forest fires.

Aerosols are usually present at high concentrations in cities. Combustion is one of the most important sources of particles, and soot or smoke has long been the most obvious urban aerosol. The larger smoke particles have become less common in the urban atmosphere as coal has been abandoned as the main domestic and industrial fuel. However, the rise of diesel powered vehicles represents a particularly important source of carbon particles. These particles are often extremely small and typically lie in the 10–80 nm range, but frequently cluster together to form larger conglomerates. Even so, diesel-derived particles are less than 2.5 microns in diameter. Furthermore, carbonaceous diesel particles are frequently associated with low volatility organic compounds such as the polycyclic aromatic hydrocarbons (PAHs). These compounds are of concern because they are often carcinogenic. Both motor vehicles and stationary combustion sources seem responsible for various PAHs, of which benzo(*a*)pyrene is widely studied, partly because it is a well known carcinogen. Recently it has become evident that PAHs can react in the atmosphere to form nitro- or chloro-PAHs. These compounds may well have enhanced carcinogenicity compared with their parent PAH. While the threat to human health is very real, there is evidence that the changes in combustion processes in urban areas over the last 50 years have brought about a decline in the concentration of major PAH fractions such as benzo(*a*)pyrene. Nevertheless, the poorly understood organic fraction remains a major component of respirable aerosol particles in urban areas.

Combustion is also responsible for the release of ashes. In the past, fly ash, especially from coal combustion, was rich in calcium and iron. Such alkaline aerosols may have neutralized some of the sulfuric acid that came from coal use and contributed to maintaining an acid balance when combustion products returned to the surface. Today, in many cities, ash particles are likely to derive from oil. Both vanadium and nickel are enriched in petroleum oils, so they are also present at high relative abundance in oil fly ash and their presence can be used as tracers of oil combustion.

Dust in cities is generated by localized activities. In arid regions, wind blown dusts from surrounding areas can be a further source that adds to anthropogenic particles in urban air.

The polluted atmosphere is very reactive and produces many secondary aerosols. The oxidation of sulfur dioxide and the nitrogen oxides to sulfuric acid and nitric acids provides important sources of these compounds in urban particles. Hydrogen chloride is released from industrial sources and incineration. These acids become associated as sulfates, nitrates and chlorides on the fine aerosols. As in remote continental air, they often become associated with ammonium salts.

Although much of the respirable particulate load in urban air is composed of organic matter, it is not clear what proportion of this is of primary origin. Oxidative reactions in the urban atmosphere produce relatively low volatility acids and aldehydes. The highly oxidized oxalic acid is often found associated with the fine particles of smog. This suggests that oxalic acid is an example of an organic aerosol component of secondary origin.

The particles in the atmosphere are removed in two ways. Over time, some slowly sediment and deposit on the ground, often filtered out by vegetation (*dry deposition*). A more important process involves their incorporation into cloud droplets and ultimate removal in rainwater (*wet deposition*). Particles typically remain in the lower troposphere (below 1.5 km) about one week before removal, although their residence times are dependent on weather conditions. Higher in the troposphere, residence times are as much as three weeks.

IMPACTS OF AEROSOLS

Particles present in air have a range of effects. In the past, the high concentrations of soot in cities were apparent from the black encrustations that disfigured buildings. Declining coal use within major cities gave some relief to this problem, but in Europe soiling once again appears to be on the increase. Now it is associated with diesel soot rather than solid fuel combustion.

Health impacts are one of the major problems likely to arise from the high concentrations of suspended particulate matter in cities. In recent years, regulatory attention has shifted to the finer fraction of the urban aerosol. Size differentiated measurements of respirable particles of 10 microns (PM_{10}) have been made for more than a decade. As more detailed studies have become available, there is evidence that the health impacts appear to be associated with yet finer fractions, so emerging regulations are likely to focus on $PM_{2.5}$ (particles of 2.5 microns diameter or less).

As we breathe in particles, some, especially the larger ones, can be trapped in the mucous that coats our airways. This is a useful protective mechanism as the mucous is driven upwards by the beating of fine hairs (*cilia*), so that the particles can ultimately be swallowed rather than reach the lung. Many finer particles are not effectively removed by the mucous and penetrate into terminal airways and alveoli. Here, macrophages engulf the particles and migrate to the ciliated parts of the respiratory system, effectively removing them from the lung. The activities of the macrophages, although important, release inflammatory compounds. The inflammatory effects may easily be transmitted to the blood. Other particles can cross the epithelium and become associated with inflammation of interstitial tissue. This pulmonary inflammation then leads to cardiovascular problems, so an enhanced death rate in particle laden air would seem an understandable outcome.

It has been difficult to evaluate the effect of urban aerosols on human health through controlled exposure of volunteers. This method is common when estimating the effects of pollutant gases, but more difficult for particles that are not so easily defined. Most evidence for the harmful effects of aerosols has come from epidemiological studies of exposed populations in cities, for example, by examining death rates and the frequency of hospital admissions. Studies in the US have indicated that a $10\,\mu g\,m^{-3}$ rise in PM_{10} concentration is likely to cause a 1% increase in daily mortality. The strongest association between exposure and death is related to the preceding 5 days exposure, which suggests a relatively rapid effect on mortality. Such fatalities can be viewed as deaths brought forward, because the affected individuals may already have been unwell, so that a high air pollution episode may cause them to die sooner. In addition to this rapid effect on mortality, lengthy exposure to high particle concentrations in the urban atmosphere may well contribute to a slower development of the debilitating diseases. Furthermore, lung cancer is a potential threat from long-term exposure to the PAHs present on urban particles.

Tropospheric aerosols have effects not only at the surface but they can change the radiative budget of the Earth. In addition to the potential influence of aerosols from human activities, it has often been argued, through the popular Gaia hypothesis, that natural marine sulfate aerosols have helped in maintaining relatively constant global temperatures. These sulfate aerosols are derived from the oxidation of dimethylsufide released to the atmosphere by phytoplankton (*see* Dimethylsul de (DMS), Volume 1). It has been argued that this suggests a biological control on global climate. Human activities have further enhanced the presence of sulfate aerosols, particularly in the Northern Hemisphere, by releasing large amounts of sulfur dioxide during fossil fuel combustion. Sulfate aerosols increase the number of cloud condensation nuclei and make clouds more reflective, with the potential for cooling the troposphere. Although at their most obvious in cities, tropospheric aerosols can thus have global impacts (*see* Aerosols, Effects on the Climate, Volume 1).

Agassiz, Louis

(1807- 1873)

Louis Agassiz was born in Switzerland in 1807. He became the leading proponent of the ice age theory and the existence of large continental ice sheets covering much of northern Europe and North America. While a professor at Neuchatel from 1835 to 1845, Agassiz studied the geological formations of Switzerland, in comparison to those of England and central Europe. He related the scratched and polished rocks, erratic boulders, and the geomorphology of the landscape to the presence of a large continental ice sheet. Although

he was not the first to develop the glacial theory (e.g., Jean-Pierre Perraudin, Ignace Venetz, Jean de Charpentier), his Discourse of Neuchatel, delivered in 1837 to the Swiss Society of Natural Sciences, brought the theory to prominence. He later extended this theory to North America. Early on, he won the acceptance of such notable scientists as the Reverend William Buckland, Charles Lyell and Charles Darwin, although they accepted a more general theory that included a combination of glaciers, icebergs, terrestrial melt water, and ocean currents to explain the features of glaciation. As a result, Agassiz s theory first became more obscure before becoming more widely accepted in the 1870s (American Council of Learned Societies, 1970; Hansen, 1970; Imbrie and Imbrie, 1986).

Agassiz obtained his PhD in 1829 at the Universities of Munich and Erlangen, studying the fishes of Brazil, and his Doctor of Medicine at Munich in 1830. In 1832 he married Cecile Braun and became a professor at the College of Neuchatel, which is where he published his ice age-related work. In 1846, he lectured at Lowell Institute in Boston. The following year his wife died (they had three children), and he started a professorship at the Lawrence Scientific School of Harvard University, where he taught until his death in 1873. He remarried in 1850 to Elizabeth Cabot Cary.

Agassiz considered himself more of a naturalist than a specialist in any one field, and he conducted exhaustive studies of the characteristics of marine biology, freshwater fishes, embryology, and fossil fishes. He also developed a love for the American landscape, and contributed to the study and education of natural history in the United States. Agassiz s Protestant background led to a belief that signs of the Creator exist in all flora and fauna. As such he became a major opponent to Darwin s theory of evolution. Whereas both Lyell and Darwin accepted Pleistocene glaciation as a mechanism for genetically linking species separated geographically, Agassiz believed that there was no relationship between different species as the Creator endowed each with its own qualities. He did not hesitate to use the public forum to try to gain acceptance for his views, although unsuccessfully. Agassiz s scientific reputation generally diminished towards the end of his career, but he did make some important contributions to the Museum of Comparative Zoology and the National Academy of Sciences (American Council of Learned Societies, 1970).

Air Pressure

Air pressure is the force exerted by the air; differences in pressure produce forces that set air into motion, thus driving winds and storms.

Pressure is the force exerted on one body by another. For fluids like air and water, pressure is measured in terms of the force exerted per unit area. In the atmosphere, this force results from the weight of the air above the measuring point. For example, the mass of the column of air above each square centimeter of the Earth s surface is about 1 kg.

Air pressure may be expressed in several ways. In English engineering units, air pressure is often measured in pounds per square inch; in this unit, the average sea-level pressure is $14.7\,\mathrm{lb\,in^{-2}}$. However, in meteorology it is more common to use metric units such as the millibar, defined as 1000 dynes per square centimeter or the more modern unit of the same magnitude, the hectopascal. Yet another common measure of pressure is the height of a barometer s mercury column that can be supported by the ambient air pressure. Thus, normal ground level pressure is sometimes expressed as $14.7\,\mathrm{lb\,in^{-2}}$, 1013 millibars, 1013 hectopascals, or 29.92 inches or 760 millimeters of mercury. In practice, pressures are often reported as sea level pressures, i.e., the pressure that would be observed at the bottom of a vertical shaft extending downwards to sea level.

Air pressure decreases rapidly with height; at an altitude of about 6 km, pressure is about half that at the surface. The pressure of air on our bodies is balanced by the pressure within, and thus does not affect us. However, differences in pressure do exert forces on the air and can set it into motion. Differential heating and cooling over the face of the globe produce regions of higher and lower pressure. As these force the air into motion, the rotation of the Earth causes the winds to adjust their direction (in the Northern Hemisphere) so that lower pressure is found to the left of the wind and higher pressure to the right. In the Southern Hemisphere, this pattern is reversed. Thus, the familiar centers of high and low pressure found on weather maps result from a complex set of processes involving heating and cooling, horizontal and vertical air currents, and condensation and precipitation processes on a rotating planet.

Air Quality, Arctic

see Arctic Air Quality (**Volume 1**)

Air Quality, Global

Douglas Whelpdale and Elizabeth Bush
Meteorological Service of Canada, Downsview, Canada

Excluding water vapor, 99.9% of the Earth's atmosphere is made up of nitrogen (N), oxygen, and the noble gases. Their concentrations have been relatively stable for the past billion years. The remaining 0.1% is composed of many different gases and particles that are present in only trace amounts. Air quality is a consequence of the relative concentrations of these trace species; poor air quality results when concentrations of trace species that harm either the Earth's environment or inhabitants are enhanced. The term global air quality (or synonymously, global air pollution, background air pollution, background air quality), although imprecisely de ned, is used here as a subjective or comparative descriptor of atmospheric quality resulting from the concentrations of the more important of these trace species at locations distant from their anthropogenic sources.

Trace gases (and small particles) in the atmosphere originate from both natural processes and human activities. Air pollution is sometimes thought of as material in the atmosphere, regardless of concentration, caused by human activity. This de nition is of limited use because atmospheric measurements are often unable to distinguish between anthropogenic and natural sources of the same species. Another de nition of air pollution relies on the derivation of threshold pollutant concentrations, above which adverse effects occur on selected receptors. This approach is falling out of favor - improved measurement techniques are lowering thresholds - and in any case, it is not particularly relevant to a discussion of global air quality. A third, and more practical, approach is to contrast air quality in areas known to be affected by human activity with air quality in locations distant from such pollution sources. One caution, however, is that the atmosphere distant from anthropogenic sources of pollution is not necessarily a spatially and chemically uniform mixture of pollutants.

The contribution made by a given trace species to the air quality at a given location depends on the species' atmospheric lifetime. The length of time that a substance remains after release into the atmosphere depends upon a number of factors that control its susceptibility to chemical destruction or physical removal: solubility, reactivity, density, shape, height of injection, location of release, etc. A substance with a lifetime of a few hours will not travel far beyond its source region. A substance with a lifetime of several weeks released in the windy mid-latitudes will be dispersed widely in the hemisphere. A substance with a lifetime of years will be transported globally and will exhibit a relatively uniform global distribution. Shorter-lived gases and particles exhibit heterogeneous distributions, with concentrations highest near sources and generally lowest in remote areas.

In this article, trace species that are commonly implicated in global air quality will be discussed. A number of potentially important species (the hydroxyl radical, DMS, trace metals, and many organic chemicals), have rather arbitrarily been excluded from this discussion.

MAJOR GLOBAL AIR MONITORING PROGRAMS

A number of global monitoring networks have been established to help characterize global air quality. Monitoring stations are located at remote sites around the globe, although Africa, South America and the southern oceans are still under-represented. The US National Oceanic and Atmospheric Administration/Climate Monitoring and Diagnostics Laboratory s (NOAA/CMDL) global cooperative air sampling network has approximately 46 sites, including four baseline observatories that have been operating since the late 1950s (Barrow, Alaska; Mauna Loa, Hawaii; American Samoa and South Pole) (Climate Monitoring and Diagnostics Laboratory, CMDL, 1998). The Advanced Global Atmospheric Gases Experiment (AGAGE) network has five remote observing stations established in 1978, and a measurement program focused on halocarbons and other species implicated in stratospheric ozone loss (Prinn *et al.*, 2000). The World Meteorological Organization s (WMO) Global Atmosphere Watch (GAW) program was established in 1989, integrating two previous programs, the Background Air Pollution Monitoring Network and the Global Ozone Observing System, established in the 1960s and late 1950s, respectively. The GAW network currently consists of about 20 global (remote) stations and about 300 regional stations. Some NOAA/CMDL and AGAGE stations are part of this network. Data from GAW stations are sent to six World Data Centers for archiving and analysis (Miller and Young, 1997) (*see* GAW (Global Atmosphere Watch), Volume 1).

In addition to these major systematic observing programs, many special short-term field campaigns have conducted extensive sampling programs. Supplemental observations are also provided by ship-, aircraft-, balloon-, and satellite-based measurement programs. Information on air pollutant concentrations prior to establishment of modern measurement programs is provided by proxy records, particularly

ice cores obtained from Greenland and Antarctica (Bradley, 1999).

CARBON DIOXIDE (CO_2)

Carbon dioxide is an important trace constituent because of the role it plays in radiative forcing in the climate system. Its concentration has been increasing dramatically since direct measurements began at the South Pole in 1957 and at Mauna Loa in 1958. Carbon dioxide concentrations are now routinely monitored at many locations globally. Data from before the late 1950s are available from ice core measurements, and extend back 400 000 years.

Carbon dioxide is a long-lived gas with an atmospheric lifetime of 50–200 years, and is therefore well-mixed globally. No single lifetime for CO_2 can be defined because of different rates of uptake and removal by different processes (Intergovernmental Panel on Climate Change, IPCC, 1996). Although CO_2 concentrations exhibit seasonal, latitudinal and hemispheric variation, annually averaged concentrations at individual remote stations are close to the global annual average. Concentrations at Mauna Loa have risen from approximately 315 parts per million by volume (ppmv) in 1958 to 368 ppmv in 1999. Over the years 1983–1997, the growth rate in CO_2 varied between 1–3 ppmv $year^{-1}$ (World Data Centre for Greenhouse Gases and Other Atmospheric Gases, WDCGG, 2000) (*see* Carbon Dioxide, Recent Atmospheric Trends, Volume 1). Pre-industrial (circa 1850) concentrations were approximately 280 ppmv, and ice core data reveal that concentrations were relatively stable around the 280 ppmv mark for the 1000 years prior to the industrial age (Intergovernmental Panel on Climate Change, IPCC, 1996) (*see* Intergovernmental Panel on Climate Change (IPCC): an Historical Review, Volume 4).

METHANE (CH_4)

Methane is the next most abundant atmospheric trace gas. It plays a key role in tropospheric chemistry, in the atmospheric greenhouse effect and in stratospheric ozone loss. Systematic direct measurement of CH_4 began in 1978 as part of the Atmospheric Lifetime Experiment (ALE), and has continued through the evolution of this program into AGAGE. The NOAA/CMDL program began making CH_4 measurements in the mid-1980s. Ice core data provide CH_4 concentrations as far back as 160 000 years ago (Chappellaz *et al.*, 1990).

Methane is a relatively long-lived gas with an atmospheric lifetime of approximately 12 years. This has been defined as an adjustment time that takes into account the indirect effect of CH_4 on its own lifetime (Intergovernmental Panel on Climate Change, IPCC, 1996). Methane exhibits a relatively even distribution globally in the upper atmosphere, albeit with latitudinal, hemispheric and seasonal variations. Near-surface concentrations are higher in the Northern Hemisphere as a result of proximity to source regions. The 1997 annual average atmospheric CH_4 concentration at the site with the longest running direct measurement program, Cape Grim, Tasmania, is 1690 parts per billion by volume (ppbv) (Carbon Dioxide Information Center, CDIAC, 2000). The 1998 global annual average atmospheric CH_4 concentration, calculated from sites contributing data to the World Data Centre for Greenhouse Gases, is 1749 ppbv. From the early 1980s to the late 1990s, CH_4 concentrations grew at a rate of 9 ppbv $year^{-1}$ (World Data Centre for Greenhouse Gases and Other Atmospheric Gases, WDCGG, 2000, 2). The atmospheric CH_4 concentration was relatively stable at approximately 700 ppbv from 1000–1800 AD, at which time concentrations began to increase (Etheridge *et al.*, 1998) (*see* Methane, Volume 1).

NITROUS OXIDE (N_2O)

Nitrous oxide is a trace gas that is implicated in both the greenhouse effect and in stratospheric ozone loss. The longest N_2O monitoring programs are those of the AGAGE network and the CMDL baseline observatories, which began in 1978 and 1977, respectively. Ice cores have also provided information on historic N_2O concentrations.

Nitrous oxide has an atmospheric lifetime of approximately 120 years (Intergovernmental Panel on Climate Change, IPCC, 1996, 15) and is a globally distributed pollutant. Global average N_2O concentrations have increased from approximately 275 ppbv in pre-industrial times (World Meteorological Organization, WMO, 1999, 1.17) to current (2000) concentrations of about 315 ppbv (Elkins, 2000). Annual average concentrations in the Northern Hemisphere are consistently about 1–2 ppbv higher than in the Southern Hemisphere. The trend in N_2O has been nearly linear over the past 13 years, averaging about 0.75 ppbv $year^{-1}$ (Elkins, 2000) (*see* Nitrous Oxide, Volume 1).

HALOCARBONS

Systematic measurements of halocarbons began in the late 1970s in the AGAGE and NOAA/CMDL programs, shortly after they were first detected in the troposphere. Measurements were launched in response to revelations that these compounds were implicated in stratospheric ozone depletion; it is now known that they are implicated in global climate change as well.

Halocarbons are carbon compounds containing a halogen, such as chlorine, fluorine and bromine. Included in this term are *chloro uorocarbons* (CFCs), hydrochlorofluorcarbons

(HCFCs), *hydro uorocarbons* (HFCs), methyl halides (e.g., methyl chloride, methyl bromide), chlorinated solvents (e.g., methyl chloroform, carbon tetrachloride) and halons (brominated carbons). Except for the HCFCs, methyl chloride, methyl bromide and a few others, these compounds are generally long-lived and eventually reach the stratosphere, where their destruction occurs. Most *halocarbons* are solely of anthropogenic origin, and thus did not occur in the atmosphere prior to the beginning of their manufacture.

Generally, concentrations of the major CFCs rose steeply from the time of their introduction into the environment until about 1990 at which time they stabilized, beginning a declining phase in the early 1990s that reflects reductions in emissions mandated through the international Montreal Protocol and its Amendments. The exception is CFC-12 whose concentration is still increasing, albeit at a reduced rate. Current concentrations of major halocarbons (e.g., CFC-11, 12 and methyl chloride) are approximately 0.5 ppbv. The concentrations of the other halocarbonss range from ~0.1 ppbv (e.g., carbon tetrachloride, methyl chloroform) to ~0.1 parts per trillion by volume (pptv) (bromocarbons) (World Meteorological Organization, WMO, 1999). The concentrations of CFC substitutes such as HCFCs and HFCs are rising rapidly but are still only present in the pptv range (Prinn *et al.*, 2000) (*see* Chloro uorocarbons (CFCs), Volume 1).

CARBON MONOXIDE (CO)

Carbon monoxide adversely affects human health and is also important in tropospheric chemistry; it is therefore of interest as a global pollutant. Carbon monoxide is monitored globally, the most extensive program being the NOAA/CMDL global sampling network (Novelli *et al.*, 1998). Ice core analyses have recently provided perspectives on historical CO concentrations over the last 2000 years (Haan and Raynaud, 1998).

Carbon monoxide has a relatively short atmospheric lifetime, ranging from weeks to months, although this can be extended to over a year in the winter polar atmosphere (Hollaway *et al.*, 2000). The concentration and distribution of CO in the atmosphere is variable, being dependent on the spatial pattern and variability of both sources and sinks, and on the effects of transport. As a consequence, CO exhibits a non-uniform distribution globally, with strong latitudinal and longitudinal gradients and strong seasonality (Novelli *et al.*, 1998). Based on data (1996) from clean, remote, continental and oceanic sites, the global average concentration is approximately 90 ppbv (World Data Centre for Greenhouse Gases and Other Atmospheric Gases, WDCGG, 2000). Annual average concentrations are about 120 ppb in the Northern Hemisphere and about 40 ppbv in the Southern Hemisphere (US Environmental Protection Agency, EPA, 2000). Ice core measurements confirm that there has been little change in CO concentrations in Antarctica over the last 2000 years (~50 ppbv) while CO measurements in Greenland ice cores suggest that there has been an increase in CO concentrations at high northern latitudes over the last century (Haan and Raynaud, 1998) (*see* Carbon Monoxide, Volume 1).

SULFUR DIOXIDE (SO_2) AND SULFATE (SO_4)

Trace amounts of several sulfur species exist as gases, particles and in precipitation in the atmosphere. The two compounds most relevant to air quality are SO_2 and SO_4; other important species include hydrogen sulfide, dimethyl sulfide, carbon disulfide and carbonyl sulfide. Both SO_2 and SO_4 are human health and environmental pollutants, causing cardio–respiratory problems and contributing to acid deposition. Sulfate particles are very small (~1 μm), hence they contribute also to visibility degradation, and interfere with the atmospheric radiation balance, both directly by reflecting incoming solar radiation and indirectly as a cloud nucleating agent.

The tropospheric lifetime of SO_2 is several hours to a few days, and that of SO_4 is several days. As a result, these pollutants are primarily regional rather than global pollutants. Sulfur concentrations are measured routinely in global networks such as the GAW, in regional networks in North America, Europe and Asia, and in many national networks. Typical SO_2 concentrations range from 20 pptv in the marine boundary layer to 200 pptv in clean continental North America to 1500 pptv in polluted continental air (Seinfeld and Pandis, 1998, 61). Non-sea-salt SO_4 concentrations in air range from less than 1 nmol m^{-3} (0.1 μg m^{-3}) in the remote marine environment to approximately 10–20 nmol m^{-3} (1–2 μg m^{-3}) in clear continental North America to >100 nmol m^{-3} (>10 μg m^{-3}) in and downwind of heavily industrialized regions (Whelpdale and Kaiser, 1996). While concentrations of SO_2 and SO_4 in remote regions have increased little since the onset of industrialization, concentrations in the most heavily industrialized regions have risen up to 50-fold.

NITROGEN OXIDES AND NITRATE

Similar to sulfur oxides, several nitrogen oxide compounds exist as gases, particles and in precipitation, and are implicated in human respiratory problems (both directly and through promoting the formation of ozone), acid deposition, and visibility degradation (*see* Nitrogen Cycle, Volume 2). The two main reactive gaseous species are nitric oxide (NO) and nitrogen dioxide (NO_2); they are often considered together as NO_x. Nitrate (NO_3) is found in both particles and precipitation. Among the other reactive

nitrogen species, nitric acid (HNO_3) and peroxyacetylnitrate (PAN) are also of interest from an air quality perspective. Sources of nitrogen oxides have high temporal and spatial variability, and this, combined with their relatively short atmospheric lifetimes of hours to a few days, results in concentrations which are also highly variable in space and time, with highest concentrations near source regions. Therefore, like the sulfur compounds, these compounds are primarily regional rather than global pollutants.

In a recent summary, Emmons *et al.* (1997) found that in clean regions median boundary layer NO concentrations are <10 pptv and NO_x <50 pptv. In highly industrialized North America and Europe NO concentrations can be >1 ppbv and NO_x >2 ppbv. Particulate nitrate concentrations range from $\sim 1\,\mathrm{nmol\,m^{-3}}$ ($0.06\,\mu\mathrm{g\,m^{-3}}$) in remote marine locations to $5\,\mathrm{nmol\,m^{-3}}$ ($0.3\,\mu\mathrm{g\,m^{-3}}$) in clean continental locations and typically up to $40\,\mathrm{nmol\,m^{-3}}$ ($2.5\,\mu\mathrm{g\,m^{-3}}$) in industrialized regions, but reaching as high as $100\,\mathrm{nmol\,m^{-3}}$ ($6\,\mu\mathrm{g\,m^{-3}}$) (Whelpdale and Kaiser, 1996). Concentrations of reactive N species have increased significantly since industrialization, as much as 50-fold in regions of heavy emissions. This trend is likely to continue as NO_x emissions continue to increase.

OZONE (O_3)

Ten percent of the Ozone in the Earth s atmosphere is found in the troposphere, the rest being stratospheric O_3. Ozone is not emitted directly, but formed in a series of complex reactions involving a number of precursor molecules that are of both natural and anthropogenic origin. In the troposphere, O_3 is considered a pollutant, both because of its adverse effects on human health and vegetation and because it is a greenhouse gas. The lifetime of O_3 is typically a few days to two months, and its global distribution is highly variable in time and space. The best O_3 data sets are from the last 20 years or so, during which time O_3 measurements were integrated into programs at sites in the GAW. The World Data Centre for Surface O_3 has only recently become operational (1998) but will soon provide an ongoing archive of surface O_3 data. National programs have also been established in several countries to monitor surface O_3.

Annual average hemispheric surface O_3 values for 1995 at remote sites were 41 ppbv in the Northern Hemisphere and 22 ppbv in the Southern Hemisphere (Oltmans *et al.*, 1998). Over the 20 years of record, most of the nine sites have experienced an increasing trend, although the magnitude varies considerably. At the South Pole, a notable decline in surface O_3 concentrations has occurred that is most likely related to the decline in stratospheric O_3 over the Antarctic (*see* Ozone Hole, Volume 1). European data for the late 1800s and early 1900s indicate that monthly average O_3 concentrations in the northern midlatitudes were $\sim$10 ppbv (Sandroni *et al.*, 1992). Modeled pre-industrial concentrations of surface O_3 for the Northern Hemisphere mid-latitudes are about twice this value (Lelieveld and Dentener, 2000). Therefore, there has been at least a doubling and possibly a several-fold increase in Northern Hemisphere mid-latitude O_3 concentrations over the last century. The Southern Hemisphere has also experienced an increase, but it is likely only on the order of 50% (Crutzen, 1995) (*see also* Stratosphere, Ozone Trends, Volume 1; Troposphere, Ozone Chemistry, Volume 1).

VOLATILE ORGANIC COMPOUNDS (VOCs)

The term VOCs is an umbrella term for those hydrocarbons (excluding CH_4) that are of low enough molecular weight to be volatile and therefore present in the atmosphere (i.e., non-CH_4 hydrocarbons) as well as all other reactive organics in the troposphere including alcohols, aldehydes and organic acids (Ehhalt, 1999). VOCs are primarily of interest for their role as precursors to tropospheric O_3. Most VOCs react locally, and therefore the concept of a global concentration for VOCs is not really applicable.

VOCs can be measured either individually or collectively. Individual VOCs (of which there are thousands) are typically present in the atmosphere in the pptv concentration range in remote and rural areas, and in the ppb range in urban locales (Finlayson-Pitts and Pitts, Jr, 2000, 591–593). For example, representative concentrations (pptv) of two major VOCs, benzene and toluene are, respectively, 0.008–0.2 and 0.01–0.25 in remote areas, 0.1–0.6 and 0.05–0.8 in rural environments, and 0.9–26 and 2–39 in urban areas (Finlayson-Pitts and Pitts, Jr, 2000, 591) (*see* Volatile Organic Compounds, Biogenic (VOCs), Volume 2).

AEROSOLS

The atmosphere contains not only trace gases but also suspensions of microscopic solid and liquid particles, termed aerosols (*see* Aerosols, Troposphere, Volume 1). Atmospheric aerosols are of both natural and anthropogenic origin, range in size from a few nm (10^{-9} m) to about a hundred μm (10^{-6} m), and can be of extremely complex chemical composition. Particles of natural origin, such as mineral and soil dust, pollen, spores, and sea-salt spray tend to be relatively larger (coarse-particle mode). Particles emitted from combustion sources or formed in the atmosphere through gas-particle conversion are smaller in size (fine-particle mode). The chemical composition of fine aerosols is complex and can include sulfates, nitrates, inorganic and organic carbons, and heavy metals. Atmospheric aerosols are of interest both because of their impact on

human health and their role in radiative forcing, where they are now believed to exert a cooling effect.

The lifetimes of particles in the atmosphere depend on their size, and on their chemical and other physical properties, and may range up to several days or a few weeks in the troposphere. The combination of diverse sources and complex chemical composition of particles ensures that the distribution of aerosol characteristics – physical and chemical – is far from uniform. Atmospheric aerosol measurements are too scarce to properly assess global levels. A long-term monitoring program has recently been initiated through the GAW that will supplement the many national and regional programs. Parameters measured may vary from network to network, and intercomparability is often lacking.

Nonetheless, some generalizations about aerosol mass concentrations in different locations can be made (Warneck, 1999). Typically, the concentration of fine aerosols in Polar Regions, especially the Antarctic, is very low ($\sim 1\,\mu g\,m^{-3}$) due to the relative absence of sources. Marine background concentrations are also generally low ($\sim 10\,\mu g\,m^{-3}$) although in windy conditions, and if sea-salt spray is included in the mass measurement, mass concentrations can become much higher. Continental concentrations generally reflect proximity to sources and vulnerability to exposure through prevailing winds. Rural levels are generally in the $30-50\,\mu g\,m^{-3}$ range. In urban centers, fine aerosol concentrations of $50-100\,\mu g\,m^{-3}$ are typical although concentrations $>100\,\mu g\,m^{-3}$ have been recorded (Finlayson-Pitts and Pitts, Jr, 2000, 618–619). Extremely high (several hundred $\mu g\,m^{-3}$) aerosol concentrations are found over and downwind of deserts and forest fires. Aerosol mass measurements are dependent on the particle sizes included in measurements. Information on trends in aerosol concentrations is very limited away from the immediate neighborhood of sources.

Albedo

Garth W Paltridge
University of Tasmania, Tasmania, Australia

The original Latin meaning of albedo (i.e., whiteness) has given way to the formal de nition found in most dictionaries and textbooks - namely: albedo is the ratio of the total radiant energy ux re ected or scattered in all directions by an object to the total radiant ux intercepted by the object. Even this formal de nition is strictly appropriate only in the context of certain special cases. These concern re ection of sunlight from entire and isolated bodies such as planets, or the re ection of sunlight (or indeed any radiation) from individual particles or molecules. In the latter case, the ratio of the uxes has the speci c name of single scattering albedo, and is a basic parameter used in the mathematical theories of the scatter of radiation in media such as the atmosphere.

Ground-level measurements of albedo are not made in a way that is consistent with the textbook definition given above. Using a horizontal surface as an example, its measured albedo is the ratio of the upward component of the flux density (flux per unit area) of radiation scattered or reflected from the surface to the downward component of the incoming flux density. The measurement is normally taken in the context of solar radiation reflected by the ground or by some other horizontal surface such as a deck of cloud. It is obtained by an albedometer, which measures separately and simultaneously both the up-welling and down-welling flux densities at some small distance above the surface in question. The sensors are flat-plate absorbers. Thus, the typical observation of albedo does not involve measurement of the radiation scattered in all directions by a particular small area of the surface. Rather, it involves measurement of the radiation scattered into a horizontal unit area above the surface from all parts of the surface within view of the downward-looking flat-plate sensor. The two situations are equivalent only if the surface is horizontally uniform and is of sufficient extent to fill the effective view of the sensor. The effective view is determined by the fact that the sensor response to radiation from an isotropically scattering surface is dominated by radiation in the mid-range of the angles between 0 and 90° from the vertical, and tails off to zero at 0 and 90°. This response pattern ensures, among other things, that the character of the surface immediately beneath the instrument has little impact on the actual measurement.

Albedo is not an intrinsic single-valued property of a surface, but is normally a function of the manner in which the surface is illuminated. In cloud-free skies where the direct beam of the Sun dominates the down-coming solar radiation, the albedos of virtually all ground surfaces increase with solar zenith angle. The increase is usually most significant at zenith angles greater than about 60° and is dependent on surface character. There can be exceptions, however, where the shadowing by surface roughness elements increases with solar zenith angle faster than does the albedo of those portions of the surface that are sunlit. Factors contributing to the angular dependence may include the broad forward-peak in the scatter pattern of individual particles making up the surface (clouds and snow are good examples); Fresnel reflection from horizontally-oriented platelets making up the surface (the leaves of certain types of vegetation are an example); and the fact that the depth of penetration of incoming radiation into a surface, and hence the depth of the actual reflection process, may be reduced as the angle of incidence decreases. The variation with zenith angle is important in the context of climate because of the many geographic and seasonal situations where the daily-average solar zenith angle is large enough for the variation to be highly significant.

Albedo is a factor determining the energy balance of surfaces, objects, or planets as a whole (*see* Energy Balance and Climate, Volume 1). It determines their net solar energy input and hence their temperature and overall thermodynamic behavior. Thus, the usual reference to albedo concerns the total spectrum of incoming solar radiation, although there can be specialist uses that refer to the spectral albedo of particular wavelength bands. In the context of photosynthesis, for instance, the interest may be in the albedo at visible wavelengths of plant leaves. The spectral albedo can vary enormously with wavelength (*see* PAR (Photosynthetically Active Radiation), Volume 2).

The climatologist is usually concerned with the average albedo over an area, which may be several hundred

kilometers on a side. Over land and sometimes over the sea, such areas are made up of a mosaic of individual patches, each of which has its own albedo and albedo behavior. Thus, much effort is currently devoted to the derivation of surface albedo from satellite measurements. In order to obtain data with sufficient resolution, and to satisfy other remote sensing applications, the satellite observations are, of necessity, narrow-beam measurements of the intensity of radiation reflected directly to the satellite from a particular small area on the ground. By using many satellite passes to take multiple observations at different viewing angles and at different solar zenith angles, it is possible to measure what is known as the *bidirectional re ection distribution function* – in other words the overall pattern of the intensity of the sunlight scatters in all directions from the surface in question – and to measure the variation of this function with solar zenith angle and with wavelength. Provided corrections are made for the scatter and absorption of the intervening atmosphere, the intensities can be integrated appropriately over angle and wavelength so as to calculate the upward flux density required to determine albedo. An albedo derived in this way is, in principle, close to the albedo of the formal textbook definition.

The Earth s temperature is highly dependent on its albedo because its thermal radiation to space must, on average, balance its absorption of solar energy. The lower the albedo, the more solar energy will be absorbed, the more thermal energy must be radiated, and the higher must be the temperature to produce that thermal radiation. The Earth s albedo is currently about 0.30, with most of the effect being caused by clouds. As a rough guide, and other things being equal, the Earth s surface temperature would rise about 2 K if the overall albedo of the planet were to be lowered by 0.01. This has an interesting consequence in the context of climate change and of the suggestion that more forests might be grown so as to limit global warming by increasing the uptake of atmospheric carbon dioxide (CO_2). Referring to Table 1, significant increases in forest cover would generally decrease the Earth s albedo. Such a darkening of the planet would tend to reduce the benefit of the increased uptake of CO_2.

Table 1 Approximate values of low solar zenith angle albedo

Surface	Albedo
Smooth water	0.02
Rough sea	0.05
Evergreen and tropical rainforest	0.1
Dry and eucalypt forest	0.15
Dry grassland and semi-desert	0.2
Desert sand to white sand	0.3–0.6
Old snow to new snow	0.4–0.8
Cirrus to middle and low-level cloud	0.3–0.6
Overall planet Earth	0.3

AMIP (Atmospheric Model Intercomparison Project)

The AMIP is an international project in which the performance of atmospheric general circulation models integrated under standardized conditions is evaluated in comparison with observations over a specified period of years. As originally formulated by the International Working Group on Numerical Experimentation of the World Climate Research Program, the AMIP protocol requires the use of the observed monthly mean sea-surface temperature and sea-ice distribution during the decade from 1979 to 1988 as lower boundary conditions for the atmospheric calculations, use of fixed values of the solar irradiance and atmospheric CO_2 concentration, and the calculation of a specific set of standard output variables. More than 30 modeling groups, representing virtually the entire international atmospheric modeling community, are participants. Results of AMIP analyses show the presence and extent of systematic errors in the simulation of many variables, and a marked scatter in the simulations of the mean seasonal cloudiness and precipitation. Comprehensive documentation and databanks for both model output and observations are maintained by the Program for Climate Model Diagnosis and Intercomparison at the Lawrence Livermore National Laboratory (Livermore, CA), while specific regional and phenomenological aspects of the models performance have been examined in a series of diagnostic subprojects conducted by the international modeling and diagnostic communities. AMIP has demonstrated the value of systematic diagnosis and validation in the process of model improvement, and a second phase (AMIP 2) is providing for expanded output and further diagnostic and experimental subprojects (Gates, 1992, 1999).

Antarctica

Charles R Bentley
University of Wisconsin-Madison, Madison, WI, USA

Antarctica, the continent around the South Pole, comprises two geologically distinct regions, East Antarctica and West Antarctica, separated by the great Transantarctic Mountains but joined together by the all-encompassing ice sheet. The presence of the high ice sheet and the polar location make Antarctica a powerful heat sink that strongly affects the climate of the whole Earth. Furthermore, the annual sea ice cover around the continent, which seasonally reaches an area greater than that of the continent itself, modulates exchanges of heat, moisture, and gases between the atmosphere and ocean and, through salt rejection when it freezes, forces the formation of cold oceanic bottom waters that spread out under the world's oceans.

Both the ice sheet and the sea ice are potentially subject to change in a changing climate; the ice sheet, in fact, may be changing now in response to past climate change. The greatest threat to the inhabited world comes from the West Antarctic ice sheet (WAIS), which rests on a bed far below sea level and so may have the potential for rapid shrinkage. The Antarctic is so vast, remote, and dif cult to monitor, however, and the physical behavior of the ice sheet so complex, that there is as yet no de nitive demonstration (or disproof) of secular change, even though a pronounced climatic warming is ongoing in one northerly portion of the continent. Measurements from satellites early in the 21st century should settle the question of current growth or shrinkage, but prediction will remain problematic for many years.

GEOGRAPHY AND GEOLOGY

Antarctica is Earth s fifth largest (area *circa* 14 200 000 km^2) and most southerly continent. It comprises two major regions: West Antarctica, which includes the Antarctic Peninsula, and East Antarctica. They are so named because they lie mostly (although not entirely) in the Western and Eastern Hemispheres, respectively. The boundary between the two is the vast Transantarctic Mountains, which extend 3000 km between the Atlantic and Pacific shores of the continent.

Most of the continent is covered with ice. The Antarctic ice cover comprises three components: the thick, grounded, inland ice that rests on a (more or less) solid bed, the thinner, permanent floating ice shelves, and the ephemeral sea ice that surrounds the continent. (By definition, the inland ice and the ice shelves together constitute the ice sheet.) The inland ice ranges in thickness up to 5 km, with an average of about 2400 m. In central East Antarctica, the ice surface rises to a height of 4000 m. Because of the ice sheet, Antarctica is, on average, by far the highest of the continents.

Antarctica lies in a circumpolar position (the South Pole lies within the continent but not at its center) completely surrounded by the ocean. Its nearest neighbor continent is South America, 1000 km from the Antarctica Peninsula, across the Drake Passage. Antarctica and South America are indirectly connected by the long, curve of islands known as the Scotia Arc (Figure 1).

The continents of the Southern Hemisphere were not always so far apart, however; 200 million years ago they were all joined in the super-continent known as Gondwana. Then, one after another the other continents separated from Gondwana until, last of all, the Drake Passage opened up about 30 million years ago. That opening completed the isolation of Antarctica and permitted the establishment of the uninterrupted Circumpolar Current in the Southern Ocean. The combination of continuous oceanic and atmospheric circumpolar circulation was instrumental in allowing the continent to cool enough for the ice sheets to become established.

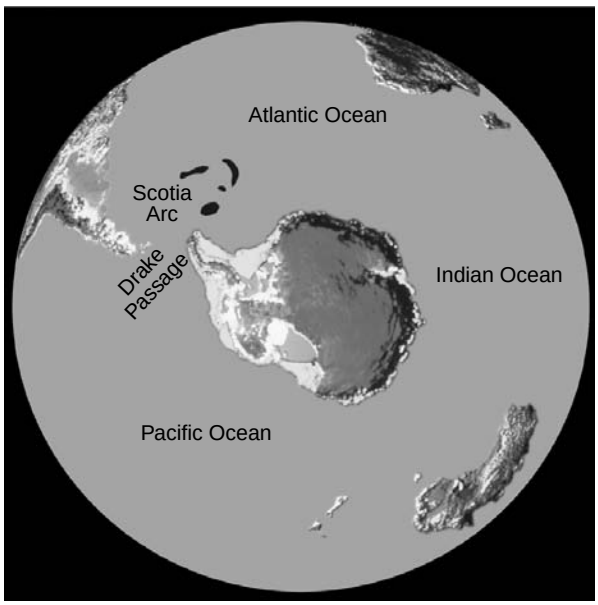

Figure 1 Antarctica in the Southern Ocean. Light-shaded area around the continent is the continental shelf. Other land masses, clockwise from the top, are Africa (with Madagascar), Australia (with Tasmania), New Zealand, and South America

East and West Antarctica are geologically very different. If all Antarctic ice were removed and the solid earth beneath were given time to rise in response to the removal of its weight (isostasy), East Antarctica would be one large continental land mass, roughly the size of Australia, with some inland seas. West Antarctica, on the other hand, would comprise several large mountainous islands separated from East Antarctica by open ocean, much of it over 1 km deep. Geographically, the whole region would resemble Australia and New Guinea, except that the intervening body of water would be much deeper in Antarctica (Figure 2).

East Antarctica is truly continental, with crustal thicknesses comparable to the other continents and with rocks of all ages (the most ancient are more than three billion years old). West Antarctica is geologically much younger with a separate history of continental drift and a central region of thin, stretched crust covered with old marine sediments.

South of the Antarctic Circle, where the vast majority of the continent lies, the Sun does not set in mid-summer and does not rise in mid-winter. At the South Pole itself, the year comprises one 6 month day and one 6 month night.

The South Pole, on the spin axis of the Earth and at high altitude on dry land (unlike the North Pole, in the middle of the Arctic Ocean), has characteristics valuable for certain types of observations, which are carried out at the United States Amundsen-Scott Station there. The axial location provides a unique simplification of some earthquake waves. The half-year-long winter night, together with the extreme clarity of the thin atmosphere, provide unparalleled opportunities for long-term, continuous astronomical observations. And instruments emplaced deep in the 2800 m thick ice sheet count flashes of light from the rare collisions between neutrinos (which have passed through the entire Earth) and water (ice) molecules.

WEATHER AND CLIMATE

Antarctica is the coldest place on the surface of the Earth. It is polar, so the Sun shines only obliquely on the surface; its surface is at mountain-top heights, in the colder part of the troposphere; and the bright snow-covered surface has a very high albedo), about 85% – so that little of the

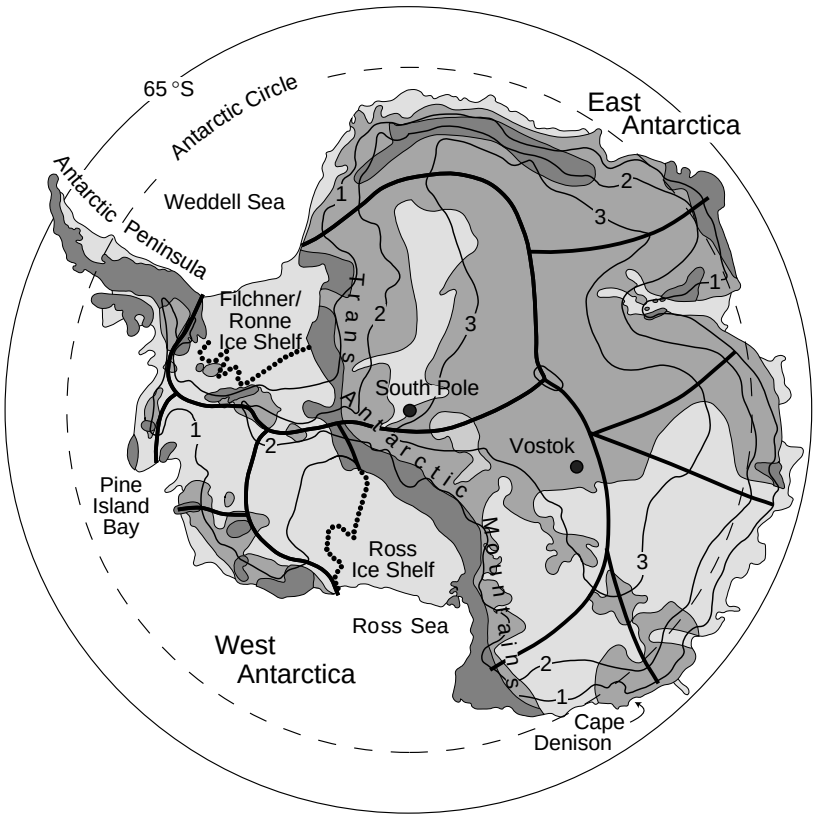

Figure 2 Physical characteristics of Antarctica. Shading indicates elevation of the continental surface. Darkest shade denotes mountains and other mostly exposed rock; lightest shade denotes bed elevations below sea level; intermediate shade denotes a subglacial bed above sea level. Thin, numbered lines give elevations of the continental surface in kilometers. Heavy dotted lines mark the grounding lines of the two biggest ice shelves. Heavy black lines demark ice drainage basins

incoming solar radiation is absorbed. The coldest recorded temperature is close to $-90\,^{\circ}$C ($-130\,^{\circ}$F) at the Russian Station Vostok in central East Antarctica. Especially during the long night, Antarctica is a powerful sink for heat – air that circulates southward in the upper atmosphere cools, sinks, and flows out along the surface, creating katabatic winds, which blow particularly strongly near the coast (at an Australian station on Cape Denison the wind averaged nearly $20\,\mathrm{m\,s^{-1}}$ (43.5 mph) for an entire year). The strong offshore winds in some places blow the sea ice away from the shore as fast as it can freeze, producing ice-free coastal polynyas, which have an important effect on both oceanic circulation and the regional climate (see later section on Sea Ice, Ocean, and Atmosphere).

The katabatic winds force a cyclonic circulation higher in the atmosphere over the continent. The resulting circumpolar vortex isolates the Antarctic atmosphere from incursions by the storms that proliferate in the oceans around the continent. It is that isolation, together with the occurrence of polar stratospheric clouds, that allows stratospheric ozone depletion (the *Antarctic ozone hole*), to occur annually.

Summers, with 24-hour daylight, are as much as $50\,^{\circ}$C warmer and less stormy than winters. Although the ice sheet has a refrigerating effect that makes it rare for the temperature to exceed freezing on its surface, more balmy temperatures abound in coastal areas where there is seasonally snow-free ground and the dark, low-albedo rocks absorb much of the incoming solar radiation. However, even in January, the warmest month, a mean temperature of $-10\,^{\circ}$C is found just a short distance inland from the edge of the ice sheet. That low temperature near the margin means there would be little surface melting even if the Antarctic climate were to warm by 4 or $5\,^{\circ}$C in an enhanced-greenhouse-effect world (see later section on The Ice Sheet).

In a CO_2-doubled world, the temperature in Antarctica may increase by several degrees; in some projections the temperature rise in Antarctica would be more than elsewhere, although in other projections it is less. Regardless of projections, a pronounced warming has been observed over the last several decades, but only along the Antarctic Peninsula. Elsewhere around the continent there appear to be warming trends in a few places and cooling trends in a few, but no significant average trend has been discerned.

An indirect way to look for temperature changes on a longer time scale than is covered by instrumental records is to examine the change in snow accumulation rates with time. Greater snowfall is naturally associated with warmer temperatures, as a warmer atmosphere can hold more water vapor. Ice cores from a majority of sites scattered about the ice sheet, both fairly near the coast and far inland, reveal an increasing snowfall over recent decades (up to a century or so), but the trend is not universal; a significant minority of sites shows the opposite trend or none at all. Furthermore, one or two sites show a reversal of trend, from increasing accumulation to decreasing accumulation, in just the last decade or two. On average for the continent, exclusive of the Antarctic Peninsula, there is no significant trend in snowfall either.

THE UPPER ATMOSPHERE

The near-surface magnetic field of the Earth can be approximated by that of an imaginary bar magnet at the Earth s center but tilted about 12° relative to the Earth s axis. The geomagnetic poles, the points on the surface directly above the ends of the imaginary bar magnet, are the points toward which the force lines of the Earth s external magnetic field converge. The South Geomagnetic Pole lies near Vostok Station.

At heights of many Earth radii, the magnetic lines of force are distorted by the stream of charged particles from the Sun, known as the solar wind, to form the magnetosphere, which deflects the solar wind away from the Earth s surface everywhere except at the geomagnetic poles, where those lines come to Earth. The charged particles flowing down through the polar cusps (the holes at the geomagnetic poles) in both polar regions collide with the atoms and molecules of the atmosphere at elevations of a few hundred kilometers to cause the auroras (*aurora australis* in the south). The auroras are merely the visually most spectacular phenomena associated with the polar cusps and the solar winds. Others include magnetic storms and worldwide radio blackouts.

These solar-terrestrial phenomena are not particularly subject to change because of human or natural activities on Earth, although they are strongly affected by variation in solar activity. The importance of Antarctica with regard to these polar phenomena is that it provides a stable platform from which they can be observed, in notable contrast to the Arctic Ocean.

THE ICE SHEET

The ice sheet is actually a giant glacier, and like most glaciers it forms by the continual accumulation of snow on its surface. As successive layers of snow build up, the layers beneath are gradually compressed into solid ice. The snow mass input is balanced by a glacial outflow, so the height of the ice sheet stays approximately constant through time. The ice is driven by gravity downhill, i.e., in the direction of the surface slope, from the highest points in the interior to the coast. There it mostly breaks off as icebergs, which are carried away by the ocean currents and eventually melt, thus returning the water to the ocean whence it came.

Only a small proportion of the mass loss from the ice sheet occurs by melting from the surface – summertime melt from the margins of the ice sheet occurs only in the northern Antarctic Peninsula and the northernmost fringes of East Antarctica.

The outflow from the inland ice is organized into a series of drainage basins, separated by ice divides, much like water flow on other continents. Most drainage basins concentrate the flow into either narrow outlet glaciers (particularly through the Transantarctic Mountains) or fast-moving ice streams, which are surrounded by slow-moving ice rather than rock walls (Figure 3). Ice in a few drainage systems flows in a diverging pattern that spreads out across a wide section of the coast. The speed of flow increases towards the coast, both because of the increasing area of snowfall upstream and because the ice generally thins outward. Where there is convergence into an outlet glacier or ice stream, the speed of flow is increased even more, attaining values that are more than a kilometer per year in a few places.

The ice sheet in West Antarctica flows mostly into the Ross Ice Shelf, at the head of the Ross Sea, the Filchner/Ronne Ice Shelf (really two separate but connected ice shelves) at the head of the Weddell Sea, and Pine Island Bay, which contains no ice shelf. The two great ice shelves are similar in size; each about the area of Spain. Ice shelves are also driven by gravity, spreading out over the ocean under their own weight. They are supplied with ice partly by the glaciers and ice streams that flow into them and partly by the snow that falls on their surfaces. Unlike the inland ice, they are subject to substantial mass exchange at their bases, melting in some places and freezing in others.

Despite the extreme cold on the high surface of the inland ice sheet, the heat from the interior of the Earth is sufficient to cause melting at the base of the ice across wide areas; the overlying ice acts as an effective protective blanket. The melting is only a few mm year^{-1} or less, but over the long history of the ice sheet it has been enough to create dozens of lakes beneath the ice, as the water flows into low spots in the bed. The largest and best studied (solely by remote sensing), Lake Vostok, whose southern end underlies Vostok Station, is the size of Lake Ontario and is apparently hundreds of meters deep. Since it is only the very old basal ice that melts, Lake Vostok and its companions contain an environment record, and possibly life, that has been isolated from the rest of the world for a million years or more. Researchers eagerly await the development of contamination-free methods of sampling the lakes (*see* Vostok, Subglacial Lake, Volume 1).

Of all the possible changes in Antarctica the one with the greatest potential for destructive consequences around the world is a diminishment in mass of the Antarctic inland ice sheet, with a corresponding, direct, and immediate rise in sea level. If all the inland ice were to melt (melting ice shelves, which are already afloat, does not change sea level), some of the resulting water would be used to fill in the depressions where the base of the ice is now below sea level, but most would go to raising sea level, by about 70 m. There is no chance of that happening within the time scale of human interest, but the loss of even a significant fraction of it could have serious consequences. Interest is concentrated particularly on the West Antartic ice sheet, because it rests on a bed far below sea level, which may make it particularly vulnerable to accelerated discharge into the ocean. If the entire WAIS were to disappear, sea level would rise by 5 or 6 m, causing substantial disruption to human life, to say nothing of coastal facilities and activities, around the world.

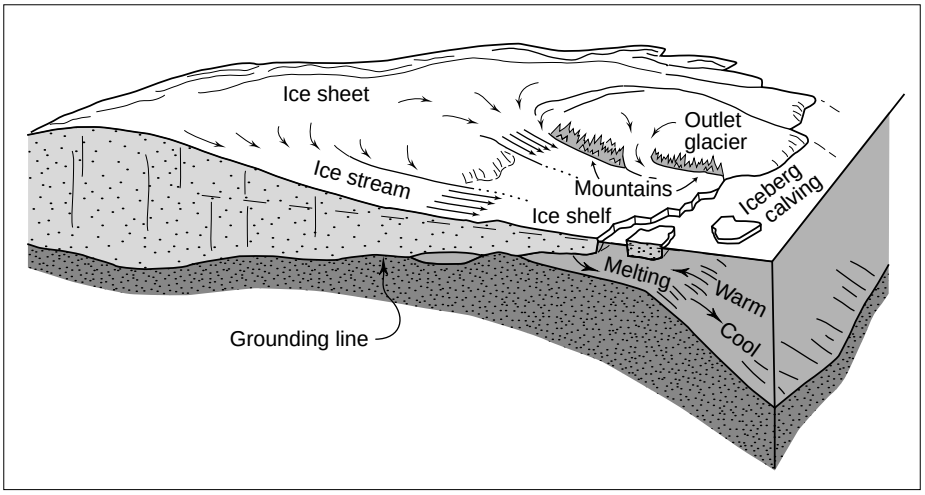

Figure 3 Diagrammatic sketch of an ice sheet containing ice streams, an outlet glacier, an ice shelf, and icebergs. Dark stippled, rock; light stippled, ice; solid gray, water. Arrows show directions of ice and water flow

At present, both the East and West Antartic ice sheets (WAISs) are nearly in mass balance, meaning that the mass inputs and outputs (both about 6 mm of sea level equivalent per year) are nearly the same. Unfortunately, measurements across the huge continent are not accurate enough overall to be more precise – the ice sheet could be producing as much as half of the 2 mm year^{-1} sea level rise or it could actually be drawing water out of the ocean (*see* Sea Level, Volume 1). Complementary satellite measurements of changes in surface height and changes in gravitational attraction (directly dependent on mass) in the early 21st century should decrease the uncertainty greatly.

Predicting the future of the WAIS, however, is more difficult. It seems clear that the WAIS substantially disappeared (and then reformed) sometime (presumably during an interglacial time) in the last 600 000 years, a time span that covers half a dozen ice age cycles. That suggests, but does not prove, that it could happen again, perhaps during the current interglacial epoch in which we now live. The crucial questions, though, from a societal standpoint, are how soon could it happen and how fast.

The only way that short-term climate change (including anthropogenic change) could effect shrinkage of the ice sheet is through oceanic warming. Because the ice shelves are in contact with the ocean, and the ocean can respond much faster to rising temperatures than the solid ice can, the undersides of the ice shelves are the most likely loci of climate-induced change – if warmer waters circulate under the ice shelves in the future, melting could be enhanced, and ice shelves could thin. One modeled result is that the grounding line, the boundary between inland grounded ice and the floating ice shelf, would retreat unstably into the interior of the ice sheet by a process of rapid acceleration of ice stream discharge. Other models, however, suggest that the ice streams would respond stably to restore a mass balance, so that nothing drastic would occur. The answer is simply not known on a theoretical or experimental basis because of too many uncertainties about the physics of ice stream flow. However, there may be a clue from Pine Island Bay, where the two fastest-flowing ice streams in Antarctica terminate. The absence of an ice shelf there might make those ice streams particularly susceptible to rapid acceleration. In fact, both of them do show shrinkage, according to recent experimental results reported (as of 2001).

Past climate may be more important to present WAIS behavior than present climate; because the large size of the ice sheet means that it takes thousands of years to respond fully to external changes. During the last Ice Age the WAIS was perhaps twice as large as now and it may not yet have achieved equilibrium. The glaciological and geological records of changes in the last few thousand years demonstrate no shrinkage of the ice sheet rapid enough to cause it to disappear in the next few hundred years, but indicate that there remains the possibility of a disappearance in the next few thousand years. In terms of sea level, the disappearance of the WAIS in 5000 years would be equivalent to an average rise in sea level of 1 mm year^{-1}, 50% of the current rate. That is enough to be worthy of serious study, but it is certainly not catastrophic.

PALEOCLIMATE

The continual accumulation of snow on the interior ice sheet without melting provides an environmental record of incomparable value. Air in the precipitated snow is preserved in bubbles in the ice, which thus contains a sampling of ancient atmospheres back to the age of the deepest, oldest ice, perhaps more than a million years old. Oxygen and hydrogen isotopes in the ice itself and the temperatures in the borehole provide additional information about past climate. A continuous, 400 000-year record has been collected by ice core drilling to a depth of 3623 m at Vostok Station.

Paleoclimatic records of the last 75 000 years or more also have been recovered from deep ice cores at other sites, in central East Antarctica, central West Antarctica, and East Antarctica near the Ross Sea. All (including Vostok) except the near-coastal site show paleo-temperatures that are different in detail from the record in central Greenland, while still showing the main broad changes. The record near the Ross Sea, however, more closely resembles that from Greenland than those from elsewhere in Antarctica. The implication is that some of the rapid changes generally associated with events in the North Atlantic Ocean (e.g., Heinrich events) have Antarctic counterparts, but that they may not have propagated far into the interior.

Ice cores have a high temporal resolution that provides a superb complement to marine sediment cores, which stretch farther back in time but with poorer resolution. Early in the 21st century additional long paleoclimatic records will be collected by ice coring in both East and West Antarctica, including at a West Antarctic site where the snow accumulation rate is high enough to anticipate dating of annual layers. These new cores will yield much new information about climatic teleconnections between the north and the south.

SEA ICE, OCEAN, AND ATMOSPHERE

In winter, the continent is surrounded by a belt of sea ice hundreds to two thousand kilometers wide, whose total area is more than that of the continent itself (*see* Sea Ice, Volume 1). A fourth of that area, however, is open water in leads and polynyas. By the end of the summer, 80–90% of the sea ice has melted away, which allows ship access

directly to most of the continent (Figure 4). It is then that supplies and personnel are brought to the Antarctic bases that dot the coast.

In contrast to the multi-year ice in the Arctic Ocean, Antarctic ice is relatively thin, mostly less than a meter. Nonetheless, it forms an effective barrier to heat and moisture exchange between the ocean and atmosphere and thus has a fundamental influence on the climate of the Southern Hemisphere. Sea ice freezes at its base, a process that leaves salt in the uppermost water, increasing its density and leading to the sinking of cold, relatively saline water that spreads northward to form the bottom waters of the world s oceans. Additionally, the sea ice zone is a critical habitat for marine algae, the primary producers of life in the ocean, and hence for higher level organisms as well.

Because Antarctic sea ice is so thin, it is particularly vulnerable to a diminishment in extent in a warmer climate; the consequent effect on physical and biological processes in the sea ice zone could be of major significance. Diminished oceanic coverage (including more extensive polynyas and leads within the sea ice zone) would increase the heat and water exchange with the atmosphere, which would tend to increase cloudiness, wintertime air temperatures, and moisture in the atmosphere. That could enhance the increase in snowfall over the continent that is expected from the direct effect of climatic warming. Diminished sea ice production near the fronts of the ice shelves could lead to decreased oceanic circulation beneath the shelves; this is a feedback that tends to counteract enhanced basal melting under the shelves from the influx of warmer ocean water. At the same time, the production of Antarctic Bottom Water would be affected (*see* Ocean Circulation, Volume 1).

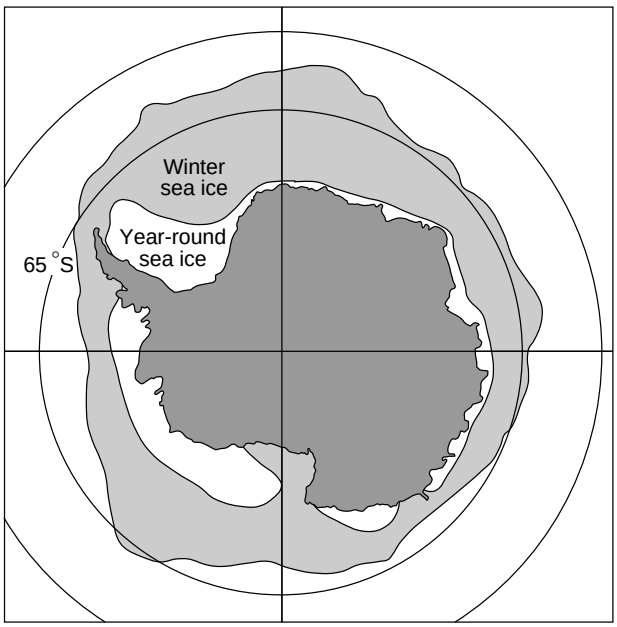

Figure 4 Average extent of sea ice around Antarctica in summer (white) and winter (white plus gray)

Sea ice is also an important regulator of gas exchange between the ocean and the atmosphere. The ocean can be either a source or a sink for carbon dioxide, depending on regional variations in physical and biological circumstances. Sea ice acts as a physical barrier to gas exchange; cold waters in the Southern Ocean tend to remove CO_2 from the atmosphere, so a decreasing sea ice extent might increase CO_2 absorption. Even more important may be the role of the sea ice in controlling oceanic primary production, which is a powerful factor in removing CO_2 from the atmosphere and, eventually, depositing it on the ocean floor (the biological pump). Changes in sea ice cover and changes in seasonal behavior of the marginal sea ice zone could have feedback effects on atmospheric CO_2, although even the sign of the change is difficult to predict.

More open water decreases the albedo of the surface, increasing the absorption of radiation. However, the sea ice zone tends to be cloudy and an increase in cloud cover will increase the albedo, thus providing a negative feedback. Generally speaking, clouds can act either to increase or decrease surface temperatures, depending on their type and height. Thus the net effect of changing cloudiness as a result of climatic change over Antarctica cannot yet be predicted, even though that effect may be important.

Satellite measurements of the extent of the Antarctic sea ice have been continuous since the early 1970s. Trends of increasing or decreasing ice cover over a decade or more have been observed in some sectors of the ocean around Antarctica and large interannual and regional variations are common, but no general secular trend has yet been detected.

INTERNATIONAL RESEARCH

Since the International Geophysical Year (IGY) in 1957–1958, there has been a continuous international research effort in Antarctica. More than twenty countries now have permanent, year-round stations in the Antarctic region. Research programs are coordinated by the Scientific Committee on Antarctic Research (SCAR), to which all nations with Antarctic research programs belong.

Anthropocene

The *Anthropocene* has been proposed by Paul J Crutzen and Eugene Stoermer (2000) as a new geological epoch

to mark the strong, in many cases dominating, impact of humans on the Earth s ecology and geology. The Anthropocene covers the most recent 200 years of the Holocene, the geological epoch of the past 10–12 thousand years since the last glacial (*see* Earth System History, Volume 1).

The proposal to introduce the Anthropocene is based on the following arguments. The expansion of humankind, both in numbers and *per capita* exploitation of Earth s resources, has been astounding. During the past three centuries, human population has increased 10-fold to 6000 million, accompanied, for instance by a growth in cattle population to 1400 million. Urbanization has increased 10-fold in the past century. Over a few centuries, humankind will virtually exhaust the fossil fuels that were generated over several hundred million years by the biosphere. The release of sulfur dioxide (SO_2) to the atmosphere by coal and oil burning, globally about 160 Tg $year^{-1}$, is at least two times larger than the sum of all natural emissions. About 30–50% of the land surface has been transformed by human action. More artificial nitrogen is now applied in the form of fertilizers in agriculture than is fixed naturally in all terrestrial ecosystems. The escape into the atmosphere of nitric oxide (NO) from fossil fuel and from biomass combustion in the tropics likewise is larger than the natural inputs, giving rise to photochemical ozone (smog) formation in extensive regions of the world. More than half of all accessible fresh water is used by humankind. Human activity has increased the species extinction rate one thousand to 10 000-fold in the tropical rain forests. The concentrations of several climatically important greenhouse gases have substantially increased in the atmosphere: carbon dioxide (CO_2) by more than 30% and methane (CH_4) by about 150% (*see* Carbon Dioxide, Recent Atmospheric Trends, Volume 1; Methane, Volume 1). Furthermore, humankind releases many toxic substances into the environment, and even some that are not directly toxic to humans cause significant impacts through indirect pathways. For example, the increasing concentrations of chlorofluorocarbon gases have caused the Antarctic ozone hole and would have destroyed much of the ozone layer if no international regulatory measures to end their production had been taken (*see* Ozone Hole, Volume 1). Coastal wetlands have also been affected by humans, resulting in the loss of 50% of the world s mangroves. Fishing removes more than 25% of the primary production of the oceans in the upwelling regions and 35% in the temperate continental shelf regions. Because of the anthropogenic emissions of CO_2, surface temperatures are projected to increase by at least several degrees, and sea level by a meter or more over the next few centuries, with some part of the changes lasting many thousands of years and perhaps may even alter the natural occurrence of glacial–interglacial cycling (*see* Projection of Future Changes in Climate, Volume 1; Sea Level, Volume 1).

To assign a more specific date to the onset of the Anthropocene is somewhat arbitrary, but we propose the latter part of the 18th century as when the global effects of human activities started to become noticeable. This date is supported by data retrieved from glacial ice cores that show the beginning of the human-induced increase in the atmospheric concentrations of several greenhouse gases, in particular CO_2 and CH_4. Such a starting date also coincides with James Watt s invention of the steam engine in 1784.

Anticyclone

An *anticyclone* is a region of high atmospheric pressure with horizontal winds that spiral outward from its center, rotating clockwise in the Northern Hemisphere (counterclockwise in the Southern Hemisphere). Anticyclones typically have a horizontal extent of a few thousand kilometers. Anticyclones are associated with sinking air, which replaces the air at the surface that is spreading outward while rotating under the influence of the Coriolis effect due to the Earth s rotation. The sinking motion, referred to as subsidence, leads to warming that suppresses cloud development and traps air pollution, so anticyclones are generally associated with fair weather, and where there are sources of pollution, with smog episodes.

Arctic Air Quality

Leonard A Barrie
Pacific Northwest National Laboratory, Richland, WA, USA

Arctic pollution was rst noticed and called Arctic haze by Canadian pilots in the late 1940s and by American of cers aboard weather reconnaissance ights in the Alaskan Arctic in the 1950s. As an environmental issue, Arctic haze lay dormant until the 1970s and 1980s. It was then investigated by atmospheric scientists and found to be widespread and linked with acid rain type air pollution originating mainly from Europe and Russia (Barrie, 1986). At that time, there was growing awareness worldwide that air pollution is not just con ned to small areas around urban or industrial sources but is transported long distances before being removed to the Earth's surface. This leads to regional problems such as acid rain and northern air pollution. Subsequent research revealed the presence of a host of other contaminants in Arctic air and snow. These include: greenhouse gases (GHG), nitrogen oxides, reactive hydrocarbons, persistent organic pollutants (POPs) such as herbicides and pesticides and other potentially toxic substances such as radionuclides, lead (Pb) and mercury (Hg) (AMAP, 1998; MacDonald et al., *2000).*

A frequent question is where does Arctic pollution come from. Of course air pollution originates from human activities somewhere on Earth, but generally not in the Arctic. These substances must be transported by winds to the Arctic. The potential upwind source region of a particular Arctic air pollutant depends on how long-lived it is in the environment. GHG, POPs and mercury are very persistent. They survive for years in the environment. This is long enough for winds to mix them throughout the Earth s atmosphere. Long-lived contaminants can therefore originate from sources anywhere on Earth or, at least those in the Northern Hemisphere (Wania and Mackay, 1996). Shorter-lived soluble or reactive gases (atmospheric lifetimes of less than three months) such as sulfur oxides, nitrogen oxides and non-methane hydrocarbons as well as particulate matter containing sulfates, heavy metals and radionuclides come from an upwind air shed that is mainly restricted to the mid to high-latitudes of the Northern Hemisphere (Figure 1). Arctic haze is formed from this shorter-lived pollution. The main potential source regions of shorter-lived Arctic haze in the Northern Hemisphere are Europe/Russia, eastern North America and Southeast Asia. However, in practice, seasonal variations in rain or snow as well as in wind trajectories conspire to deliver most of this pollution to the Arctic from Europe and Russia over frozen snow-covered land during winter and spring (see arrows in Figure 1). Most pollution from eastern North America and Southeast Asia blows eastward over the stormy Atlantic and Pacific Oceans where it is removed by rain and dissolution in ocean water. In the period December–April, atmospheric concentrations of sulfate haze aerosols in the Arctic are 10–20 times higher than in the rest of the year and they follow trends in emissions of sulfur dioxide (SO_2) from Europe and Russia (Sirois and Barrie, 1999).

Another frequent question is what impact does this pollution have on people and the environment. The primary effect of air pollution are contamination of food sources by airborne POPs, mercury and radionuclides deposited to Arctic ecosystems (AMAP, 1998). Arctic people are generally exposed to radionuclides through terrestrial food webs and to POPs and mercury through aquatic food chains. They are most exposed to polychlorinated biphenyls (PCBs), certain pesticides and mercury through long aquatic food webs that result in bioaccumulation in mammals, birds and

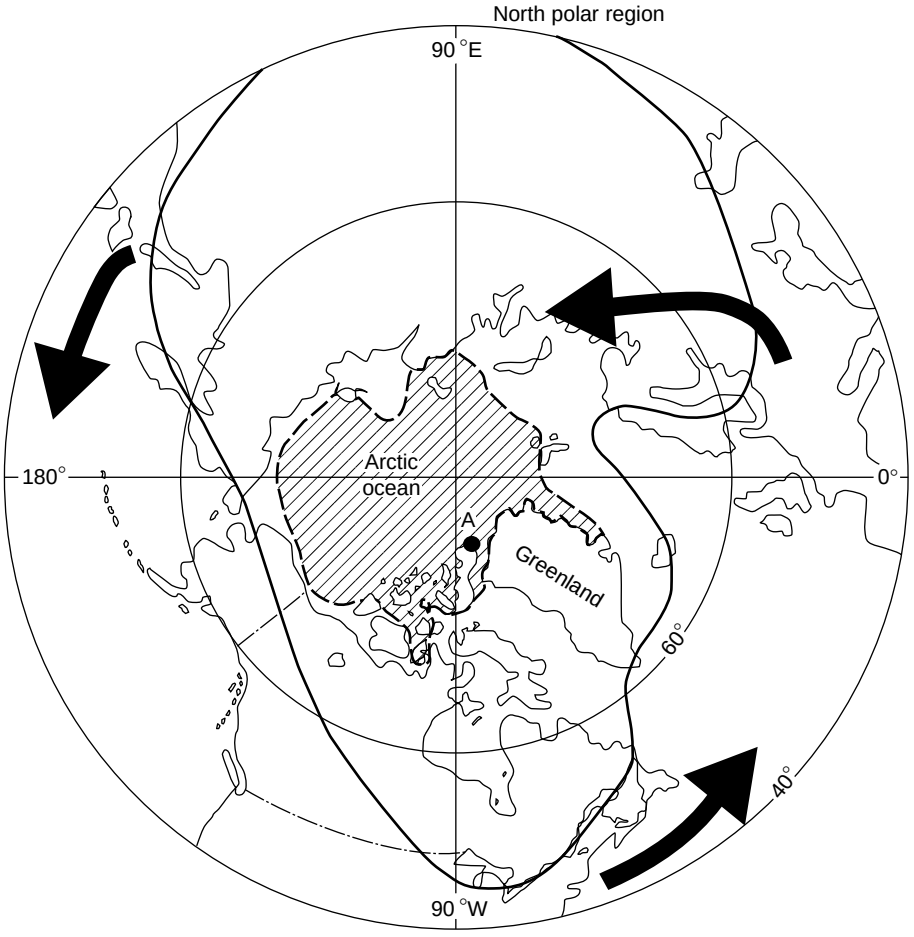

Figure 1 The Northern Hemispheric source region of shorter-lived Arctic haze type air pollution, the main pathways of air out of the three major continental source regions (arrows), the mean position of the Arctic front in winter (dark line) and the location of ice cover on the Arctic ocean at its minimum in summer (hatched area). European and Russia sources are channeled directly into the Arctic in winter while sources in eastern North America and Southeast Asia move eastward over stormy ocean (adapted from AMAP (1998) with permission)

fish. Exposure to radionuclides from nuclear bomb tests or nuclear power plant accidents is mainly through atmospheric transport and deposition to terrestrial ecosystems. Particular soil and vegetation characteristics concentrate some radionuclides in plants and animals (reindeer/caribou, game, mushrooms).

POPs consist of two classes of persistent synthetic organic compounds: those synthesized for industrial purposes and those for pesticidal and herbicidal applications. The ones that are seen in remote regions such as the Arctic have largely been banned from usage in many countries but their presence continues to be felt because of persistence and/or continued use in some countries (MacDonald *et al.*, 2000; Harner *et al.*, 2000). Compounds that have been detected in the Arctic include eight industrial POPs and 10 pesticidal/herbicidal POPs or their metabolites. They have been measured throughout the Arctic in the 1990s (Halsall *et al.*, 1998).

The most abundant POP in the Arctic Ocean is hexachlorocyclohexane (HCH). It is the only one that has been measured long enough to correlate levels in Arctic air with global usage in agriculture (Li *et al.*, 1998). It serves as an example of the complex nature of pathways of these substances and of the unique physical and chemical properties of the Arctic environment that lead to preferential cold-trapping of this substance in the polar region. Production of HCH started approximately in 1950 and peaked in 1980. Most use was in China, India and the former Soviet Union. This high level of use coupled with strong partitioning of HCHs into colder water resulted in a preferential out-gassing in warm climates, transport to the Arctic and cold-trapping by the Arctic Ocean. It is estimated that several thousand tonnes of HCHs are now contained within the surface layer of the Arctic Ocean (MacDonald *et al.*, 2000) providing a reservoir for sea-atmosphere exchange and a continuous source of contamination in the Arctic food

chain. By 1993, HCH emissions declined to approximately 10% of their 1980 levels as a result of bans or restrictions in China and other major use countries. Arctic atmospheric levels of HCH have paralleled usage trends decreasing to a point that this reversibly soluble gas is flowing back out of Arctic Ocean waters into the Arctic atmosphere.

The Arctic atmosphere near the ocean surface after polar sunrise from February–May has a unique chemistry that destroys atmospheric ozone and enhances mercury deposition. Discovered in the late 1980s (Barrie *et al.*, 1988), surface ozone depletion occurring in spring over vast areas of the Arctic Ocean and Hudson Bay in the lower atmospheric (0–2 km) is a phenomenon somewhat analogous to stratospheric ozone destruction but with a difference. It is driven by sea salt bromine (Br) and chlorine (Cl) generated from chemical reactions occurring in sunlight on surface snow and ice, whereas in the stratosphere, ozone depletion is driven by bromine and chlorine from solar degradation of gases such as chlorofluorocarbons (CFCs) and methyl bromide (CH_3Br) used in termite control . The most remarkable impact is on the biosphere through enhancement of mercury deposition by a factor of approximately six (Schroeder *et al.*, 1999). Elevated mercury levels in Arctic char and lake trout are in part due to this effect.

Arctic Climate

Gunter Weller

University of Alaska Fairbanks, Fairbanks, AK, USA

The climate of the Arctic has produced one of the most inhospitable and extreme environments on Earth, characterized by limited sunlight for much of the year, extreme temperature excursions and a short growing season. The Arctic is often de ned by climatic parameters, e.g., as the area where the average temperature for the warmest month is below 10 °C (Köppen, 1936). Sea ice, snow cover, glaciers, tundra, permafrost, boreal forests and peatlands are expressions of this severe climate, as well as being sensitive indicators of climatic change. Their presence and extent are susceptible to subtle variations in sunlight, surface temperature, and heat transport through the atmosphere and ocean.

The Arctic also plays an important part in the complex interactions of the Earth System. The mean global circulation patterns of the atmosphere and ocean are controlled by equator- pole temperature differences. Polar feedback processes affect the global climate and global warming due to the greenhouse effect, amplifying this effect at high latitudes. Greenhouse warming in the Arctic is likely to have major impacts on the environment, including melting of sea ice and glaciers, and thawing of permafrost, with potentially profound societal impacts, not only regionally but also around the globe. The Arctic climate is thus governed by many complex interactions, which are part of the global climate system, and in turn climatic conditions shape much of the Arctic environment.

THE CURRENT ARCTIC CLIMATE

Temperature and Precipitation

The Arctic climate varies greatly by location and season. Sea ice, snow cover, glaciers, tundra, permafrost, boreal forests and peatlands (Figure 1) are expressions of this severe climate, as well as being sensitive indicators of climatic change. Mean annual surface temperatures range

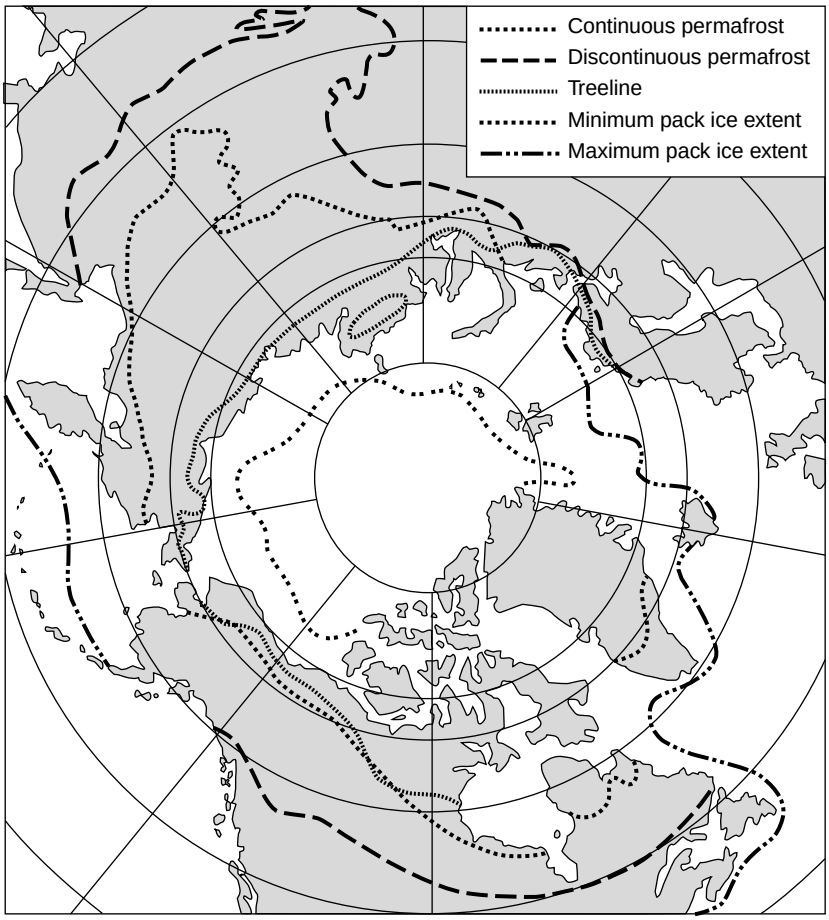

Figure 1 Climate-related features of the Arctic and sub-Arctic, including continuous and discontinuous permafrost boundaries and the tree-line on land, and maximum and minimum pack ice extent in the ocean

from 0 °C at Murmansk, Russia (69 °N) to −12.2 °C at Point Barrow, Alaska (71.3 °N), −16.2 °C at Resolute, Canada (74.7 °N), −18 °C over the central Arctic Ocean to −28.1 °C at the crest of the Greenland ice sheet (about 71 °N). Some of these differences are due to the poleward intrusion of warm ocean currents such as the Gulf Stream and the southward extension of cold air masses. Arctic tundra areas in North America have at least a 50% frequency of being in Arctic air in July and the median location of the polar front in July corresponds approximately with the northern limit of the boreal forest (Barry, 1967).

Precipitation in the Arctic is difficult to measure, because it is generally light and is associated with storms and also because for the greater part of the year it falls as dry snow, which is redistributed by winds according to exposure and local topography. With an annual precipitation of 200–300 mm and frequently less than 100 mm (e.g., 104 mm year^{-1} at Barrow, Alaska; 130 mm year^{-1} at Resolute, and 95 mm^{-1} measured in the central Arctic Ocean on Soviet ice islands (NP 7–8)), the Arctic is comparable to arid regions elsewhere.

Much of the Arctic consists of cold deserts largely devoid of vegetation. It should be noted, however, that climatically arid regions can have wet surfaces when permafrost prevents drainage of the seasonally thawed layer, even though the precipitation may be low.

Seasonal Variability

Winter in the Arctic tundra is 6–9 months long and is characterized by a relatively shallow (30–40 cm) snow cover, by darkness, and by January temperatures that average about −30 °C in North America, somewhat lower in Asia (Siberia) and much higher (−10 °C) in Northern Europe. Spring and autumn are short transition periods, respectively. Late winter and spring are generally characterized by clear skies and receipt of a high percentage of the possible solar radiation. Temperatures begin to rise, but lag 4–6 weeks behind the increase in solar radiation. Mean daily temperatures are above freezing during the short summer, but over the Arctic Ocean and the coastal areas cloudiness and fog prevent temperatures from rising much above 5 °C even in

July. Temperatures increase from the coast inland to the forest-tundra ecotone, which can have July mean temperatures of 10 °C and higher.

Atmospheric Circulation

Surface weather systems associated with a large-scale cold-cored westerly circumpolar circulation are distinctive of the polar atmosphere. Cyclones and anticyclones are embedded in, and are steered by, this flow, and changes in this circulation can radically affect the weather and climate of the planet. The synoptic (large-scale instantaneous state of the atmosphere) activity in the Arctic between 1952 and 1989 has been described by Serreze *et al.* (1993). They found that winter cyclone activity is most common near Iceland, between Svalbard and Scandinavia, the Norwegian and Kara Seas, Baffin Bay and the Eastern Canadian Arctic. Cyclone tracks in winter most frequently enter the Arctic from the Norwegian and Barents Seas. Winter anticyclones are most frequent and strongest over Siberia and Alaska/Yukon, with additional but weaker systems over the Central Arctic Ocean and Greenland. During summer, cyclones are common in the same regions as in winter.

Since 1952, cyclone numbers in winter, spring and summer have increased significantly, as have anticyclone numbers in spring, summer and fall (Serreze *et al.*, 1993). Proshutinsky and Johnson (1997) have shown that the atmospheric circulation over the Arctic Ocean alternates between typical anticyclonic and cyclonic circulation regimes approximately every 10–15 years. This effect has been named the Arctic Oscillation (*see* Arctic Oscillation, Volume 1) and has important implications for the Arctic s thermohaline (temperature and salinity) structure, salinity anomalies observed in the Greenland Sea, and the variability of sea ice in the Arctic Ocean.

ARCTIC MICROCLIMATES

Arctic Tundra Microclimates

Arctic tundra covers about 5.5% of the land surface of the Earth and constitutes a major surface feature of the Arctic. The word *tundra* is broadly used to refer to the landscapes that are found above the altitudinal or latitudinal treeline (*see* Tundra, Volume 2). The boundary between tundra and the northern edge of the boreal forests, the forest-tundra *ecotone* (*see* Ecotones, Volume 2), is not very well defined. The most common description of the tundra is treelessness, and trees may be defined in this context as woody plants with a single central stem at least 2 m tall. Of the world s major ecosystems, tundra has the lowest temperatures and the shortest growing season. The tundra plants are adapted to the cold winters and chilly summers of Arctic and alpine regions. For these species the environment is not severe either physically or biologically.

The environmental conditions within a few meters above and below the ground surface, where most biological activities take place, constitute the microclimate of a region. The microclimate is characterized by the radiation, temperature, and moisture regimes of these near surface layers. It is determined largely by the regional climate, as modified by local topography and by the vegetation cover. In the Arctic tundra environment with its low and exposed vegetation, large variations in microclimate may exist within a small area. Even a few centimeters difference in microtopography can produce marked differences in soil temperature, depth of snow, wind effects, snow drifting and resultant protection of plants.

Energy Balance and Surface Conditions

Quantitatively, the microclimate is described by the energy balance, which expresses how the available net radiative energy is converted into sensible and latent heat to warm the air and ground and to melt snow or evaporate water from the surface. The microclimate of the Arctic coastal tundra is characterized by an 8-month winter phase with net radiative losses, compensated primarily by sensible heat fluxes towards the surface, in the presence of steep temperature inversions (Figure 2). This is followed by a brief, but distinct, phase related to snow melting. Towards the end of this phase, the tundra is completely wet and evaporation rates reach 6 mm day^{-1}, with mean values of 4.5 mm day^{-1}. Through the melting phase, within a span of 2–3 weeks, the net radiation increases by a factor of 10 and the latent heat flux by a factor of 40. Evaporation continues throughout summer, but by the time freezing of the tundra occurs in early September, net radiation has been reduced appreciably and evaporation rates are down to about 1 mm day^{-1}. Soon thereafter, snow covers the tundra and the radiation balance becomes negative again.

PAST CLIMATES

Climate Variability

Historical climate records generally do not go back more than a few hundred years but past climates can be reconstructed from many different proxy indicators, including tree rings (1000 years), ice cores (100 000 years), lake sediments (1 million years), and marine sediments (10 million years), among others. From these indicators, the climate of the Arctic is known to have undergone large variations in the past. The Little Ice Age and Medieval Warm Period were the most recent examples of cooler and

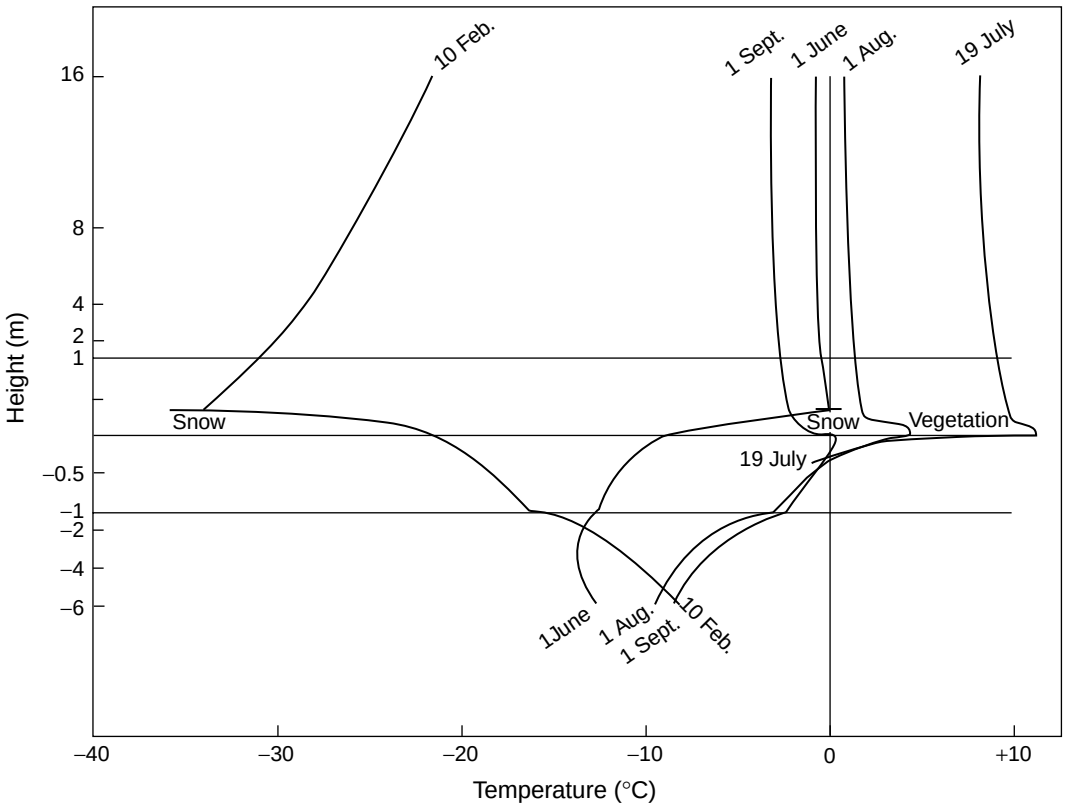

Figure 2 Typical temperature gradients in air, snow, vegetation and soil at Barrow, Alaska. The vertical height scale from +1 to −1 m is expanded. Note the effects of snow and vegetation (from Weller and Holmgren, 1974)

warmer climates, respectively. The North Atlantic region was unusually mild when the Norse first settled Greenland in the 10th century AD, then plunged into a 500-year cold spell known as the Little Ice Age, starting about 1300 AD (*see* Little Ice Age, Volume 1; Medieval Climatic Optimum, Volume 1). By 1500, archaeological and historical evidence shows that the Norse settlers had vanished. The changing climate was undoubtedly a factor and illustrates the potential impacts of climate change on humans and human activities.

The Ice Core Record

Ice ages have occurred at roughly 100 000 year intervals during the Pleistocene. Indications are that they are caused by changing amounts and distribution of sunlight on the planet due to long-term variations in the Earth s orbit and the inclination of its spin axis to the Sun (the so-called Milankovich cycles after the Yugoslav mathematician who computed them 75 years ago; *see* Climate Model Simulations of the Geological Past, Volume 1; Milankovitch, Milutin, Volume 1). During ice ages, large ice sheets covered parts of the Northern Hemisphere continents and the Bering Strait was above sea level. Recent results obtained from the deep ice cores recovered by European and American researchers from the Greenland ice sheet have produced remarkable new insights into short- and long-term climatic changes, with the abrupt changes revealed by the ice cores being a particular surprise.

The ice core record shows great detail of past climatic variability. At the end of the last ice age, about 13 000 years ago, the climate was beginning to warm during a period called the B lling–Aller d when it suddenly plunged back to ice age conditions. This 1300 year long cold period is named the Younger Dryas because the polar wildflower *Dryas octopetala* had a resurgence in Europe during this period. Temperatures in Greenland dropped by about 7 °C back to full ice age conditions. At the end of the Younger Dryas the climate returned to warmer and wetter interglacial conditions. Further back, during the last ice age, there are unexpected abrupt climate shifts. These oscillations, called *Dansgaard- Oescheger cycles*, (*see* Dansgaard- Oescheger Cycles, Volume 1) lasted from centuries to millennia, jumping abruptly from cold to warm climates before slowly reverting to cold conditions again. Many of these oscillations seem to be associated with the collapse of big ice sheets, which sent numerous icebergs into the North Atlantic, the so-called Heinrich events.

PRESENT AND FUTURE CLIMATE TRENDS

Observed Climate Trends in the Arctic

Chapman and Walsh (1993) examined the climate trends in the Arctic for the period 1961–1990, using the climate data set of the Climate Research Unit of the University of East Anglia. The results, including updated data for 1966–1995, indicate considerable warming over the landmasses of Eurasia and North America, particularly in winter and spring. Over the last three decades trends have been towards higher surface temperatures in these areas at rates of up to $1\,^{\circ}\mathrm{C}\,\mathrm{decade}^{-1}$ in the annual mean and up to $2\,^{\circ}\mathrm{C}\,\mathrm{decade}^{-1}$ in winter. On the other hand, there are also smaller areas of cooling of similar magnitude within the Arctic regions, particularly in the South Greenland and Davis Strait area. There is little change in summer and slight cooling in the fall for most areas.

Pronounced reductions in seasonal snow, glaciers, permafrost and sea ice, following a warmer climate in the Arctic, have also been observed. Some of the changes include:

- Sea ice extent in the Bering Sea has been reduced by about 5% over since the 1950s, with the steepest decrease occurring in the late 1970s. Sea ice extent has also decreased in the East Siberian Sea.
- Sea ice thickness, a sensitive indicator of climate change, seems to have decreased between 1976 and 1987, based on limited submarine sonar records.
- Glaciers have generally receded, with typical ice thickness decreases of 10 m since the 1950s, but some glaciers have thickened in their upper regions. A warming of $1\,^{\circ}\mathrm{C}$, if sustained, appears to reduce glacier lengths by about 15%.
- Borehole measurements in continuous permafrost have shown warming of up to $2–4\,^{\circ}\mathrm{C}$ over the last century.
- Discontinuous permafrost throughout Alaska has warmed, and some of it is currently thawing from the top and bottom.
- Cyclone and anticyclone frequency have increased over the Arctic between 1950–1990.
- Annual snowfall has increased in the same period over northern Canada (North of $55\,^{\circ}\mathrm{N}$) by about 20% and by about 11% over Alaska.

Modeling Future Climates

The future climate of the Arctic may be strongly affected by the increasing greenhouse effect. Numerous general circulation models (GCMs) have attempted to simulate the global climate for this effect. All of these models show a temperature amplification in the annual mean in the Arctic; the warming is even more pronounced in winter and spring. These results are the basis of the World Meteorological Organization (WMO)/United Nations Environmental Programme (UNEP) Intergovernmental Panel on Climate Change (IPCC) (IPCC, 1996) projections that the Arctic will warm more than the global mean, particularly in winter. The IPCC report also projects that Arctic landmasses will warm more rapidly than the ocean, although some models show the greatest temperature increases over the Arctic Ocean.

A comparison of GCM performances in the Arctic as part of the Atmospheric Model Intercomparison Project (AMIP) shows a wide divergence of results, however. The temperature simulations for the seasonal mean surface air temperatures in the Arctic Ocean of 19 GCMs were compared with observations. The majority of the models produced temperatures that were too cold. Simulation of other climate parameters also showed large differences. Sea level pressure was well simulated by several models, particularly the ones with higher resolution. Precipitation was too large, in some cases by more than a factor of two. There were also wide variations in cloud cover. The reliability of the simulated climate change scenarios is likely not to be high, but model performance is improving.

IMPACTS OF CLIMATE CHANGE

The IPCC Report

The IPCC report *Climate Change 1995* (IPCC, 1996) includes a chapter (Chapter 7 of Working Group II on the cryosphere) on climate change and its impacts on the polar regions for a simulated doubling of atmospheric CO_2. The report provides the following projections, including the degree of confidence in each case:

- Many components of the cryosphere are sensitive to changes in atmospheric temperature because of their thermal proximity to melting. The extent of glaciers has often been used as an indicator of past global temperatures (High Confidence).
- Projected warming of the climate will reduce the area and volume of the cryosphere. This reduction will have significant impacts on related ecosystems, associated people and their livelihoods (High Confidence).
- There will be striking changes in the landscapes of many high mountain ranges and of lands at northern high latitudes (High Confidence). These changes may be exacerbated where they are accompanied by growing numbers of people and increased economic activities (Medium Confidence).

The chapter goes on to state that the following changes and associated impacts on the polar regions are likely:

- Pronounced reductions in seasonal snow, permafrost, glacier and periglacial features with a corresponding shift in landscape processes (High Confidence).

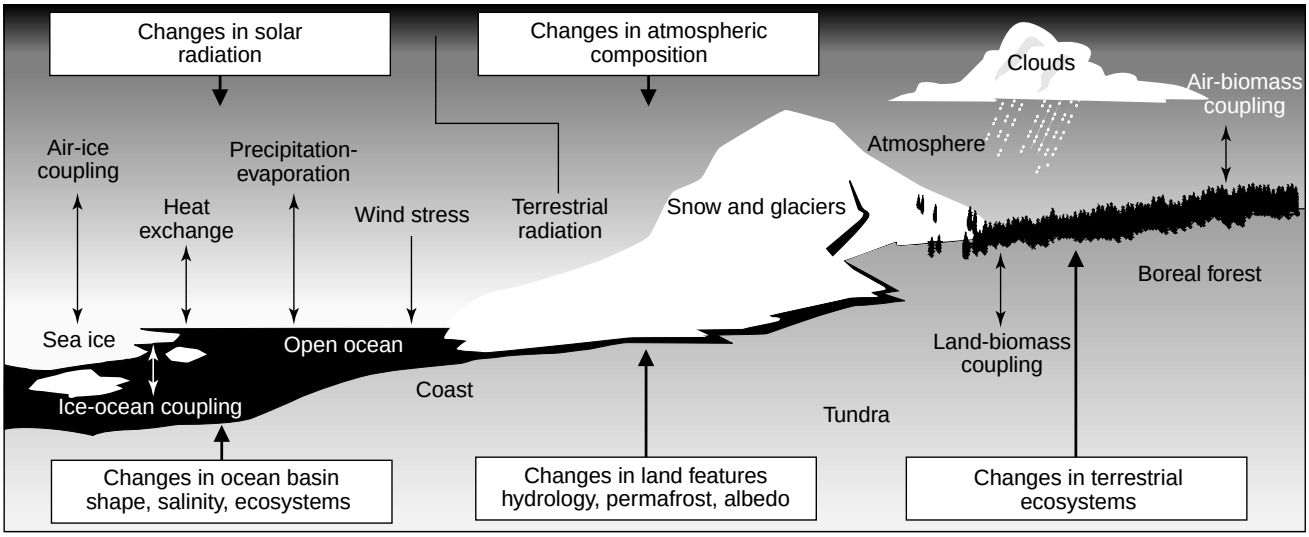

Figure 3 A diagrammatic transect across the Arctic landscape, showing the principal external forcing functions of change (top boxes), the Arctic internal interactions (middle arrows), and the effects on the Arctic (bottom boxes). (Illustration used by permission of the Arctic Research Consortium of the United States)

- Increases in the thickness of the active layer of permafrost and the disappearance of most of the ice rich discontinuous permafrost over a century-long time span (High Confidence).
- Disappearance of up to a quarter of the presently existing mountain glacier mass (Medium Confidence).
- Less ice on rivers and lakes. Freeze-up dates will be delayed, and break-up will begin earlier. The river ice season could be shortened by up to a month (Medium Confidence).
- A large change in the extent and thickness of sea ice, not only from warming but also from changes in circulation patterns of both atmosphere and oceans. There is likely to be substantially less sea ice in the polar oceans (Medium Confidence).

Figure 3 shows a schematic diagram of the causes, effects, interactions and feedbacks of climate change involving the various components of the Arctic environment.

Economic Impact of Climate Change

The economical impacts of a major climate change in the Arctic regions are still largely unknown but some impacts in recent decades have been summarized by Weller and Lange (1999). As the climate continues to get warmer, widespread loss of discontinuous permafrost will trigger erosion or subsidence of ice rich landscapes. Permafrost thawing will reduce slope stability and increase the incidence of natural hazards for people, structures and communication links. Buildings, roads and pipelines will be threatened. Thawing of permafrost could also lead to disruption of petroleum production and distribution systems in the tundra, unless mitigation techniques are adopted. Engineering and agricultural practices will need to adjust to changes in snow, ice and permafrost distributions. Arctic fisheries and forestry may also be affected.

Not all of the impacts are likely to be negative. For example, improved opportunities for water transport, tourism and trade are expected from a reduction in sea, river, and lake ice. Reduced sea ice may also aid new exploration and production of oil in the Arctic Basin. Agriculture and forestry may benefit from a warmer climate. These will have important implications for the people and economies of the Arctic.

Arctic Ocean

Claire L Parkinson
NASA Goddard Space Flight Center, Greenbelt, MD, USA

The Arctic Ocean is the smallest of the Earth's four major oceans (the Paci c, Atlantic, Indian, and Arctic), covering 14 $\times$ 10^6 km^2 located entirely within the Arctic Circle (66° 33′N). It is a major player in the climate of the north polar region, has a variable sea ice cover, and is home to a multitude of plant and animal species. Its temperature, salinity, and ice cover have all undergone changes in the past several decades, although it is uncertain whether these predominantly re ect long-term trends, oscillations within the system, or natural variability.

The Arctic Ocean is surrounded largely by the land masses of Eurasia, Greenland, and North America (Figure 1). Its principal connection to the rest of the Earth s oceans lies between Greenland and Scandinavia, where it connects to the North Atlantic. Smaller connections include the narrow (85 km wide) Bering Strait, linking it to the North Pacific, and the passageways within the Canadian Archipelago and between the Archipelago and Greenland, leading to Baffin Bay and thence to Davis Strait and the North Atlantic.

The Arctic Ocean has an unusually broad and shallow continental shelf on the Eurasian side, extending more than 1000 km northward from Scandinavia and approximately 800 km northward from Siberia. The deeper portion of the Arctic is divided by the Lomonosov Ridge into two main basins, the Canadian Basin and the smaller and deeper Eurasian Basin, which has a maximum depth exceeding 5000 m.

Water flows into the Arctic principally from the Atlantic as a warm, salty undercurrent. There are also smaller oceanic inputs through the Bering Strait and cold, freshwater inputs from many rivers, most significantly the Lena, Yenisei, and Ob rivers in Russia and the Mackenzie River in Canada. A large part of the outflow from the Arctic is through the Fram Strait between Greenland and Svalbard. Surface currents in the Arctic tend to be clockwise in the Canadian Basin, with occasional reversals to this flow, and more linear along the Transpolar Drift Stream flowing from north of Russia, across the Eurasian Basin and the vicinity of the North Pole, and out through Fram Strait (*see* Ocean Circulation, Volume 1).

The water inflows and outflows play a major role in the temperature and salinity structure of the Arctic (*see* Salinity Patterns in the Ocean, Volume 1). The warm, salty Atlantic layer from the Atlantic inflows is most prominent closest to the entrance regions but is also apparent throughout the Arctic at depths exceeding 200 m. Overlying the Atlantic layer, the Arctic surface water, in contact with

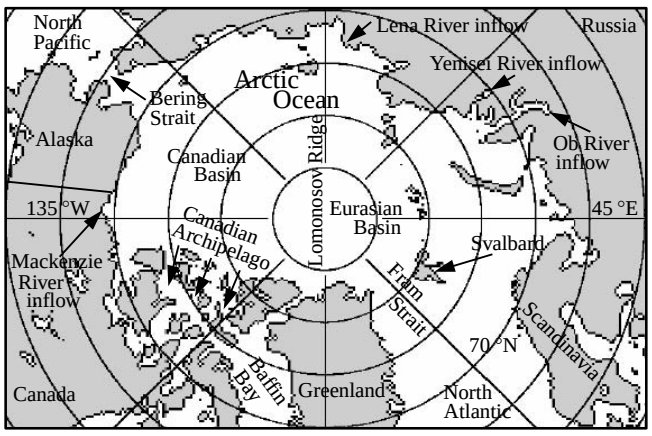

Figure 1 The Arctic Ocean and its surroundings

the cold Arctic atmosphere and subject to the freshwater inputs from the surrounding rivers, is colder and less saline. The upper 30–50 m of the surface water tends to be fairly well mixed vertically, with temperatures near the freezing point and salinities ranging from highs exceeding 34 parts per thousand (ppt) near the North Atlantic to lows below 29 ppt near river inflows. Surface salinities in the Bering Strait are approximately 31 ppt. Vertically, salinities tend to increase with depth from the bottom of the mixed layer down to the Atlantic layer, with this vertical variation forming a prominent halocline, especially in the Eurasian Basin. The resulting stable density stratification hinders the warm Atlantic layer waters from upwelling to the surface.

Importantly, the Arctic Ocean is largely capped by a thin, broken layer of sea ice, generally less than 6 m thick and covered by snow (*see* Sea Ice, Volume 1). The sea ice restricts exchanges of heat, mass, and momentum between the ocean and the overlying atmosphere and, due to its high reflectivity, also tremendously restricts the input of solar radiation to the ocean. Ice covers almost all of the Arctic Ocean in winter, to an ice concentration (percent areal coverage) of at least 90%, and most of the Arctic Ocean in summer. Sea ice is considerably less saline than the ocean water from which it forms and tends to decrease in salinity over time, as more of the salt content is washed downward through the ice during periods of summer melt.

The Arctic ice cover is in constant flux, being melted by solar radiation, augmented by additional freezing, and moved by winds, waves, and currents. As ice floes separate, openings appear, called *leads* when linear and *polynyas* when large and non-linear. In contrast, when the forces acting on the ice result in floes colliding forcefully together, the ice breaks and piles of ice rubble form. The above-water portions of these are called *ridges*, and the more massive underwater portions are called *keels*. A ridge/keel combination can have an ice thickness of 30 m or more, far exceeding the level-ice thickness.

Despite the cold temperatures, the Arctic is home to a host of plant and animal life, including algae colonizing the sea ice, sometimes at a concentration of millions in a single ice floe, and protozoans, crustaceans, and nematodes, most of which are smaller than 1 mm in length, also living in the ice and feasting upon the algae. Although biomass tends to be low under the permanent ice pack, high phytoplankton and zooplankton concentrations are frequently found in the ice-free waters. The resulting availability of food makes the ice-free waters popular for numerous species of birds and marine mammals. Amongst the larger animals, polar bears and Arctic foxes roam over the ice, and seals, walruses, and whales live in the ocean waters.

The Arctic has received considerable attention during the late 20th century and the start of the 21st century because of various changes reported to be occurring in it and the sense that these could be related to a possible global warming. Among the changes are the following:

1. A warming and spatial expansion of the Atlantic layer, at depths of 200–900 m, determined from ship-based conductivity–temperature–density (CTD) measurements in the 1990s versus data from 1950–1989 (Morison *et al.*, 2000; Serreze *et al.*, 2000).
2. A warming of the upper ocean in the Arctic s Beaufort Sea (north of Alaska) from 1975 to 1997, found from *in situ* measurements (McPhee *et al.*, 1998).
3. A considerable thinning, perhaps as high as 40%, of the Arctic sea ice cover in the second half of the 20th century, found from submarine data (Rothrock *et al.*, 1999).
4. A lesser and uneven retreat of the ice cover, averaging approximately 3% per decade between late 1978 and the end of 1996, found from satellite data (Bjørgo *et al.*, 1997; Parkinson *et al.*, 1999), and a related shortening of the length of the sea ice season throughout much of the region of the Arctic Ocean s seasonal sea ice cover, also found from satellite data (Parkinson, 2000).
5. An increase of 5.3 days per decade in the length of the melt season on the perennial ice cover, found from satellite data for 1979–1996 (Smith, 1998).
6. A decrease in the salinity of the upper 30 m of the central Beaufort Sea from 1975 to 1997, found from *in situ* measurements. This freshening of the water has been attributed largely to sea ice melt (McPhee *et al.*, 1998) and to increased runoff from the Mackenzie River (Macdonald *et al.*, 1999).
7. A mixed pattern of salinity increases and decreases through the expanse and depth of the rest of the Arctic Ocean (Morison *et al.*, 2000). This includes an increase in the salinity of the surface waters in the mid-Eurasian Basin during the 1990s, found from submarine data, and a thinning of the halocline separating the surface from the warm Atlantic layer waters (Steele and Boyd, 1998; Morison *et al.*, 2000).

In view of the highly coupled nature of the Arctic climate system, many of the changes occurring within it are likely connected. In particular, the freshening of the upper ocean in the Beaufort Sea is likely a response in part to the thinning of the ice, as ice melt adds freshwater to the upper ocean which consistently is much less saline than the ocean average. Similarly, the reduction in the sea ice cover and warming of the upper ocean are probably both connected to the Arctic surface air temperature increases reported, for instance, by Serreze *et al.* (2000).

The causes of the late-20th century changes in the Arctic system remain uncertain, although it is likely that several factors are involved. The increase in carbon dioxide and

other greenhouse gases in the global atmosphere, is believed to cause atmospheric warming, although some human influences, such as the increase in particulate matter in the atmosphere, tend to offset a portion of the warming (*see* Arctic Climate, Volume 1). Atmospheric warming contributes to oceanic warming, sea ice melt, and upper ocean freshening, all observed in recent decades in portions of the Arctic.

Other potential influences, however, are more oscillatory in nature, such as the impacts of the North Atlantic Oscillation (NAO) and the Arctic Oscillation (AO), two major decadal-scale oscillations in atmospheric pressure patterns, or the impacts of El Niño/La Niña cycles. The NAO and AO in particular have received attention because many of the patterns of change in the ocean and ice cover of the Arctic can be explained by changes in the NAO and AO in recent decades (e.g., Parkinson *et al.*, 1999; Morison *et al.*, 2000). It remains uncertain, however, whether the changes in the NAO and AO are exclusively natural fluctuations in the climate system or are related to long-term, perhaps anthropogenically induced climate change (*see* Arctic Oscillation, Volume 1; El Niño, Volume 1; North Atlantic Oscillation, Volume 1).

Arctic Oscillation

Drew Shindell

Columbia University, New York, NY, USA

The Arctic Oscillation (AO) is a hemispheric scale seesaw of heat and mass between the Arctic region and Northern Hemisphere middle latitudes. This pattern dominates the variability in the Northern Hemisphere winter, and has the second largest impact of all the Earth's climate cycles (after the El Niño/La Niña cycle). The strength of the AO pattern is closely associated with surface wind speeds and temperatures in the Northern Hemisphere. Variability induced by the AO is especially important in the wintertime, when the oceans are warmer than the land because they have retained more heat from the previous summer. Increased winds then carry relatively warm Atlantic oceanic air across northern Europe and Asia, causing a local rise in temperature. Similarly, onshore winds from the Paci c warm North America, while surface temperatures fall in the vicinity of the Bering Strait and Newfoundland due to the offshore ow of colder continental air. A bias in the AO has been observed since the early 1970s, and is associated with roughly half of the observed wintertime surface warming over Europe and Siberia, and at least part of the observed cooling in the vicinity of Newfoundland and the Labrador Sea.

The AO, sometimes called the *Northern Annular Mode*, is created by internal atmospheric interactions of eddy momentum and heat fluxes with the mean flow. These affect temperatures, pressures, and atmospheric motions, all of which exhibit AO-related variability. The most common definition of the AO is based on *Empirical Orthogonal Functions* (EOFs). These are mathematical representations of a data set by a number of fixed spatial patterns, each derived to explain the maximum amount of variance possible, while remaining independent of the other patterns. The AO pattern is the first EOF of sea-level pressure (Figure 1), and therefore is the pattern that explains the most variance. It accounts for roughly 1/4 of the Northern Hemisphere variability during winter, more than twice that of the next pattern. The variability associated with this pattern extends from the surface up into the stratosphere during winter, and the variability pattern can be equivalently defined as being composed of variability at all levels

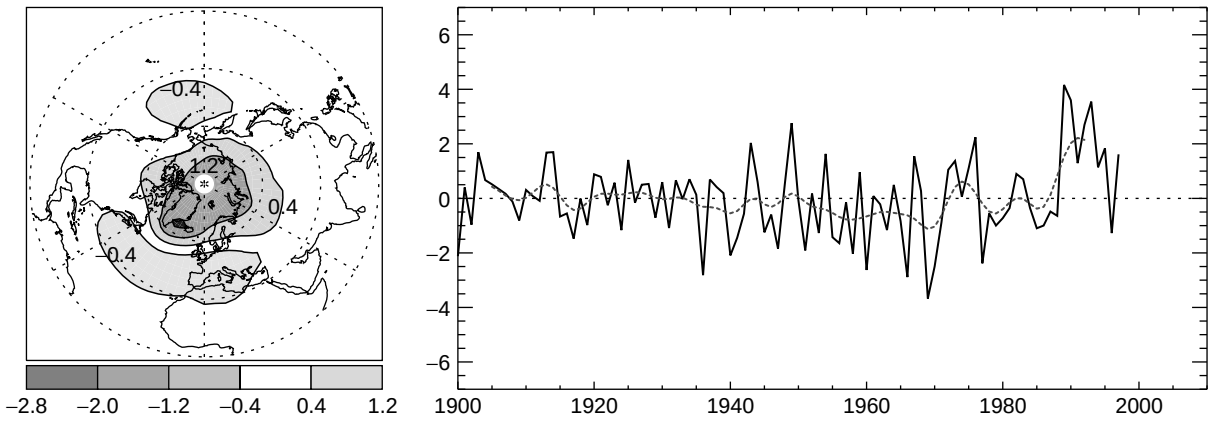

Figure 1 The AO and the AO index. The left side shows the leading variability pattern of Northern Hemisphere wintertime sea level pressure (arbitrary sign), while the right side shows the amplitude of this pattern over time. The index is scaled to units of pressure (mbar or hPa), while the spatial pattern has unit amplitude poleward of 60°N. The dashed line is a 10-year smoothed fit to the index. (Reproduced by permission of *Nature* (Shindell *et al.,* 1999) © (1999) Macmillian Magazines Limited)

from the surface through the lower stratosphere. A particular AO pattern has a typical persistence time of about 1–2 weeks.

The time series of the size of the first EOF is often called the *AO index* (Figure 1). The classic North Atlantic Oscillation contrast between subtropical and high-latitude sea-level pressure is the subset of the broader AO which appears in the Atlantic region (*see* North Atlantic Oscillation, Volume 1). The AO variability pattern is present throughout the year, but it is largest in winter, when its amplitude actually increases with altitude. The AO also shows significant wintertime correlations in the lower stratosphere with the Quasi-Biennial Oscillation (*see* Quasi- Biennial Oscillation (QBO), Volume 1). Similar variability is present in the Southern Hemisphere, showing almost identical patterns in sea-level pressure, zonal winds, and temperatures. It has been called the *Antarctic Oscillation* (AAO) or *Southern Annular Mode*.

During the high phase of the AO, sea-level pressure is lowered in the Arctic as the atmosphere at high latitudes cools, while at middle latitudes it warms. Consistent with these temperature changes, the speed of the westerlies blowing at Northern Hemisphere mid-latitudes increases. The prevailing westerly winds are caused by the natural difference in temperature between the colder polar region and the warmer lower latitudes, so that an increase in the temperature gradient with latitude strengthens the winds. The high phase of the AO therefore weakens the subtropical jet and strengthens the subpolar vortex jet. The laws of physics governing the atmosphere require consistency between changes in motion, pressure and temperature, so that the AO can be equally well described by the variability in westerly wind speed or in the temperature, mass, or sea-level pressure patterns. In addition to its effects on zonal winds, the AO also modulates the mean meridional circulation and hence the total column ozone, as well as tropopause height.

Observations show that the AO index remained relatively constant from around 1900 to 1970, perhaps even decreasing very slightly. Beginning in the 1970s, it began to increase. This apparent trend in the AO accounts for slightly more than half the total observed trend in sea-level pressure, and nearly the entire trend towards increasing subpolar westerly winds. Because the strength of the AO affects continental surface temperatures, this is associated with a significant portion of the observed wintertime warming. This warming has been 4–6 °C (~7–11 °F) over large areas of the Northern Hemisphere continents from the mid-1960s to the mid-1990s. During this period, the AO contribution to the Siberian warming has been +3–4 °C (~5–7 °F), while it has contributed roughly 2–4 °C (~4–7 °F) cooling to the Newfoundland/Labrador Sea area (this cooling may also be related to oceanic circulation changes). Over the same period, globally and annually averaged surface temperatures have increased by only about 0.5 °C (0.9 °F).

It is not yet certain whether the observed high values of the AO index will continue, or what is causing them. There is clear evidence from observations that the AO pattern at the ground is closely related to the wind pattern in the stratosphere, however (*see* Stratosphere, Temperature and Circulation, Volume 1). Observations also suggest that changes in the two coupled patterns typically originate in the stratosphere, and then propagate downwards to the Earth s surface. Changes in the stratosphere may therefore play a large role in the apparent AO trend. Possible causes for the initial changes in the stratosphere are anthropogenic greenhouse gas emissions, Arctic

ozone depletion, or solar variability. Climate model simulations show that it is possible for all of these to alter the latitudinal temperature gradient in the stratosphere. In the case of increasing greenhouse gases or ozone depletion, this leads to a strengthening of the westerly jet stream in the lower stratosphere, and hence of the Arctic polar vortex. The effect works its way down as the enhanced stratospheric winds alter the propagation of energy coming out of the troposphere, which then changes the wind speed at progressively lower altitudes. Observations and model simulations both show a distinct shift in energy flow over the past few decades, supporting the mechanism outlined above. Furthermore, a trend has been observed in the AO only during wintertime, when variability in the lower atmosphere is strongly coupled to the stratosphere by planetary waves, and is therefore the only season in which this mechanism is effective.

If in fact the increased amplitude of the AO index is caused by human activities, then it will likely continue to increase. Furthermore, a sizeable fraction of the large wintertime continental warming trends should therefore be attributed to human impacts on climate, and not to natural variability.

ARM (Atmospheric Radiation Measurement) Program

The ARM is a highly focused observational and analytical research effort that collects data for comparison with and improvement of the atmospheric component of global climate models (AGCMs). The primary focus for ARM has been on acquiring the data needed to improve understanding of the role of clouds and the treatment of cloud-radiation feedbacks (*see* Cloud- Radiation Interactions, Volume 1). The program is sponsored by the US Department of Energy as part of its contribution to the US Global Change Research Program, and is also closely coordinated with a number of international research programs.

To gather the needed data, ARM observatories have been established at a number of locations experiencing quite different types of cloud cover. The first ARM site was the Cloud and Radiation Test-bed (CART) facility set up in the southern Great Plains of the US; this site experiences a wide variety of continental cloud types and began collecting data in the spring of 1992. The second ARM site, which is located in the tropical western Pacific Ocean and which began operations in September 1996, has stations in Manus and Nauru. The third ARM site, located on the North Slope of Alaska, began operations in the summer of 1997. Data from each of the sites are assembled using a centralized data system and are made available in near real-time to participating scientists. Data for the general science community are made available through a data archive established at the Oak Ridge National Laboratory.

Using the data, the program s objectives are to quantify the radiation balance from the surface to the top of the atmosphere, to determine the atmospheric characteristics responsible for this balance, to improve the parameterization of the formation and evolution of clouds in climate models, to operate an experimental test-bed for testing process models being used in AGCMs, and to provide satellite ground-truth measurements. The research program gathers data both from networks of ground-based remote-sensing instruments and, during focused campaign studies, from manned and unmanned aircraft. Measurements include

vertical profiles of temperature, water vapor, trace gases, aerosols, and solar and infrared radiation. In addition, ARM gathers satellite data to supplement the ground-based and *in situ* data. The ARM data are intended to be used as a testbed for evaluating the process models and their treatments of the cloud-climate feedbacks in AGCMs and mesoscale models.

MICHAEL C MACCRACKEN *USA*

Arrhenius, Svante

(1859- 1927)

Svante Arrhenius, Swedish physicist and chemist, received the Nobel Prize in Chemistry in 1903 for his theory on electrolytic dissociation. In environmental science he is best known for his pioneering work on the atmospheric greenhouse effect of carbon dioxide.

Arrhenius got his PhD from Uppsala University in 1884 based on a thesis in which he developed a theory for electrical conductivity of aqueous electrolytes. During the following years he spent long periods at various European universities. Among his achievements during these years was the formulation, inspired by J H van t Hoff in Amsterdam, of the well-known law for the temperature dependence of chemical reactions.

In 1891 Arrhenius was employed as a teacher at Stockholm s Hogskola (now Stockholm University). In 1895, he became a full professor, a position he held until his retirement in 1927. He was the rector of the Hogskola from 1896 to 1902. Soon after he joined the Hogskola in 1891, Arrhenius took the initiative to form the Stockholm Physics Society, which brought local scientists in physics, chemistry and geosciences together for informal and very fruitful discussions on topics such as climate variations and other large-scale interdisciplinary issues related to the oceans, the atmosphere, the solid Earth and space. One of the discussion topics was the cause of the Quaternary glaciation cycles. The geologist Arvid Hogbom had suggested that volcanic eruptions might have caused large variations in the atmospheric concentration of carbon dioxide and Arrhenius wanted to find out if such variations might explain the temperature variations during the glacial cycles. Arrhenius was not first to describe what is now referred to as the greenhouse effect (the credit for this should go to the French scientist Joseph Fourier who, in 1824, introduced the glass bowl analogy to the heating effect of infrared absorbing gases in the atmosphere), but Arrhenius was the first to make a quantitative estimate of the magnitude of the greenhouse effect. In a now classic paper published in 1896 (On the Influence of Carbonic Acid in the Air on the Temperature of the Ground, *The Philosophical Magazine*, 41, 237–276) Arrhenius estimated that a doubling of the carbon dioxide concentration would lead to a 5.7 °C increase in the mean surface temperature. In view of the very limited data Arrhenius had at his disposal, this estimate is surprisingly close to the present estimate of 1.5–4.5 °C. In his calculation, Arrhenius also took into account the positive feedback on the temperature of the increasing amount of water vapor in a warmer atmosphere.

Although Arrhenius first estimate of the greenhouse effect of carbon dioxide was made with the purpose of finding a possible cause of the glacial temperature cycles, he soon realized its relevance for the issue of a human-induced impact on climate. His first estimate of a man-made global temperature change, due to carbon dioxide emissions from fossil fuel combustion, was also published in 1896. He then estimated that the burning of coal alone would thus be capable of raising the temperature of the earth by somewhat more than one thousandth of a degree centigrade per annum. This is about 20 times smaller than current estimates, the reason for the difference being mainly Arrhenius failure to anticipate the enormous growth in fossil fuel use that has taken place since his days.

Arrhenius spent much time and effort educating the general public about the new domains conquered by science. His books *Textbook of Cosmic Physics* (1903) and *Worlds in the Making: The Evolution of the Universe* (1906), were translated into several languages.

Asteroids and Comets, Effects on Earth

Curt Covey
Lawrence Livermore National Laboratory, Livermore, CA, USA

Collisions of asteroids and comets with Earth are rare events, but over the long span of Earth's history such events have taken place many times. They will continue to occur unless future technology is used to prevent them. An asteroid or comet collision produces an explosion of enormous energy, equivalent to thousands of times the explosive energy of all the world's nuclear weapons at the height of the Cold War. Early in Earth's history these collisions occurred more frequently than they do today. They may have hindered the early evolution of life. On the other hand, comets may have provided Earth with much of the water and other substances necessary for life to exist.

A variety of disastrous effects would result from any such collision. Likely global-scale effects include stratospheric ozone depletion, acid rain, global wild res, and enough smoke and dust to block sunlight and cool the surface for months. After the smoke and dust cleared, substantial global warming would result if the collision had caused large amounts of water or carbon dioxide to enter the atmosphere. The most recent time that a large asteroid or comet collided with Earth was 65 million years ago, at about the same time that the dinosaurs and many other species became extinct. It seems probable that that collision caused or at least contributed to these extinctions. Several other mass extinction events in Earth's history may be connected with asteroid or comet impacts.

An asteroid or comet collision as severe as the one 65 million years ago is unlikely to happen again during the next several million years. Less energetic impacts occur more frequently. The probability is quite low that a collision severe enough to endanger the global environment will occur during the next few human generations. It is an open question whether such an unlikely but gravely consequential event warrants human concern at this time.

IMPACTS OVER EARTH HISTORY

The 1994 collision of Comet Shoemaker-Levy 9 with Jupiter served as a reminder that collisions of asteroids and comets with planets occur from time to time. The effects on Jupiter s clouds were visible even in small telescopes for months afterward. A quarter of a century of spacecraft exploration preceding this spectacular event revealed that impact craters are the dominant landforms on most of the solid bodies (planets, moons and asteroids themselves) in the solar system. Indeed, these bodies – as well as the cores of giant gaseous planets like Jupiter – are believed to have formed over 4.5 billion years ago by the accretion of numerous smaller rocky and icy planetesimals.

The crater-covered surface of the Earth s Moon provides the closest and most detailed record of asteroid and comet impacts over the past several billion years. Dating of lunar rocks returned to Earth by astronauts and automated spacecraft, together with mapping of craters by telescopes and lunar-orbiting satellites, gives a history of asteroid and comet impacts spanning the past 4 billion years. At the beginning of this period, impacts were several times more frequent than today, but they decreased rapidly to near present day rates by about 3 billion years ago. The rapid pace of cratering nearly 4 billion years ago is sometimes referred to as the late heavy bombardment. It may have been the final phase of the Moon s – and presumably Earth s – accretion from planetesimals.

Due to erosion and other geologic processes, craters on Earth are not nearly as well preserved as they are on the Moon. It is also necessary to distinguish impact craters from volcanic craters. Careful surveys have revealed over 150 impact craters on the continents with a few new discoveries made each year (Figure 1). Among the most evident is Meteor Crater in Arizona, 1.2 km in diameter, but others are considerably larger. Examples include the Manicouagan and Sudbury craters in Canada, of 100 and 140 km diameter, respectively, and the comparably sized Chicxulub crater discussed later. Over the past several hundred million years the rate at which sizeable craters have appeared on Earth, according to the geologic record, is roughly consistent with both the lunar cratering rate inferred for the same period and the number of asteroids and comets that astronomers observe today.

The role of such impacts during the earliest phases of Earth history can only be guessed. Because water and carbon-containing molecules are present in some asteroids and all comets, it is possible that these materials – which are essential for life as we know it – were supplied to Earth during the time of the late heavy bombardment. For example, comets are nearly half water (ice), and the number of comets impacting Earth since its formation could provide more than enough water to supply all of the present day oceans. On the other hand, comet impacts may have been sufficiently energetic to blast as much water as the comets contained back into space. Recent measurements of the composition of three comets suggest that this process (impact erosion) may have prevented comets from supplying a significant amount of water to Earth. The ratio of heavy to light isotopes in the hydrogen in these comets is about twice that of ocean water, implying a source other than (or in addition to) comets. Conventional wisdom holds that Earth s water – and other volatile materials

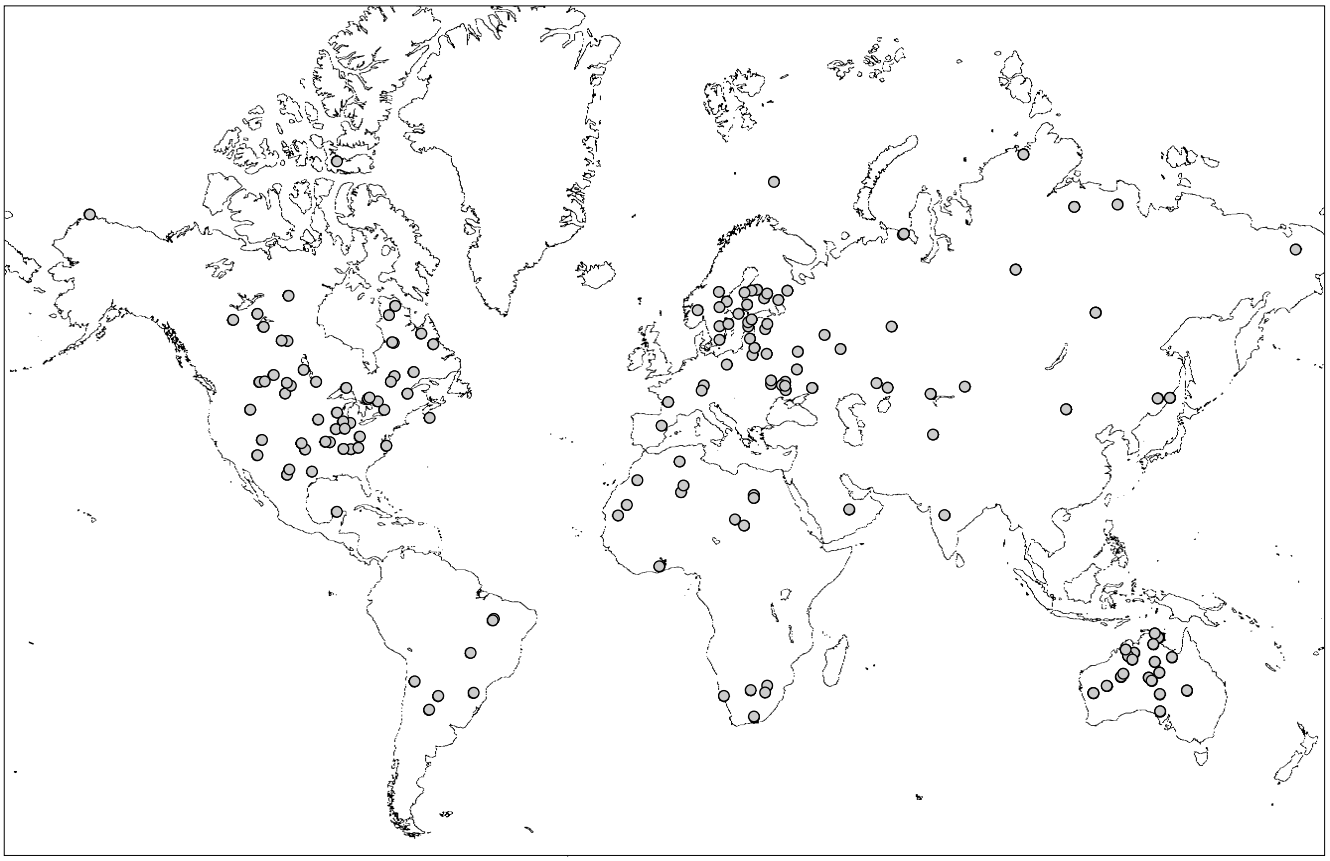

Figure 1 Locations of currently known terrestrial impact craters. Updated from Grieve and Shoemaker (1994). (Reprinted by permission of the University of Arizona Press)

such as the gases comprising the atmosphere – were chemically bound to the rocky material that originally formed the planet. According to this theory, the Earth s ocean and atmosphere formed gradually as the volatile materials outgassed from the interior of the planet in volcanic eruptions.

Rather than promoting life, the late heavy bombardment may have actually hindered its emergence. The lunar record implies that not only the frequency, but also the energy of impacts on the very early Earth was far greater than it has been during more recent times. Collisions prior to about 4 billion years ago could have repeatedly evaporated the oceans and destroyed all forms of life. It is possible that life originated several times on the early Earth but only survived to give rise to the known biosphere after the late heavy bombardment diminished. This scenario is perhaps consistent with the fossil record, which indicates that life has existed continuously on Earth for at least the past 3.5 billion years. During this time, individual impacts were not sufficiently energetic to extinguish all life, and the extinction events they caused may have opened new niches for other forms of life including humans.

ASTEROID AND COMET POPULATIONS TODAY

Asteroids are rocky bodies ranging in size from ~1000 km diameter downward. Although the vast majority of them reside between Mars and Jupiter, a substantial number are perturbed into orbits that approach or cross that of Earth. Over 250 such near-Earth asteroids greater than about 1 km in diameter have been found in systematic surveys by telescopes. It is estimated that twice that number exist but are undiscovered as yet. If the orbits of the known near-Earth asteroids are typical of the entire population, then about five such objects greater than 1 km in diameter would be expected to collide with Earth every million years. (A far greater number of very small asteroids in Earth-crossing orbits provide the source of ordinary meteorites: about 4000 larger than 1 kg in mass strike Earth each year.) From this cosmic perspective the big collisions are like unusual rolls of dice in a game. They are rare events, randomly spaced in time, but virtually guaranteed to occur repeatedly if the game goes on long enough.

Comets also collide with Earth. These bodies are distinguished from asteroids not only by their icy

composition – which generates a bright tail of gas and dust when comets are sufficiently near the Sun – but also by their highly eccentric and often retrograde orbits about the Sun. From these orbital characteristics, it appears that comets originate from among an enormous number of icy bodies residing at very great distances from the Sun (about 40 000 times the Earth–Sun distance on average). Random external perturbations such as a passing star occasionally send an icy body much closer to the Sun, where it becomes visible as a comet and often passes inside the orbit of Earth. Telescopic surveys and statistical theory, similar to the considerations discussed above for asteroids, imply that a solid comet nucleus greater than about 1 km in diameter should collide with Earth roughly every 2–10 million years.

Earth s collisions with comets are thus estimated to be less frequent than its collisions with asteroids. This situation may not always have been the case. Stars or interstellar clouds passing near the solar system could send a greatly enhanced number of comets into the planetary region. From the number and movement of stars and clouds in our part of the Galaxy, such events have been estimated to occur roughly every 10 000–400 000 years. Tentative evidence for these comet showers has been inferred from the geologic record.

Collision frequencies depend strongly on the size of the objects considered (Figure 2). Larger asteroids and comets are far less abundant than smaller ones, and thus they collide with Earth much less often. For example, the average rate of asteroid collision is believed to be roughly once every few hundred thousand years for kilometer-size objects but only once every 50–100 million years for objects 10 or more kilometers in diameter.

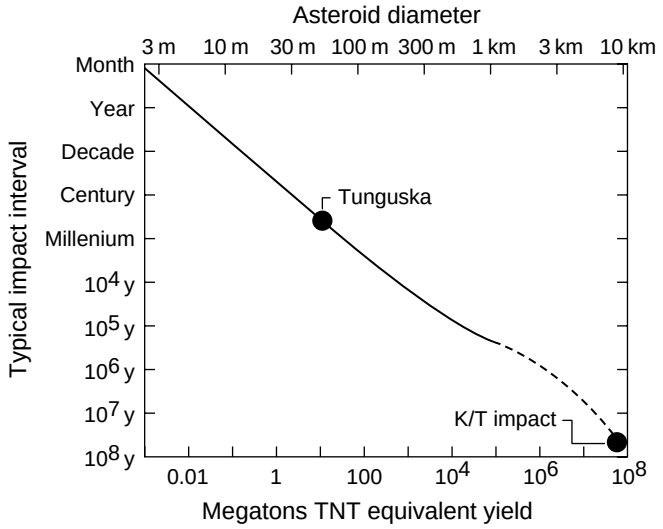

Figure 2 Typical interval between impacts as a function of asteroid diameter, or equivalently (for typical asteroid density and velocity) the explosive energy of impact. The solid curve is obtained from crater counts. The dashed curve extrapolates the data to the K–T impact. The other point locates the diameter of the Tunguska impacting body on the assumption that it was an asteroid rather than a comet (*see* **Tunguska Phenomenon**, Volume 1). From Morrison *et al.* (1994). (Reprinted by permission of the University of Arizona Press)

THE CRETACEOUS–TERTIARY IMPACT

The geologic record contains evidence of several impacts over the past several hundred million years. By far the most complete evidence to be discovered comes from 65 million years ago, the transition between the Cretaceous and Tertiary eras (or K–T boundary). The discussion below focuses on this one event, but similar effects could be expected from any impact of similar magnitude (*see* Extinctions and Biodiversity in the Fossil Record, Volume 2).

Primary evidence for an impact 65 million years ago comes from sediments deposited at that time. The K–T transition can be precisely identified in sedimentary rock layers by an abrupt disappearance of fossilized microscopic Cretaceous plants and animals: they are far less abundant immediately above the boundary than they are immediately below it. It has been estimated that half the genera of living organisms perished at the end of the Cretaceous – including dinosaurs, many land plants, and marine creatures of all sizes in addition to most of the microscopic plankton – setting the stage for the proliferation of other life forms including, ultimately, humanity.

K–T sediments contain greatly enhanced concentrations of iridium, an element that is relatively depleted in Earth s crust but more abundant in meteorites (which originate from asteroids). Enhanced iridium at the K–T boundary has now been detected at over 80 locations worldwide. Enhanced concentrations of other so-called platinum-group elements appear at the K–T boundary, in the same ratios to each other as in meteorites (which distinguishes the K–T sediments from volcanic deposits). Peculiar rounded grains (spherules) of glassy material – apparently arising at impact from the melting and mixing together of different types of rock – are also present at the K–T boundary. So are grains of quartz containing microscopic bands of deformation, seen elsewhere only in rocks near known impact craters or in nuclear explosion craters, and evidently produced by shock waves passing through the target rock.

After discovery of the evidence described above, a worldwide search to locate the site of the K–T impact culminated in discovery of a buried crater, at least 180 km in diameter, near Puerto Chicxulub (pronounced cheek-shoe-lube) on the Yucatan coast of Mexico. The Chicxulub crater is buried under sediments deposited during the slow sinking of the Yucatan area over the past several million years. The crater can be seen in maps depicting subtle irregularities of Earth s gravitational or magnetic fields. Drilling samples

from Chicxulub (originally obtained by geologists exploring for oil in the area) match the isotope composition of deposits at the K–T boundary in neighboring regions of the Caribbean and Gulf of Mexico. These deposits appear to record the passage of enormous ocean waves (tsunami) at the time of impact (Figure 3). The Chixulub samples themselves contain rocks that were melted at the precise time of the K–T event, according to inference from their radioactive isotope composition.

Taken as a whole the evidence suggests that the impacting body 65 million years ago was an asteroid, although it is possible it may have been a comet nucleus. The worldwide amount of excess iridium and other trace elements deposited at the K–T boundary, together with the concentrations of this element found in asteroids, implies that the impacting body was about 10 km in diameter. If it struck Earth at a velocity typical of asteroids, 15 km s^{-1}, the resulting energy released on impact would have been equivalent to the detonation of about 50 million megatons (or 50 trillion tons) of high explosive. If the impacting body was a comet, the impact energy would likely have been much larger – perhaps as large as a billion megatons – due mainly to the higher impact velocities typically arising from comet orbits. These enormous numbers contrast with values of the order of 10 megatons for the energies of both Meteor Crater s formation 50 000 years ago and the 1908 Tunguska explosion (*see* Tunguska Phenomenon, Volume 1).

Fifty million megatons is thousands of times the total explosive energy of all the world s nuclear arsenals at the height of the Cold War. A single explosion of this magnitude would create a crater of the order of 100 km in diameter (roughly consistent with the size of the Chixulub crater). Blast and earthquake damage would extend for thousands of kilometers and – if the impact was located in an ocean – tsunami would devastate the surrounding coastal margins. Fully global effects, however, would arise only indirectly as a consequence of the explosion s interaction with the atmosphere, as discussed in the following section.

Figure 3 The K–T boundary in north-eastern Mexico. This region was underwater in the Gulf of Mexico at the close of the Cretaceous. At and below the geologist's hand is impact debris, unusually thick because this site is near the impact point at Chixulub. The layers above record the passage of enormous ocean waves (tsunami) that broke up and mixed together the original ocean bottom deposits. The lowest sediments date from before the impact. From Smit (1994). (Reprinted by permission of the University of Arizona Press)

GLOBAL CONSEQUENCES

Even before an asteroid or comet strikes the Earth s surface, its passage though the atmosphere would produce shock waves in which air is heated and nitrogen and oxygen (the two most common atmospheric constituents) chemically combine to form nitrogen oxide. This compound destroys ozone in a highly efficient catalytic process. Together with other atmospheric changes, nitrogen oxide production could cause severe depletion of the stratospheric ozone layer, although the resulting increase in harmful solar ultraviolet radiation might well be intercepted by impact-generated pollutants before it reaches the surface. Acid rain would also be produced as the nitrogen oxide converts to nitric acid in cloud droplets (and possibly by analogous processes involving sulfate compounds). These changes in atmospheric chemistry are difficult to quantify but probably would produce a substantial stress on the biosphere.

The energy of an asteroid or comet impact would be sufficient to melt or vaporize all of the impacting body, together with a comparable amount of target rock, and to launch the resulting debris on ballistic trajectories into space. (For a body the size of the K–T impactor, with a size about twice the average depth of the oceans, this would occur whether the impact occurred on land or sea.) Friction with the atmosphere on reentry of this material could produce enough heat to ignite wildfires worldwide. This sequence of events appears to have occurred following the K–T impact. Soot is deposited at the K–T boundary in amounts equivalent to 1–2% of the aboveground carbon content of the Cretaceous biosphere. Since fires convert only a small fraction of carbon to soot, the implication is that much of the Cretaceous land biomass (considerably more than today s aboveground plant material) was consumed.

Apart from the catastrophic direct effects of global wildfires, the soot they produce would strongly absorb sunlight, preventing it from reaching the surface. In amounts found at the K–T boundary – over 10 mg for each cm^2 of Earth s surface area – an atmospheric layer of soot absorbs essentially all incident sunlight. Impact-produced dust would have a similar effect. In addition to melting or vaporizing a considerable amount of material, the energy of impact would pulverize a much larger quantity of target rock, at least 100 times the mass of the impacting body according to

theoretical calculations, and propel it into the atmosphere. Shocked quartz grains in K–T deposits provide observational evidence of this process. A fraction of this material would be microscopic in size. Upon reaching the stratosphere, it could be expected to remain there for a year or two, by analogy with the microscopic sulfate particles that major volcanic eruptions produce. Asteroid or comet impacts themselves might produce sulfate particles if sufficient amounts of sulfur were present in either the impacting body or the target rock. The latter case appears to have occurred at the K–T impact site.

All of the above effects would reverse the normal situation in which most incident sunlight penetrates the atmosphere and is absorbed at Earth s surface. Instead, following a major impact most solar energy would either be absorbed high in the atmosphere or reflected back to space. In either case the result would be surface cooling. Computer simulations of climate (similar to those used to predict human-induced global warming) imply that the interiors of continents would cool rapidly, approaching the freezing point of water within a week or two after the impact, even in summertime. Ocean and coastal areas would not cool significantly, however, because the large volume of water in the upper oceans stores enough heat to mitigate a loss of sunlight for several years (see Figure 4). As noted above, dust and other particles are expected to remain in the stratosphere no longer than a few years. The tremendous perturbations to surface and atmospheric temperature during this time would undoubtedly lead to major changes in weather patterns. One possibility implied by the computer simulations is global drought resulting from the stabilized atmosphere (higher temperatures above cooler temperatures) and the resulting suppression of cloud formation.

After the dust, smoke and sulfate particles cleared from the atmosphere, it is possible that the global cooling they caused could be replaced by global warming due to an enhanced greenhouse effect. This effect would occur if an asteroid or comet impact – or its primary effects – injected sufficient quantities of carbon dioxide or water vapor into the atmosphere. Wildfires of the extent inferred for the K–T event would produce several times the carbon dioxide present in today s atmosphere. Impact into carbonate sediments could add to the effect of fires. On the other hand, the Cretaceous atmosphere is thought to have already contained enhanced carbon dioxide levels compared to the present, and it is not clear if the additional enhancement resulted in noticeable long-term warming. An ocean impact would inject far more water into the stratosphere than is normally present there, although most of it would be removed at least as fast as smoke and dust particles.

In light of the overwhelming evidence that a substantial sized ($\sim$10 km diameter) asteroid or comet collided with Earth at the end of the Cretaceous, and the possible global

effects listed previously, it seems reasonable to conclude that the impact was responsible for the K–T mass extinction. This inference, however, is weakened by the scarcity of evidence geologists and paleontologists have for such a remote time. Nor can one exclude the possibility that separate but simultaneous effects were operating. Indeed, there is evidence that an upsurge in volcanic activity occurred at the end of the Cretaceous, possibly adding to the carbon dioxide greenhouse effect mentioned above. Perhaps the safest thing to say is that the major asteroid or comet impact that evidently occurred at the K–T transition would surely have pushed many plants and animals in the direction of extinction.

A natural follow-up question is whether other impacts caused other mass extinction events. The K–T boundary marks the most recent of five great mass extinction events since the detailed fossil record began 570 million years ago. Some evidence of an asteroid or comet impact has been found for other mass extinction events, for example shocked quartz grains at the boundary between the Triassic and Jurassic eras 205 million years ago. In addition, enrichment of platinum-group elements has been detected for the times of smaller extinction events 11, 34 and 91 million years ago. It is possible – although difficult to prove – that asteroid or comet impacts contributed to most of the extinction events that mark transitions between the major subdivisions of Earth s geologic history.

THE IMPACT HAZARD TODAY

As discussed previously, both the record of crater formation on Earth and the Moon, and the numbers of asteroids and comets found in near-Earth orbits, provide estimates of how often impacts of such bodies on Earth could be expected. The very low probability obtained for a sizeable impact is consistent with the apparent absence of any during recorded history. The largest observed event is the Tunguska explosion, probably caused by an asteroid of the order of 100 m in diameter. Impacts of this size are expected to occur once every few centuries. Evidently the damage they cause has gone largely unnoticed, an unsurprising situation considering the local nature of the destruction and the relatively low human population during most of recorded history. The Tunguska explosion, for example, flattened a remote Siberian forest but resulted in only two reported fatalities.

For asteroids and comets about half a kilometer in diameter, the typical impact interval is between 50 000 and 100 000 years. Objects this large would produce craters about 10 km in diameter and extensive regional damage rivaling or exceeding that of the greatest natural disasters in human experience. Blast, earthquake and fire damage would extend for 100 km or more. If the impact occurred in an ocean basin, the resulting tsunami would sweep over all adjacent coastlines. At somewhat larger size – about 1–2 km diameter – asteroids and comets would begin to produce global effects as discussed above for the K–T impact.

Should asteroid and comet impacts be a cause for concern? Although the likelihood of a sizeable collision in the near future is exceedingly small, the results if one occurred would be disastrous beyond human experience. How to deal with such low probability, high consequence events is not obvious. For example, one might assume that 1-km objects strike Earth roughly once every 300 000 years. One such impact could kill something like a billion people if worldwide disruption of agriculture resulted. Multiplying these two numbers together ($1\,000\,000\,000 \times 1/300\,000$) gives an average fatality rate of about 3000 people per year. What if anything this number implies is a matter of individual interpretation.

Some protective action could be undertaken with today s technology. A large fraction of near-Earth asteroids greater than 1 km in size have already been identified. Nearly all of these objects could be tracked with a modest extension of present day efforts. Because an asteroid destined to collide with Earth will typically make a large number of close approaches before impact, the observing system would likely provide at least several decades of warning. During that time the missile and nuclear weapon technologies of the Cold War might be adapted to deflect the asteroid. This leisurely schedule would not apply to long-period comets – which enter the planetary region with rarely more than 1 year of advance notice – or to smaller but still dangerous asteroids that would be detected only when they are extremely close to Earth. Examples of the latter class include three asteroids (all with diameters greater than 100 m) that in the past decade approached Earth to within twice the Earth–Moon distance. It is not obvious that ensuring protection against all such objects is achievable with present day technology.

Atlantic Ocean

The *Atlantic Ocean* is the body of water bordered by the American continents, Greenland, Europe, Africa, and the Antarctic region. It is connected to the Indian Ocean south of Africa and to the Pacific Ocean south of South America by a continuous current (Antarctic Circumpolar Current) that flows eastward around Antarctica and to the Arctic Ocean through passages across the ridge stretching from Greenland to the UK (*see* Ocean Circulation, Volume 1). The average depth of the Atlantic is around 4000 m. Its maximum depth is 8648 m, in the Puerto Rico Trench. The Reykjanes Ridge and Mid-Atlantic Ridge are significant topographic features that separate the western and eastern portions of the Atlantic throughout its length. Three marginal seas impact the water properties of the Atlantic Ocean: the Mediterranean Sea through its high salinity, the Inter-American Seas (Caribbean region) as a conduit for part of the Gulf Stream, and the Arctic Ocean through its production of very dense water. Some areas that are part of the open North Atlantic Ocean have specific geographical names: the Labrador Sea between Labrador and Greenland, the Irminger Sea between Greenland and the Reykjanes Ridge, and the Sargasso Sea south and east of the Gulf Stream and west of the Mid-Atlantic Ridge.

The Atlantic is the most saline of the three major oceans, as a result of higher net evaporation rates over a large area (*see* Salinity Patterns in the Ocean, Volume 1). The northern North Atlantic is one of the two global sites for deep-water formation, the other being around Antarctica. Deep waters in the northern North Atlantic are approximately 20 years old, compared with 500 years for the deep North Pacific where there is no deep-water source. Through ocean–atmosphere coupling, the tropical Atlantic provides a major inter-annual climate signal that impacts the neighboring regions. Coupling with the atmosphere in the North Atlantic and Arctic provide decadal climate signals called the *North Atlantic* and the *Arctic Oscillations* (*see* Arctic Oscillation, Volume 1; North Atlantic Oscillation, Volume 1), which impacts weather and especially precipitation in Europe and eastern North America.

Atmospheric Angular Momentum and Earth Rotation

Richard D Rosen
Atmospheric and Environmental Research, Inc., Lexington, MA, USA

The study of angular momentum provides a natural framework for understanding the dynamics of rotating systems. Much of our knowledge about the general circulation of the atmosphere has been gained through studies of its angular momentum about the polar axis, an integrated measure over all parcels of air of the product of their mass, westerly component of motion, and distance from the axis. As a whole, the atmosphere is rotating faster than the Earth beneath, so its relative angular momentum is positive (on average, equal to about 1.4×10^{26} *kg m*^{2} *s*$^{-1}$*). The main sources and sinks of angular momentum at the atmosphere's lower boundary, as well as the role of large-scale waves in maintaining the mean circulation through the transport of angular momentum from the tropics to the midlatitudes, have been well documented (Peixoto and Oort, 1992). Atmospheric angular momentum should, therefore, serve as a fundamental measure of the atmosphere's dynamic response to global environmental change.*

The development of improved data sets over the past two decades has heightened awareness of the close relationship

between changes in the axial component of the global atmosphere s angular momentum (AAM) and that of the solid Earth, the latter being reflected in small, but measurable, changes in the planet s rate of rotation. In the absence of external torques on the coupled dynamical system comprised of the atmosphere and the solid Earth, the law of angular momentum conservation dictates that changes in the momentum about the polar axis of one component of the system must be simultaneously matched by equal, but opposite, changes in the momentum of the other. Given the size of the changes observed in the large-scale wind field responsible for changes in AAM, this relationship implies that compensating changes in Earth s rotation rate, reckoned in terms of changes in the length of the day (ΔLOD), will be no more than fractions of a millisecond (10^{-3} s). Remarkably, modern space geodetic techniques are capable of detecting such tiny fluctuations in the length of the day, and once the effects of known tidal forces are removed from time series of ΔLOD, this series correlates strongly with series of AAM over a wide range of time scales (Rosen, 1993). In conforming to the momentum conservation principle, this agreement attests to the quality of modern atmospheric and geodetic data sets, and to the secondary role played by other geophysical processes (such as changes in ocean currents or the redistribution of fresh water on land) in affecting ΔLOD.

Much of the variability in AAM and ΔLOD that occurs on interannual time scales is related to the El Niño/Southern Oscillation (ENSO) phenomenon (*see* El Niño/Southern Oscillation (ENSO), Volume 1). When water temperatures in the tropical Pacific Ocean are unusually high, as during the warm phase of ENSO, winds in the subtropical jet stream become anomalously strong, leading to larger values than normal of AAM and ΔLOD. This signal has been reproduced in simulations of the recent past by atmospheric general circulation models that are driven by historical sea surface temperature (SST) fields (Hide *et al.*, 1997). From an extended run of one such model attempting to simulate the climate of the 20th century, the angular momentum of the model atmosphere was analyzed for interannual and multidecadal signals (Rosen and Salstein, 2000). The interannual variability of the model s AAM compares well with that derived from observed AAM values available since the middle of the century. In both the model and observed series, there is a notable increase in year to year variability since the 1970s, coinciding with a marked change in atmospheric circulation regimes at that time. In the model, the recent high level of variability is comparable to that during the first two decades of the century, but this result is strongly dependent on the quality of the SST field used in the experiment, because of the strong linkage between AAM variability and ENSO. Observations do point to a tendency towards more ENSO warm events and a warmer tropical Pacific in general by the end of the 20th century, and as a consequence, a trend in AAM towards larger values is discernible. Based on the observations of AAM available since around 1950, this trend, in equivalent units of LOD, amounts to lengthening the day at a rate of around 0.5 millisecond (ms) per century.

How will AAM and ΔLOD respond to a possible warming of the globe in the 21st century? This question was first addressed by Rosen and Gutowski (1992) but more recently by Huang *et al.* (2001) using a coupled atmosphere–ocean global climate model in which the concentration of greenhouse gases is allowed to increase through the year 2100. A significant increase in tropical SSTs is found in this experiment, accompanied by a similar rise in AAM. The implied increase in the length of the day during the 21st century is, again, about 0.5 ms. This possibility of human intervention with Earth s rotation, via the atmosphere s response to an accumulation of greenhouse gases, is noteworthy.

Atmospheric Composition, Past

James C G Walker
The University of Michigan, Ann Arbor, MI, USA

In recent decades, scientists have been able to demonstrate that the composition of Earth's atmosphere has changed from the natural composition prevailing over the previous 10 millennia. The records and analyses indicate that the atmosphere is an ephemeral reservoir, easily altered by the exchange of material with the much more massive ocean and solid Earth. Ice core records deciphered during recent decades have also demonstrated that the composition of Earth's atmosphere can change quickly and has changed signi cantly over the entire course of the Earth's history. Change results from both biological and geological processes, which continually convert atmospheric constituents into solid and liquid compounds or restoring them to gaseous form. At the same time, changes in atmospheric composition have affected the metabolic capabilities of living creatures as well as the climate. Through these connections, it is clear that the various components of the Earth System are closely linked and evolve together. Human beings are part of the Earth System, able to affect its evolution, but not able to escape its constraints.

Given the evidence of both natural and human-induced change, it now seems dif cult to understand how scientists could, at one time, have taken for granted an assumption of an unchanging atmosphere under which Earth and life evolved. Perhaps scientists, like many other people, were more comfortable in a world without change; perhaps an unchanging atmosphere seemed most consistent with the in uential doctrine of uniformity or perhaps an assumption of no change was the most reasonable one in the absence of unambiguous evidence concerning past composition.

*Early interest in atmospheric composition was stimulated largely by environmental issues. The scienti c study of air pollution in Southern California in the 1960s called attention to the chemical reactivity of many atmospheric constituents. Research on the depletion of stratospheric ozone in the 1970s and 1980s made it clear that seemingly small, local additions of gas to the atmosphere could have global consequences. There was also an unresolved theoretical question dating from the end of the 19th century about the fate of the carbon dioxide (CO_2) released to the atmosphere as a result of the burning of fossil fuels. This question was resolved, in part, by the work of C. D. Keeling, who in 1960 reported unambiguous measurements of an increasing concentration of CO_2 in the atmosphere (*see *Keeling, Charles David, Volume 1).*

RESERVOIRS, FLUXES, AND RESIDENCE TIMES

Stimulated by issues ranging from air quality to climate change, atmospheric scientists have learned to think about atmospheric composition in terms of the processes that add gases to or remove gases from the atmosphere and the rates of addition or removal compared with the amounts in the atmosphere. The atmosphere is thought of as a reservoir that contains trace amounts of a particular chemical compound, carbon dioxide (CO_2), for example. Various processes, called *sources*, add that compound to the atmospheric reservoir at rates specified as amount added over a given time. Other processes, called *sinks*, remove the compound from the atmospheric reservoir at rates specified as amount removed over a given time. The sources and sinks together are called fluxes, as they represent flows of matter into or out of the atmospheric reservoir. If the sum of all the sources of a particular compound is equal to the sum of all the sinks, the amount of that compound in the atmosphere is not changing with time. But if the sources exceed the sinks, the compound must be accumulating in the atmosphere; that is the amount of that compound in the atmosphere, its concentration, must be increasing.

Scientists get a sense of how rapidly the concentration of a particular compound can change by dividing the amount of the compound in the atmosphere by the flux in or out, the sources or the sinks. The ratio is called the residence time (*see* Residence Time (of an Atom, Molecule or Particle), Volume 1) of that compound in the atmosphere. The concentration of a given compound in the atmosphere would rise from zero to its actual value in one residence time if the sources were constant and there were no sinks. Alternatively, the atmospheric reservoir would empty in one residence time if the sinks were constant and there were no sources.

Careful evaluation of the sources and sinks and reservoir sizes of the various gases in the atmosphere has revealed that the concentration of all of the gases could have varied during the course of Earth history (*see* Earth System History, Volume 1). The most abundant gases, oxygen and nitrogen, could have varied only over periods of tens to hundreds of millions of years because their residence times are this long. The less abundant and chemically more reactive gases, like hydrogen and methane (CH_4), have residence times of years to decades and so can vary significantly over the course of a human generation if sources and sinks are not equal.

Thousands of Years

The first assessments of past atmospheric composition were theoretical attempts to deduce the properties of the atmosphere when the fluxes of particular gases were very different. Oxygen attracted the most interest. The oxygen in

the modern atmosphere is almost entirely a product of photosynthesis by plants and algae. So was there any oxygen in the atmosphere before photosynthesis originated, and if so, how much? This topic is still of great interest. Oxygen affects many of the chemical processes in the atmosphere and oceans, and it obviously affects life. But photosynthesis appears to have originated more than a billion years ago. This article deals first with the more recent past.

Remarkable data on past atmospheric composition have been derived from measurements of bubbles of air (sometimes called antique-air) trapped in polar ice. Snow accumulates each year on the ice caps of Greenland and Antarctica. This snow is gradually compacted to ice by the weight of subsequent snowfalls. In the process, air, more or less from the time of accumulation, is trapped in the ice. The age of the ice and of its entrapped air increases with depth. Annual accumulations are apparent in ice cores and can be counted. So the ice preserves samples of air of known age.

The analysis has now been carried back about 420 000 years, which is probably close to the limit of what is possible. Old ice flows gradually away from the interior of the ice cap toward lower elevations. Annual layers therefore become thinner and more distorted as the age and depth increase. There may be older ice at the bottom of the ice caps in Greenland and Antarctica, but its age is hard to determine.

For the last two million years, Earth has endured a recurrent sequence of ice ages separated by warm interglacial periods. We are currently enjoying an interglacial that began with a sudden warming and ice melting about 10 000 years ago. The previous interglacial (*see* Eemian, Volume 1) began about 140 000 years ago. The intervening ice age took the form of a gradual decrease in the average surface temperature of the globe, accompanied by a gradual advance of ice sheets over Europe and North America. Earlier ice ages followed the same pattern of gradual cooling followed by sudden warming repeated at approximately equal intervals of time. These periodic fluctuations in Earth s climate are caused by regular changes in Earth s orbit about the Sun that result from gravitational interactions between the Sun, Earth, and the other planets, but it is not clear just how the orbital changes cause major changes in climate. Nor is there agreement among scientists about why the ice ages began just two million years ago.

The ice core data on atmospheric composition reveal a clear record of change closely correlated with the waxing and waning of the last four ice ages. Although other atmospheric constituents, including dust, are preserved, of most interest are the measurements of CO_2 and CH_4. Both of these greenhouse gases increased suddenly in concentration during the sudden onset of an interglacial period and decreased gradually during the subsequent gradual cooling of the globe. The range of variation is between 200 and 280 parts per million by volume (ppmv) for CO_2 and between 0.35 and 0.65 ppmv for CH_4. Both gases contribute to the warming of Earth s surface by absorbing outgoing infrared radiation and returning heat energy to the ground, but their contributions to the greenhouse effect are not large enough to account for ice age changes in Earth s average temperature.

Much of the background CH_4 concentration in the atmosphere is a result of the decay of vegetation in poorly aerated swamps. It seems that swamps were more widespread during interglacial periods when there was more rain in the tropics. Glacial periods were characterized by dry conditions at low latitudes. CH_4 is destroyed in decades by chemical reactions in the atmosphere, so the concentration in the atmosphere also changes whenever the source strength changes. A change in global climate results in a significant change in atmospheric composition.

Explanations of the changing concentration of CO_2 remain controversial. The gas is exchanged between the atmosphere and other large reservoirs, the carbon dissolved in the ocean, and the carbon stored in living matter and decaying vegetation. It may be that ocean chemistry or circulation changes in such a way as to absorb more atmospheric CO_2 during ice ages and releases more during interglacial periods. Alternatively, the mass of carbon stored in forests, swamps, and soil may increase during ice ages and decrease during interglacial periods. It is quite likely that both processes contribute to the observed changes.

Millions of Years

As far as we know, there are no preserved samples of ancient air older than a few hundred thousand years. Inferences concerning atmospheric composition earlier in Earth s history depend on theoretical arguments and indirect indicators (*see* Carbon Dioxide Concentration and Climate Over Geological Times, Volume 1).

The theoretical method begins with an analysis of the processes controlling the present composition of the atmosphere. If we understand these processes well enough, we can imagine how they may have changed in the past and can estimate how the atmosphere would have responded to the changes we imagine. Among the changes that need to be considered are the evolution of life and the metabolic processes that consume and release atmospheric constituents. The production of oxygen and consumption of CO_2 by photosynthesis is a prime example, but organisms release a multitude of other gases to the atmosphere, including CH_4, hydrogen, and nitrous oxide. Climate change affects temperatures and rainfall, and thus the abundance of living creatures and the rates of chemical reactions between atmospheric gases and between gases and rocks or gases and seawater. Climate also controls the circulation of the ocean, and thus the exchange of gas between ocean and atmosphere.

A third potential cause of change in atmospheric composition is geological activity, including the release of gas by volcanoes, the lifting up and eroding away of mountains, and the drifting of continents across the surface of the globe. Chemical interactions between atmospheric gases and the rocks and minerals of the solid Earth are slow, but the Earth contains so much more material than the atmosphere that these interactions determine atmospheric properties over geological times lasting hundreds of millions of years. Mountain building and continental drift affect the atmosphere indirectly through their influence on global climate and ocean circulation and directly through their influence on the composition of the rocks exposed to air and the rates at which these rocks react with atmospheric constituents.

Theoretical analysis can provide an indication of past atmospheric composition, but observational confirmation is certainly needed. The fossil record of life is one important source of information. As long as there have been animals on Earth that breathe oxygen, there must have been enough oxygen in the air, or dissolved in water, to sustain them. On these grounds, we can be confident that the atmosphere has contained more than a few percent of oxygen for the last billion years or more. This is not a trivial observation. Earth, like the solar system and the universe, is reducing in overall composition – it contains more than enough iron and other elements that react with oxygen to consume all of the oxygen in the atmosphere. Reactions between air and rocks are fast enough to deplete atmospheric oxygen in less than 10 million years in the absence of a source. That oxygen has never been depleted in more than a billion years implies that there must be a steady, reliable source of oxygen. The fossil record tells us the source is green plants, which release oxygen during photosynthesis. They have caused the atmosphere to become rich in oxygen and they have maintained enough oxygen to sustain animal life.

On the other hand, plants require CO_2. Carbon dioxide dissolves in rainwater and seawater, where it reacts with the products of rock weathering to precipitate as solid carbonate minerals. These processes are fast enough to remove all of the CO_2 from the atmosphere in less than a million years, in the absence of a source. Yet for billions of years there has been enough CO_2 in the atmosphere to sustain plant life. The sustaining source is Earth s hot interior. The high temperatures there drive CO_2 out of its solid compounds and release it as a gas from volcanoes and hot springs. Over periods of millions to billions of years, the amount of CO_2 in the atmosphere is set by a balance between this volcanic source and the consumption of CO_2 in reactions with cold rocks at the surface of the Earth. On the shorter time scales of hundreds to thousands of years, atmospheric CO_2 concentrations depend on exchange with the large oceanic and terrestrial living reservoirs of carbon.

Some idea of the past CO_2 concentration can be gained from paleoclimate studies because CO_2 is a greenhouse gas, warming Earth s surface. It appears that Earth has been cooling for the last 60 million years, a cooling that culminated in the onset of the ice ages two million years ago. This cooling is attributed, in part, to a decreasing concentration of CO_2 in the atmosphere, caused by some combination of reduced volcanic activity and an increased consumption of CO_2 in weathering reactions with rocks. The rate of weathering may have been increased by mountain building, which exposes fresh reactive rock at the surface, or by the activities of life, which may have evolved more aggressive ways to attack and dissolve rocks to obtain essential mineral nutrients.

Additional support for the notion that CO_2 has decreased comes from the fossil plant record and from measurements of carbon isotopes. Plants have recently, in geological terms, developed a photosynthetic pathway that is adapted to low concentrations of CO_2. This development may have been a response to the decreasing CO_2 concentration. Furthermore, photosynthesis favors the abundant, light isotope of carbon, tending to leave the rare, heavy isotope in atmospheric CO_2 while producing organic matter enriched in the abundant, light isotope. This fractionation of the carbon isotopes is strongest when CO_2 is abundant. Careful measurements of the isotopic composition of ancient organic matter in sediments compared with carbonate minerals of the same age reveal larger fractionation in the past, indicative of higher concentrations of CO_2.

No single argument is persuasive. The reconstruction of past atmospheric composition calls for a careful reconciliation of suggestive observations and incomplete theoretical understanding. At present, it seems reasonable that the concentration of CO_2 60 million years ago may have been as much as several times its pre-industrial level. This is an active area of research.

Billions of Years

Uncertainties are even larger further back in time. The state of the Earth in those days is hard to imagine and to analyze theoretically, and the early rock record is sparse because most old rocks have been destroyed by more recent geological activity. Research on atmospheric composition in the first few billion years of Earth s history has focused mainly on CO_2 and on oxygen.

The CO_2 discussion centers again on its climatic effects. The problem is straightforward. The Sun is getting brighter as it ages and gradually consumes its nuclear fuel. The young Earth, warmed by the faint, young Sun, would have been completely frozen without a greenhouse effect very much larger than that of the present day. Ancient sedimentary rocks make it clear that liquid water was abundant at Earth s surface as long ago as 3.8 billion years. Various greenhouse gases have been evaluated as potential solutions to the cool sun problem. None is as plausible as CO_2, possibly augmented by haze.

This analysis suggests an atmosphere four billion years ago consisting largely of CO_2 with a surface pressure of only a few bars.

Perhaps this suggestion should not surprise us. The atmospheres of Mars and Venus consist largely of CO_2, and the surface pressure on Venus is 100 bars. The volcanic sources of CO_2 would have been large when the Earth was young with a hot interior. The consumption of CO_2 in reactions with rocks may have been slow when there was little land exposed to the atmosphere and no terrestrial life to promote weathering. It is believed that the CO_2 concentration decreased through time as landmasses increased in area, the interior of the Earth cooled, and the Sun grew brighter, warming Earth s surface. Weathering reactions are faster at higher temperatures.

Deductions concerning oxygen are also based on a combination of theory and observation. The oxygen-rich atmosphere we now enjoy, which is unique among known planets, is sustained by the photosynthetic activities of green plants. There can have been little oxygen in the atmosphere before green plants evolved. Sedimentary rocks provide the best evidence concerning the rise of atmospheric oxygen. The preponderance of this evidence indicates an oxygen-free environment for the weathering and deposition of sedimentary rocks before about 2.3 billion years ago. Oxygen accumulated in the atmosphere at this time, but the deep ocean remained anaerobic for hundreds of millions of years. During this period, sediments continued to form, containing abundant iron, which must have been dissolved in seawater free of oxygen. The difference between atmosphere and deep ocean arose because the exchange of material between these reservoirs is slow, the deep ocean receives reduced compounds from Earth s interior, and the oxygen source, which requires sunlight, is located at the surface. By about 1.5 billion years ago, it seems that the photosynthetic oxygen source was large enough to overwhelm the source of reduced compounds in most parts of the deep sea. There have been speculative discussions about subsequent changes in atmospheric oxygen, but the evidence is not convincing.

ORIGIN OF THE ATMOSPHERE

Earth s atmosphere consists of gases that react with the materials of the Earth to form solid compounds. It is deficient, relative to the Sun, in the inert gases that do not react. This observation has been understood for nearly half a century to imply that Earth s materials accreted originally as solid compounds, not as gases, and that high temperatures inside the Earth drove the gases of the atmosphere, along with ocean water, out of these compounds. It was, at one time, thought that Earth was initially cold, and that atmosphere and oceans accumulated gradually as the interior of the planet heated up. It now seems more likely that Earth had a hot origin followed by gradual cooling. This view implies that most of Earth s volatile constituents were driven out of the interior to form a dense original atmosphere while the planet was accreting. This atmosphere was probably composed mainly of steam. When the planet stopped releasing gravitational heat, the steam condensed to form oceans, and the remaining gases, mainly CO_2, began to react chemically with water and with rock to form dissolved and solid compounds. The components of Earth s atmosphere and ocean are gradually returning to the interior of a cooling planet.

Atmospheric Composition, Present

Peter Brimblecombe
University of East Anglia, Norwich, UK

Although the atmosphere can be seen as an inert matrix of nitrogen and oxygen, many of the gases found at lower concentration are highly reactive, with only short lifetimes, such that their concentrations are maintained through a balance between sources and removal processes. Sources may be geochemical activities that lead to volcanic emissions or wind-blown dust and sea-spray. Biological releases, particularly those from microorganisms, are important in producing a wide range of organic trace gases and human activities can now affect atmospheric composition on a global scale, re ected most importantly in the carbon dioxide driven greenhouse effect.

The composition of the atmosphere was of interest to scientists from the earliest times. The ancient Greeks regarded the air as an element, although educated farmers were already aware that it carried other substances that could damage or benefit crops. With the growth of modern science in the 17th century, there was further interest in the atmosphere. Robert Boyle, remembered for Boyle s Law, studied the composition of the air and was aware that there were minute trace components that contributed to its corrosiveness.

In the 18th century the Phlogiston Theory was developed to explain the properties of air, but the discovery of oxygen

by Scheele and Priestley overthrew this theory. Dalton s atomic theory gave a better understanding of air that was proving to be a mixture, not a compound, but a formula such as $N_{15}O_4$ seemed unlikely. Evidence against air being a compound became so strong that the notion had to be discarded.

We now know air to be composed of nitrogen and oxygen, which occupy almost constant proportions throughout the atmosphere and make up almost 99% of its dry volume (Table 1). Oddly enough, carbon dioxide, a much lesser component, was discovered much earlier than either oxygen or nitrogen, when the Scottish chemist Joseph Black investigated the properties of carbonate minerals in the 1750s.

Throughout the 19th century scientists became aware of many trace components in air: ozone, ammonia, hydrogen sulfide, sulfur dioxide, etc. However, the most surprising discovery came at the end of the century when Ramsay discovered argon in the atmosphere, which made it the third most abundant compound in dry air. Argon is formed from the radioactive decay of potassium-40 over very long time periods. This revelation was gradually followed by the discovery of a number of other inert gases.

So far, we have stressed that the air is dry. This is not true, because air also contains water vapor, but at highly variable concentrations. The amount of water is dependent on temperature and relative humidity. At 20 °C and 100% relative humidity, air is about 2.3% water vapor.

In recent decades, scientists have come to realize that the atmospheric composition has a more dynamic nature, with none of the constancy assumed when looking at the major gases, such as nitrogen, oxygen and argon. It is often convenient to think of the gases in the atmosphere as falling between two extreme types, stable and highly reactive gases.

Long-lived gases are at a relatively constant concentration throughout the atmosphere. Generally these are the gases that are unreactive – nitrogen, oxygen and the noble gases (helium, neon, argon, krypton, xenon).

Table 1 The concentration of some components of dry tropospheric air

	ppm
Nitrogen	781 000
Oxygen	209 000
Argon	9340
Carbon dioxide	360[a]
Neon	18
Helium	5.24
Methane	1.75[a]
Krypton	1.14
Hydrogen	0.5
Nitrous oxide	0.3[a]
CFC-11	0.0003[a]

[a] Changing due to human activities.

Many other gases are not so stable, but still long-lived enough to be well mixed in the atmosphere.

These include carbonyl sulfide, nitrous oxide, methane, and carbon monoxide. Although these gases have lifetimes in the order of 1 year, they are maintained at steady state concentrations by production at the Earth s surface. The sources are often geochemical or biological. Their long lifetimes mean that they may not necessarily degrade in the lower atmosphere, but cross the tropopause into the stratosphere, where they make contributions to stratospheric chemistry. Methane contributes to water vapor in the upper atmosphere, carbonyl sulfide to the sulfate aerosol layer and nitrous oxide is involved in stratospheric ozone depletion.

Gases that have lifetimes of just a few days tend to be present at highly variable concentrations in the atmosphere. We can understand this in terms of radon-222. This is a radioactive gas that emanates from land. It decays with a half-life of 3.8 days, so it is easy to imagine that its concentrations far out over the ocean will be low.

The oceans cover 70% of the Earth s surface and represent an enormous source of trace gases for the atmosphere. Seawater has high concentrations of chloride and sulfate, so it is hardly surprising to find that the oceans are large sources of sulfur and chlorine-containing trace gases. In particular we find hydrochloric acid, derived from sea salt above the oceans, and alkyl chlorides important. The long-lived carbonyl sulfide also comes from the ocean.

The oceans are far less rich in nitrogen, so we often look to the land as a predominant source of nitrogen compounds. Nitrogen oxides arise from soil respiration. Ammonia comes from the degradation of proteinaceous material or urea. Wetlands also prove an important source of methane. They are also sources of other trace gases that seem especially unusual: dimethyl selenides or diphosphane. This latter gas may ignite the methane from marshes and be responsible for will-o-the-wisps.

Human inputs also change the composition of the atmosphere. The combustion of fossil fuels has caused the concentration of carbon dioxide to rise by 70 ppm in the last century (*see* Carbon Dioxide, Recent Atmospheric Trends, Volume 1). This change in concentration is recognized as enhancing the greenhouse effect (*see* Greenhouse Effect, Volume 1). The concentrations of other greenhouse gases are also on the increase. Methane has increased substantially over the last few centuries, driven by increased agriculture: cattle and paddy fields are important sources, but mining is also significant (*see* Methane, Volume 1). Carbon monoxide has natural sources, but human activities have probably been responsible for the increase to a peak in the early 1990s, but levels have declined since then.

Nitrous oxide has also been on the increase (*see* Nitrous Oxide, Volume 1).

Anthropogenic gases, such as the chlorofluorocarbons (*see* Chloro uorocarbons (CFCs), Volume 1), cause so much concern because, although unreactive in the lower atmosphere, they degrade the ozone layer (*see* Stratosphere, Ozone Trends, Volume 1). These gases have shown sharp changes in concentration. First they rose, as their use increased, and subsequently declined as production was curtailed in response to various international protocols. They have often been replaced by hydrofluorocarbons and hydrochlorofluorocarbons that are now released in substantial amounts, but have smaller long-term impacts on global atmospheric chemistry.

Atmospheric Electricity

R Giles Harrison and Karen L Aplin
University of Reading, Berkshire, UK

By atmospheric electricity, we usually mean the composite effect of all electrically charged atmospheric matter, which includes molecular ions and charged aerosol particles, as well as the charge exchanged between the ice, liquid and vapor phases of water. Global climate change may increase planetary thunderstorm activity. Associated with this could be a change in lightning distribution that would affect, in turn, the xation of atmospheric nitrogen, carbon dioxide concentrations from lightning-initiated forest res and atmospheric ozone concentrations. Ions owing in the atmospheric electrical circuit may be implicated in condensation nucleus formation; thus the atmospheric electrical system may also have an indirect effect on cloud formation.

PLANETARY ELECTRIFICATION

Earth is not alone in having an electrified atmosphere. If we regard lightning as a key signature of atmospheric electrification, then at least Jupiter, and Saturn s largest moon – Titan – probably qualify. In order for a planet s atmosphere to become electrified, it seems it must contain polar molecules (such as ammonia or water) present in different phases, and strong convection must be taking place, usually driven by powerful differential heating. Lightning is not a recent phenomenon on Earth. When lightning strikes sand it fuses it into a glassy column, which, if preserved, becomes a fossil. Such fossilized lightning strikes, or *fulgurites*, have been found in sediments dated to be at least 250 million years old.

Two pioneering 18th century scientists are particularly associated with early work on atmospheric electricity and lightning. Benjamin Franklin (*see* Franklin, Benjamin, Volume 1) is well known for his kite-flying experiments in which he discovered the similarity between atmospheric charge and that produced in laboratories artificially, but John Canton was performing much more sensitive experiments in England at a similar time. In 1754, Canton observed that clouds that didn t produce lightning could also be electrified, and could carry positive or negative charge. He also identified hail as being important in the electrification of thunderclouds.

THE ATMOSPHERIC ELECTRICAL SYSTEM

The atmospheric electrical system arises because of the vast differences in scale between the different forms of charge-exchange occurring on the planet: charge is principally generated in vigorous thunderstorms, and dissipated elsewhere in regions where the weather is less disturbed. If we regard the thunderstorms, mostly occurring in the tropics, as the source of charge, rather like a battery, and the currents flowing in the undisturbed regions as the sink of the electrical energy, then it is possible to construct a simple electrical circuit (Figure 1). Although simplistic, this model is a useful description of the system. The current flowing in the circuit is not constant, although typically about 2000 Amperes, as it depends on the global activity of thunderstorms, which varies as a result of surface heating. An ampere (often abbreviated to amps or A) is the unit of electric current, which is the rate at which electric charge is passed in a circuit. Common domestic electrical currents vary from a few thousandths of an amp to operate a digital clock, to tens of amps to operate an electric cooker. Monitoring the total current flowing by measuring the voltage of the upper atmosphere, using balloon-carried probes and sounding rockets, shows that there is a daily cycle in the voltage associated with a similar cycle in global thunderstorms as the planet rotates.

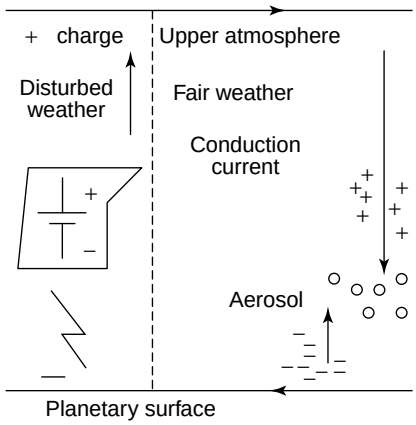

Figure 1 Simplified schematic description of the atmospheric electrical circuit. Charge separation in thunderstorms causes a current of about 2000 A to flow between conducting regions in the upper atmosphere and the surface, causing the upper atmosphere to charge positively to about 300 kV. The majority of the 2000 A current arises from charge exchange in lightning flashes: a smaller fraction occurs from non-lightning point discharges beneath clouds. It is not yet known how above-cloud discharges (e.g., sprites) contribute to the global circuit. In fair weather regions (which cover a much greater area of the planetary surface than thunderstorms), a compensating conduction current flows, consisting of ions formed in the atmosphere by cosmic ray-induced ionization. Aerosol in the lower atmosphere removes some of the ions and reduces the local electrical conductivity

This cycle was first identified from the research voyages of the vessel Carnegie in the 1920s. The Carnegie was a research ship entirely constructed of wood so that it could be used for geophysical (including terrestrial magnetic and electrical) studies. No metal was permitted on board. It was ultimately destroyed by fire. This voltage variation has since been shown to follow the variations in thunderstorms caused by the sequential heating of continental landmasses as the planet rotates. Thunderstorms generated on the African landmass dominate the global electrification in the late afternoon and early evening, Greenwich time.

The ionosphere and the Earth s surface also form a cavity within which radio waves can propagate, although the radio properties of the ionosphere vary with the time of day and the solar cycle. Lightning discharges generate radio waves at a variety of frequencies, some of which can be detected at great distances from the lightning discharge and can therefore be used in lightning location systems. Of particular interest is the *Schumann resonance*: this is an extra low-frequency (8 Hz) radio wave, which has a wavelength equal to the equatorial circumference. The amplitude of this radio signal can be used to monitor the amount of global lightning.

THUNDERSTORMS

Thunderstorms occur when large cumulonimbus clouds become electrically charged. The exact mechanism for this charging has been disputed for many years, but it is increasingly accepted that it is due to electrical interactions in the collisions between soft hail (known as *graupel*) and ice. The falling graupel carries negative charge downwards, and ice crystals rise in vigorous central updrafts to the upper parts of the cloud, where they form the characteristic anvil-shaped tops associated with such clouds. The base of the cloud often contains some positive charge (Figure 2). Charging continues for the life of the thundercloud, which is about an hour, and lightning flashes within and from the cloud result.

LIGHTNING

Lightning occurs when the electric fields generated by the cloud are so intense that air ceases to be an insulator (*see* Lightning, Volume 1; Lightning and Atmospheric Electricity, Volume 1). Breakdown of air occurs and a transient electrical discharge – lightning – results. A typical lightning strike may be several kilometers in length. Lightning exists in many forms. If it occurs within clouds it is known as *intracloud*, between clouds *intercloud*, below clouds *cloud to ground* (CG) and above clouds variously as *red sprites* or *blue jets*. Sprites and jets have only been studied in the last few years when satellite and space shuttle observations became available. Sprites are particularly intriguing forms of lightning because they occur on such massive scales – they are 5–30 km wide, and about 50 km high. Although not well understood, they are thought to be associated with positive lightning strokes to ground. Intracloud discharges are most common, but the greatest visual spectacle is CG, often seen as forked lightning, which accounts for about 20% of discharges. A CG strike leads to tens of Coulombs of charge, most commonly negative, flowing from the cloud. (The Coulomb is the unit of electric charge. One ampere is the current flowing when one coulomb passes each second.)

CG lightning begins as a weak initial discharge (the stepped leader), which, after reaching the surface, is followed by the luminous return stroke. A stepped leader propagates at about $100\,\mathrm{km\,s^{-1}}$, and within a narrow channel of about 5 m. When the stepped leader is near the surface, intense local electric fields are generated, and charges (streamers) begin moving upwards to the leader. If the upward streamer charge contacts the leader, the vigorous return stroke results, and currents of tens of thousands of amps flow within tens of microseconds. During the remainder of the discharge, the current falls to hundreds of amps for a longer period of several milliseconds. If there is no more charge in the cloud, the lightning discharge will then

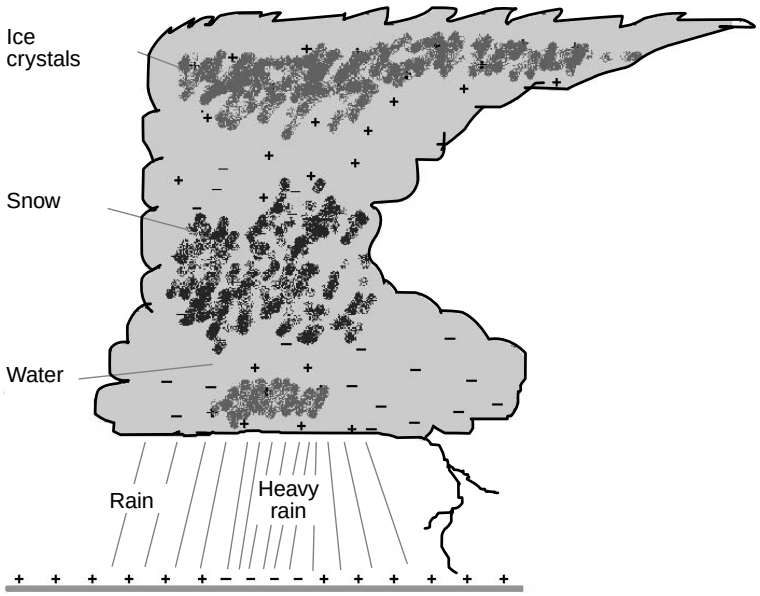

Figure 2 Thunderstorms are the most spectacular demonstration of the interactions between meteorology and electricity. Charging occurs because of collisions between ice crystals and soft hail (graupel) in the intense vertical updrafts within a deep convective cloud. The upper anvil of a thundercloud contains positively charged ice crystals, and the middle part of the cloud negative charge. There is a small positive charge in the base of the cloud, the temperature of which is usually above the freezing threshold

end, but it is possible for several strokes to flow along the same ionised channel. Crackles due to the electrical energy from thunderstorms, with fundamental frequencies of about 10 kHz, can be picked up by radio receivers and are known as *sferics*. Radio location of thunderstorms is used to assist forecasts of disturbed weather.

Associated with the return stroke channel are temperatures and pressures much higher than those of the surrounding air, and the channel expands, generating an acoustic shock wave. This shock is heard as thunder, some time after the lightning is seen because the speed of sound in air is less ($\approx 300\,\mathrm{m\,s^{-1}}$) than the speed of light. At significant distances from the storm, the sound is more reminiscent of a rumble rather than a bang, because of acoustic refraction along the sound path. Thunder lasts from about one-tenth to $1-2$ s.

Until recently, it was not possible to monitor lightning occurrences globally, but a new National Aeronautics and Space Administration (NASA) satellite instrument, the optical transient detector, can record lightning from space in daylight. These new observations have led to data such as the annual total of detected lightning flashes across the world, as shown in Figure 3. Because the satellite orbits the Earth frequently, daily variations in thunderstorm activity can also be extracted from its observations. This system has detected electrical activity patterns very similar to the ones observed during the Carnegie voyages. Global flash rates are now thought to be about 50 flashes $\mathrm{s^{-1}}$, although the precise figure currently remains uncertain. It is considered important to quantify this more thoroughly in the context of global change, because the flash rates may vary with local surface temperature, and therefore perturb the nitrogen cycle and ozone production.

FAIR WEATHER ELECTRIFICATION

Although thunderstorms are the most dramatic and apparent manifestation of atmospheric electricity, undisturbed (or fair weather) electrical regions cover most of the planet for most of the time. Figure 1 illustrates the atmospheric electrical system, in which the fair weather component was seen essentially to provide the conduction current. The conduction currents can only flow because there are charged particles (small ions) present that are sufficiently mobile to be accelerated by the small electric fields present in the atmosphere. Small ions are formed by bombardment of air molecules by natural radioactivity and cosmic rays, making the air slightly electrically conductive. The air also contains a myriad of small particles with a spectrum of sizes, from cloud droplets down to molecular clusters, known as aerosol. Small ions can become attached to aerosol particles, causing them to become electrically charged. Some aerosol particles can act as nuclei for cloud formation, and it is also apparent that clusters of small ions can facilitate the production of ultrafine aerosol particles. Fair weather electricity is, therefore, also increasingly becoming identified as relevant to the climate system.

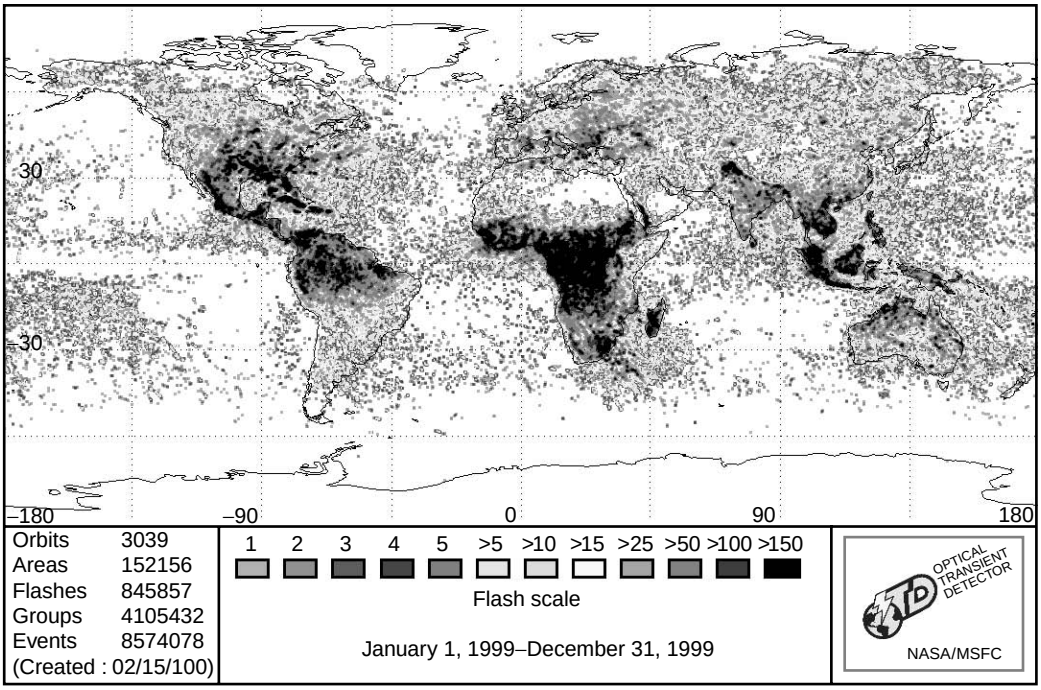

Figure 3 Annual global lightning flashes for 1999, as determined by the NASA satellite-borne optical transient detector. The lightning flash scale indicates the number of flashes per square kilometer per year. Darker regions indicate a greater number of flashes. (Data provided by the Global Hydrology Resource Center at the Global Hydrology and Climate Center, Huntsville, AL (see http://thunder.msfc.nasa.gov/data))

EFFECTS OF GLOBAL CLIMATE CHANGE

The effects of global climate change are uncertain, but one possible implication is a change in the planetary thunderstorm activity. This could lead to a modified lightning distribution, which may have significant feedbacks, because lightning affects the fixation of atmospheric nitrogen, forest fire initiation and ozone concentrations. If climate change does affect lightning, this may indirectly affect the other components of the global atmospheric electrical circuit, although the magnitude and sign of the effect are difficult to determine. For example, the ions comprising the fair weather current flow in the circuit may be relevant in condensation nuclei formation, which may influence cloud formation and properties. The effects of global climate change on such complex and sensitive processes are not yet known.

Atmospheric Motions

Anders Persson

European Centre for Medium Range Weather Forecasts (ECMWF), Reading, UK

With the first pictures looking down on the Earth from a space platform in the 1960s, the beauty and complexity of

the atmospheric motions were immediately evident: the long streaks of jet stream clouds, the large spirals of developing mid-latitude storms, and the strings of pearls of towering thunderstorm clouds in the equatorial regions.

It was a beautiful view, but it was not entirely unexpected. By the end of the 19th century meteorologists had managed to deduce the essential parts of the global circulation, from soundings by balloons and cloud drift observations at higher levels. Steady improvements of observational technology, radar, remote sensing and, above all satellite observations have provided an ever-increasing amount of data on the state and motion of the atmosphere, not only in the lowest 10- 15 km (the troposphere), but also at higher levels (the stratosphere, mesosphere and ionosphere).

There were surprises to come. In the 1890s, when balloon soundings started to reach above 10 km, they recorded that the temperature, from having rapidly decreased, suddenly at some height became more or less constant. This marked the discovery of the tropopause, the cold dividing boundary between the troposphere and the stratosphere. During the First World War, when the thunder on the western front could be heard in London, meteorologists began to speculate that the only explanation must be a warm layer at a height of about 50 km; the existence of the stratopause, the warm boundary between the stratosphere and the mesosphere was later con rmed by more advanced measurements. The third great surprise was of course the jet streams: long, narrow bands of very strong winds of 30 m s^{-1} or more at high altitudes. In the 1960s observations from 30- 50 km height in the equatorial region revealed that the winds turned from westerly 20 m s^{-1} to easterly 50 m s^{-1} over a period of, oddly, 13 months. In recent decades the interactions between the oceans and the atmosphere, most notably the El Niño, have added to our understanding of the complexities of the atmosphere.

The main task for meteorology is to explain, or at least describe, the general circulation of the atmosphere and its variations in accordance with the basic principles of uid dynamics, radiation and thermodynamics. To what extent are the processes that give rise to these complicated circulation systems really understood? The answer depends to a great extent on what is meant by an explanation.

INTRODUCTION

Computer Models

In 1956, Norman A Phillips, an American meteorologist, achieved something remarkable: he fed a computer with the basic facts about the size of the Earth, its gravitational pull, its rotational velocity and the chemical composition of the gases that constitute its atmosphere. Programmed with simplified versions of the mathematical equations that describe the atmosphere s motions and physical processes, the computer was able to generate the observed three-dimensional general circulation of the Earth s atmosphere, including jet streams, travelling cyclones, fronts and high-pressure areas.

Doubling of computer power every one and a half years has since then provided an ever increasing ability to simulate and forecast most atmospheric features. Numerical simulations of the general circulation using supercomputers serve as an atmospheric laboratory, in which we can perform experiments, observe the effects and hopefully predict its future state. However, many meteorologists are not satisfied and think that it is not enough that the computers seem to understand. We want to know, for example, why the westerly winds so dominate the mid-latitudes, why the Sun s radiation reaches the Earth s surface without being hindered by clouds in the subtropical areas, why northwestern Europe s winters are so mild compared to those at the same latitude in northeastern North America and why the storms in the tropics are so different from the storms that rage over the Atlantic or the Pacific.

Watching Atmospheric Motion

Our understanding of the atmosphere is like that of the spectator at a football match. Without any insight into the rules of the game, it will only appear to be a lot of people randomly running around chasing a ball. Those who know the rules and the logic of the game might not be able to make predictions of what will happen in the next minute, but can make sense of what is unfolding in front of their eyes.

Our knowledge of the atmosphere is often summarized in a statistical way. But using statistics brings advantages and disadvantages. We gain in simplicity, but also lose because we have thrown something away. Whenever there are averages, there are fluctuations or deviations from these averages. In addition, a mean picture does not necessarily represent a typical picture. In environmental studies, we are for example interested to know the evolution and trajectory of individual air parcels: Where does the moist air go? From where comes the polluted water? What makes the air lose its ozone? One good illustration of how knowledge can enhance understanding is the movement of a water droplet in a simple water wave.

Two Ways to Look at Motion

Consider a train of waves on a water surface moving from left to right, as depicted in Figure 1(a). The fluid is rising as the ridge of the wave approaches and falling after it passes. The mean motion, as inferred by averaging

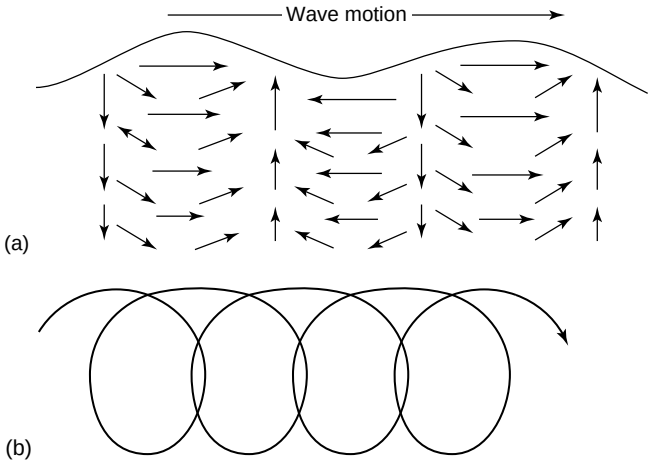

Figure 1 (a) A train of waves moving from left to right. For further discussion, see text. (b) The individual particles in the water are subjected to a net displacement to the right

the motions at individual points in space over a large number of waves, will everywhere be zero because all motions, vertical and horizontal in the long run cancel out (sometimes called *Eulerian averaging*). However, if we concentrate on individual parcels, we can see that they move in clockwise circuits. If we look carefully, we see that the extent of the motion decreases with depth, so we may realize that parcels move a little farther towards the right at the top of their path, than they move toward the left farther down. Hence, there is a net rectifying displacement toward the right, as pictured in Figure 1(b). To understand the motions of the air we must therefore also make use of averages that are geared to the movement of individual air parcels (sometimes called *Lagrangian averaging*).

Motion without Fricton

The motions of the atmosphere show patterns, regularities and mutual relationships, which make sense if certain basic mechanisms are understood. Many of these patterns are easily accommodated with everyday experience: the bubbles in a pan of boiling water resemble the production of convective clouds; the downhill flow of water resembles the katabatic winds that flow down mountain slopes; etc. What is difficult is the seemingly simple. Many processes, particularly in the free atmosphere, occur under almost frictionless conditions. Pure inertia is actually a very difficult process to comprehend with our senses because our everyday life very much involves friction. The fact that the motion takes place on a rotating planet also has some counterintuitive consequences.

These energy conversions occur in the interplay between gravity, the effect of the Earth s rotation and friction.

THE DRIVING AND RETARDING FORCES

The Sun provides the energy that drives the atmospheric circulation, but this energy is not evenly distributed over the globe. While gravity acts to equalize these differences by setting the air in motion, friction seeks to bring all motion ultimately to rest.

The Incoming Radiation from the Sun

Understanding the atmosphere involves the unraveling of a lot of paradoxes. It is, for example, not primarily the Sun that warms the atmosphere, but the Earth. Or rather the Sun warms the air indirectly by first warming the surface of the Earth, which then warms the air. The radiation from the Sun is short wave (visible) and the cloud-free atmosphere allows much of it to pass through without much absorption. Of all the solar energy that initially enters the Earth s atmosphere, about half reaches the surface to warm the land masses and oceans. About 30% of incoming solar radiation is reflected back to space, mostly by clouds, snow and ice; and about 20% is absorbed in the atmosphere (*see* Energy Balance and Climate, Volume 1).

When the land and oceans heat up, they emit long-wave (infrared) radiation, to which the atmosphere is not very transparent. The atmospheric absorption of long-wave radiation is due to the presence of radiatively active gases, the most important of which is water vapor. Together with carbon dioxide, ozone and the other trace gases (methane, nitrous oxides, chlorofluorocarbons, etc.), these gases account for the normal greenhouse effect, without which most parts of the Earth would be uninhabitably cold because much more radiation would leave the atmosphere and much less downward long-wave radiation would warm the surface (*see* Infrared Radiation, Volume 1). Although there is a debate about the magnitude of the *enhanced* greenhouse effect caused by human emissions, there is no such debate about the greenhouse effect as such (*see* Greenhouse Effect, Volume 1). What further complicates this already complex balance of in- and out-going radiation is that it depends on latitude, the seasons and the distribution of land and sea.

The Uneven Heating and Cooling

The farther away from the tropics, the lower the Sun rises over the horizon. This means that the Earth s surface is not as efficiently heated in the higher latitude regions as in lower latitudes. The incoming solar radiation depends also on the orientation of the hemispheres relative to the Sun; thus it changes with the seasons. The summer hemisphere

receives more insolation than the winter hemisphere; during the summer the polar regions receive as much solar radiation per day as the tropics!

The outgoing radiation is, however, less dependent on latitude. Because land and sea have different physical properties, they react differently to the influx of solar radiation. Land has a comparatively small heat capacity and its immobility means that heat can only spread through conduction and diffusion. Land surfaces can therefore go through temperature changes on the order of several degrees within hours down to depths of several centimeters. Water bodies have a much greater heat capacity and a lower albedo (reflectivity) than land; water s mobility also enables an efficient transfer of heat vertically as well as horizontally. For these reasons, oceans absorb more solar radiation and to greater depth than land. The vertical mixing in the ocean spreads the heat deeper, so that the sea surface temperature changes little even on seasonal time-scales (*see* Sea Surface Temperature, Volume 1). In the latitude band up to 40° north and south the continents are on average warmer than the oceans; poleward of 40° the oceans are warmer. These differences in heating and cooling create differences in the density and the mass distribution of air. It is these contrasts that gravity tries to equalize.

Gravity – The Great Equalizer

If the ultimate source of energy is the Sun, the ultimate mover is the Earth s gravitational pull. Gravitation is always trying to turn everything into perfect spheres, including the Earth and its atmosphere. Due to the centrifugal effect of the Earth s rotation, its shape is a sort of oblate ellipsoid, bulging outwards at the equator (this shape is referred to as the *geoid*). Any material surface that does not follow such a geoid, but stands out against it is subject to a gravitational pull.

Pressure falls off more slowly with altitude in warm air than it does in cold air. Therefore, the same atmospheric pressure is found at higher elevations in the tropics than in the polar region. If the pressure at a certain level is not horizontally uniform, gravity accelerates the air from high to low pressure to equalize the pressure distribution. We talk about this acceleration as due to the *pressure gradient force* (PGF), which is not any new kind of force, just the name we have given to the effects of gravity in this context.

Gravity also generates vertical motions by making colder and heavier air sink and warmer and lighter air rise. Rising air experiences decreasing pressure with height, and so expands and cools; sinking air encounters increasing pressure, and so is compressed and warms. Rising air therefore tends to have a cooling effect on the environment, sinking air to have a warming effect. One important exception is, as we will see, rising moist air where the water vapor condenses.

The Three Phases of Water

Heat melts ice into water, and vaporizes water into a gas. The energy used for these processes is stored in liquid water and water vapor, respectively. When water vapor condenses into liquid water, or water freezes into ice, this *latent heat* is released again. A rainfall of 8 mm, which is the same as 8 liters per square meter, releases the same amount of energy as the same area would have received from the Sun during one day. The same happens during snowfall when liquid water freezes to ice, although the amount of energy released is less. A large proportion of the energy received from the Sun is stored in this way and this plays an important role in the dynamics of the Earth s atmosphere because energy can be transported long distances before it is released as latent heat.

Ice, water and water vapor are important also for their reflective characteristics. The proportion of solar radiation that is reflected back to space (albedo) varies significantly with location because it depends on the proportion of ice-covered land and sea, and on the ice crystals in the upper parts of the clouds. Water vapor also absorbs and emits radiation differently from liquid water. The water drops and ice crystals in the clouds reflect the Sun s short wave radiation, which prevents it from reaching the Earth s surface. The expected cooling of the air beneath the cloud is to some extent compensated by warming from long-wave radiation that is trapped by the same cloud.

Finally, water has a high specific heat capacity; that is, water takes a lot of energy to warm, and it cools slowly. Energy stored in the oceans at tropical latitudes does not dissipate rapidly when transported to higher latitudes, serving as a regulator and conveyor of energy. Without these ocean currents, the temperature difference between poles and equator would be 90–100 K instead of the 40–45 K that is observed. The energy conversions related to water in all three forms, and their different radiative properties, contribute to making predictions of any change in the climate very difficult.

Friction

Friction plays a double role: on the one hand it is slowing down all motion; on the other hand, it is through friction (and gravity) that the atmosphere feels that it is on a rotating Earth. Large-scale friction like lee-effects of the large mountain ranges affects the atmosphere s tendency to form large-scale vortices.

THE RELATIONSHIP BETWEEN WIND AND PRESSURE

When the PGF starts to equalize by accelerating the air from high to low pressures, the rotation of the Earth tries

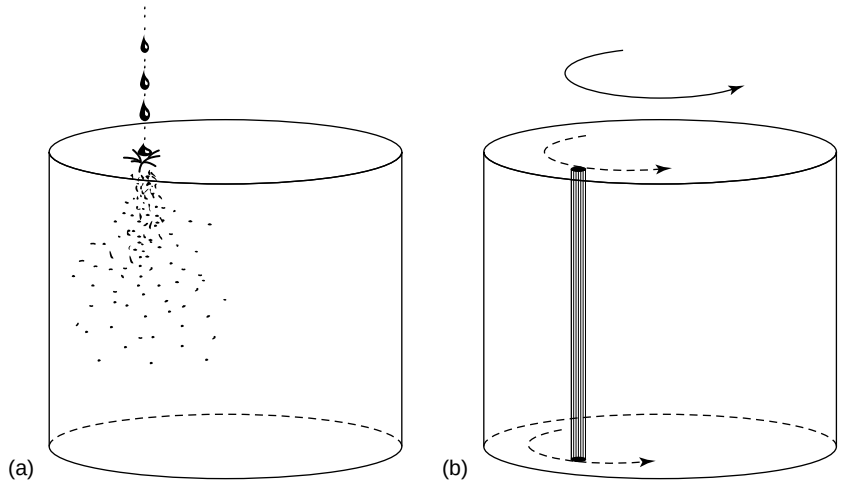

Figure 2 (a) Ink inserted into a non-rotating water tank would disperse immediately. (b) The same ink inserted into a rotating tank would, due to the Coriolis effect, form vertical columns. Such vertical columns are called ''Taylor columns'' after the British scientist who first conducted this experiment

to return the air from where it came. The struggle between these two contesting forces shapes the pressure and wind patterns.

The Effect of the Rotation of the Earth on an Air Parcel

Due to the Earth s rotation, wind and ocean currents are deflected to the right in the Northern Hemisphere and to the left in the Southern Hemisphere. This is due to the so-called *Coriolis force* (fV, where f is the Coriolis parameter and V the wind speed) (*see* Coriolis Effect, Volume 1); it has the effect of opposing any displacement by trying to restore the air to its initial position.

A striking demonstration of this can be made using a rotating tank of water. When a drop of ink is inserted in the water, it falls slowly downward. But instead of dispersing and coloring the water, it remains in a vertical column moving around with the tank as a rigid body. What happens is that when the ink particles start to spread out horizontally, they are immediately affected by the Coriolis force (fV), which forces them into circular motions. If the tank rotates with one revolution in two seconds ($\omega = 2\pi/2 = 3.14\,\mathrm{rad\,s^{-2}}$), and the ink spreads out with a velocity of $1\,\mathrm{cm\,s^{-1}}$, the fV would yield circles with radius of less than 2 mm (Figure 2).

An airflow in the atmosphere of $10\,\mathrm{m\,s^{-1}}$, only affected by the fV, would be confined in a circular trajectory with a radius of 100 km, about the size of London or Los Angeles. In the equatorial regions, where the horizontal component of the fV is relatively weak, velocities of the order of $30\,\mathrm{m\,s^{-1}}$ would be needed to move an air parcel from the equator to poleward of 20 °latitude. Were it not for the existence of strong PGFs, it would be very difficult for air parcels in the atmosphere to move any considerable distance.

The Relationship Between the Wind and Pressure

With two effects, the PGF and the fV, pulling in opposite directions, it is no surprise that they quite often balance each other,

$$f \cdot V = PGF$$

If this is the case, the air moves by itself with no acceleration (Figure 3). Winds blowing under these conditions are called *geostrophic* (from Greek *geos* meaning Earth and *strophein* meaning turning). For such conditions,

$$V_{\mathrm{geostrophic}} = \frac{PGF}{f}$$

The farther away from the equator, the stronger the PGF has to be to balance the fV. That is why pressure maps over the tropics and subtropics contain relatively

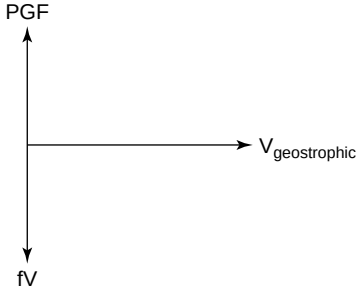

Figure 3 The wind is geostrophic if the PGF and the fV, balance each other

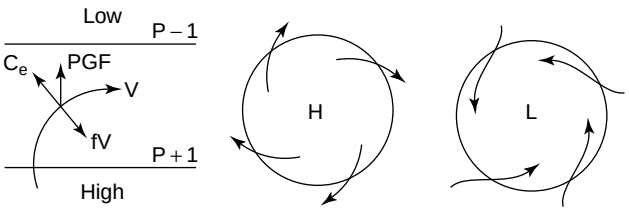

Figure 4 An air parcel accelerating into a pressure field will describe a curved motion and be affected also by a centrifugal force (C_e). A wind accelerated out from a high pressure area by a PGF will be deflected to the right by the fV and, after adjustment describe a clockwise circulation; a wind accelerated into a low pressure area by PGF will be deflected to the right by the fV and, after adjustment describe an anti-clockwise circulation

fewer isobars (lines of equal pressure) than at higher latitudes.

The Effect of Curved Flow

When the pressure field drives the air into a curved motion, it is affected also by a *centrifugal force* (C_e) that disrupts the bilateral balance between the fV and the PGF (Figure 4). Centrifugal forces are always directed outward from the center of rotation and, depending on how the trajectory is curved, the C_e will support either the fV or the PGF (Figure 5).

In a stationary high-pressure system (where the air moves in clockwise trajectories), the C_e supports the PGF; in a stationary low-pressure system (where the air follows anticlockwise trajectories), the C_e supports the fV. This is why high pressure systems, where the C_e supports the PGF, normally have weaker pressure gradients (fewer isobars); and low pressure systems, where the PGF must balance both the fV and the C_e, generally have stronger pressure gradients (more isobars).

Airflow in which the PGF, the fV and the C_e balance each other is called *gradient flow*. In small, intense vortices, with high velocities and small radii, such as in tropical cyclones, the C_e may dominate over the fV. These are called *cyclostrophic flows* (Figure 6).

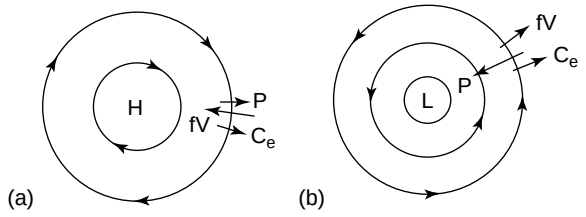

Figure 5 (a) The gradient wind approximation for cyclonic and anticyclonic flows. For curved air trajectories around a high pressure area (H), the C_e will support the PGF P; (b) for curved trajectories around a low pressure area (L), the C_e will support the fV

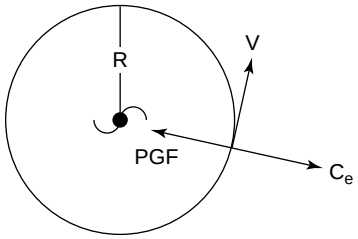

Figure 6 For very intense vorticies like mature tropical cyclones, the C_e dominates over the fV, which can be neglected, although it may have played a decisive role in the initial stages of the formation

The Effect of a Moving Flow Pattern

If the circulating system is not stationary, but moving, the relation between the C_e, the PGF and the fV is more complicated. The trajectories will alternately be more or less curved, compared to those of a stationary vortex. The reason why the winds on the southern side of a cyclone moving eastward close to geostrophic is because the air trajectories are rather straight (a large radius of curvature). On the other hand, on the northern side, the winds are much weaker, although the pressure gradients might be the same, because the air trajectories are more curved (Figure 7).

The Dynamics of Pressure Changes

Had the wind in the free atmosphere been in complete geostrophic, gradient or cyclostrophic wind balance, it would be frozen in a permanent state. What instead keeps the atmospheric circulation changing is that these balances are never fulfilled. It is the *ageostrophic* wind component, the part of the wind that is not in geostrophic balance, that drives the atmospheric patterns. If the wind at some instant happens to be in geostrophic balance, it sooner or later moves into a region where it is no longer in geostrophic balance (Figure 8). The PGF and the fV then provide a mechanism for restoring the balance by moving mass horizontally between lower and higher pressure.

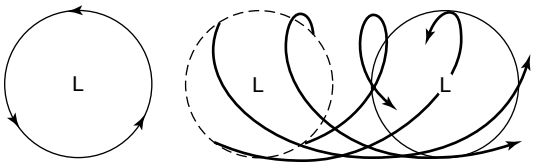

Figure 7 For an eastward moving circular vortex the trajectory of an air parcel on the southern side (where the air is moving in the same direction as the vortex) will have less curved trajectory than on the opposite side, where the air is moving in the opposite direction the trajectory will be more curved

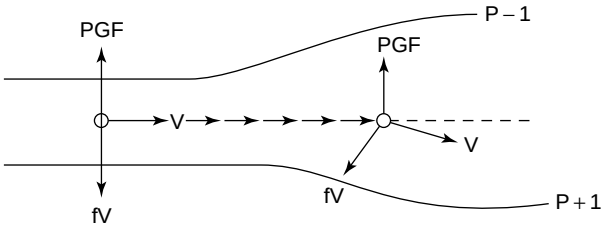

Figure 8 The wind is only temporarily in geostrophic balance; the motion of the air soon brings it into areas where this balance is no longer valid. In the schematic picture the wind is in geostrophic balance upstream where the pressure gradient is stronger than further downstream. When the wind enters this downstream region, it becomes supergeostrophic, and is deflected to the right by fV. The flow will thereby transport air towards higher pressure, which will strengthen the pressure gradient at the same time as the wind weakens it, until a new balance is reached

If the wind is sub-geostrophic, i.e., weaker than the geostrophic balance requires, the PGF will accelerate the air towards lower pressure. Mass will be transported from higher to lower pressure and thereby weaken the PGF. At the same time the wind will increase, and so will the fV, until a new temporary balance with the PGF is established (Figure 9a).

If the wind is supergeostrophic, i.e., stronger than the geostrophic balance requires, the fV will drive air towards higher pressure. Doing so, an air mass will be transported from low to high pressure, thereby increasing the PGF. At the same time, the wind will weakens and so will the fV, until a new temporary balance with the PGF is established (Figure 9b).

The Ice Skater Effect

An important mechanical effect in the atmosphere is the *ice skater* effect. By contracting or widening their arms, ice skaters increase or decrease their rate of rotation. Something similar happens for a body of gas (or fluid) which contracts or expands. But there are also vertical motions in the gas. Rising motion is associated with an inflow of air at lower layers and an outflow in upper layers. Sinking motion is associated with an inflow of air at upper layers and an outflow in lower layers. Due to the fV, the air flowing inwards forms an anticlockwise spiral; air flowing outwards forms a clockwise spiral. The pressure then adjusts to create a low pressure distribution for the inward spiral or a high pressure distribution for the outward spiral (Figure 10).

THE ATMOSPHERIC ENGINE

On average the equatorial region receives more heat from the Sun than is sent back to space, while the opposite is true at high latitudes. The accumulated result of the heating is an expansion of the air at low latitudes, setting the atmospheric engine in motion.

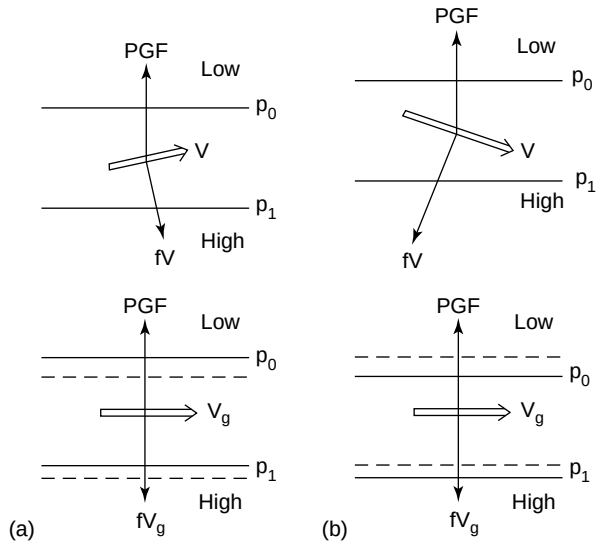

Figure 9 (a) When the PGF is stronger than the fV the wind *accelerates* towards lower pressure. At the same time the PGF weakens when mass is transported from high to low pressure. The wind moves parallel to the lines of equal pressure (isobars) when the two forces fV and PGF have reached a balance. (b) When the PGF is weaker than the fV the wind *decelerates* towards higher pressure. At the same time the PGF strengthens when mass is transported from low to high pressure. The wind moves parallel to the isobars when the two forces fV and PGF have reached a balance

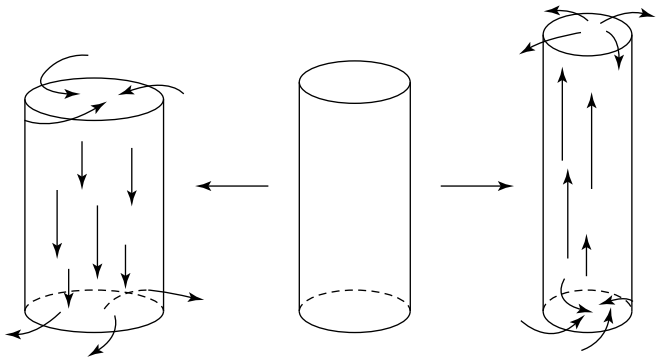

Figure 10 Schematic illustration of the ice skater effect. In the Northern Hemisphere, upward motion is associated with air spiraling anticlockwise inward at lower levels, clockwise outward at higher. For downward motion the opposite is the case

Hadley Circulation

Because pressure falls off more slowly with height in warm air than in cold air, the same pressure in the atmosphere is

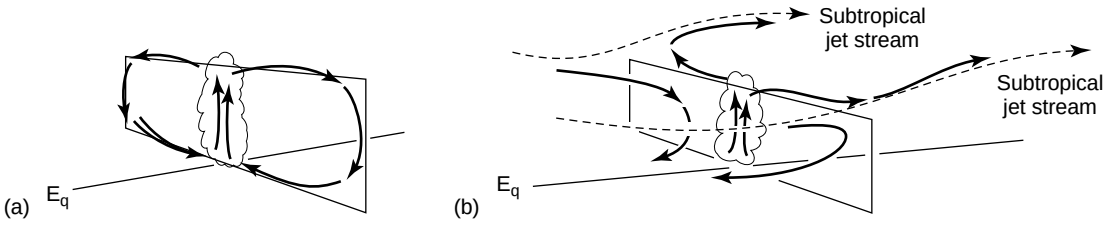

Figure 11 The Hadley cell is characterized by rising motion in the equatorial region, poleward flow at upper levels, sinking at higher latitudes and a return flow equatorward at low levels. (a) The traditional Eulerian view, which depicts the average north–south motion and vertical motion; (b) an attempt at a Lagrangian view, which aims at depicting the average motion of individual air parcels which necessarily involves a three dimensional image including and east–west motion

found at higher elevations in the tropics than elsewhere. From these upper levels, air is accelerated towards the poles. This is the driving mechanism behind the Hadley circulation, named after the 18th century British scientist who first suggested the Earth s rotation and differential heating were major components in the atmosphere s general circulation (Figure 11). The removal of air from the upper levels is felt farther down as a decrease in pressure and leads to a groove of low pressure at low levels along the Equator. From the surrounding areas of relatively higher surface pressure, air is accelerated into this groove, creating the *Trade Winds*. Due to the fV, the Trade Winds arrive at the equator from a northeasterly direction in the Northern Hemisphere and from a southeasterly direction in the Southern Hemisphere (*see* Hadley Circulation, Volume 1).

Intertropical Convergence Zone

A large part of the heating in the equatorial region does not originate directly from the Sun, but through a delayed effect. Through evaporation from rivers, seas and the vegetation the Sun s energy is stored in the atmosphere as water vapor. It is then transported by the Trade Winds and converges in a band along the equatorial zone called the Intertropical Convergence Zone (ITCZ). The ITCZ is a surprisingly narrow belt of vigorous convective activity and heavy precipitation, usually made up of a large number of distinct cloud clusters a few hundred kilometers wide separated by clear skies. Of particular importance are the so-called *hot towers*, large cumulonimbus clouds that concentrate the main heating.

Over the oceans the ITCZ is not located exactly at the equator. Sometimes it is split up into two parallel bands on either side of the equator. This is because of the relatively low sea surface temperature often present at the equator. How this colder water has been brought there is worth a short explanation because it involves the action of the fV. The steady Trade Winds from the east drive the surface water towards the west. Although the fV is weak close to the equator, it has an accumulated deflective effect on the water due to the steadiness of the driving wind, and so fV deflects the surface water away from both sides of the equator. This leads to an outflow of surface water, which causes an upwelling of deeper and colder water from deeper layers. This mechanism is particularly prominent over the eastern Pacific Ocean where an equatorial pool of cold water generally prevails. This is known as La Niña (Figure 12) (*see* Intertropical Convergence Zone (ITCZ), Volume 1).

Monsoons

The fact that land has a small heat capacity compared to ocean is profoundly significant for many atmospheric features. The absorption of solar radiation raises the surface temperature over the land much more rapidly than over the oceans and causes and creates local wind systems. In the smallest scale we find the sea breeze, in the largest scale the monsoon, a gigantic land and sea-breeze circulation caused by the seasonal warming and cooling.

The largest monsoon circulation is created by the vast Asian landmasses and the Himalayas. During the cold season, the cooling of the Asian continent north of the Himalayas causes cold air to sink. Sinking motion is linked with inflow at upper levels and outflow at lower levels, the ice skater effect. The fV drives these flows into outward spiraling anticyclonic and inward spiraling cyclonic patterns, respectively. Due to the pressure adjustment, a vigorous surface high-pressure area is created over Siberia, with a tendency to lower pressure aloft. The cold air from Siberia moves southward over China and Southeast Asia. This is the winter monsoon.

During the warm season the heating creates a vast upper air high-pressure system that is centered over the Indian peninsula and the Himalayan mountain plateau. This leads to an upper outflow; a surface low-pressure area is formed and moist air is drawn in from the surrounding areas. The weakness of the fV over the Indian Ocean allows air, even from south of the equator, to be drawn into the low-pressure region over the Indian Peninsula. The influx of moisture gives rise to the formation of strong

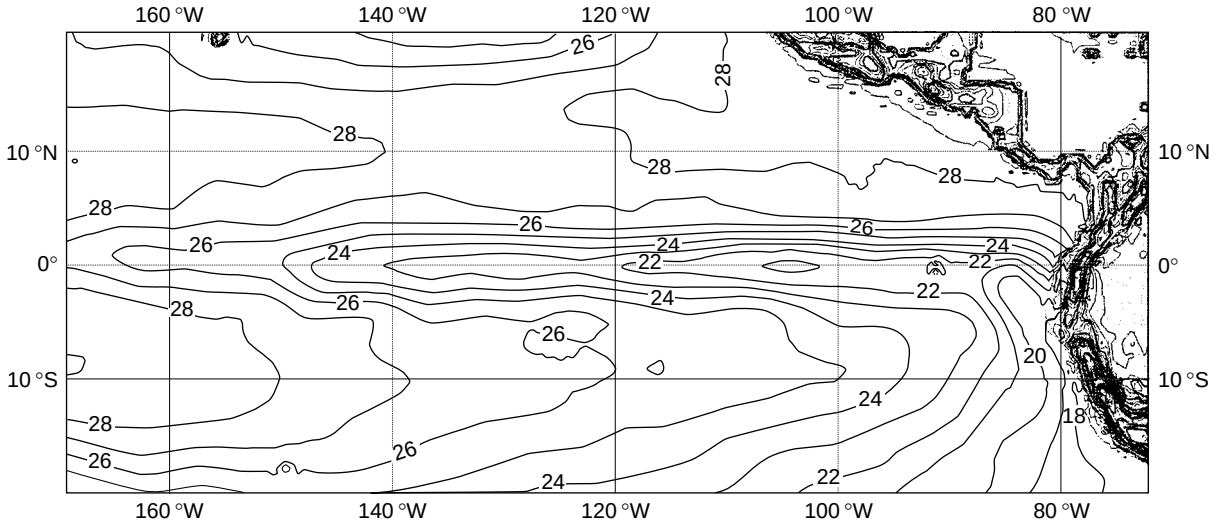

Figure 12 Mean sea surface temperature of the eastern part of the Pacific Ocean for the period 5 Sep to 5 Oct, 1998. The relatively colder water along the equator has been brought up from deeper layers through the action of the fV. Although the fV is weak close to the equator, the steady trade winds from the east account for a small accumulated effect, so that water on both sides of the equator is deflected away from it. This divergence causes an upwelling of deeper and colder water

cumulonimbus convection that leads to further heating of the air due to the release of latent heat.

The monsoon circulation, in particular the summer monsoon, also has an impact on the neighboring continents. The dry regions over northeast Africa are assumed to have their climate determined by the intensity of the Indian monsoon. One contributing factor to this westward directed influence might be the formation of a strong easterly jet stream formed over the northern part of the Indian Ocean on the southern flank of the upper air high pressure system over the Indian peninsula mentioned above (*see* Monsoons, Volume 1).

Easterly Waves and Tropical Cyclones

The Trade Winds blow steadily, interrupted only by minor westward moving easterly waves. When they interact with disturbances that have come down from higher latitudes, they develop into subtropical storms, which can become very intense due to the release of latent heat. These disturbances can sometimes move into higher latitudes and affect developments there.

During the warm season, when the subtropical high-pressure belts are displaced poleward, the easterly waves appear in regions with slightly stronger fV. This allows individual easterly waves to develop into small, intense tropical cyclones, hurricanes (or typhoons as they are called over the Pacific, Willy–willys in Australia) driven by the release of latent heat (*see* Hurricanes, Typhoons and other Tropical Storms - Descriptive Overview, Volume 1; Hurricanes, Typhoons and other Tropical Storms - Dynamics and Intensity, Volume 1). The fV, which has been instrumental during the formation of the initial vortex, soon becomes overpowered by the C_e, resulting in a cyclostrophic flow. The outward pushing C_e causes a sucking effect that draws down dry air from high levels down into the center of the storm. This is the cloudless eye of the storm.

Because tropical cyclones depend crucially on latent heat release from moist air, their development occurs almost exclusively during the peak of the warm season. The air and water temperature (which peak at different times) should not be below $+28\,^{\circ}$C. Most tropical cyclones die out over land due to friction and lack of supply of sufficiently warm and moist air from below. Because of the cold ocean water from the Antarctic, there are never any hurricanes in the South Atlantic and Southeast Pacific.

Walker Circulation

A third major tropical circulation system driven by heating from below is the so-called *Walker circulation*. Its rising branch is over the Indonesian archipelago and the western part of the equatorial Pacific Ocean, a region of very warm sea surface temperatures and high mountains with intense rainfall, causing extensive release of latent heat. The descending branch is over the central parts of the Pacific where the sea surface is relatively cooler (Figure 13).

Unlike the Hadley circulation and the Monsoon, the Walker circulation is hardly affected by the fV. The air that has been brought to high altitudes over Indonesia is blown straight eastward toward the eastern Pacific. The return flow over the equatorial Pacific is associated with a

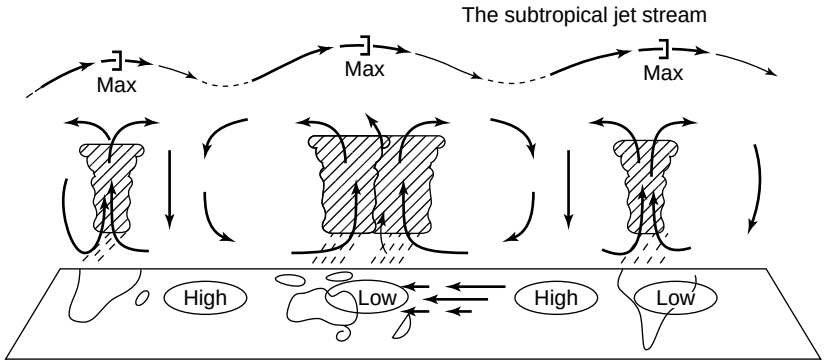

Figure 13 The Walker circulation has rising motion due to convection over Africa, the Indonesian archipelago and South America. The surface flow over the Pacific is easterly, which creates an upslope in the water north of Australia. Shown schematically above these cells are the approximate locations and wind velocity tendencies of the subtropical jet streams that surrounds the Walker circulation at about 30°N and 30°S. With the long distance between the center of the subtropical jet over Indonesia and the center over South America, the Coriolis fV might manage to deflect the jet stream from both hemispheres to cross the equator

weak pressure gradient, with high pressure over the Pacific and low pressure over Indonesia. For not quite understood reasons, this gradient reverses its direction with a period of 2–5 years. These semi-regular variations are known as the Southern Oscillation (*see* Southern Oscillation, Volume 1), which is associated with one of the most important semi-regular variations in the ocean, the El Niño (*see* Walker Circulation, Volume 1).

El Niño and La Niña

The steady easterly Trade Winds coming from the Pacific into the Indonesian region cause a pile-up of warm surface water, creating an upslope hill. From time to time the Trade Winds weaken, allowing the water to spread back towards the central Pacific. This is the El Niño, which is Spanish for the Christ child. This term was originally applied to a warming of the coastal waters of Peru and Ecuador that occurs around Christmas time. As the warmest water moves eastward, the tropical convective clouds and rain and heating maximum follows suit, moving towards the central Pacific. In this way, the whole Walker circulation is displaced eastward, which leads to profound consequences throughout the tropics, with changed patterns of rainfall leading to floods in some regions and drought in others (Figure 14).

This shift extends its influence over North and South America, and probably also to the Atlantic where the frequency of tropical storms (hurricanes) is affected. These changes constitute a striking example of how feedbacks between the atmospheric and ocean circulations act together to drive irregular or semi-regular variations, influencing climate and climate change (*see* El Niño and La Niña: Causes and Global Consequences, Volume 1).

Because the El Niño (EN) and Southern Oscillations (SO) are highly interrelated phenomena, they are often treated together under the name ENSO. It is not quite known what triggers the change. It could be a change in either the atmospheric or the ocean component of the system. Some observations point to an influence of the decaying monsoon over the Indian Ocean. Still, the ENSO events are becoming predictable, at least to some extent, by computer models. Also, to some extent, their anomalous weather consequences for other parts of the tropics are also predictable, including some aspects affecting North and South America and the Atlantic. An important question is whether the El Niño would have the same character in a warmer atmosphere resulting from enhanced greenhouse warming.

The Formation of the Subtropical Jet Stream

Why does the Hadley circulation extend only to 30° and not to the poles? Part of the answer is contained in an elementary calculation (often found in old meteorological textbooks). The student is invited to calculate the poleward acceleration of air due to the meridional pressure difference at upper levels. A thermal contrast of 40 K is assumed between pole and equator. It turns out that the corresponding acceleration is only $0.7\,\mathrm{mm\,s^{-2}}$. This does not sound like much, but in 24 hours this tiny acceleration would have increased wind speeds to velocities of $60\,\mathrm{m\,s^{-1}}$ and carried the air a distance of more than 2500 km, which is more than 20 degrees latitude.

The accelerated air is increasingly affected by the fV, which tries to make it return to the equator. A balance is eventually established when the air on the one hand is prevented from moving farther poleward by the fV, and on the other is prevented from returning equatorward by a strengthened PGF. With the typical heating and rotation of our particular planet, this balance between wind and

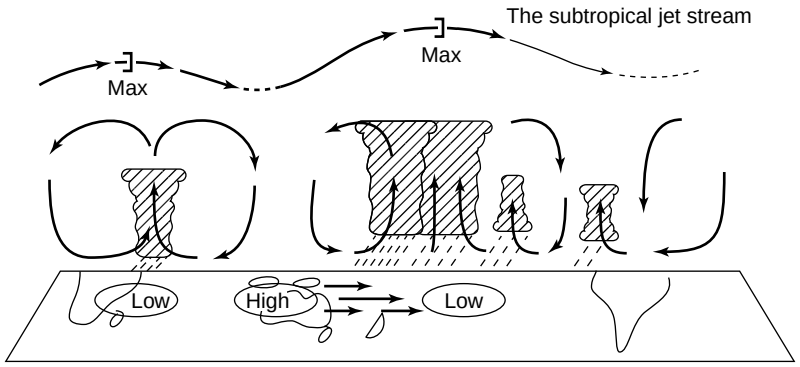

Figure 14 The El Niño occurs when the warm ocean water in the western Pacific spreads back towards the east. The main area of convection follows suit, which leaves Southeast Asia in the subsiding, dry region. With the eastward shift of the heating, the subtropical jet stream is also shifted eastward. This reduces the distance to the next center over South America and effectively prevents any deflections of the jet winds over the equator

Figure 15 A schematic illustration of the formation of the subtropical jet stream. Air accelerated by the upper-tropospheric PGF gains speed poleward, but is simultaneously affected by the fV, which, by deflecting it clockwise in the Northern Hemisphere (anti-clockwise in the Southern Hemisphere) tries to bring the air back towards the equator. A balance is reached around 30 ° latitude

pressure is established around 30 °latitude. Here we find at 7–13 km height a strong westerly flow with winds of 30–80 m s^{-1}. This is the subtropical jet stream, the largest, strongest and most persistent wind system in the Earth s atmosphere. It also sets the poleward limit of the Hadley circulation (Figure 15).

With a faster rotation of the planet, and/or weaker Hadley circulation, the subtropical jet would have been closer to the equator and weaker. If the Earth on the other hand rotated more slowly and/or the Hadley circulation had been stronger, we would have a much stronger jet stream at higher latitudes.

The Longitudinal Variations of the Subtropical Jet

The strongest heating of the atmosphere occurs over the Caribbean and the Amazon basin, over the Sahel and the African rainforests, and over the Indonesian archipelago and Australia. This is where the upper level high-pressure systems are strongest, and it is poleward from these regions where the subtropical jet has wind maxima. Over the oceans, where the heating from below is less intense, the meridional pressure differences are weaker and so are the PGFs.

Due to the irregular distribution of continents and oceans, these regions of maximum heating are not evenly distributed longitudinally. The maximum over East Asia and Australia around 120 °E is far upstream of the next downstream maximum over the Americas, which is located around 80 °W, almost half the circumference of the Earth. The Subtropical jet stream, which originates over the western Pacific, therefore has a long distance to the next heat source over Latin America. During the long passage over the Pacific, the fV has plenty of time to affect the jet stream, trying to drive it into a circular motion toward the equator. This is facilitated by the SST distribution, with the warmest water in the west Pacific. As the temperature of the ocean surface water decreases eastward, the upper level PGF therefore weakens and allows branches of the subtropical jet occasionally to cross the equator from either hemisphere (Figure 16a).

During an El Niño this does not happen. Then the relatively cold sea surface water in the central and eastern Pacific is replaced by warm water, the heating increases and so has the upper PGF, which prevents the fV from deflecting the winds over the equator. The extra heat source over the central and eastern part of the equatorial Pacific creates an upper-air high-pressure area that effectively prevents the fV from deflecting the wind across the equator (Figure 16b).

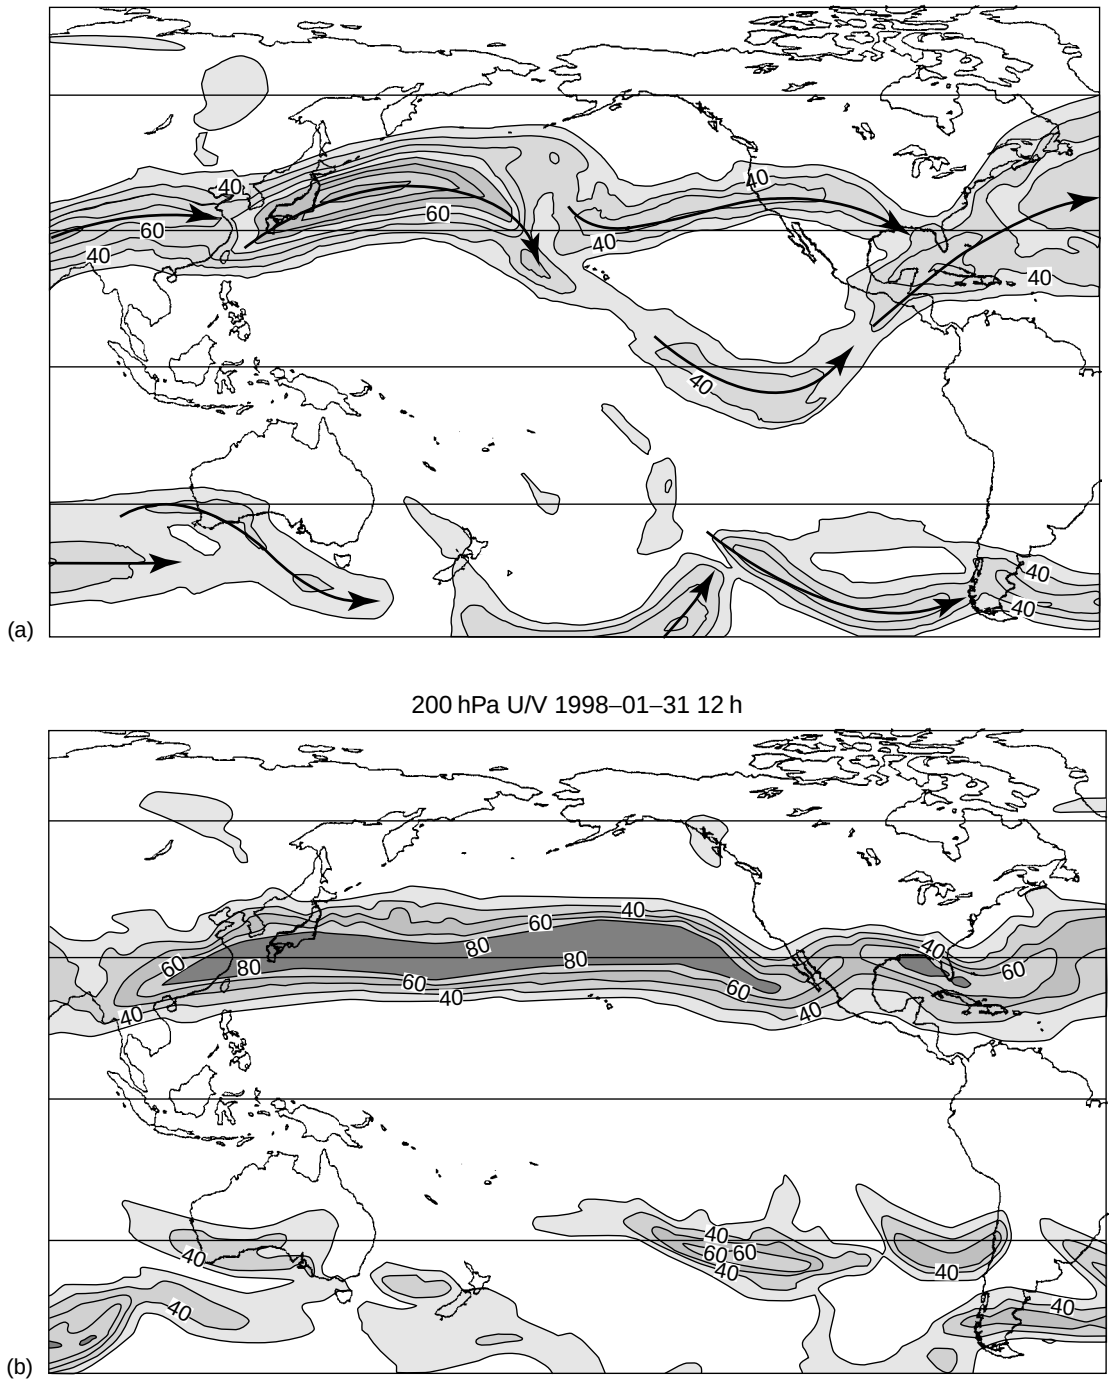

Figure 16 (a) The winds at 200 hPa (approx. 12 km) on 19 February, 1999. The isolines indicate the wind speed in intervals of 10 m/s. The subtropical jet stream over eastern Asia is almost permanently positioned over southern Japan. Halfway across the North Pacific, due to the action of the fV and the reduced heating from below, the wind can be deflected across the equator. Because the fV deflects winds to the left in the Southern Hemisphere, the jet wind is normally deflected back to the Northern Hemisphere. (b) The same as (a) for 31 January, 1998. This is a typical upper tropospheric flow pattern over the Pacific during an El Niño period with the two subtropical jet streams clearly separated in each hemisphere (*Source:* ECMWF analyses)

Seasonal Variations of the Subtropical Jet

The subtropical jet streams show large seasonal variations, particularly in the Northern Hemisphere. Indeed, there is nothing that shows the close connection between the subtropical jet stream and large-scale heat sources better than the extraordinary change in the subtropical jet that regularly occurs from winter to summer. When summer approaches, the heat source for the atmosphere is extended well into the middle latitudes. Due to strong insolation over the large subtropical land masses of the Northern Hemisphere, the large mass circulation of winter that transports heat poleward is greatly weakened and the westerly subtropical jet stream disappears as a circumpolar phenomenon (Figure 17a,b).

The Caging In of the Atmospheric Machine

The fact that air moving from the equator into the subtropical jet stream is, on the one hand, prevented from moving farther poleward by the fV, and on the other, prevented from returning equatorward by the PGF, causes a congestion of air in the upper troposphere. This is felt at lower levels as a small (1–2%) increase in the pressure. This creates the subtropical high-pressure belts that are found around 30° latitude in each hemisphere underneath

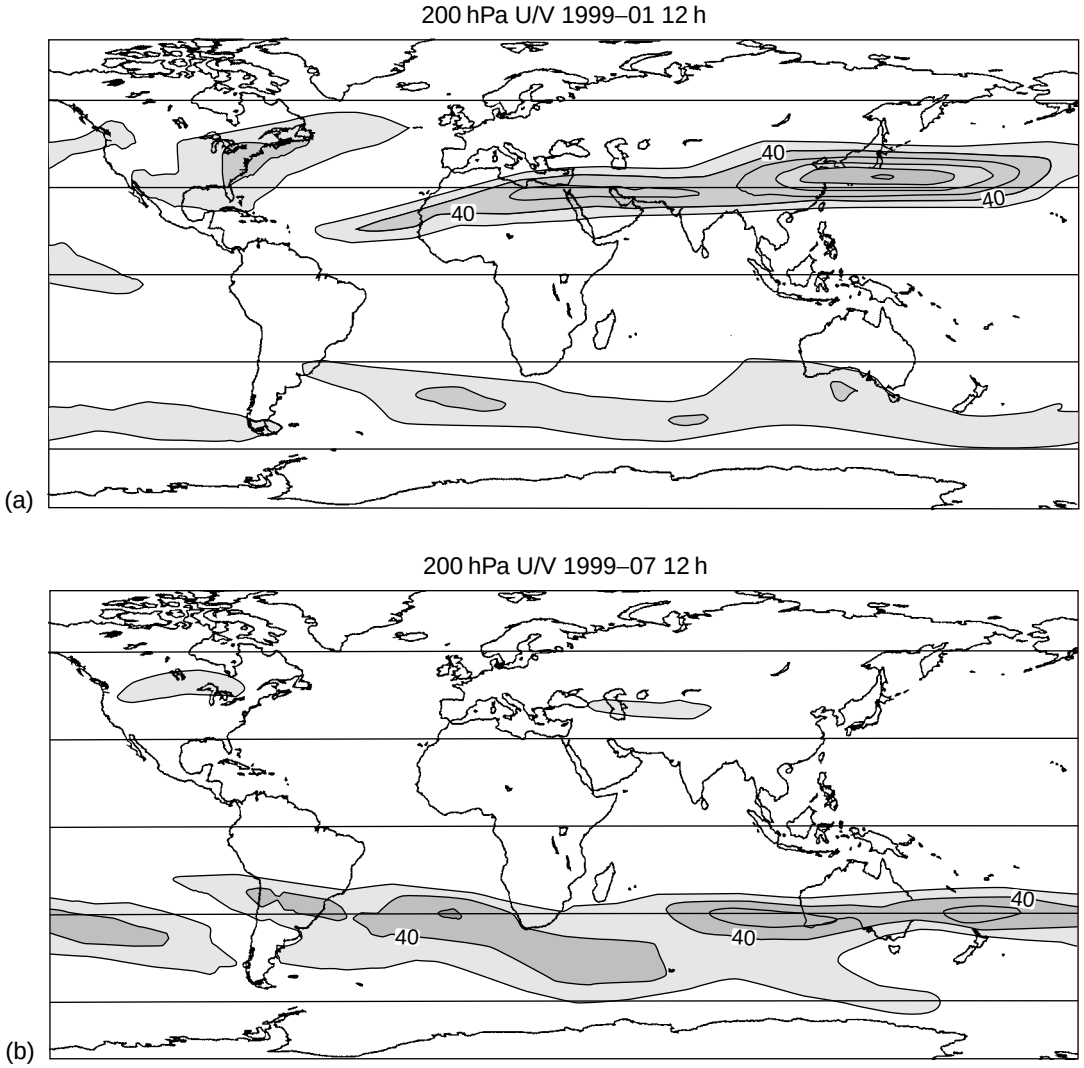

Figure 17 (a) The mean wind speed at 200 hPa (ca 12 km) during February 1999. The Northern Hemisphere subtropical jet stream is clearly seen around 30 °N, whereas its counterpart in the Southern Hemisphere is weak. The mid-latitude jet streams around latitude 50° do not come out strongly on the monthly averages due to their great geographical variability. (b) The same as (a) but for August 1999. The subtropical jet stream in the Northern Hemisphere has disappeared, but its counterpart in the Southern Hemisphere is clearly seen around 30°. The mid-latitude jet streams around 50 °S are still visible due to their strength and interaction with the subtropical jet stream

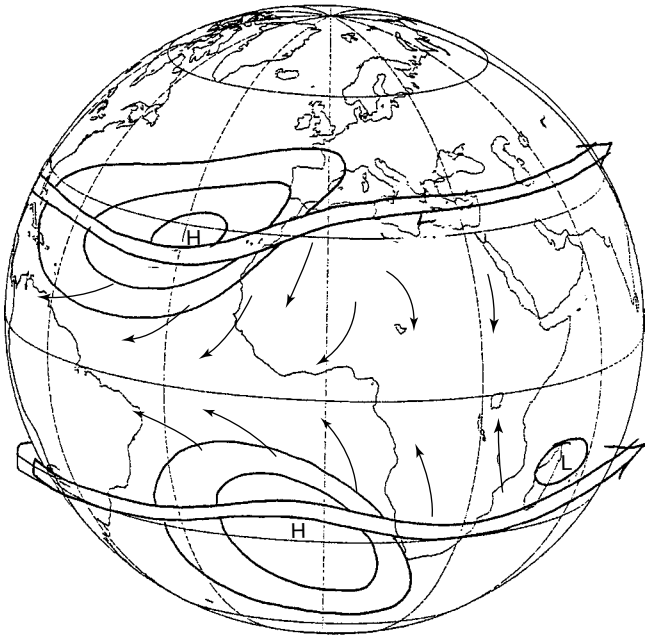

Figure 18 The subtropical high pressure belt is located beneath the subtropical jet stream. The high pressure is particularly strong over the oceans, which coincides with the left entrance of the jet stream where strong sinking motion occurs

the subtropical jets (Figure 18). The convergence of air at high levels also leads to sinking motions, which in turn leads to a drying of the air and dissipation of the clouds. The clear skies at subtropical latitudes lead to increased outward radiation into space and cooling, which is compensated during daylight hours by dry convection, bringing air heated by the underlying surface to higher levels in the atmosphere.

In the subtropical belt, individual high-pressure centers are formed over the subtropical oceans due to a combination of dynamic and thermal effects. These were called the *Doldrums* or the *Horse latitudes* by seamen due to their weak winds. The subtropical highs are closest to the equator during the respective winters, and displaced poleward during the respective summers.

The Polar Regions – Another Source of Energy

Not only do the tropics supply energy to the atmosphere, but so do the polar regions to a small degree. Around the Pole, air is constantly cooled, which makes it heavier and causes it to sink. As we saw with the ice skater effect, sinking motion is linked with inflow of air at upper levels and outflow at lower levels. The upper air becomes a gigantic inward spiral, the lower an equally large outward spiral. Due to the Coriolis effect and the adjustment between pressure and wind, a low-pressure region is found at upper levels and high pressure at lower levels. From this polar cap cell, air is accelerated away from the polar regions and deflected by the fV to create a regime of northeasterly winds down to 60–70 °N. During summertime, with its strong insolation, this process disappears.

WHERE THE ENERGY IS LOST

If it is in the tropics that the Sun s radiative energy is transformed into energy of different kinds, then it is in the mid-latitude westerlies (the roaring forties) that most of this energy, released in storm developments, finally returns to frictional heat and is radiated back into space.

The Mid-latitude Westerlies

The mid-latitude westerlies mirror the tropical easterlies. While the tropical easterlies blow in the opposite direction to the Earth s rotation, and thereby slow it down, the extratropical westerlies speed up the Earth s rotation. These two effects balance, on average, but due to the seasonal variations of the wind regimes, the Earth s rotation, and thereby the length of the day, the Earth s rotation undergoes a periodic variation of the order of milliseconds (*see* Atmospheric Angular Momentum and Earth Rotation, Volume 1).

But why do we have westerlies at all in the mid-latitudes? And why are they not, as in the Tropics, compensated at upper levels by winds in the opposite direction? The reason is that the winds in the mid-latitudes are created and maintained by other mechanisms than those decisive in the tropics. One is the effect of the Earth s rotation; while it can be neglected in the tropics, in the mid-latitudes it plays a very important role.

When the wind is accelerated poleward from the subtropical high-pressure belt, it is affected by an increasing fV. A strong adjustment between wind and pressure is continuously taking place. As a result isobars typically become oriented from WSW to ENE in the Northern Hemisphere, WNW to ESE in the Southern Hemisphere. Where the fV tries to drive the air equatorward, back towards higher pressure, the pressure gradient sharpens. Part of the kinetic energy of the winds is then converted back into potential energy, which delays its further transport up into the mid-latitudes. Pressure decreases with height more slowly in warm air than in cold, so the meridional temperature contrast gives rise to pressure differences at upper levels. Due to the strong fV, the wind and the pressure field rapidly adjust, resulting in wind from a westerly direction.

The strong fV is also the reason why, on average, the subtropical air masses are confined to latitudes equatorward of 45°. Also, at high latitudes the strong Coriolis deflection makes it difficult for the cold air masses from the high-pressure areas around the poles to extend very far. Arctic air masses are normally found poleward of 65 °latitude,

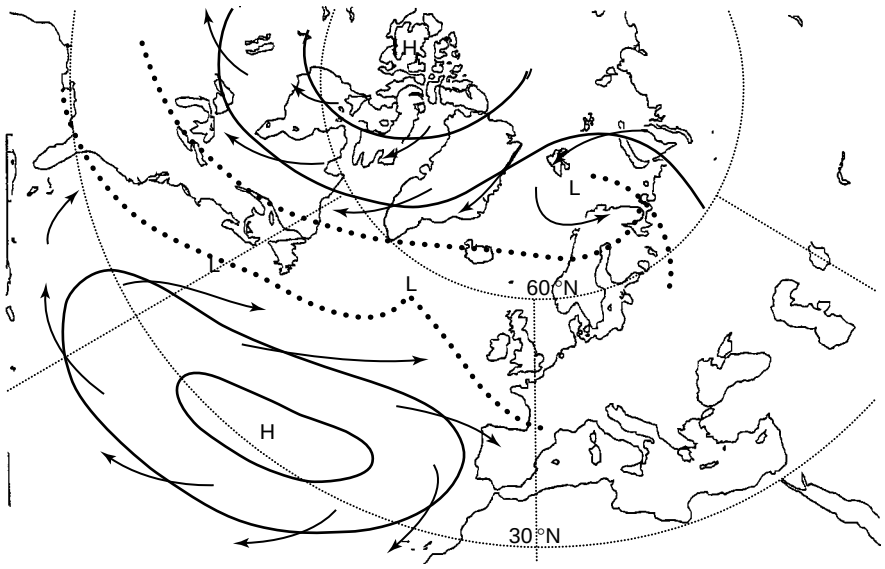

Figure 19 The acceleration of the winds out from the subtropical high pressure belt and the polar cap high pressure system. Winds moving poleward from the subtropical high pressure belt encounter an increasing fV, and a strong adjustment with the pressure field takes place. The fV acts to confine air masses so that cold air from the poles cannot easily penetrate equatorward of 60–65° and subtropical air masses not poleward of 40–50°. The air mass boundary around 45° is called the Polar Front, which in winter extends from the southwestern USA across the Atlantic to the British Isles, and from the northern Mediterranean eastward into Asia. The borderline around 60°, the Arctic Front, is most pronounced over Alaska, western Canada and northen Europe. Another branch of the Polar Front extends from the waters south of Japan across the Pacific Ocean to the US-Canadian border

and then only in wintertime. In summertime the insolation prevents cold air masses from forming. The intermediate latitude band between 45° and 65° is occupied by stagnant air, either from the tropics which has cooled, or from the Arctic regions, which has warmed (Figure 19).

Jet Streams and Fronts

In contrast to the tropics, where the main motion is due to vertical temperature contrasts that create convection that heats the atmosphere, the important driving forces in the mid-latitudes are horizontal temperature contrasts between air masses of different temperature and density. Through the action of the fV, these contrasts are concentrated in narrow zones, so called fronts or Polar Fronts.

In the broad river of air which constitutes the mid-latitude westerlies, long, narrow bands are imbedded between 8 and 13 km altitude where the winds reach 30–80 m s^{-1}, and are on rare occasions 100–150 m s^{-1}. These are the Polar Front jet streams. In contrast to the subtropical jet, which gains its strength from winds accelerated in the Hadley circulation, the Polar Front jet streams thrive on the thermal contrasts along the Polar Front (*see* Fronts, Volume 1; Jet Stream, Volume 1).

The fronts and their associated jet streams do not form a homogenous, uninterrupted band around the hemisphere, but rather separate bands stretching over 60–90° longitudinal sectors where the temperature contrasts and the horizontal pressure differences are more concentrated and the winds stronger than in the intermediate sectors.

As the air moves through the non-uniform pressure field, it is constantly accelerated at the upstream end of a major jet stream, decelerated at the downstream end. With the acceleration, kinetic energy is drawn from the potential energy associated with the pressure and thermal contrasts; with the deceleration, kinetic energy is converted back to potential energy associated with the pressure and thermal contrasts. When the potential energy decreases upstream, these contrasts (gradients) weaken; when potential energy is increased downstream, the contrasts are strengthened. This has the consequence that the whole pressure and temperature pattern will slowly be displaced downstream, while the wind rapidly moves through (Figure 20a–c).

Vertical Motions around Fronts and Jet Streams

Cold and warm air masses of different densities would under buoyancy forces (gravity) tend to arrange themselves horizontally, with cold dense air sinking under the warm light air. Doing so, the system s center of gravity is lowered. But this re-arrangement would involve horizontal motion that would immediately be affected by the fV, which would try to bring the air back. The frontal surfaces are left to slope when a balance is reached between buoyancy forces, which try to create a horizontal stratification, and

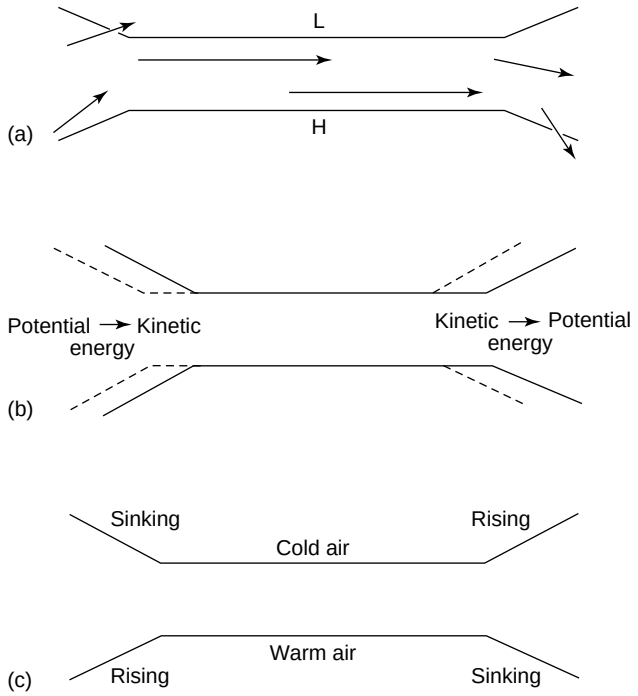

Figure 20 (a) The inflow and outflow in a jet stream. The acceleration of the air at the entrance implies an increase of kinetic energy at the expense of potential energy, the deceleration at the exit implies a decrease of kinetic energy and an increase of the potential energy. (b) Because the level of potential energy is associated with the strength of the pressure differences, these decrease at the entrance and increase at the exit, which leads to the whole pressure system being slowly moved in the direction of the flow. (c) A decrease in potential energy means that the system's center of gravity is lowered. This implies rising of warm, light air and sinking of cold heavy air. With warm air on the equatorward side and cold air on the poleward side, this means at the entrance of the jet rising motion to the right, sinking motion to the left. With a similar reasoning, it can be understood why, at the exit of the jet where potential energy is increasing, cold air to the left is rising and warm air to the right is sinking

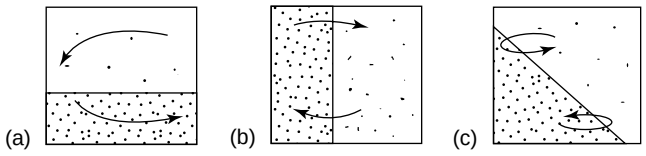

Figure 21 The motion at frontal boundaries is determined by two opposing mechanisms: (a) the thermal contrast tries to create a *horizontal* stratification; (b) the rotation of the Earth tries to create a *vertical* stratification. (c) Neither of the mechanisms is dominant, leaving the frontal surfaces to slope with an inclination of the order of 1 : 50 to 1 : 200

the rotation of the Earth, which tries to create a vertical stratification (Figure 21a–c).

The reversal of this process, against the buoyancy forces, and thus against gravity, involves lifting of cold air and sinking of warm air. Because this would raise the center of gravity and increase the potential energy, it can only occur through external mechanical forcing. It is the fV that provides this mechanical forcing when it, being stronger than the PGF, drives the air towards higher pressure, which slows down the wind. Note that it is the PGF, not the fV, that slows down the wind. This can be compared to a ball rolling down a hill. Gravity accelerates the ball when the kinetic energy, increases. Inertia might then drive the ball uphill, but the work, the conversion from kinetic to potential energy, is still made by gravity slowing down the speed of the ball.

The induced vertical motions affect the temperature, sharpening or even creating fronts. This conversion between potential and kinetic energy is reflected in the waves that develop and the accompanying changes of the frontal slopes: flattening when kinetic energy is created, steepening when the kinetic energy returns to potential (Figure 22). During these transitions the frontal surface oscillates like a membrane. Frequently, for reasons which are not well understood, the waves along the frontal boundary escalate into intense vortices.

The Development of Extra-tropical Storms

The subtropical highs are created and maintained by air at higher levels converging into the subtropical jet stream.

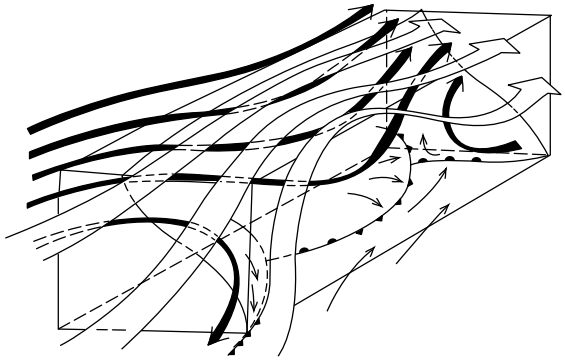

Figure 22 The circulation in extra-tropical weather systems involves a complex interplay of rising and descending motions. Air masses coming from higher and lower latitudes converge in the western part, the ''entrance,'' and diverge in the eastern part, the ''exit''. While staying separate, they undergo large vertical displacements. Whereas at the left entrance and right exit, where the air is sinking, there is a tendency for downward motion and dynamical stability, at the right entrance and left exit of a jet stream, where the air is rising, there are favorable areas for storm development. The combined sinking of cold air and ascent of warm air represents a conversion of potential to kinetic energy, which maintains the jet stream. Heat and moisture is transported downstream, maintaining and even sharpening and extending the frontal zone

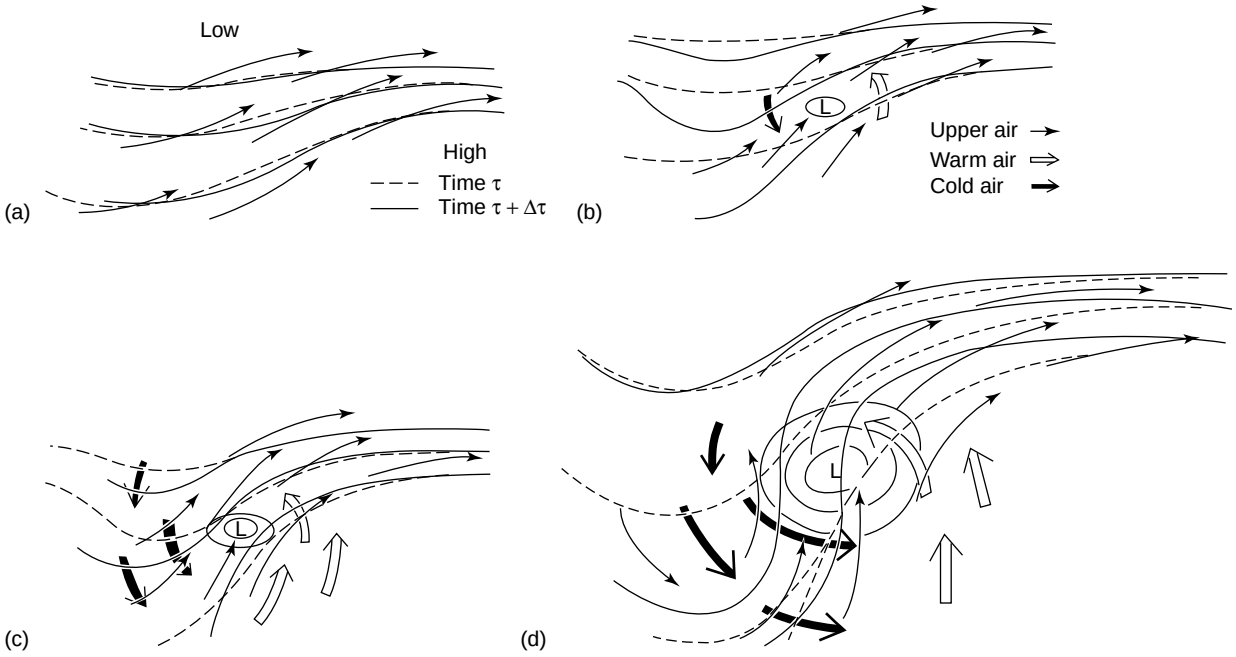

Figure 23 (a) The initial development of a deepening storm. The zone between warm air to the south and cold air to the north; strong pressure differences and a jet stream have developed at high levels. The wind is accelerated into the jet stream and the gradient is weakening [(- - - - -) lines for equal pressure at an early stage, (———) at a later stage]. (b) More air is exported out of the region than imported. This upper divergence causes the pressure to fall at lower levels. A new circulation is rapidly established due to the balance between the PGF and the fV. (c) The transport of warm air northwards makes the upper flow more anticyclonic and increases the acceleration of air out from the region; the transport of cold air southward makes the flow more cyclonic and weakens the acceleration of the wind. (d) The changes in the pressure field lead to an increase in the wind divergence. A chain reaction has come under way with the pressure at lower levels falling, increasing the thermal transports and the amplification of the flow pattern

The opposite process, divergence of the wind at higher levels, creates pressure drops at low levels that often initiate the development of mid-latitude cyclones. There are various mechanisms causing upper-air divergence, the most common of which is when the wind is accelerated into or out of a jet stream. The wind is subject to a strong acceleration, partly reflected in the curvature of the wind flow, from a cyclonically (anti-clockwise) curved flow to an anticyclonically (clockwise) one in the Northern Hemisphere (Figure 23a).

If the air leaving a region is not replaced by the same amount of air coming in, this is felt at lower levels as a drop in pressure. As the wind at lower levels adjusts to the pressure field, a cyclonic circulation is created (Figure 23b). This circulation affects the temperature distribution, which close to jet streams is normally characterized by strong horizontal temperature differences.

East of the low-pressure system the wind at lower levels transports warm air poleward. Pressure decreases more slowly upward in warm air and the influx of warm air increases the pressure at upper levels. This intensifies the anticyclonic circulation at upper levels and accelerates the wind even more. As a consequence, more air is exported out of the region (Figure 23c).

To the west of the low, the induced wind circulation transports cold air equatorwards. Because pressure decreases more rapidly upward in cold air, the influx of cold air decreases the pressure at higher levels and intensifies the cyclonic (anticlockwise) circulation. The increased curvature of the airflow further slows down the wind velocity and less air is imported into the region.

With more air exported, and less air imported, the pressure at lower levels will continue to fall, the circulation around the low-level system will intensify, and so will the transport of warm air northward and cold air southward (Figure 23d). A chain reaction has started that leads to a major storm development with strong winds circulating around the low pressure area, warm air rising above cold air at the front of the system, and cold air sinking below warm air at the rear of the system. It comes to an end when the circulation has spread from lower levels to higher levels and established the warm air in a position above the cold air.

Upper air divergence can also be caused or enhanced by latent heat release when moist air condenses. The heating of the air raises the pressure at higher levels and further enhances the upper outflow of air. This is the main driving mechanism in tropical and subtropical storms, but also plays an important role in extra-tropical developments. The latent

heat release at the right entrance of the jet maintains the thermal contrasts in the upstream part of the jet and keeps it in a westerly position where new cyclones can form. This can lead to a succession of frontal cyclones forming and, within a couple of days, to the creation of a cyclone family.

Downstream Development

The kinetic energy released during the cyclonic development takes two routes: one into the storm itself, where it is soon to a large extent lost in the frictional process at the Earth s surface; the other route into the mid- and upper-troposphere jet winds where it is rapidly transported downstream. Arriving in the next system downstream, these huge amounts of energy can have a profound effect, either directly or through conversion back to potential energy through the action of the fV (forcing the PGF to do negative work on the air). Although the density of the air in the upper troposphere is only 1/3 of the density at the ground, the wind velocities are about ten times stronger, which makes the kinetic energy 30 times larger. The kinetic energy of an upper level jet stream of $60\,m\,s^{-1}$ is the same as a hurricane force wind at the ground of $35\,m\,s^{-1}$.

When the downstream storm develops, which receives the energy in the same way, it transports part of its released kinetic energy into the next system downstream, and so on. As long as the dynamic conditions are favorable, the influence of one storm rapidly spreads downstream to the next in a hemispheric domino effect (Figure 24). The speed of this downstream development is roughly $30\,m\,s^{-1}$, which corresponds to $30^{\circ}\,day^{-1}$ at 45° latitude, but slightly less in summertime. This should be compared with the typical phase speed of $10^{\circ}\,day^{-1}$ of a normal frontal cyclone wave. In the Southern Hemisphere the typical velocity of the downstream influence is $40^{\circ}\,day^{-1}$ due to the predominant zonal flow.

The fact that the influence of a weather development spreads three times faster than the weather system has consequences for weather forecasting. A five day weather forecast for Europe is dependent on the initial atmospheric conditions over North America, a five day forecast for North America on the conditions over the Northwest Pacific, although the weather systems in those areas may not necessarily arrive in the target area.

Cut-off Lows and Blocking Highs

The downstream development not only deepens cyclones, it also amplifies high-pressure systems. A strong explosive cyclogenesis creates strong pressure differences high up in the troposphere that force the jet stream poleward and helps to amplify a downstream ridge. The poleward transport of warm air further increases the pressure and supports the creation of a high pressure system through a deep vertical layer, a so called *blocking high*. The upper current moving over the ridge, partly due to the anticyclonic curvature, accelerates and make the fV stronger than the PGF. The wind, thus driven towards higher pressure by the fV, creates a low-pressure system, a so-called cut-off low (Figure 25).

Flow Patterns Forced by the Earth's Surface

The uneven heating and cooling of the oceans and the continents also contribute towards shaping the large-scale

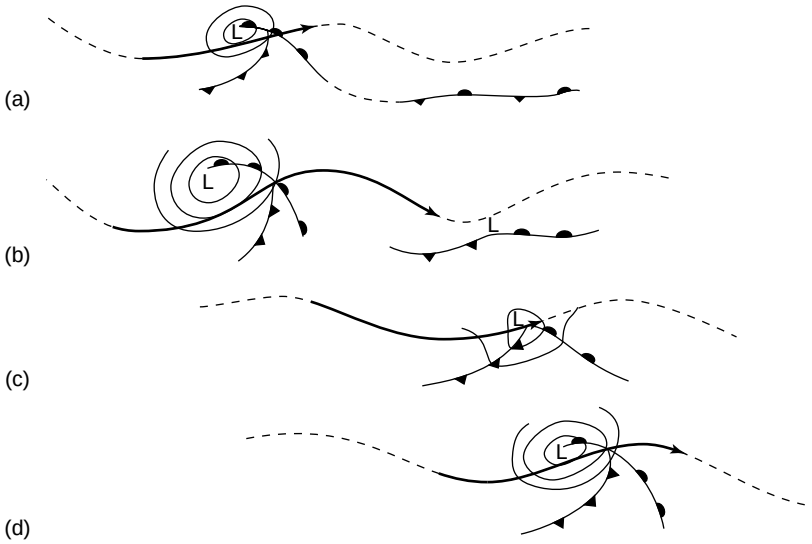

Figure 24 Down stream development. The kinetic energy released during the development of one storm (a) is transported downstream in the jet stream (b) and in a short period of time affects the next system (c),which then during its development releases additional kinetic energy into the upper tropospheric flow (d)

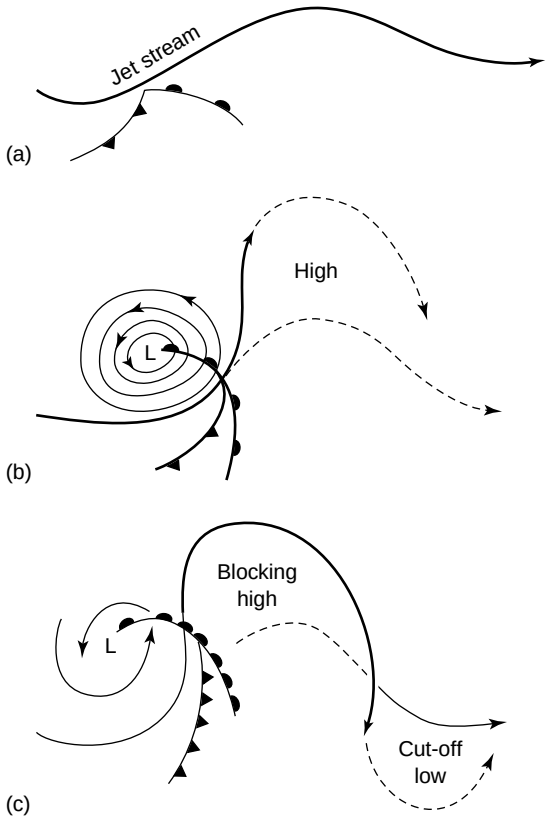

Figure 25 (a) Blocking highs tend to develop as a response to explosive cyclones. (b) When huge amounts of kinetic energy are ejected into the upper atmospheric flow, bringing into a new direction and often amplifying a downstream high pressure system. (c) When the strong winds in the free atmosphere reach the downstream side of these amplified high pressure systems, there is a tendency to form low pressure circulations, so called ''cut-off lows''

flow over the Earth. In wintertime there is a strong cooling over the continents due to radiative losses. The cooled air has a general tendency to sink. This sinking motion is associated with upper inflow and, in line with the ice skater effect, cyclonic circulation. At lower levels there is outflow and anticyclonic circulation.

When the cold air is transported out over surrounding warm ocean waters, which normally are to the east of the continents, there is widespread and intense rising motion due to heating from below. This creates favorable conditions for low pressure and low level cyclonic circulation. Cyclones develop easily and strongly by drawing from these thermal contrasts, which are found in the western Atlantic and the northwest Pacific. In summertime the heating of the continents contributes to rising motion with low level inflow and upper level outflow, with a tendency for anticyclonic circulation.

Another influence, which contributes to the shape of the large-scale flow, is from the major mountain ranges. The atmospheric flow tends to accumulate air on the windward side, creating or strengthening a PGF across the mountain. This accelerates the wind to an extent that the fV becomes stronger than the PGF on the lee-side of the mountain ridge. The wind therefore starts to deviate towards higher pressure and, similar to the cut-off process described above, creates a cyclonic circulation and a low-pressure system. The tendency to have cyclonic shaped flow in the lee of major mountain ranges facilitates the development of cyclones in this area, whereas there is a enhanced tendency for high pressure systems on the windward side.

The waves generated by a combination of land-sea contrasts and the orography, further enhanced by cyclone developments where the dynamic conditions are favorable, ultimately create geographically very large waves or weather zones, so called Planetary or Rossby waves (*see* Rossby Waves, Volume 1). They are responsible for periods of persistent dry or wet, cold or warm weather types. The so called *beta-effect*, the latitudinal variation of the fV, is particularly prominent in systems of large north–south extent and may make the waves become stationary and even move slowly westward, against the general current (*see* Coriolis Effect, Volume 1).

A SUMMARY OF THE ATMOSPHERIC CIRCULATION

A simple two-dimensional summary of the general circulation of the atmosphere must be accompanied by some words of caution when the picture is interpreted. As was discussed in the Introduction, average values do not necessarily represent what is typical and it is not normally possible to deduce the path of air particles from average wind fields.

Two Ways to Look at the Meridional Circulation

The commonly depicted, tri-cellular, cross-section of the atmosphere with rising motion in the tropics and the mid-latitudes, sinking motion in the polar regions and subtropics should not be interpreted as showing the approximate path of any individual air parcel. The cross-section is based on averages of winds in fixed locations (called Eulerian averages) (Figure 26a). A picture of the average routes of air parcels can only be accomplished by averaging in terms of trajectories (called Lagrangian averaging). If one wishes to determine the likely spread of a pollutant in the atmospheric circulation, the Lagrangian view would give a much better idea than the Eulerian (Figure 26b).

The Eulerian and Lagrangian methods do not necessarily have to show different pictures. Due to the steadiness of the Hadley cell, the two averages portray similar pictures of the rising branch within the summer hemisphere and large mass transports into the winter hemisphere. But at subtropical and middle latitudes, where the motion is more complicated (see

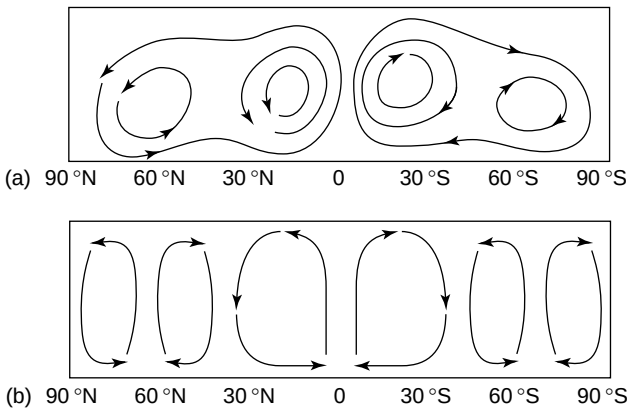

Figure 26 Cross sections of the atmospheric circulation using: (a) Lagrangian averages; (b) Eulerian averages. A common mistake is to visually interpret the Eurlerian average, which denotes streamlines, as if it were Lagrangian, which represents the tracks of individual air parcels (trajectories)

Figure 11) the two averages display very different images. Instead of three cells in the Eulerian picture, the Lagrangian view depicts one single cell extending from the tropics to polar latitudes.

Correlated Fields

The (Eulerian) average wind flow depicts rising motion at mid-latitudes between 50° and 70°, sinking at subtropical latitudes around 35°. Because the air is colder at higher latitudes than lower, such a circulation seems to imply rising of cold air and sinking of warm, which would imply an increase in potential energy. This interpretation has supported the notion that between the Polar Cap cell and the tropical Hadley cell, both sources of kinetic energy, there is a third cell, the *Ferrel cell*, that is supposed to convert kinetic energy back to potential. But this notion of a mid-latitude cell is due to a misinterpretation of statistics.

It is true that the 50° – 70 °latitude band has a tendency for upward motion, but these are mostly associated with rising tongues of warm air in connection with passing cyclones. The same applies for the subsidence around 35° subtropical latitude, which is associated with outbreaks of cold air that are generally associated with sinking motion (Figure 27). The relevant correlation, the one which can be given a physical interpretation, is not between mean values, but between instantaneous values of temperature and vertical velocity.

The Atmosphere's Energy Budget

The interpretation of the atmosphere s energy budget must be done with care. On a long-term average, the potential energy of the atmosphere is converted into kinetic, which, in turn, is lost in friction against the Earth s surface and internal friction (viscosity) (Figure 28a). On average, the contributions from the Sun to the potential energy makes up for the average loss in friction. However, this is the

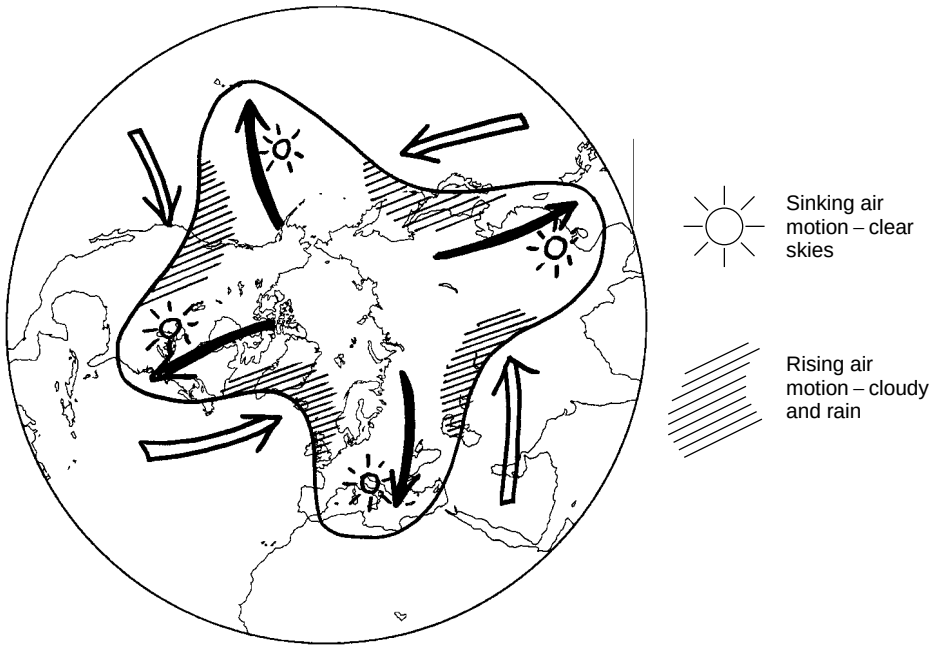

Figure 27 Advances of warm air poleward is often associated with rising motion (denoted by hatching symbolizing precipitation) whereas cold outbreak to low latitudes often are accompanied with sinking air and rather cloudless conditions (here symbolized with a sun)

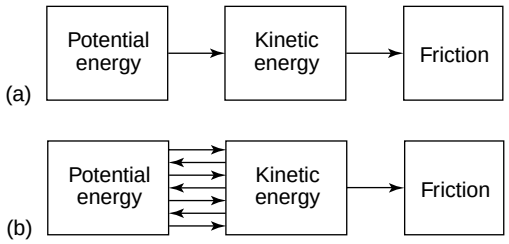

Figure 28 (a) The net energy budget shows that potential energy is lost to kinetic energy, which in its turn is lost to friction. (b) Only the kinetic energy to friction conversion is irreversible, the potential to kinetic is highly reversible

net effect, or budget, and does not necessarily tell what is going on at every moment at any place where there is a constant conversion between potential and kinetic energy (Figure 28b).

In the atmosphere, it is the subtropical high pressure belts that act as sources for kinetic energy; the low pressure systems in the mid-latitudes act as sinks for kinetic energy due to frictional losses. But before the kinetic energy is lost to friction, it has been recycled several times through reversible conversions between potential to kinetic energy in the mid-latitude cyclones, most clearly reflected in the downstream development process.

A schematic cross-section of the atmosphere is given in Figure 29. The Hadley cell circulation should be seen as a longitudinally elongated spiral into the diagram where air rising at one longitude descends at another far downstream. Due to the seasonal variations of the maximal heating from the Sun, the Hadley cell is slowly oscillating around the equator and also varies in intensity.

The fronts and jet streams in the westerlies are drawn in a way to suggest their general orientation from WSW to ENE. The vertical motion in the area might on average be upward, but, again, this is just the net result of very strong up- and downward motions.

The Stratosphere

The flow in the lower stratosphere, the part of the atmosphere at 10–25 km height, is generally characterized by a rising motion of cold air from the equatorial belt in the summer hemisphere to a sinking motion of warmer air in the mid-latitudes and around the poles. With this circulation, converting kinetic energy into potential energy, its energy cycle differs considerably from that of the atmosphere as a whole. It is rather like a heat engine in reverse, or a thermodynamic refrigerator. This can only come about through mechanical forcing, and it is the motions in the atmosphere below that provide this mechanism (*see* Stratosphere, Temperature and Circulation, Volume 1).

However, the stratosphere also has dynamics of its own where instabilities create strong vortices or blocking highs, so called *sudden warming*. The dynamics of the stratosphere is further complicated by a complex interaction between radiative, dynamical and photochemical processes in the ozone layer.

The stratosphere has been under intense study since it was discovered 100 years ago, still new discoveries

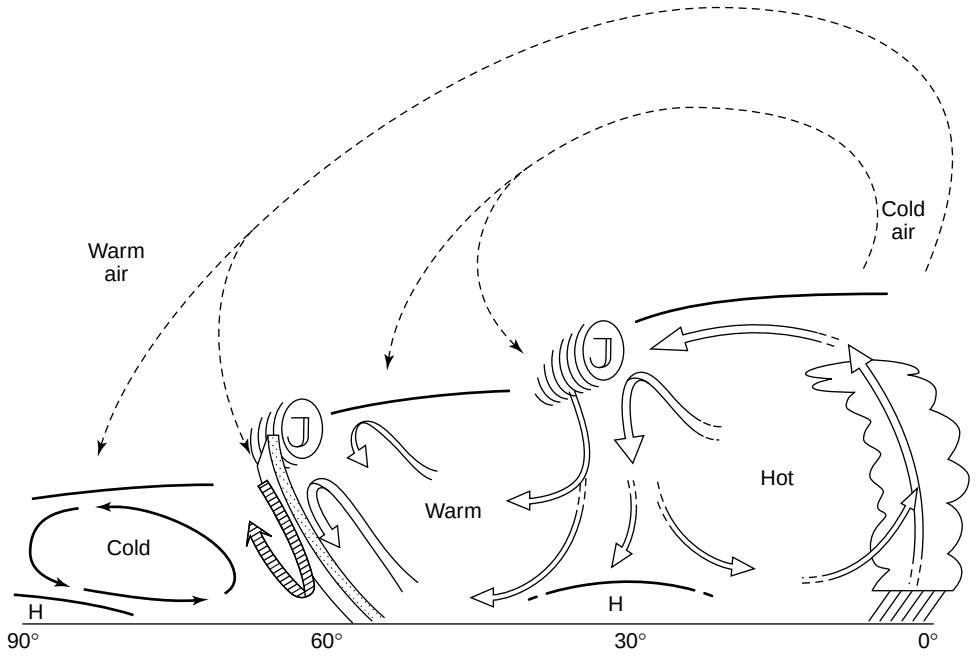

Figure 29 A schematic cross section of the atmosphere (troposphere and lower stratosphere)

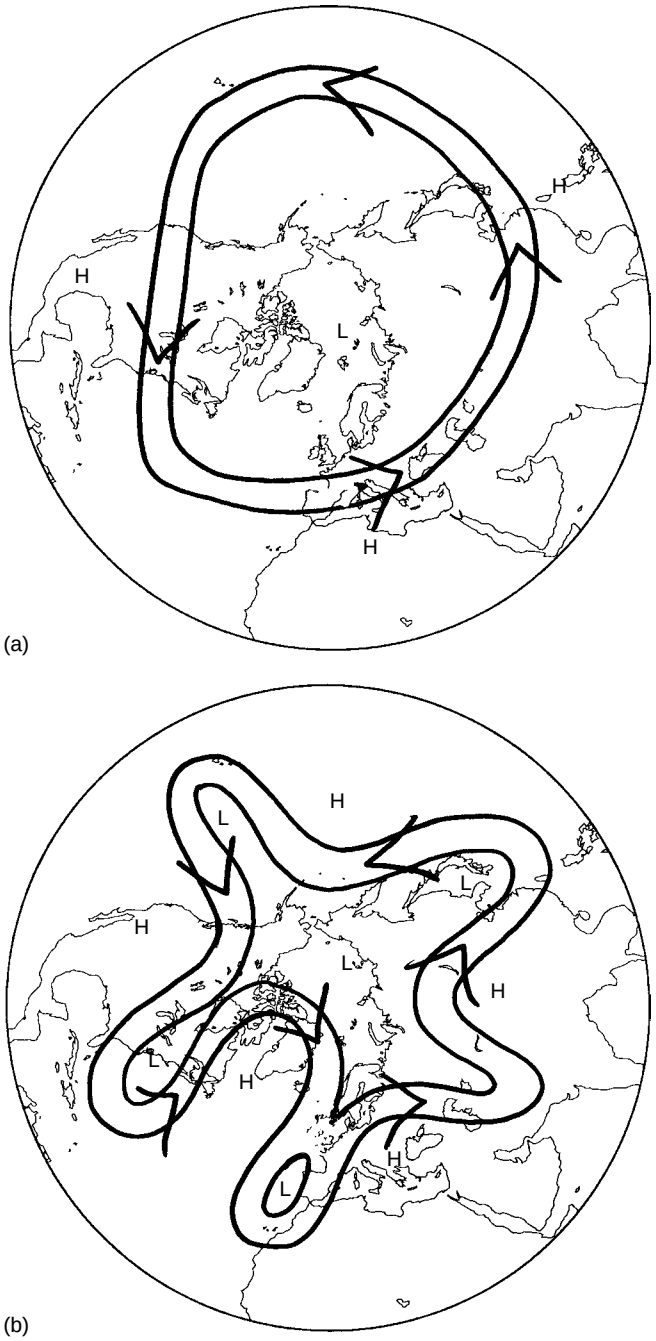

Figure 30 The atmospheric flow vacillates between two regimes, (a) one zonal (mostly east-west flow) and (b) one meridional (much north-south flow) with pronounced high pressure formations (''blocking'') and small, isolated low pressure systems (''cut-offs''), both created when there are strong imbalances between the pressure field and the winds

are made almost every decade. So for example, a 26-month oscillation in the upper winds has been found in the tropics. This Quasi-Biennial Oscillation (QBO) is still not fully understood, nor the general interaction between the stratosphere and the underlying atmosphere (*see* Quasi- Decadal Oscillation, Volume 1). There are still discoveries to be made and surely many surprises in store!

Can the Atmospheric Flow Change?

There has been much research into the dynamics of the large-scale flow to acquire a deeper understanding of past climate changes (the ice ages) and possible scenarios for the future. It is not yet clear why the atmospheric flow can be anomalous for relatively short periods like several months or years. Why were the mid-1990s characterized by dry conditions over Western Europe, why have the last five years been wetter than before?

One process where an understanding is growing concerns the mechanisms that induce wave patterns because the land-sea contrasts and the orography may not necessarily pull the atmosphere in the same direction. There is also a seasonal variation in the land-sea contrast, which is only slightly evident in the orographic forcing. Due to this misfit, the large scale flow is never quite in a stable state and tends to vacillate between two preferred states: one relatively straight zonal type with a well-developed and fairly broad westerly current in middle latitudes, and the other large meridional flow patterns which extend meridionally with strong cyclonic vortices at low latitudes and anticyclonic flow at high latitudes (Figure 30). Each pattern persists for several weeks, whereas the transition from one to the other is relatively brief.

There are reasons to assume that the typical flow regimes that we regard as normal might be just one of several possible quasi-stable states of the atmosphere. Any change of the overall temperature of the atmosphere will most likely change the flow pattern as well. This might have unexpected consequences; an over-all warming of the atmosphere might lead to some regions getting colder temperatures due to the change of flow regimes. This can only be fully understood if the motion of the general circulation also includes the motions of ocean currents. It might be that neither the atmosphere nor the oceans can undergo any radical changes on their own, they might only be able to change if they change together.

Atmospheric Structure

Peter Brimblecombe
University of East Anglia, Norwich, UK

Atmospheric structure is usually represented in terms of temperature pro les which de ne the boundaries of the troposphere and stratosphere. It is also possible to describe the structure of the atmosphere in terms of composition. The best known example of this is the ionosphere where free electrons abound. However, high in the atmosphere gases separate gravitationally (heterosphere) and at its extreme edges (exosphere) molecules so rarely collide that they can undergo ballistic trajectories and escape from the atmosphere.

The atmosphere appears to be a transparent gas and initially devoid of obvious structure. However, more careful examination reveals that there are layers. Clouds, especially those with flat bases make this fairly obvious.

Although there is a gradual decrease in pressure with altitude, it is the thermal changes with altitude that are most often used to define structure. Through the lowest part of the atmosphere, the troposphere, temperature decreases with altitude at about $6.5\,^{\circ}\mathrm{C\,km^{-1}}$ (*see* Lapse Rate, Volume 1). Air closest to the ground is warmest and this is the region we are most familiar with. It is here that our weather takes place. Convection can be active in the troposphere and is dramatically seen in the formation of thunderclouds. At times, air close to the ground can become cold, particularly at night. Under these *inversion* conditions, the air is resistant to vertical mixing, pollutants can accumulate or fogs can form.

Higher up in the atmosphere the absorption of radiation by the ozone layer warms the atmosphere. Thus, temperature increases above the *troposphere* (Figure 1), in a layer called the *stratosphere*. The increase in average temperature with height means that the stratosphere is very stable with respect to vertical mixing, hence the tendency for well defined strata of air to form. Yet it is so cold that water is present in very small amounts and clouds are very rare and

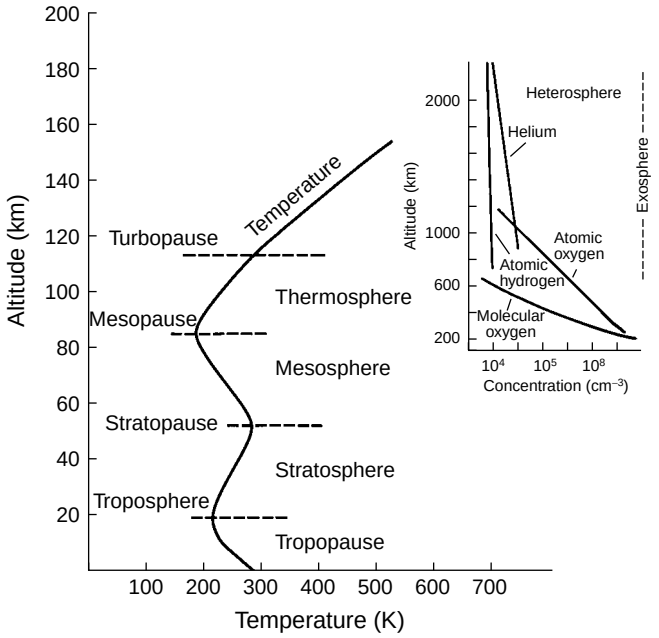

Figure 1 The structure of the atmosphere. Note how the boundaries at the top of each of these layers are called the tropopause, stratopause, mesopause. (Adapted from Andrews *et al.*, 1996)

consist of sulfuric and nitric acid containing droplets or icy crystals.

Above the stratosphere, the air cools again in the *mesosphere*. Here, noctilucent clouds can be observed in the summer at high latitudes. These are formed through water nucleation onto dust or ions, possibly from meteor trails, which penetrate the mesosphere. The water probably derives from the photooxidation of methane, which has led to speculation that increases in atmospheric methane has caused an increase in the frequency of noctilucent clouds.

Even higher, we encounter the *thermosphere*, where the atmosphere has a very low density and the molecules are warmed by direct impact of hard photons from the Sun. Its high temperature is sensitive to output of solar radiation, which varies as the Sun passes through its quiet and active phases every 11 years. Although the temperatures are very high, the gas is so tenuous that it carries little heat, so does not control the temperature of objects such as spacecraft operating at these altitudes.

There are other ways we can define atmospheric structure. The lower atmosphere is well mixed, where turbulent processes are stronger than the gravitational settling of the gases. The top of this well mixed part of the atmosphere, above which gases settle out dependent on their molecular weight, is called the *turbopause*. Below the turbopause the atmosphere is often termed the *homosphere* where the gases are well mixed. Above the turbopause it is called the

heterosphere where we find the light gases beginning to dominate at the top of the atmosphere (Figure 1).

The inset of Figure 1 shows the heterosphere and we can see that the gases have separated out due to gravitational settling, but many are not the familiar gases we know at ground level (*see* Atmospheric Composition, Present, Volume 1). Even oxygen and nitrogen are not in their familiar diatomic form. The photodissociative processes at high altitude break the molecules down into atoms, thus, at the very top of the atmosphere we find a dominance of hydrogen and helium.

These divisions of the atmosphere have only considered the neutral molecules. The upper atmosphere is affected by ions in a region known as the *ionosphere*. These ions are at relatively low concentration, but their effects are so pronounced that they have been much studied. In particular the way they affect radio waves has been of importance for much of the 20th century. The ionosphere is structured into a number of regions. Early studies used radio waves as probes, which detect changes in electron density in the upper atmosphere. This meant that early studies focussed on the electron distribution of the ionosphere, although scientists were well aware that the charge would be balanced by positive ions. The advent of rockets allowed the positively charged species to be identified.

In the upper atmosphere incoming meteors, although contributing only small amounts of material, have noticeable effects because the atmosphere is so tenuous. As the meteors ablate volatile materials such as water they leave a trail. In addition, less volatile materials such as sodium, magnesium and iron are ablated and form distinctive layers.

At the very outer extent of the atmosphere we encounter the *exosphere*. Here, the gas is so tenuous that molecules follow ballistic trajectories, kilometres in length before colliding with another molecule. Some of the molecules travel so fast that their ballistic trajectories at thermospheric temperatures allow them to escape from the atmosphere completely and become lost to space. In the case of the upper atmosphere of the Earth it is hydrogen and to a lesser extent helium that escape with residence times of about a thousand and many millions of years, respectively. The rapid escape of hydrogen is important as it allows atmospheres to become more oxidizing over time.

Bjerknes, Jacob

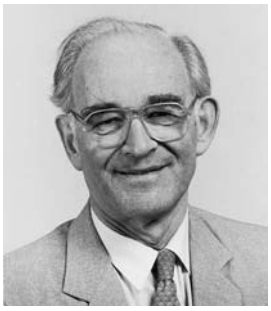
(1897- 1975)

Jacob Aall Bonnevie (Jack) Bjerknes, perhaps now best known for his work on ocean–atmosphere interaction, especially El Niño and the Southern Oscillation (ENSO), was one of the founders of modern theoretical and forecast meteorology. He was part of the Bergen School directed by his father, the theoretical physicist Vilhelm Bjerknes. This group was influential in changing meteorology from a largely observational science to one grounded in physical principles. Bjerknes 1918 paper, *On the Structure of Moving Cyclones*, written at age 20, introduced his frontal cyclone model. This theory, extended in a 1922 paper (with H Solberg), *The Life Cycle of Cyclones and the Polar Front Theory of Atmospheric Circulation*, formed the basis for weather forecasting as well as explicating the principal mechanism for meridional heat transport in the mid-latitude atmosphere. In the 1920s and 1930s he further developed both theory and forecasting practice, including important extensions to waves in the upper troposphere.

Bjerknes 1939 lecture tour in the US became a permanent move after the German invasion of Norway. During the war he organized a training school for air corps weather officers. In 1940, Bjerknes began an association with the University of Los Angeles (UCLA) that lasted until his death. In 1945, the Department of Meteorology was established at UCLA with Bjerknes as head.

In the late 1950s, Bjerknes changed his research direction to ocean–atmosphere interaction. Based largely on data from the 1957 International Geophysical Year, he realized that an El Niño event, then thought of solely as a warming along the South American coast, typically involved a rise in sea surface temperature (SST) in the vast equatorial region from the coast to the dateline. He also noted that it was accompanied by all the atmospheric changes connected to a low phase of Sir Gilbert Walker s Southern Oscillation. In his 1969 and 1972 papers, Bjerknes went beyond the empirical connection to suggest that ENSO was part of a single coupled phenomenon generated by a chain reaction between the ocean and atmosphere in the tropical Pacific. Bjerknes was also the first to propose that the changes in atmospheric heating associated with tropical Pacific SST anomalies cause changes in mid-latitude circulation patterns, generating the global response Walker had found to be associated with the Southern Oscillation. His hypothesis, augmented by the linear ocean dynamics shown to be needed by the observational work of Klaus Wyrtki, is the foundation of our present understanding of ENSO (*see* El Niño and La Niña: Causes and Global Consequences, Volume 1).

MARK CANE *USA*



Bolin, Bert

(1925-)

Bert Bolin, Swedish scientist and science organizer, received a PhD degree in Meteorology at Stockholm University in 1956 based on a thesis dealing with the interaction between wind and pressure fields and its application to numerical weather prediction. His subsequent research has been mainly focused on global biogeochemical cycles and on the global carbon cycle in particular. His 150 scientific papers and books also include work on the use of chemical

and radioactive tracers in the atmosphere and in the sea, the acidification problem, atmospheric greenhouse gases and aerosols, and their role in determining the climate and impacts of climate change.

As a student of meteorology in the late 1940s and early 1950s, Bolin was supervised by Professor C-G Rossby (*see* Rossby, Carl-Gustaf, Volume 1), in whom he found long-lasting inspiration. Bolin was appointed Professor of Meteorology at Stockholm University in 1961, a position he held until his retirement in 1990.

Bolin served as president of the Committee of Atmospheric Sciences (CAS) of the International Council of Scientific Unions (ICSU) from 1964 to 1967, and was involved in the proposal for the creation of the Global Atmospheric Research Programme (GARP). In 1967 he organized the scientific planning conference that led to the launching of GARP jointly by ICSU and the World Meteorological Organization (WMO). He served as the first president of the Joint Organizing Committee (JOC) of GARP from 1967 to 1971. As a member of JOC he organized the first international conference for the formulation of a World Climate Research Programme (WCRP), which was later launched in 1980.

In 1970 Bolin took the initiative leading to the preparation of Sweden s Case Study for the United Nations Conference on the Human Environment, held in Stockholm in 1972. This case study contained the first comprehensive description of the acid deposition problem that had then recently been discovered.

Bolin took part in the first assessment of the climate change issue in 1979, organized by the US National Academy of Sciences. He later led the first broad international assessment (1983–1986), which was asked for by the United Nations Environmental Programme (UNEP), WMO and ICSU. The final report adopted in 1985 served as one of the basic documents in the preparation of the UN Report *Our Common Future: The Brundtland Report.*

Bolin served as chairman (1985–1986) for the committee that proposed the initiation by ICSU of the International Geosphere-Biosphere Programme (IGBP), launched in 1986.

Despite the many previous important achievements as organizer of international scientific cooperation, Bolin s most fundamental contribution in this field is probably his role in leading the Intergovernmental Panel on Climate Change (IPCC) (*see* Intergovernmental Panel on Climate Change (IPCC): an Historical Review, Volume 4), which was set up in 1988 by UNEP and WMO. Under Bolin s leadership (1988–1997) IPCC produced two major assessments of the climate change issue (1990 and 1995). With his deep and broad knowledge of the subject, his moral integrity and his engagement, Bolin represented the community of climate scientists in an outstanding way in the transfer of information to the policy makers during the critical early period of international negotiations on a climate convention.

Bolin is a member of some ten science academies and has received numerous awards including the International Meteorological Organization (IMO) Prize from WMO in 1981, the Tyler Prize from the University of California, USA in 1988, and the Blue Planet Prize from the Asahi Glass Foundation, Japan in 1995.

HENNING RODHE *Sweden*

Broecker, Wallace S

(1931-)

Wallace Smith Broecker is a renowned chemical oceanographer and one of the foremost interpreters of how the Earth operates as an intercoupled biological, chemical, and physical system. He is particularly well known for utilizing isotopic tracers to document his conceptualization of the global ocean circulation as a giant conveyor belt that is driven in large part by conditions in the North Atlantic Ocean.

Broecker was born in Chicago, Illinois on November 29, 1931. After completing his first 3 years at Wheaton College in Wheaton, Illinois, Broecker took a summer job at the Lamont–Doherty Geological Observatory (now Lamont–Doherty Earth Observatory, LDEO) and he has stayed on throughout his entire career. He completed his senior year of undergraduate work at Columbia University and received his AB Degree in 1953. Broecker s research at LDEO, working with carbon-14, provided the basis for his dissertation research, and he received his PhD from Columbia in 1958. He was appointed assistant professor at Columbia University in 1961, and full professor in 1977. Since 1979, Dr Broecker has been the Newberry Professor of Geology.

Broecker began his research in the 1950s with the development of techniques for measuring the radiocarbon content of ocean waters, and using this information to determine the ages and accumulation rates of deep sea and lake sediments. Broecker also developed techniques for using uranium daughter products as time clocks and environmental tracers, thereby creating new tools for use in paleoclimatic studies. Using such techniques, Broecker and his colleagues dated marine shells, for example, found in sediment deposits on the sea bottom, contributing to reconstruction of glacial and interglacial periods and transitions.

Broecker pioneered the study of the circulation of chemical elements in the sea, which provided detailed information about the mixing of surface and deep waters of the ocean that takes place over periods of 1000–2000 years. Urged on by oceanographer Henry Stommel, Broecker was instrumental in the creation of the Geochemical Ocean Sections (GEOSECS) program. This program, carried on in the 1970s, gathered a wealth of isotopic information about the world s oceans, providing a much clear picture of how ocean waters circulated. Broecker s book *Tracers in the Sea*, published in 1982 and co-authored with T H Peng, has become an indispensable guide for geochemists. Using the accumulated base of isotopic information, Broecker constructed a theory of the global ocean circulation, often termed the conveyor belt (*see* Ocean Conveyor Belt, Volume 1). Not only do the isotopic tracers indicate the path taken, but also sediment records can be used to determine the speed of the conveyor belt and to identify periods when it has essentially stopped.

While researching changes in the Earth s climate that occurred in the past 200 000 years, Broecker discovered that major climate shifts may have occurred much more rapidly than previously had been believed possible. For example, Broecker and colleagues found that temperatures in Northern Europe suddenly plummeted about 11 000 years ago and remained low for about 1000 years before snapping back to the warm conditions that exist today. The actual transition from the prevailing warm conditions to the cold conditions of the Younger Dryas (*see* Younger Dryas, Volume 1) may have taken as little as 20 years. Broecker has suggested that this cold spell was caused by a temporary disturbance in the global circulation of the world s oceans (*see* Thermohaline Circulation, Volume 1). Because this global current is linked in complex ways to the atmosphere and the precipitation cycle, he has suggested that the carbon dioxide (CO_2) emissions from fossil fuel combustion could trigger a major disruption of this circulation, causing a significant disturbance of at least the climate of the North Atlantic region, particularly Europe, although he thinks such transitions may not be as likely during warm climatic conditions as during cold conditions.

Broecker s interest in the carbon cycle began early in his career, often working with his colleague Taro Takahashi. In 1965, Broecker served, along with Roger Revelle, C D Keeling (*see* Keeling, Charles David, Volume 1; Revelle, Roger Randall Dougan, Volume 1), Harmon Craig, and Joseph Smagorinsky, on a panel that advised the President s science advisory committee panel on environmental pollution on the emerging issue of the growing concentration of atmospheric CO_2, the first such recognition of this issue by the US government.

A key area of study has been the uptake of carbon by the oceans, which could be tracked using tracers of various types. For example, in the 1980s, Broecker and colleagues used information about the distributions of radioactive fallout from nuclear bomb tests conducted in the 1960s as chemical tracers to study the rate of uptake of fossil fuel CO_2 by the ocean. More recently, Broecker has organized the research program for Biosphere 2, a very large glass house in Arizona that originally was home to the Biospherians, but is now used for scientific research about how increased CO_2 concentrations may affect ecosystems (e.g., how higher CO_2 levels will alter the oceanic composition in ways that weaken coral structures).

In recognition of his wide-ranging studies, Broecker has received many honors. He was elected a member of the US National Academy of Sciences in 1979, and has been a member of the American Academy of Arts and Sciences since 1976. Broecker was the recipient of the Maurice Ewing Medal in 1979, the Arthur L Day Medal in 1984, the AG Huntsman Award for Excellence in the Marine Sciences in 1985, the Urey Medal, the Alexander Agassiz Medal, and the UM Goldschmidt Award in 1986, the Vetlesen Award in 1987, the Joseph Priestly Award and the Wollaston Medal in 1990, and the American Geophysical Union s Roger Revelle Medal in 1995. In 1996, he was named winner of the Blue Planet Prize for his achievements in global environmental research, an honor equivalent in this field to winning the Nobel Prize.

MICHAEL C MACCRACKEN *USA*

Budyko, Mikhail Ivanovich

(1920-)

Mikhail Ivanovich Budyko is an internationally recognized Russian (Soviet) environmental scientist whose work has focused on the study of natural and anthropogenic climate change, surface hydrology, and the Earth s radiative balance. He is a pioneer in the development of the theory of anthropogenically induced greenhouse gas climate change and a leader in the field of climatological studies of the thermal balance of the Earth s surface.

Budyko received his Master of Science degree in 1942 from the Physics Division of the Leningrad Polytechnic Institute. He was first employed as a researcher in the Voeikov Main Geophysical Observatory (MGO). While at the MGO, Budyko developed a procedure to calculate the components of the thermal balance of the Earth s surface, including a method that allowed calculation of the components of the heat balance from measurements of the lapse rate of atmospheric temperature and the humidity of the surface layer of the atmosphere. Using these techniques, Budyko compiled the first maps of the components of the annual thermal balance of the southern European part of the USSR, determined the latitudinal distribution of the thermal and moisture balance components of land and ocean surfaces for the Northern Hemisphere, and established the factors governing the characteristics of this distribution. In 1951, Budyko received the degree of Doctor of Science from the MGO, and in 1954 he was chosen to be its Director. In his follow-up research, Budyko developed a method for calculating the radiation balance of land from data on the water balance. For his work on the thermal balance, Budyko was awarded the Lenin National Prize in 1958.

As early as 1961, Budyko recognized the possible initiation of anthropogenic global warming. Primarily through analysis and interpretation of observational data, Budyko developed a quantitative relationship between surface temperature and incoming solar radiation, which he used to formulate one of the earliest one-dimensional global climate models, the *energy-balance model* (*see* Energy Balance Climate Models, Volume 1). Using it he deduced that the Earth s climate might be sensitive to small disturbances in the radiative balance. In 1964, Budyko became a corresponding member of the Academy of Sciences of the USSR.

Since 1970, Budyko and his colleagues have carried out theoretical and experimental investigations to explore the dependence of the photosynthetic productivity of agricultural crops on the principal meteorological factors. Also, the thermal conditions of people in different climates have been studied by calculating the thermal balance of a person s body. For this research Budyko received the Professor Lithke Gold Medal of the Russian Geographical Society in 1972.

Since 1975, Budyko has led research at the Department for Investigating Climatic Changes and the Hydrologic Cycle of the Atmosphere in the State Hydrological Institute (Leningrad). Since 1980, he has taken the lead in applying the paleoanalog approach to project future anthropogenic global warming. By doing this Budyko opened the possibility of estimating climate sensitivity via the reconstruction of greenhouse gas radiative forcing and retrieving past global temperature changes for the same periods. In 1987, Budyko was awarded the International Meteorological Organization (IMO) Prize by the World Meteorological Organization (WMO). In 1989, the Russian Academy of Sciences awarded him the A P Vinogradov Prize, and in 1991 he received a Diploma of the First Degree from the Russian Knowledge Society. In 1992, Budyko became an Academician of the Russian Academy of Sciences, and in 1995 he won its A Grigoryev Prize.

Since 1972, Budyko has played an important role in studies of the greenhouse effect under the auspices of Working Group VIII of the US-USSR Bilateral Agreement on the Protection of the Environment. In 1994, Budyko received the Professor R Horton Medal of the American Geophysical Union for his contribution to the study of the hydrologic cycle, and in 1998 he was awarded the prestigious Blue Planet Prize.

NATALIA G ANDRONOVA *USA*

C

Carbon Dioxide Concentration and Climate Over Geological Times

Elizabeth K Berner and Robert A Berner
Yale University, New Haven, CT, USA

The concentration of atmospheric carbon dioxide (CO_2) has been directly measured since 1958 and during this time has risen rapidly from 315 ppmv to 367 ppmv in 1998. The source of this rise is primarily anthropogenic fossil fuel emissions and to a lesser extent deforestation. Measurements of CO_2 concentrations in air bubbles trapped in glacial ice cores from Antarctica and Greenland have provided a means to extend the record of atmospheric CO_2 concentrations back in time. The concentration of CO_2 was about 280 ppmv in the pre-industrial era (before 1850) and varied only about plus or minus 10 ppmv during the preceeding 1000 years. Ice core data also provide a record of CO_2 and temperature changes for the last 400 000 years, including four glacial- interglacial cycles. CO_2 concentrations dropped 80- 100 ppmv during cold glacial periods to a glacial minimum of ~180 ppmv and rose to an interglacial maximum of 280- 300 ppmv accompanied by a glacial- interglacial surface temperature variation of about 12 °C at Vostok in Antarctica.

Atmospheric CO_2 concentrations from 500 000 to 550 million years ago varied considerably and generally were higher than any time during the past 500 000 years. Information about atmospheric CO_2 in this interval comes from a variety of indirect methods and the variations can be explained by models of the long-term carbon cycle. CO_2 is released by volcanoes and removed from the atmosphere by weathering of silicate rocks and the burial of organic matter. Warm climates are generally associated with high concentrations of CO_2 and cold climates with low CO_2 concentrations. Prior to 550 Myr during the Precambrian, CO_2 fell from very high concentrations shortly after the formation of the Earth to much lower concentrations about 0.5 Myr. This drop in CO_2 was accompanied by a rise in solar radiation and also a rise in atmospheric oxygen (O_2) resulting from the beginning of photosynthesis.

LAST 500 000 YEARS (HOLOCENE AND LATE PLEISTOCENE)

Atmospheric Carbon Dioxide (CO_2) Measurements Since 1958

Beginning in 1958, accurate direct measurements of atmospheric CO_2 have been made on top of Mauna Loa on the island of Hawaii by C D Keeling and associates (Keeling and Whorf, 1999). It has been observed that the CO_2 concentrations which began at 315 ppm in 1958 increased rapidly over time. By 1998, the CO_2 concentration measured was 367 ppmv (Figure 1). The growth rate of CO_2 in the atmosphere increased exponentially for much of the 20th century, except during World War II and since the late 1980s when the rate of increase was roughly linear rather than exponential. The source of this increase in atmospheric CO_2 is largely due to anthropogenic emissions from fossil fuel combustion and cement production, which amounted to about 6.5 gigatons of carbon per year (Gt C year^{-1}) in 1996 (Ledley *et al.*, 1999). The rise in atmospheric CO_2 tends to parallel fossil CO_2 emissions, providing support for isotopic evidence that associates the rise with anthropogenic emissions. Another smaller anthropogenic source is changes in forest storage of carbon due to deforestation which is thought to be partially balanced by forest regrowth (1.6 ± 1.0 Gt C year^{-1}). The CO_2 curve from Mauna Loa also shows a yearly cycle with a drop in CO_2 due to net photosynthesis and carbon storage during the Northern Hemisphere spring and summer and a rise in CO_2 due to net respiration or decay of plant material during the fall and winter.

Atmospheric CO_2 absorbs infrared radiation emitted by the Earth s surface and atmosphere. This tends to warm the atmosphere, which in turn reradiates energy back to the Earth s surface and lower atmosphere, keeping them warmer than they would be otherwise. This is commonly referred to as the *greenhouse effect*. The concern over

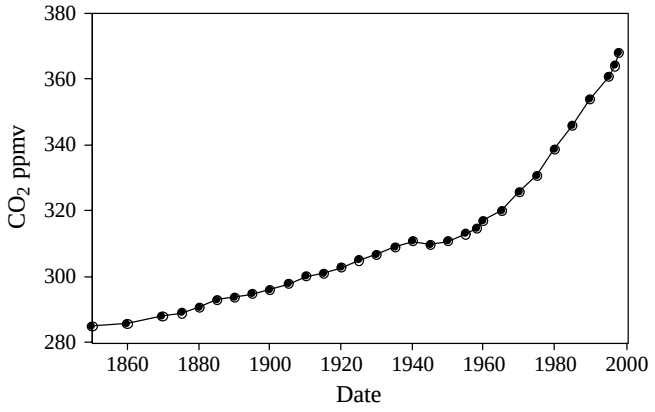

Figure 1 Atmospheric CO_2 concentrations in ppmv from 1850 to 1998. The data, beginning in 1958, are direct measurements made on Mauna Loa, Hawaii (Keeling and Whorf, 1999). The prior data comes from air bubbles in ice cores from Antarctica. (Reproduced using data from Hansen *et al.*, 1998)

possible global warming due to an enhanced greenhouse effect has led to attempts to determine how much change there had been in the CO_2 concentration since pre-industrial times (generally thought to be since about 1850) when anthropogenic changes became important.

Changes in Atmospheric CO_2 During the Industrial Era (1850 to Present) and in Pre-industrial CO_2 During the Last Millenium

Information about atmospheric CO_2 concentrations prior to 1958 comes from air bubbles trapped in glacial ice in Greenland and Antarctica. The ice must be unmelted, unfractured and not contaminated. Antarctic ice appears to yield more consistently reliable CO_2 measurements than Greenland ice. Recent ice core data are compared with direct atmospheric CO_2 measurements for verification. The ice data show a steep rise in CO_2 from about 280 ppm in 1800 to 315 ppm in 1958 when direct measurements began (Figure 2).

Pre-industrial CO_2 levels from ice cores over the last 1000 years vary about ± 10 ppmv from the average value of 280 ppmv (Barnola *et al.*, 1995). The largest change occurred from about 277 ppmv in 1200 AD to 285 ppmv around 1350 AD, followed by a slow decrease to 280 ppmv in 1800 during what was known as the Little Ice Age in medieval Europe (Barnola *et al.*, 1995). These natural changes are much smaller than the 75 ppmv increase during the industrial era (see Figure 2).

Another indication of the introduction of fossil fuel CO_2 to the atmosphere during the period 1800–1950 was the drop in the ratio of atmospheric ^{14}C to total carbon preserved in coral and tree rings in this interval. Fossil fuel contains no ^{14}C because it is old and the ^{14}C has been lost due to radioactive decay.

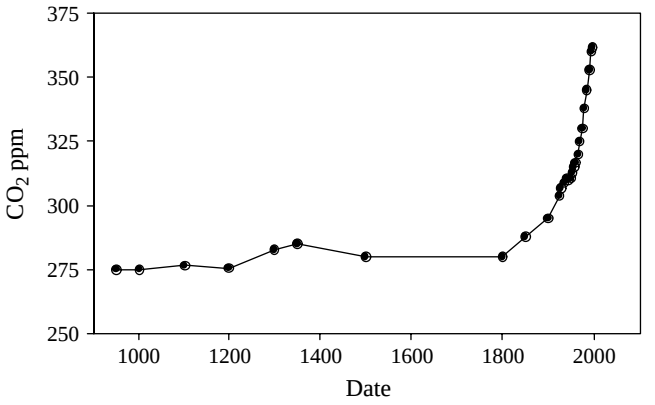

Figure 2 Atmospheric CO_2 from 950 until present based on ice core data until 1958. After 1958 the data is from direct measurements. (Reproduced using data from Hansen *et al.*, 1998; Barnola *et al.*, 1995)

Temperature Changes Since 1850 Compared to Changes Over the Past Millenium

Changes in the CO_2 concentration over the past millennium prior to the industrial period are very small so, not surprisingly, they do not correlate well with temperature changes (Barnola *et al.*, 1995), which are more controlled by changes in some of the various other factors that influence temperature. Surface temperatures would be expected to rise, however, in response to the considerable rise in atmospheric CO_2 over the last 150 years. Various authors have estimated an increased global mean annual temperature of 0.3–0.6 °C in this interval (Nicholls *et al.*, 1996). However, this temperature increase is not much greater than the natural variations in annual temperature due to various natural causes. Proxy temperature measurements such as retreat of valley glaciers (due to melting) also imply warmer temperatures. In addition, based on studies of proxy temperature indicators such as tree ring width and delta ^{18}O in ice cores, Mann *et al.* (1999) concluded that the late 20th century is anomalously warm in comparison with the rest of the millennium, and that the 1990s were the warmest decade and 1998 the warmest year of the past 1000 years. In addition, the 20th century warming overcame a millennium scale cooling trend, that may be due to long-term variations in solar radiation reaching the Earth due to changes in astronomical factors (Mann *et al.*, 1999).

Glacial–interglacial CO_2 and Temperature Changes from Ice Core Records for the Last 420 000 Years

When account is taken of time lags coupling temperature and the carbon cycle, changes in CO_2 and temperature correlate reasonably well over four glacial–interglacial cycles from Vostok, Antarctica, ice core records going back 420 000 years (Petit *et al.*, 1999). CO_2 concentrations

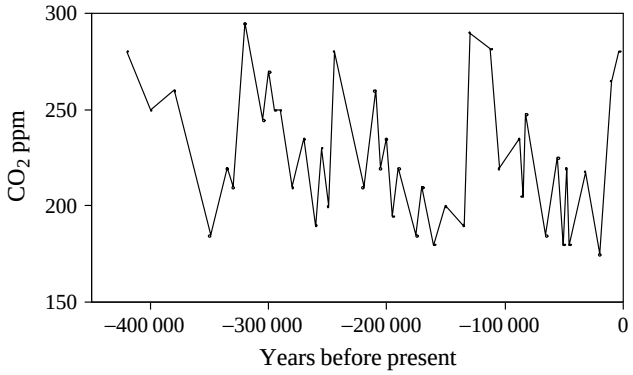

Figure 3 Atmospheric CO_2 for the past 420 000 years based on ice core data from Vostok, Antarctica. (Reproduced using data from Petit *et al.*, 1999)

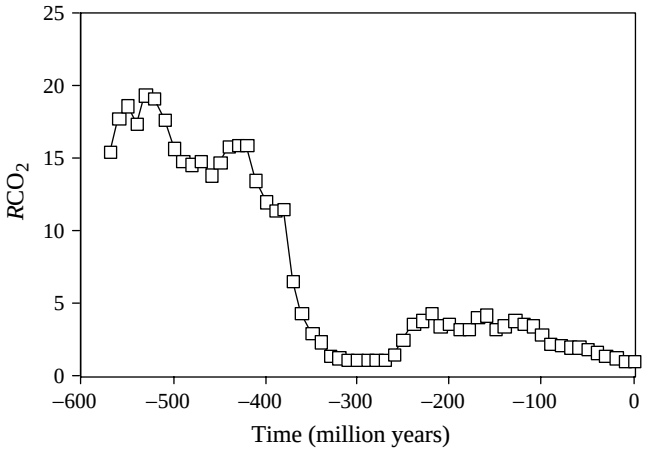

Figure 4 Atmospheric CO_2 over the past 550 million years. The parameter RCO_2 is the ratio of CO_2 at some past time to that for the pre-industrial present (300 ppmv). Results are based on the theoretical long-term carbon cycle model of Berner (1994) as amended by Berner (1997). The theoretical curve agrees, within modeling sensitivity error (±50%), with many different independent estimates of paleo-CO_2 (for a summary see Berner, 1997). Shorter-term CO_2 variations, such as what occurred around 65 million and 55 million years ago, cannot be discerned by the model because it calculates only longer-term average values

are generally lower by 80–100 ppmv during cold glacial periods than during warm interglacial periods (see Figure 3). The glacial–interglacial surface temperature variation (in Antarctica) as calculated from isotopic information in the Vostok ice record indicates a temperature range of 12 °C. CO_2 decreases more slowly to its minimum (~180 ppmv) during glacial times than it rises to its maximum (280–300 ppmv) during interglacial times. The drop in CO_2 occurs several thousand years after the temperature drop according to the ice core record. Methane (CH_4) concentrations also correlate with CO_2 and temperature in Antarctica. The maxiumum CO_2 concentrations recorded in the ice are 280–300 ppmv, considerably less than the present day CO_2 concentration of about 368 ppmv.

The correlation between temperature and CO_2 and methane concentrations suggests that these gases have contributed to glacial–interglacial changes by amplifying the effects of solar radiation changes resulting from variations in the Earth s orbital parameters (precession, obliquity, and eccentricity). The Earth s eccentricity has a strong ~100 000 year cycle that is particularly evident in the records of ice core temperature and gas concentration changes. The sequence suggested by Petit *et al.* (1999) during each glacial termination is that orbital forcing (due to changes in eccentricity) is followed first by amplification by greenhouse gases (CO_2 and methane) and then by deglaciation and ice-albedo feedback. (The melting of the glacial ice reduces the surface albedo, which increases absorption of solar radiation because ice is more reflective than bare earth; this warms the Earth).

CARBON DIOXIDE FROM 550 MILLION TO 500 000 YEARS AGO (PHANEROZOIC TIME)

The Phanerozoic Eon, or last half billion years of Earth history, is the period of time over which the vast majority of organisms we see today and in the fossil record arose and evolved. During this time, the level of atmospheric CO_2 varied considerably (see Figure 4) and most of the time it was higher than during the past half million years. The causes of this variation can be explained in terms of the long-term carbon cycle.

The Long-term Carbon Cycle

The term *carbon cycle*, as normally used, refers to the exchange of carbon between the atmosphere, oceans, biota (mainly terrestrial vegetation), and soils, and it is this cycle that has dominated the controls on atmospheric CO_2 over the past 500 000 years and which acts as a modern sink for anthropogenically produced CO_2. However, there is another cycle that operates more slowly over millions of years and during which it dominates CO_2 concentration. It is the long-term carbon cycle. According to this cycle carbon is exchanged between rocks and a surficial reservoir made up of the combination of the atmosphere, oceans, biota, and soils. Carbon is added to rocks by the burial of calcium and magnesium carbonates and organic matter in sediments. These forms of carbon represent the remains of organisms, both their hard parts (carbonates) and soft parts (organic matter). Some of this carbon is eventually returned to the Earth s surface by the thermal breakdown of carbonates and organic matter at great depth to form CO_2, which is then outgassed to the atmosphere and oceans by volcanoes, hot springs, and by simply seeping out of

the ground. The rest of the carbon is eventually uplifted onto the continents as old organic matter and carbonates in sedimentary rock, which are subjected to the release of carbon to surface waters and to the atmosphere by the process of rock weathering (*see* Carbon Cycle, Volume 2).

Factors Affecting CO_2 and the Long-term Carbon Cycle

A key process in the long-term carbon cycle is the chemical weathering of calcium and magnesium silicate minerals on the continents. This involves the conversion of atmospheric CO_2 to dissolved bicarbonate ions in ground water and river water. After rapid delivery to the sea by rivers, the bicarbonate undergoes reaction with dissolved calcium and magnesium to form calcium and magnesium carbonates. In this way, atmospheric CO_2 is removed from the atmosphere and buried in sedimentary rocks.

The combined processes of Ca–Mg silicate weathering and Ca–Mg carbonate burial have been greatly modified over the past 550 million years. This is partly because of the rise and evolution of land plants. Approximately 400 million years ago, trees began to grow on the land in upland areas and to send down extensive root systems that secreted organic acids for attacking Ca and Mg silicate minerals. This gave rise to enhanced weathering (dissolution) of these minerals and enhanced removal of CO_2 from the atmosphere, ultimately to form Ca–Mg carbonates in marine sediments. This increase in weathering rate is evident in Figure 4 by the large drop in CO_2 that occurred between 400 and 350 million years ago. Added to enhanced weathering by trees was the production of a new type of organic matter, in the form of wood, that is resistant to microbial decomposition and can be buried in sediments. This wood production led to the increased burial of organic matter in sediments, which resulted, after deep burial, in the formation of coal and coal-like organic matter. This accelerated burial of organic matter led to a further drop in atmospheric CO_2 concentration between 350 and 280 million years ago (Figure 4).

The very high values of atmospheric CO_2 found before 400 million years (early Paleozoic) were likely due mainly to the lack of large terrestrial plants, such as trees, to bring about enhanced weathering and CO_2 removal. The moderately high values during the period 250–60 million years ago (Mesozoic Era) were due to a greater rate of degassing of CO_2 to the atmosphere by volcanoes and hot springs, combined with decreased rates of CO_2 uptake by weathering due to a relative lack of high mountains. (High mountains accelerate the chemical weathering of Ca and Mg silicate minerals by causing greater rainfall and by the exposure of the minerals to acid-bearing waters by the erosional removal of protective clays.) The decrease in CO_2 from 100 million years ago to the beginning of the industrial era was due mainly to decreased degassing and the uplift of major mountain belts, such as the Himalayas.

Climate Over the Past 550 Million Years

Accompanying the changes in CO_2 over the past half billion years have been very large changes in climate (Crowley and North, 1991). The early Paleozoic (550–350 million years ago) was marked by warm seas and little evidence of polar glaciation except for a short-lived glaciation around 440 million years ago. The period from about 350 to 280 million years ago was marked by a major Southern Hemisphere glaciation where at times glaciers reached within 30° of the equator. During Mesozoic time (250–60 million years ago) climates were warm and marked by the absence of major polar glaciation and the presence of unusually high temperatures at high latitudes. This is shown by such things as the remains of forests in Antarctica and palm trees and alligators in northern Canada and Greenland, and this was the time of the dinosaurs. During the Cenozoic (past 60 million years) there was gradual cooling of the land and the sea, leading ultimately to the late Cenozoic (Pleistocene) glaciation discussed in a previous section.

These climate changes correlate with levels of atmospheric CO_2 shown in Figure 4, within the limits of a million year time scale resolution. Warm climates are associated with elevated CO_2 levels and cool climates with lowered CO_2 levels. This gives added evidence that the atmospheric greenhouse effect has been important in affecting climate during the geological past. The overall downward trend of the CO_2 curve in Figure 4 is due to an additional factor, the aging of the Sun. Solar output has increased by about 6% since 550 million years ago. This has meant an acceleration of the silicate weathering component of the long-term carbon cycle and, consequently, a gradual lowering of CO_2 concentration. The aging Sun effect helps to explain why the climates of the early Paleozoic and Mesozoic were equally warm, even though the CO_2 level was considerably higher during the early Paleozoic. A warmer Sun combined with a lower CO_2 level during the Mesozoic gives the same warming as a cooler Sun and higher CO_2 level during the early Paleozoic (Crowley and Baum, 1992).

CARBON DIOXIDE BEFORE 550 MILLION YEARS AGO (PRECAMBRIAN)

The Earth originated at about 4.6 Gyr (billion years ago) from the solar nebula of gas and solid material (planetesimals). The planetesimals accreted together to form the Earth, but the primary gaseous atmosphere was lost. The present atmosphere is secondary and was derived from volatiles trapped in the original planetesimals, and released

upon heating. More volatiles were derived from subsequent meteor impacts. The earliest Earth had a steam atmosphere plus CO_2, carbon monoxide (CO) and nitrogen (N_2). At 4.6 Gyr the concentrations of CO_2 are thought to have been more than 300 times the present atmospheric level and the surface temperature was probably about 80–90 °C (versus 15 °C today) (Kasting, 1993). By about 4.5 Gyr the steam rained out to form an ocean, leaving the atmosphere dominated by CO_2, N_2 and water (H_2O), and possibly CH_4 (Kasting, 1997).

The reason that such high early concentrations of CO_2 (or another greenhouse gas such as methane) are thought to have been present is to compensate for a 30% lower solar luminosity at 4.6 Gyr. Without higher concentrations of greenhouse gases in the atmosphere, this reduced solar heating would have caused the Earth s surface temperature to drop below the freezing point of water and should have resulted in near global glaciation. However, the geologic evidence shows that this did not happen and points to a warmer climate due to higher greenhouse gas concentrations. It is known that the first sedimentary rocks (including carbonates derived from CO_2) were laid down in water at 3.8 Gyr and life originated in the presence of liquid water by 3.5 Gyr. Sufficient warmth was needed to prevent liquid water from freezing.

Significant meteor bombardment of the Earth stopped by about 3.8 Gyr and life began about this time (Des Marais, 1994). The atmosphere at 3.8 Gyr was dominated by CO_2 and N_2 with lesser amounts of CH_4, CO, hydrogen (H_2) and reduced sulfur gases, and oxygen was essentially absent near the surface. This contrasts to our present atmosphere containing 21% oxygen (O_2) and 0.036% CO_2.

Atmospheric oxygen was primarily produced by photosynthesis by cyanobacteria and this required the development of life. Among the earliest life forms were probably mats of cyanobacteria (blue–green algae) which produce organic matter by photosynthesis from H_2O and CO_2 and give off excess O_2 to the atmosphere. If the organic matter produced is buried and not broken down, the O_2 remains in the atmosphere and CO_2 is essentially removed from the atmosphere. A fossil record of these algal mats, referred to as stromatolites, is found by 3.5 Gyr, indicating O_2 production by photosynthesis should have been occurring by then. However, atmospheric O_2 probably did not build up rapidly, because of reaction with reduced iron and sulfur.

The first known glaciation did not occur until 2.3–2.5 Gyr. Although reduced solar luminosity at that time was compensated by higher concentrations of atmospheric CO_2 than at present, CO_2 was thought to have dropped sufficiently that by 2.5 Gyr when glaciation occurred, the CO_2 level was only 10–100 times the present atmospheric value (Kasting, 1993, 1997; Rye *et al.*, 1995).

Evidence for low atmospheric O_2 until ~2.0 Gyr comes from several sources. Minerals, such as uraninite and pyrite, which would decompose under today s O_2 levels, were carried in stream gravels before 2.0 Gyr. Soils which formed during this time and are preserved, show evidence of iron transported in solution, which is only possible with low atmospheric O_2. There appears to have been little O_2 at depth in the oceans, allowing iron to occur there in solution. When the dissolved iron was carried into ocean surface water, it encountered dissolved O_2 and precipitated out as the so-called banded iron formations (a rich Precambrian iron ore). These deposits were only formed until about 1.8–1.9 Gyr, by which time atmospheric O_2 was too high for an anoxic deep ocean.

The major way that CO_2 was removed from the pre-Cambrian atmosphere was by weathering Ca and Mg silicate rocks, and the major source of atmospheric CO_2 was from volcanic emissions. Thus, the Archean concentration of atmospheric CO_2 depended upon the balance between these two processes. Because land area was small, CO_2 removal by weathering was probably reduced, which would have contributed to higher CO_2 and temperature (Des Marais, 1994). This was particularly true before large-scale production of buried organic matter by photosynthesis, which contributes to both CO_2 removal from the atmosphere and O_2 production.

After ~2.0 Gyr, atmospheric O_2 appears to have increased considerably and atmospheric CO_2 continued to drop. By 0.6 Gyr when another glaciation occurred at the end of the Precambrian, atmospheric CO_2 was ~1–10 times the present atmospheric level (Kasting, 1993).

Carbon Dioxide, Recent Atmospheric Trends

Kaz Higuchi[1] and Takakiyo Nakazawa[2]

[1]*Meteorological Service of Canada, Toronto, Canada*
[2]*Tohoku University, Tohoku, Japan*

Analyses of air bubbles retrieved from ice cores tell us that the atmospheric carbon dioxide (CO_2) concentration, before the Industrial Revolution began in Europe during the 1800s, was around 280 parts per million by volume (ppmv). Since that time, the increase in the CO_2 concentration has paralleled the amount of CO_2 emitted by fossil fuel combustion, with about 50% of the fossil fuel CO_2 remaining in the atmosphere, and the rest going into the land biosphere and the oceans. The present atmospheric CO_2 concentration is close to 370 ppmv, representing more than a 30% increase in the CO_2 concentration in the atmosphere since the mid 1800s. In addition to the global fossil fuel CO_2 emission of over 6 gigaton of carbon (Gt C) year^{-1} (1 Gt C = 10^{15} grams C), it is believed by many scientists that the deforestation activities in the tropics are emitting a net CO_2 ux of about 1.5 Gt C year^{-1} into the atmosphere at the present time. This means that the land biosphere and/or oceans are absorbing more CO_2 from the atmosphere than hitherto recognized. The carbon cycle scientists call this the missing carbon sink problem.

The future level of the atmospheric CO_2 is very dif cult, if not almost impossible, to predict accurately. It depends greatly on human behavior, because the main cause of the increase in the atmospheric CO_2 concentration over the last 150 years or so has been the anthropogenic combustion of fossil fuels to satisfy the almost exponential need for power to feed the lifestyles of the industrialized nations. The oceans and the land biosphere have been absorbing almost half of what humans have been emitting into the atmosphere. But there is some scienti c evidence now to indicate that, under a warming climate, these two major carbon reservoirs will take up less and less CO_2 from the atmosphere. For example, under global warming, the sea surface temperature will increase, causing the oceans to absorb less CO_2 from the atmosphere. Also, the soil temperature will increase, causing the land biosphere to emit more CO_2 into the atmosphere through accelerated decay and respiration. If the industrialized nations continue to do what they have been doing, then the atmospheric CO_2 concentration will certainly double. This problem will be compounded by the almost certain possibility that developing nations will increasingly burn fossil fuels to satisfy their needs for power. The biggest problem we have right now is to predict when the doubling, or tripling for that matter, of the atmospheric CO_2 concentration will occur.

CO_2 CONCENTRATION IN THE ATMOSPHERE

The first systematic and accurate monitoring of the CO_2 concentration in the atmosphere started during the International Geophysical Year (IGY), which took place from July 1, 1957 to December 31, 1958 (*see* IGY (International Geophysical Year), Volume 1). The IGY involved more than 5000 investigators from over 60 countries; these scientists measured and observed major phenomena of the Earth

simultaneously. One of the those who participated was a young scientist from the Scripps Institution of Oceanography, La Jolla, California. His name was Charles David Keeling (*see* Keeling, Charles David, Volume 1). His responsibility was to initiate and maintain measurements of the atmospheric CO_2 concentration at the South Pole and Mauna Loa, Hawaii sites. These two locations are remote and were chosen to represent background conditions of the CO_2 gas in the atmosphere. Sampling and analysis for atmospheric CO_2 was not an easy task at that time, being fraught with technical difficulties, some of which we still face today. (A brief description of measurement procedures for obtaining CO_2 concentration values is provided in Appendix A.) Keeling showed tenacity in his work and overcame many of these difficulties. Thanks to his efforts, we have a 45-year systematic and accurate record of atmospheric CO_2 concentration that can be used to examine long-term trends, as well as inter-annual variations in the seasonal cycle of atmospheric CO_2 concentration.

Figure 1 shows the time series of CO_2 from Mauna Loa (on a mountain above the trade wind inversion) and the South Pole, from 1958 to the present. One of the striking features is that the Mauna Loa station time series shows a very distinct sinusoidal oscillation (seasonal cycle) in the Northern Hemisphere, with annual maxima and minima in early spring and late summer, respectively. This variation is caused mostly by the metabolic cycle of the mid to high latitude land biosphere, with photosynthetic uptake of atmospheric CO_2 by the vegetation dominating the release of CO_2 by respiration and decay during the summer season. The CO_2 seasonal cycle observed at the South Pole shows very small amplitude compared to that seen at Mauna Loa, because there is very little land biosphere in the Southern Hemisphere. It is also opposite in phase from Mauna Loa because the seasons are out of phase between the Northern and Southern Hemispheres. There is also an exchange of air between the two hemispheres, but this atmospheric mixing takes about 6–12 months, adding to the phase difference.

If the seasonal cycle of the atmospheric CO_2 concentration is caused mainly by the seasonal cycle of the land biospheric activity, then it is logical to assume that any change in the biological activity of the land vegetation would be reflected in the inter-annual variation of the atmospheric CO_2 seasonal cycle. Many scientists have exploited this property of the global carbon cycle to find out if the land biosphere has become more active in recent years, thus absorbing more and more CO_2 from the atmosphere. One such study was conducted by Keeling and his colleagues (Keeling *et al.*, 1996). They showed that the seasonal amplitudes observed at Mauna Loa, Pt Barrow (Alaska) and Alert (northern tip of Ellesmere Island in the Canadian Arctic) have been increasing during recent times. The scientists interpreted the results to mean that the Northern Hemisphere land biosphere has become more active. They also found that the drawdown of the atmospheric CO_2 concentration (that portion of the seasonal cycle that begins with

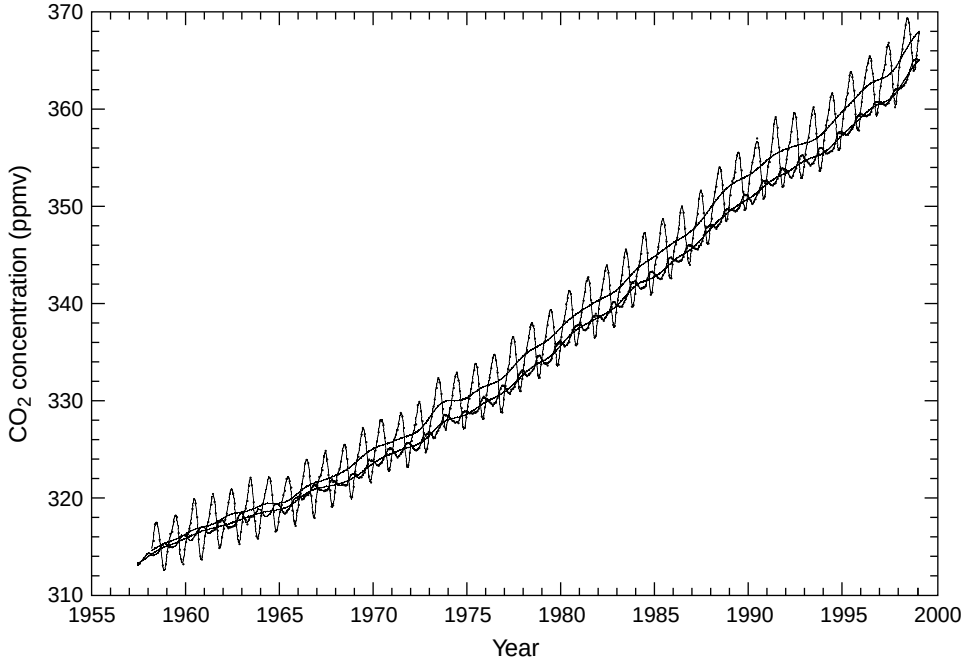

Figure 1 Time series of the atmospheric CO_2 concentration measured at Mauna Loa, Hawaii (larger seasonal cycles) and at the South Pole (smaller seasonal cycles), from 1958 to 1998. The secular increase observed at Mauna Loa is indicated by the upper solid line, while that at the South Pole is indicated by the lower solid line

a decrease in the CO_2 concentration each spring) begins earlier now. This result indicates that the photosynthetic process is starting earlier each year, causing the land biosphere to absorb an increasing amount of atmospheric CO_2 each year. The researchers have attributed the earlier starting of the photosynthesis to the increase in the global average surface temperature.

Another interesting feature of Figure 1 is that the Mauna Loa values show an annual concentration level that, year-to-year, is about 3–4 ppmv higher than the concentrations observed at the South Pole. This difference, or gradient, has been maintained from year to year over the last few decades. The secular upward trend we see at these stations (as well as at other sites added to the global network in the last 20 years, now totaling over 50 stations) in recent atmospheric CO_2 concentration is caused mainly by the accelerating increase in the emissions of CO_2 from burning of fossil fuels by the industrial nations located mainly in the Northern Hemisphere. The inter-hemispheric difference is therefore noticeably smaller at the beginning of the record. Figure 2 shows a worldwide network of atmospheric CO_2 sampling sites operated by the NOAA/CMDL; included in the network are those sites where samples are collected co-operatively with agencies of other countries.

At the beginning of the CO_2 measurement programs at Mauna Loa and the South Pole, the annually averaged atmospheric concentration was around 315 ppmv. Since then, the annually averaged concentration has risen to almost 370 ppmv in the Northern Hemisphere in the year 2000, an increase of 17% from the value observed in the late 1950s. Averaged over a number of years, it has been found that the atmosphere retains about 50% (or even a little more) of the CO_2 emitted into the atmosphere from fossil fuel combustion. Figure 3 shows fossil fuel CO_2 emission from 1850 to 1997. Using mathematical models of varying hierarchical complexity of the global biogeochemical cycle of carbon, scientists have determined that the remaining portion of the fossil fuel CO_2 in the atmosphere is absorbed mainly by the world s oceans. (It should be noted here that many scientists involved in carbon cycle research accept the fact that there is an additional anthropogenic net source of CO_2 resulting from deforestation in the tropics. An amount of atmospheric CO_2 almost equivalent to that emitted by the deforestation activities is conjectured by a number of scientists to be absorbed by the terrestrial biosphere in the Northern Hemisphere. Since the land biospheric uptake is so uncertain, it is a hotly debated issue in the scientific community, and is sometimes referred to as the *missing carbon sink* issue.) An example of how sensitive the atmospheric CO_2 concentration is to fossil fuel combustion emission can be seen in Figure 3. During the so-called oil crisis in 1973 and 1974, the consumption of fossil fuels (and oil in particular) by the industrial nations dramatically declined. This contributed to the dip seen in the secular CO_2 trend at Mauna Loa around the same time; the dip was also observed at other CO_2 monitoring stations located world-wide. The growth rate of the atmospheric CO_2 concentration also declined during the major energy crisis in the early 1980s (see Figure 3), but its impact on the actual CO_2 concentration appears to be less obvious in Figure 1 than the impact of the early-1970s oil crisis. This is because such natural phenomena as the El Niño and the Mount St Helen (State of Washington, USA) volcanic explosion in the early 1980s also influenced the atmospheric CO_2 concentration growth. It should be added that an El Niño did occur during the 1973–1974 period of the first oil crisis identified in Figure 3, but it was much weaker than the one that occurred during the 1982–1983 period.

ATMOSPHERIC CO_2 FROM ICE CORES

If the recent changes in the CO_2 concentration level observed in the atmosphere are caused mainly by the combustion of fossil fuels by the industrial nations for power, then it is only logical to ask what the atmospheric CO_2 level was before industrialization began. To find the answer to this question, we go to an icy world.

In places like Antarctica, Greenland and high-altitude mountains, annual-averaged air temperatures are below $0\,^{\circ}C$, the melting point of snow and ice. Even in summer, air temperatures at these locations do not usually rise above $0\,^{\circ}C$. Snow that falls does not melt and thus accumulates year after year. A fresh layer of snow has a fluffy texture because the space between flakes is filled with air at the time of the snowfall. As more and more layers of snow accumulate on top of this layer, it becomes more and more compacted under the overlying pressure, eventually turning into ice. Some of the air that filled the space between the snowflakes gradually becomes trapped in the ice as air bubbles. This has popularly been called *antique air*. During the transition of the layer from snow to ice, the air in the layer is still in contact with the atmosphere. It takes many decades before the air bubbles become completely sealed off from the atmosphere. This means that the air bubbles are younger than the ice layer in which they are embedded. The information on the relative gaseous composition of the atmosphere contained in the air bubbles reflects atmospheric composition at a time more recent than the age of the ice layer from which these bubbles are retrieved. This fact is taken into account when scientists assign an age to the CO_2 concentration value analyzed from air bubbles obtained from a certain layer in the ice core. If we can retrieve and analyze the mix of gases in air bubbles present throughout the depth of an ice core, say, from Antarctica (or Greenland or any other location where snow does not melt during the year), then we can find out what the atmospheric

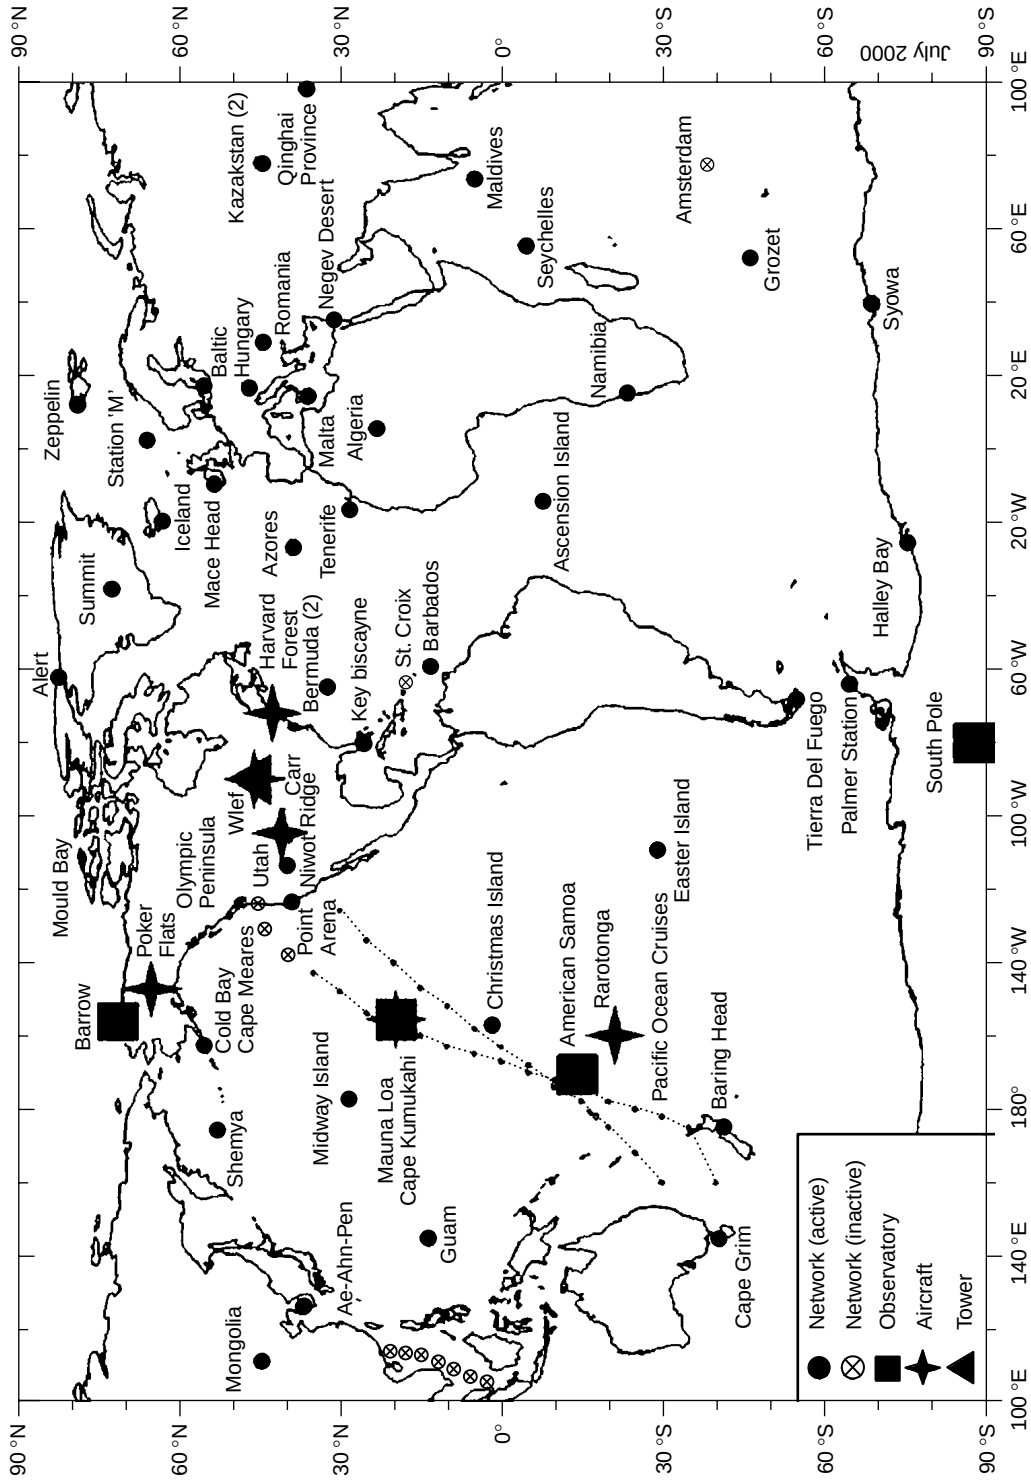

Figure 2 The world-wide network of CO_2 sampling stations operated by National Oceanic and Atmospheric Administration/Climate Monitoring and Diagnostics Laboratory (NOAA/CMDL). The network includes those stations where atmospheric samples are collected co-operatively with agencies of other countries. Inclusion of all stations operated by other countries would total more than 50 sites at the present time. (*Source:* http://www.cmdl.noaa.gov)

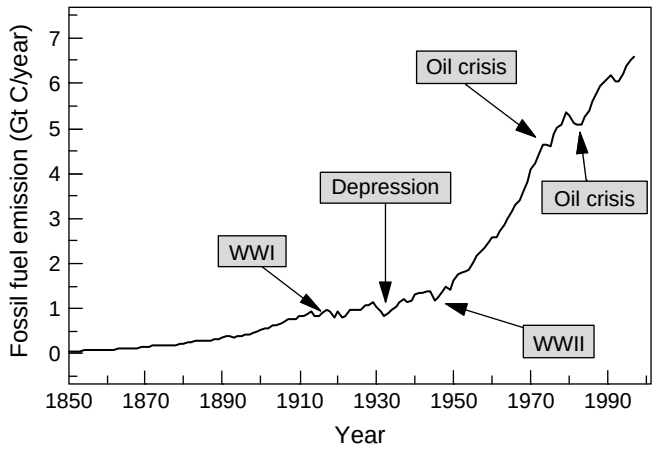

Figure 3 Fossil fuel CO_2 emissions, in Gt C/year (or billions of metric tons per year), from 1850 to 1997. Times of major economic perturbation are identified. Over the last 30 years, two major energy crises (one in the early 1970s, and another one in the early 1980s) have contributed to a slight, short-lived reduction of the total global fossil fuel CO_2 emission. (Data obtained from the Carbon Dioxide Information Analysis Center, Department of Energy, USA)

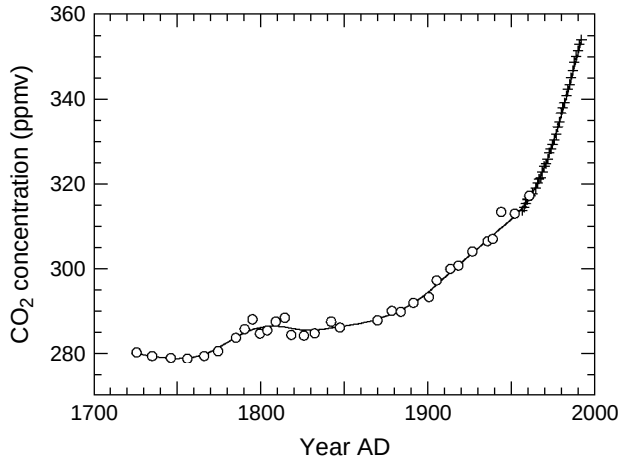

Figure 4 Atmospheric CO_2 concentration values analyzed from trapped air bubbles extracted from an ice core obtained at an Antarctic site known as H15. The CO_2 concentration in the atmosphere has risen from about 280 ppmv prior to the Industrial Revolution to about 355 ppmv around 1990. By the end of 20th century, the level had risen to almost 370 ppmv

CO_2 concentration levels were in the recent past. (A brief description of the retrieval and analysis procedures is given in Appendix B.)

Figure 4 shows the atmospheric CO_2 concentration values from the early 1700s to around 1960, as obtained from analysis of the composition of air trapped air bubbles in a high quality ice core recovered from an Antarctic site known as H15 (69°05′ S, 40°47′ E). The H15 ice core drilling site is located at 1057 m above sea level, and has a mean annual air temperature of −20.5 °C. Prior to the Industrial Revolution that started in Europe around the mid 1800s, the air bubbles from the H15 ice core clearly show CO_2 concentration levels around 280–285 ppmv. From around the mid 1800s, the atmospheric CO_2 concentration starts to rise exponentially, merging very nicely into the instrumental CO_2 record shown in Figure 1. So, since the beginning of the Industrial Revolution, the atmospheric CO_2 concentration level has increased by over 30%, not a trivial amount! This rise in the concentration is consistent with the exponential release of CO_2 into the atmosphere from the burning of fossil fuels by the industrialized nations. Analyses of ice cores from other sites in Antarctica and Greenland show a similar rise in the atmospheric CO_2 concentration.

INTER-ANNUAL VARIATION IN THE NET CO_2 FLUX FROM NATURAL SOURCES

The relationship between the rise of the atmospheric CO_2 concentration level and the increasing amount of CO_2 emitted by anthropogenic activities, particularly the fossil fuel combustion, is valid on a time scale of several years or more. On an inter-annual year-to-year basis, however, the relation is weaker because there are other natural processes that add CO_2 to, or remove CO_2 from the atmosphere.

A close examination of the CO_2 time series in Figure 1 shows that the rate of increase in the atmospheric CO_2 concentration is not exponentially smooth, and is not always correlated very well with the anthropogenic emission rate of CO_2 into the atmosphere from year to year. There are times, such as the oil crisis of 1973–1974, when the lower emission of fossil fuel CO_2 is reflected in a slowed rate of growth of CO_2 in the atmosphere. There are also times when changes in the atmospheric CO_2 concentration from one year to the next depend significantly on the processes governing the net flux of CO_2 between the atmosphere and the other two major carbon reservoirs in the oceans and the land biosphere. Thus, in order to explain the secular increase and the inter-annual variability of the atmospheric CO_2 concentration, as well as developing techniques to predict future concentration levels, we need to achieve a greater understanding of the relative contributions of the oceans and the land vegetation to the global carbon cycle.

In order to obtain quantitative estimates of the relative contributions that the oceans and the land biosphere make to the secular increase and the inter-annual variability in the atmospheric CO_2 concentration, scientists have exploited chemical and physical properties of carbon isotopes in various mathematical models of the global carbon cycle. One of the isotopic signatures of CO_2 is labelled $\delta^{13}C$. It

is a ratio of ^{13}C to ^{12}C ($^{13}C/^{12}C$), and is defined as:

$$\delta^{13}C = \left(\frac{\left(\frac{^{13}C}{^{12}C}\right)_{\text{sample}}}{\left(\frac{^{13}C}{^{12}C}\right)_{\text{standard}}} - 1 \right) \times 1000$$

At the present time, the atmospheric reservoir has a $\delta^{13}C$ value of $-8\,\text{mil}^{-1}$ (parts per thousand), while the oceanic and the land biospheric reservoirs have, on average, about $+1\,\text{mil}^{-1}$ and $-25\,\text{mil}^{-1}$, respectively. The ^{13}C isotopic signature of each carbon reservoir is caused by the isotopic fractionation effect. For example, when a plant absorbs CO_2 during its photosynthesis, it prefers CO_2 molecules containing ^{12}C (six protons and six neutrons in each carbon atom) rather than those containing ^{13}C (six protons and seven neutrons in each carbon atom) because they are lighter. This differentiation, or isotopic fractionation, process causes, during photosynthesis, lighter CO_2 molecules (those containing ^{12}C) to be absorbed into the plant preferentially, leaving heavier ^{13}C to be left in the atmosphere. That is why the land biosphere shows a deficit in ^{13}C ($-25\,\text{mil}^{-1}$), compared to that of the atmosphere ($-8\,\text{mil}^{-1}$). There is very little net isotopic fractionation in the CO_2 exchange across the air-sea interface.

Both ^{12}C and ^{13}C are called stable isotopes of CO_2. However, there is one more isotope of CO_2, labeled ^{14}C, which is radioactive. Typically, every millionth CO_2 contains ^{14}C. Radioactive CO_2 is created as a by-product of cosmic radiation bombardment with the atmosphere. Its half-life is around 5700 years, and after about 40 000 years the amount becomes so small that it is very difficult to measure. Fossil fuel CO_2 contains practically no radioactive ^{14}C. Therefore, it decreases the $^{14}C/^{12}C$ ratio ($\delta^{14}C$) in the atmosphere; this process is called the *Suess Effect* (*see* Suess Effect, Volume 2). Therefore, measurements of $\delta^{14}C$ in atmospheric CO_2 can be used to differentiate the contribution, to the atmospheric CO_2 variability, of the fossil fuel CO_2 from that of the land vegetation; these two carbon reservoirs have similar $\delta^{13}C$ signature but very different $\delta^{14}C$ signature. Explosions of nuclear bombs in the late 1950s and the early 1960s have made the task very difficult, however.

When CO_2 enters the atmosphere from either the oceans or the land biosphere, it carries with it the $\delta^{13}C$ value of its source. By doing so, it can change the atmospheric $\delta^{13}C$ value. Fossil fuels have a similar $\delta^{13}C$ signature to that of the land vegetation because fossil fuels are just fossilized vegetation. By measuring the inter-annual variations in the atmospheric CO_2 concentration and its corresponding $\delta^{13}C$ value, scientists can estimate inter-annual variations in the net flux of CO_2 from the oceans and the land biosphere. This mathematical technique is called the *inverse method*. In this method, the effect of the fossil fuel CO_2 emission on the atmospheric $\delta^{13}C$ value is eliminated quite early in the calculation. Scientists can do this because they know relatively well how much fossil fuel CO_2 is being emitted into the atmosphere every year.

Figure 5 shows a result of a study conducted by a group of scientists from Japan and Canada using the inverse method (Morimoto *et al.*, 2000). The result is compared to those obtained from studies by Roger Francey from Australia and his colleagues (Francey *et al.*, 1995) and by CD Keeling from the US and his colleagues (Keeling *et al.*, 1995). Flux anomaly values in each study are obtained by subtracting an average calculated over the period of data record. Figure 5 shows the relative change from year to year in the net CO_2 flux across the atmosphere–ocean and the atmosphere–land biosphere interfaces. There are differences among the results of these studies; however, within the context of trying to obtain some understanding of the secular and inter-annual changes in the atmospheric CO_2 record, we note that the variations in the net flux from either the oceans or the land biosphere can be almost as large as 50% of the fossil fuel CO_2 flux of about 5–6 Gt

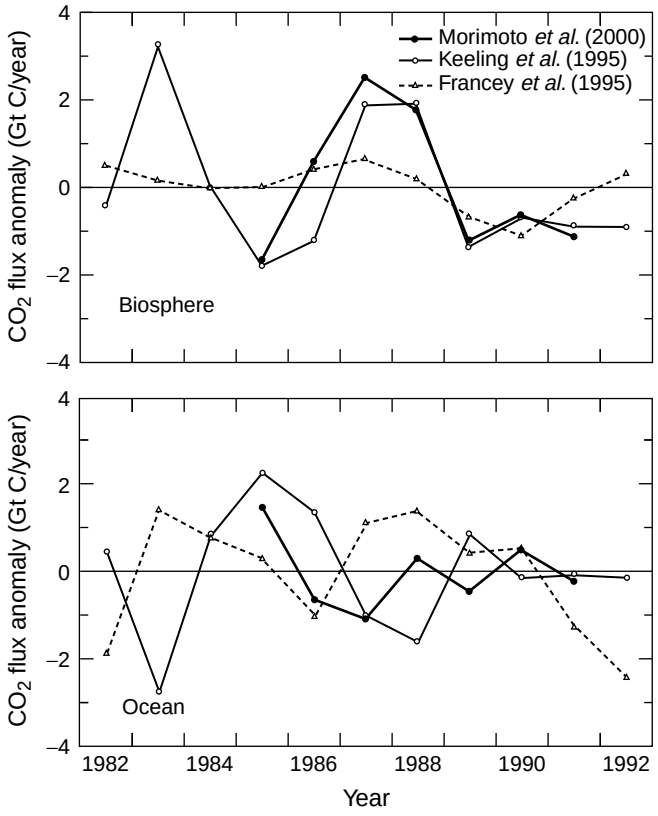

Figure 5 Calculated inter-annual variation in the net CO_2 flux anomaly across the atmosphere–ocean and the atmosphere–land biosphere interfaces. Note that the year to year variability can be as large as 50% of the annual fossil fuel CO_2 emission into the atmosphere. (*Source:* Morimoto *et al.*, 2000)

C per year So the future year-to-year trend in atmospheric CO_2 depends greatly on the behavior of the land biospheric and the oceanic carbon reservoirs, particularly in determining how much of the anthropogenic CO_2 emitted into the atmosphere will be absorbed by these two large carbon reservoirs.

APPENDIX A

One of the simplest and most economical ways of measuring atmospheric CO_2 concentrations is to take samples of air in small containers (flasks) on a regular basis, usually about once every week. These containers vary in size and composition, depending on the laboratory taking the samples. Nonetheless, they are usually made of Pyrex glass, aluminum or stainless steel. They usually vary in size from 2 to 5 liters. Once the atmospheric samples are taken, they are shipped back to a main laboratory for analysis of the CO_2 concentration.

At these laboratories, the air samples are injected into a CO_2 analyzer called a non-dispersive infrared (NDIR) analyzer. The NDIR system is basically composed of two cells, one of which is filled with a standard gas of known CO_2 concentration. (For the convenience of our discussion, we can call the cell containing the standard gas the standard gas cell.) Infrared (IR) light is emitted from one side of the standard gas cell and is registered as an electric current at the receptor on the other side. Because CO_2 is a good absorber of the IR radiation, the amount of IR light that reaches the receptor depends on the CO_2 concentration in the standard gas; the more CO_2, the less IR and thus less electric current.

The other cell in the NDIR system is the one in which we put an air sample whose CO_2 concentration we would like to determine. Into this sample gas cell we shine IR light, as we did in the standard gas. By comparing the electric currents from the standard gas cell and the sample gas cell, we can determine the CO_2 concentration of the air sample. The overall precision is about ± 0.05 ppmv.

Flask sampling is a good monitoring method for measuring the long-term secular trend in atmospheric CO_2 concentrations, as well as some basic aspects of the CO_2 seasonal cycle. However, some of the important scientific issues regarding temporal and spatial distributions of carbon sinks and sources require more continuous monitoring of the behavior of the atmospheric CO_2 level. To provide a temporal resolution of minutes to hours, the NDIR system is used directly at the monitoring station. This is typically done at such reference stations as Mauna Loa, South Pole, Pt Barrow, Alert and Cape Grim (Tasmania).

APPENDIX B

Ice coring procedures allow scientists to retrieve long cylindrical cores of ice from ice caps on Greenland and Antarctica, as well as from glaciers on top of tall mountains. Deeper layers of ice in the ice core represent older ice containing correspondingly older bubbles of air. Thus, analyses of air bubbles from successive layers of ice represent historical time series of the composition of trace gases in the atmosphere. The extraction and analysis procedures for CO_2 in the air bubbles differ from laboratory to laboratory, but they usually follow the procedure outlined below.

For the purpose of extracting air samples, ice samples of several 10 to a few 100 g each are typically used for determining the CO_2 concentration only. The ice sample is placed in a stainless steel chamber after removing contamination from the surface by using a bandsaw and a knife. The ice sample is then placed in an evacuated chamber at $-20\,^{\circ}$C for at least two hours, to sublimate the ice surface for further cleaning. After the cleaning process is finished, the ice sample is crushed into fine powder to release air from the bubbles. After passing through cold traps held at $-100\,^{\circ}$C to remove water vapor, the air released from the ice sample is collected into a sample tube cooled to $-269\,^{\circ}$C by liquid helium. Using a gas chromatograph, the CO_2 concentration of the air samples thus extracted is determined by comparison with standard gas mixtures with concentrations ranging from 200 to 300 ppmv. The overall precision of this kind of air extraction and analysis procedure is estimated to be better than ± 1 ppmv. A more technically-based description can be found in a paper published by a group of Japanese scientists (Nakazawa *et al.*, 1993).

Carbon Monoxide

The gas *carbon monoxide* (CO) is produced by natural and human activities. Roughly half to two-thirds of atmospheric CO is emitted from fossil fuel combustion and industrial activities. The remaining CO comes from biomass burning, oceanic and land plant emissions, and the oxidation of methane (CH_4) and non-methane hydrocarbons. Roughly 1800–2800 Tg CO year^{-1} are released each year. The largest sink for CO is reaction with OH, accounting for 85% of the CO. An additional, smaller sink is uptake by soils.

Present day concentrations of CO range from 40–200 parts per billion volume (ppbv), with a global average of roughly 90 ppbv. CO results mainly from land-based sources. Thus, CO concentrations are higher in the Northern Hemisphere, which has both more land and human sources than the Southern Hemisphere. The concentrations in the Southern Hemisphere are lower (roughly 60 ppbv) and more uniformly mixed, both horizontally and vertically. Because CO is emitted almost exclusively from surface sources, concentrations also tend to be lower in the free troposphere than in the boundary layer.

The concentration of CO varies with season. Because the largest CO sink is reaction with OH, as the concentration of OH increases in the summer, the concentration of CO tends to decrease. The residence time for CO in the troposphere is roughly one month in the tropics, and four months in the mid-latitudes. Pre-industrial concentrations of CO (prior to 1850) appear to be have been ~55–60 ppbv in the Southern Hemisphere and ~90 ppbv in the Northern Hemisphere (based on ice core data).

CEOS (Committee on Earth Observation Satellites)

CEOS is an international organization charged with coordinating civil space-borne missions designed to observe and study our planet. Created in 1984, it now comprises 41 space agencies and other national and international organizations and is recognized as the main international forum for the coordination of Earth observation satellite programs and for the interaction of these programs with users of satellite data and information worldwide. Individual participating agencies use their best efforts to implement CEOS recommendations. The main goal of CEOS is to ensure that critical scientific questions relating to Earth observation and global change are covered and that satellite missions do not unnecessarily overlap each other. CEOS s three primary objectives are: (1) to optimize benefits of space-borne Earth observations through cooperation of its participants in mission planning and in development of compatible data products, formats, services, applications and policies; (2) to serve as a focal point for international coordination of space-related Earth observation activities; and (3) to exchange policy and technical information to encourage complementarity and compatibility of observation and data exchange systems.

CEOS is working closely with the Integrated Global Observing Strategy (IGOS) partnership in the development and implementation of the IGOS partnership. IGOS intends to unite the major satellite and ground-based systems for global environmental observations and monitoring of the atmosphere, oceans, land and life, in a framework that delivers maximum benefit and effectiveness in their final use. IGOS focuses on the observing dimension of the process of providing environmental information for decision-making IGOS, while linking research and operational programs as well as data producers and users.

CEOS meets in plenary annually, with activities and coordination occurring throughout the year. The Chair organization of CEOS rotates at the annual plenary. A permanent secretariat provides most of the coordination between plenary sessions and is maintained by the European Space Agency, the National Aeronautics and Space Administration, jointly with the National Oceanographic and Atmospheric Administration of the United States, and the Science and Technology Agency jointly with the National Space Development Agency (NASDA) of Japan, and is headed by the CEOS chair organization. CEOS has two permanent working groups which meet regularly. The objectives of the Working Group on Calibration and Validation are to enhance coordination and complementarity, to promote international cooperation and to focus activities in the calibration and validation of Earth observations. The Working Group on Information Systems and Services seeks to facilitate data and information management and services for users and data providers in dealing with global, regional and local issues.

CEOS issues a number of information products and services which are available from the CEOS homepage (www.ceos.org.) or from the secretariat (points of contact

also available on the website). CEOS also creates *ad hoc* working groups when needed to address specific issues such as the development of Earth observation education and training or the role of remote sensing in natural disaster monitoring and management.

Chandler Wobble

Richard S Gross
Jet Propulsion Laboratory, Pasadena, CA, USA

The Earth rotates about its axis once a day, but does not do so uniformly. Instead, the rate of rotation uctuates by up to a millisecond per day, and the Earth wobbles as it rotates. Much like the wobble of an unbalanced automobile tire, the Earth wobbles because the mass of the Earth is not balanced about its rotation axis.

The wobbling motion of the Earth was first detected by Seth Carlo Chandler, Jr, in 1891 and has been under observation ever since. In these observations, the wobble manifests itself as an oscillation of the rotation pole about the North Pole of the Earth. This oscillation can be characterized by its *period*, which is the time that it takes the rotation pole to complete one circuit about the North Pole, and by its *amplitude*, which is the size of the offset of the rotation pole from the North Pole. Analyses of these observations reveal that the Earth has, in fact, two dominant wobbling motions:

1. an annual wobble with a period of 12 months and an amplitude of about 3 m; and
2. the Chandler Wobble with a period of 14 months and an amplitude that varies between about 3–6 m.

The annual wobble is a forced motion of the Earth that is caused largely by the annual appearance of an atmospheric high pressure system over Siberia every winter. This system annually loads the Siberian crust, causing the Earth to wobble with an annual period. The Chandler Wobble on the other hand is not a forced motion of the Earth, but is rather a resonant motion that was first predicted by the Swiss mathematician Leonhard Euler in 1765. Euler studied the general translational and rotational motion of rigid bodies and, by applying his theory to the Earth, predicted that if the Earth s mass were not balanced about its rotation axis, then the Earth should wobble as it rotates. Assuming that the solid Earth is rigid, the period of this Eulerian wobble is about 10 months.

Despite numerous subsequent attempts by astronomers to detect this predicted wobbling motion of the Earth, it was not until 1891 that Chandler finally detected such a motion, but with a period of 14 months. A year later, Simon Newcomb explained the lengthening of the period from 10 to 14 months by the fact that the solid Earth is not perfectly rigid and will therefore deform as it wobbles, and by the fact that the oceans will respond to the wobbling of the underlying solid Earth. Further analysis of the observations by Chandler revealed the additional presence of a wobble with a period of 12 months. The 14-month wobble is now known as the Chandler Wobble in honor of the person who first detected it.

Frictional forces associated with the wobble-induced deformation of the solid Earth would cause the Chandler Wobble to freely decay with an exponential time constant of about 68 years if no mechanism or mechanisms were acting to excite it. Observations of the Chandler Wobble taken during the past century show that there are times when the amplitude of the Chandler Wobble has actually increased. Thus, some mechanism or mechanisms must clearly be acting to excite the Chandler Wobble. Because it is known that the annual wobble is largely caused by changes in atmospheric pressure over land, and because the period of the Chandler Wobble is close to that of the annual wobble, many studies have been conducted to determine if atmospheric pressure fluctuations over land are also energetic enough to excite the Chandler Wobble. However, these studies have generally concluded that atmospheric pressure changes over land have only about a quarter of the power needed to excite the Chandler Wobble. Only recently, more than a century after its discovery, has it been shown that the combination of atmospheric and ocean-bottom pressure changes are likely to have enough power to excite the Chandler Wobble.

The recent availability of numerical general circulation models of the oceans has allowed the impact of oceanic processes on the Earth s rotation to be studied. In particular, such models have been used to show that the change in the load on the oceanic crust due to changes in the weight of the overlying column of water associated with changes in the distribution of the oceanic mass is about twice as effective in exciting the Chandler Wobble as is the changing atmospheric pressure over land. In fact, the sum of the

changing atmospheric pressure over land and the changing ocean-bottom pressure can fully explain the excitation of the Chandler Wobble.

Atmospheric pressure changes are the primary cause of the annual wobble, and the sum of atmospheric and ocean-bottom pressure changes are the primary excitation source of the Chandler Wobble. Thus, pressure changes associated with weather systems cause the Earth to wobble as it rotates. In addition, the dominant cause of changes in the rotation rate of the Earth, or, equivalently, changes in the length of the day (*see* Atmospheric Angular Momentum and Earth Rotation, Volume 1), are changes in the strength and direction of atmospheric winds. In fact, changes in the strength and direction of the jet stream associated with the El Niño/Southern Oscillation phenomenon have been shown to cause changes as large as a half a millisecond in the length of the day. Thus, among its many other consequences, climate change also affects the rotation of the Earth.

Chaos and Predictability

Cecil E Leith

Lawrence Livermore National Laboratory, Livermore, CA, USA

Perhaps the oldest and most ubiquitous of prediction problems is that of the weather. It is, of course, well recognized that there is a practical limit of a few days to the range of useful weather forecasts. Less well known is the fact that there is a theoretical limit to the useful range of such forecasts, even if they are based on a perfect forecasting model. This is owing to the inherent growth of the initial errors that arise from the necessarily imperfect knowledge of the initial state of the atmosphere.

Such sensitive dependence on initial conditions characterizes dynamical systems that are called chaotic. Thus, although the underlying dynamics are purely deterministic, the evolving behavior appears to be increasingly random and unpredictable and leads to chaos.

HISTORICAL BACKGROUND

During the 19th century, much philosophical discussion dealt with the question of whether the world behaved in a way that was completely deterministic, or did not, and thus in some way allowed room for individual free will to be exercised. The Scottish mathematician and physicist J Clerk Maxwell entered the debate with an essay on the possible role of the physical sciences in considering this question. In his text *Matter and Motion*, Maxwell (1876) summarized his views in a statement of General Maxim of Physical Sciences:

> There is a maxim which is often quoted, that The same causes will always produce the same effects. There is another maxim that must not be confounded with that quoted . . ., which asserts that like causes produce like effects.

Maxwell gives the rather dramatic example:

> . . . in which a small initial variation may produce a very great change in the final state of the system, as when the displacements of the points causes a railway train to run into another instead of keeping its proper course.

To which he adds in a footnote:

> . . . In so far as the weather may be due to an unlimited assemblage of local instabilities, it may not be amenable to a finite scheme of law at all.

It is this sensitive dependence on initial conditions that characterizes a dynamical system that is called *chaotic*. In this context, chaos becomes a technical term for the behavior induced by a chaotic dynamical system. It imposes a limit on the predictability of such a system.

PREDICTABILITY OF THE WEATHER

Following the proposal made in about 1911 by Richardson (1922), numerical weather prediction was attempted by John von Neumann and colleagues at the Institute for Advanced Study in Princeton in the early 1950s. The first such effort was able to track a November storm for a few days across the United States with moderate success. However, in the course of time the forecast bore no resemblance to the actual evolving weather. The question naturally arose as to the possibility that even a perfect prediction model would be limited in the range of its skill, as suggested by Maxwell, by the growth of the inevitable

errors in the specification of the initial atmospheric state, i.e., weather may be chaotic.

Lorenz (1963) suggested that there were three ways to quantitatively determine the rate of this error growth. The most direct was to rerun a numerical forecast model with a small difference in its initial state and to note the rate at which this difference grew. This, of course, revealed the predictability of the model atmosphere but perhaps not that of the real atmosphere. The second (the *analogue method*) was to search the weather records for pairs of times at which the atmosphere was in nearly the same state and then to record the rate at which the ensuing states diverged. Although this approach dealt with the predictability of the real atmosphere, the records were unfortunately not long enough to provide any close pairs, and an estimate had to be made based on extrapolation to close pairs of results obtained from pairs that were not very close. Finally, one could turn to a somewhat dubious theory of the turbulent nature of the large-scale motions in the atmosphere in order to estimate the expected error growth rate.

Robinson (1967) used this turbulence approach with an assumption that the classical energy-cascading inertial range for three-dimensional isotropic turbulence proposed by Kolmogorov (1941) was relevant to atmospheric motions, and made the rather pessimistic estimate that prediction could not be useful beyond a day or so. However, the planetary scales of motion in the atmosphere have horizontal length scales of thousands of kilometers. These are much larger than the thickness of the atmosphere, which thus behaves more in accordance with turbulence confined to two dimensions rather than with the three-dimensional isotropic turbulence theory of Kolmogorov. This leads to a replacement of the classical $(-5/3)$ power-law energy spectrum of Kolmogorov (1941) with the (-3) power-law spectrum considered by Batchelor (1969) and Kraichnan (1967) and Leith (1971). The two-dimensional turbulence approach gives a result for the error growth rate, which is more consistent with the other two approaches, namely, that the doubling time of the root-mean-square error is about two days and thus that useful predictions may be possible for a week or more.

The question of the predictability of the weather was considered of such importance that it led to the establishment of an international program called the Global Atmospheric Research Programme (GARP), described by Robinson (1967) (*see* GARP (Global Atmospheric Research Program), Volume 1). The success of this program and its successor, the World Climate Research Programme, helped to establish the basis for current operational weather and climate prediction.

DYNAMICAL PHASE SPACE

A numerical model used for weather prediction utilizes of the order of a million numbers to specify the hydrodynamic and thermodynamic state of the atmosphere at a particular time. The model provides a computational process that is used to advance the state to a new state for a slightly later time, and this process continues to be repeated in order to determine the evolving state of the atmosphere for a forecast period of several days. Such a set of a million numbers can be considered as coordinates of a point in a million-dimensional space whose motion defines a curve or orbit in that space. In general, for such a dynamical system, this is called a *phase orbit* in the *phase space* of the system. Lorenz (1963) examined the properties of such a phase orbit in a phase space in which he had drastically reduced the dimension from one million to only three. He was then looking at only the grossest scales of motion in his model atmosphere. However, his three modes were coupled through non-linear interaction terms in his equations of motion that simulate such interactions in the real atmosphere. It was then fairly straightforward for him to make a plot of the evolving orbit. He found that these orbits were attracted to, and finally confined to only a part of the three-dimensional phase space rather than wandering around throughout the whole space.

These final sets have become known as *strange attractors* owing to their unusual topological properties. They appear to be two-dimensional sheets, but they are twisted and stacked in a strange way. They also appear to have two separate components such that an orbit will remain in each component for a period of time with an occasional transition to the other. Lorenz (1963) called such a bimodal system *almost intransitive* to distinguish it from a classical transitive or ergodic system in which the phase orbit fills a region of the phase space more or less uniformly.

An interesting possibility is that there exists a strange attractor for the atmospheric dynamical system. Such an attractor would lower the dimension of the dynamical phase space and might, thereby, save variables and computing time in numerical prediction. However, the dynamical equations for evolution confined to the attractor would be so complicated compared to those currently in use that any potential computational gain most probably would be lost.

Searches for bimodal behavior in the real atmosphere have not been particularly successful, although there is some suggestion that the Himalayan Massif may act as a fluidic switch for the flow of the jet stream about it. There is clearer evidence of such bimodal behavior in the currents of the North Atlantic Ocean, and this, of course, can have an indirect effect on the atmosphere and its predictability.

PREDICTABILITY OF TURBULENT FLOWS

Turbulent flows in general have limited predictability and thus are chaotic. As mentioned previously, there is a difference between the predictability of turbulence in two and in three dimensions.

In the classical analysis (Kolmogorov, 1941) of three-dimensional turbulence, one considers a statistically stationary situation in which a stirring source feeds kinetic energy at large scales into a fluid at a fixed rate ε. This energy is then transferred at the same rate through an inertial range of smaller scales until it is finally dissipated, still at the same rate ε, at scales small enough for viscous dissipation to be effective. Dimensional analysis is then based on the assumption that the energy spectrum function $\mathrm{E}(k)$ of the inertial range depends only on the energy cascade rate $\varepsilon[L^2T^{-3}]$ and the wave number $k[L^{-1}]$, defined as $k = 2\pi/\delta$, where δ is the scale wavelength. The total kinetic energy per unit mass is $E[L^2T^{-2}] = \int \mathrm{E}(k)\,\mathrm{d}k$; thus for dimensional consistency one must have $\mathrm{E}(k)[L^3T^{-2}] = C_{\mathrm{K}}\varepsilon^{2/3}k^{-5/3}$ where C_{K} is the dimensionless Kolmogorov constant found experimentally to be about equal to 2.

For two-dimensional turbulence, as noted, for example, by Batchelor (1969), Kraichnan (1967) and Leith (1971), there exist additional inviscid integrals of the motion based on the detailed conservation of vorticity $\omega[T^{-1}]$, i.e., the curl of the velocity field, which is always normal to the plane of motion and can, therefore, be treated as a scalar rather than as a vector quantity. In particular, the enstrophy $\Omega[T^{-2}]$, defined as half the square of the vorticity, is a conserved quantity that cascades from large scales to small ones at a constant rate $\eta[T^{-3}]$. Now the dimensional scaling arguments lead to a different energy spectrum function $E(k)[L^3T^{-2}] = C_{2D}\eta^{2/3}k^{-3}$, where $C_{2\mathrm{D}}$ is another dimensionless constant also about equal to 2.

The predictability of turbulent flow depends on how rapidly the errors in very small scales, thus at large values of k, will induce, through non-linear interactions, errors at somewhat smaller values of k, and lead to a back-cascade of error to ever smaller k and larger scales. At a particular wave number k, the non-linear interaction rate is found by dimensional analysis to be proportional to $[k^3\mathrm{E}]^{1/2}$. For a $(-5/3)$ power-law spectrum, this rate becomes extremely rapid for large values of k, whereas for a (-3) power-law spectrum the rate is independent of k, and the back-cascade of error is therefore much slower.

Although the dynamical behavior of the atmosphere is far more complex than that of two-dimensional turbulence, the analogy is close enough so that a (-3) power-law spectrum is, in fact, observed for the larger scales of motion of global atmospheric flow. The atmosphere is therefore far more predictable than it might have been had Robinson s original estimate been valid.

PREDICTABILITY OF THE CLIMATE

One might, at first, think that since the weather is of limited predictability, the climate is also. However, the climate consists of the probabilistic properties of the weather. As Lorenz has put it climate is what you expect; weather is what you get. Most numerical climate models at present are, however, really weather models that are run for long times from arbitrary initial states with an average taken over time in order to estimate climate properties.

The interesting climate prediction questions have to do with determining the sensitivity of the climate to changing influences.

This is done by making a long baseline run with a numerical model and then repeating the run with some specified perturbation in the influence of interest, such as the concentration of carbon dioxide in the model atmosphere. Usually these artificial changes are made rather large in order to obtain a significant response, which is then scaled down to the size of interest with the assumption of a linear dependence of the response on the perturbation.

Here it is important to consider the sampling fluctuations associated with any estimate of climate properties based on a finite time sample of either a numerical model or of the real atmosphere. It is known, for example, that a collection of N independent samples drawn from an infinite population has a sample mean which, as an estimate of the population mean, has a sampling error proportional to $1/N^{1/2}$.

To apply this result to a statistically stationary time series requires knowledge of the number N of effectively independent samples in a time interval of length T. This depends on the time interval τ between effectively independent samples which is given by $\tau = \int R(|s|)\,\mathrm{d}s$, where $R(|s|)$ is the correlation between values of the series at times separated by a time interval s. For typical atmospheric variables, this correlation time τ is about one week, and thus, for example, the effective sample size for a season is $N \sim 13$. Clearly then, much of the variability of seasonal average quantities from one year to the next is simply the consequence of sampling fluctuations. This variability is not unlike the sort of variability found in hands dealt in the card game of contract bridge.

In more general human endeavors, we must often deal with the relative importance of skill versus luck. A cloud of uncertainty always obscures predictive skill. It is clearly important to predict not only a quantity of interest but also to predict the uncertainty in that prediction, that is, to track the associated chaos. Gauss, as a teenager, gave an early example of this when he provided astronomers with a useful prediction of when and in what region of the sky the asteroid Ceres would be found again following its initial discovery in 1801 and its later obscuration by sunlight. Although Gauss was, at the time, already well known in the pure mathematics community, this prediction made him so famous in the larger scientific community that his mathematical colleagues accused him of selling out to popular applied science.

A straightforward way of predicting uncertainty along with a forecast is to carry out, in fact, a collection or ensemble of forecasts starting from a cluster of initial states that reflect the initial uncertainties in observations and analysis (Leith, 1974). The mean and standard deviation of the ensemble provide estimates of the forecast and of its uncertainty. Such ensemble forecasts have become standard in operational weather prediction. Although an ensemble average forecast may technically minimize the mean square error, it suffers from producing a weather map that looks unreasonably smooth compared to those observed.

SUMMARY AND OUTLOOK

Chaotic dynamical systems are those for which small disturbances lead to large consequences. The prototypical example is that of the weather system for which errors in the determination of the initial state of the atmosphere have an rms doubling time of about two days. The theoretical limit of predictive skill with a perfect forecasting model is, thus, about 10 days. In fact, the practical range of forecast skill is only about five days owing to model imperfections. Of course, the major imperfections in early forecast models have already been recognized and removed. The remaining imperfections are, thus, individually small although large in number. It will therefore be a slow and tedious process to identify and remove them.

It seems likely that such a multitude of small imperfections plague attempts to build models to predict the evolution of other more complex chaotic dynamical systems, such as the economy, and that the weather system provides a relatively well understood example of a general problem.

Charney, Jule Gregory

(1917- 1981)

Jule Charney, one of the greatest meteorologists of the 20th century, made original and fundamental contributions to the fields of meteorology and oceanography.

Charney was born January 1st, 1917 in San Francisco, CA. He received his undergraduate education in mathematics and physics at the University of California, Los Angeles. While pursuing further graduate studies, he became interested in fluid dynamics and meteorology and took part, initially as a student and then teacher, in the university s emerging meteorology program.

As World War II ended, Charney, with little or no guidance or supervision from the faculty, began work on the mathematical theory of instability in atmospheric flow. The 1947 publication of the resulting PhD thesis established him as a world leader in dynamic meteorology. Displaying deep physical insight, extraordinary brilliance, and creative genius, he provided a theoretical explanation for the genesis, intensification and propagation of large-scale waves in the atmosphere – the theory of atmospheric baroclinic instability. He showed that the observed large-scale fluctuations in the lowest 10 km of the atmosphere are manifestations of hydrodynamic instability of the extra-tropical middle-latitude westerly winds, the speeds of which increase with height between the warmer tropical and colder polar regions of the rotating planet.

The next few years took Charney to Chicago, Bergen (Norway), and then Princeton, while his interests turned

to the forecasting problem. He applied a systematic scaling technique to develop a simplified set of equations of motion, referred to as the quasi-geostrophic equations, that can be used for numerical weather prediction. In collaboration with the noted mathematician, John von Neumann, and others, he pioneered the application of electronic computers to weather forecasting, leading to the first successful numerical predictions in 1952. Charney s deep physical and theoretical insight transformed weather prediction from guesswork to science.

In the following years, Charney made numerous other significant scientific contributions on diverse problems, including: the growth of hurricanes; the Inter-Tropical Convergence Zone (ITCZ); the assimilation of satellite data; the dynamics of the Gulf Stream; the equatorial undercurrent in the ocean; ocean boundary currents; geostrophic turbulence; the theory of desertification; the theory of blocking and multiple flow equilibria; and the predictability of monsoons. In 1956, he joined the faculty of the Massachusetts Institute of Technology (MIT), which remained his primary affiliation for the remainder of his career.

In 1957, Charney was appointed to the US National Academy of Sciences Commission on Meteorology, where he called attention to the potential of global satellites, new instrumentation for detailed observation, and electronic computers – factors that led him to promote formation of the National Center for Atmospheric Research and eventually the Global Atmospheric Research Programme. The Global Weather Experiment of 1979, the first major international global weather measurement field program, is considered his brainchild.

Elected to Membership in the National Academy of Sciences in 1964, Charney continued to participate in many of its studies. Notably, he led a brief study in the summer of 1979 that produced an influential estimate of the influence of the increasing atmospheric carbon dioxide concentration on climate. That estimate of the range in global climate sensitivity, namely a warming of 1.5−4.5 °C for a doubling of the carbon dioxide (CO_2) concentration, has been since then the range used in developing estimates for future climate change.

Charney was an active participant in the anti-war efforts of the US academic community during the Vietnam War. After the US invasion of Cambodia, he was very active in raising funds for the anti-war candidates for political offices in the 1970 elections.

Charney died June 16th, 1981 in Boston, MA. Throughout his academic career, Charney mentored a stream of talented students recruited from varied countries and disciplines. His theoretical insights, the predictive capabilities we now enjoy, and perhaps above all the productive scientists whom he nurtured, remain his enduring legacy.

Chlorofluorocarbons (CFCs)

Mack McFarland
DuPont Fluoroproducts, Wilmington, DE, USA

Chloro uorocarbons (CFCs) are compounds containing only chlorine, uorine and carbon. The normal state of these compounds at standard temperature and pressure ranges from gases to liquids to waxes to solids. CFCs with suf cient vapor pressure to escape to and remain in the atmosphere contribute to both ozone-depletion and global climate change. These compounds are not destroyed in the troposphere and have very low water solubility. They are destroyed primarily by photolysis in the stratosphere where the chlorine is released. The chlorine acts as a catalyst for ozone destruction. Because transport to the stratosphere is a slow process, atmospheric lifetimes of CFCs are 45 years or longer. CFCs have signi cant infrared absorption cross-sections and, thus, contribute to global climate change with global warming potentials (GWPs) of 4600 or larger. CFCs are controlled under the Montreal Protocol for the Protection of the Ozone Layer and, except for minor exempted uses, their production for use has been phased out in developed countries and is to be phased out in developing countries by 2010. The most commonly used CFCs were CCl_3F (CFC-11), CCl_2F_2 (CFC-12), $CClF_3$ (CFC-13), CCl_2FCClF_2 (CFC-113), $CClF_2CClF_2$ (CFC-114) and $CClF_2CF_3$ (CFC-115).

CFCs were developed in 1929 as efficient alternative refrigerants to replace toxic and flammable fluids, including ammonia and sulfur dioxide, in use at that time. Commercial production began in 1931. CFCs are nonflammable, low in toxicity, thermally and chemically stable and relatively low in cost. These properties led to development of a wide range of other applications. After about 1950 they began to be used as aerosol propellants, cleaning agents and blowing agents for plastic insulating and cushioning foams. For example, through the early 1990s, CFC-12 was the primary refrigerant in home refrigerators/freezers. The insulating foam in the walls of those appliances was produced with CFC-11. A combination of properties including low vapor phase thermal conductivity contributed to efficient insulation in the small space available. CFC-11 as well as other CFCs were also used in many other thermal insulating plastic foams for the construction industry. Up until about 1995 CFC-12 was used as the refrigerant in automobile air conditioners. The CFC properties listed above in addition to desirable solvency and surface tension properties contributed to the widespread use of CFC-113 as a cleaning agent in the electronics industry, as well as specialized metal cleaning

applications. Both CFC-12 and CFC-11, and other CFCs to a lesser degree, were used as propellants in a wide variety of consumer products including hair sprays and perfumes. CFCs were chosen for these applications, even though they were more expensive than hydrocarbon propellants, because they are non-flammable and because of their chemical stability, appropriate vapor pressures at room temperature and miscibility with the various products. Consumption of CFCs expanded rapidly during the 1960s and early 1970s reaching almost a billion kg year^{-1} in 1974 with almost 70% of that use as an aerosol propellant (Figure 1).

As a result of the publication of the ozone depletion hypothesis by Molina and Rowland (1974) use of the compounds as aerosol propellants declined rapidly, especially in North America and Scandinavia where bans on the use for this application were eventually enacted. However, use of the compounds in other applications continued to grow. Continuing advances in the understanding of the potential impact of CFCs and other chlorine and bromine containing compounds on the ozone layer led to negotiation and adoption of the Vienna Convention for the Protection of the Ozone Layer in 1985. This agreement called for international cooperation to protect the ozone layer and provided a framework for agreements to control use of human produced ozone depleting substances such as CFCs. Further advances in the understanding of the science of ozone depletion provided the basis for the Montreal Protocol on Substances that Deplete the Ozone Layer (The Protocol), an instrument under the Vienna Convention, in 1987 (*see* Ozone Layer: Vienna Convention and the Montreal Protocol, Volume 4). This agreement initially required a 50% reduction in consumption of CFCs in developed countries over a ten-year period beginning in 1989 with similar controls for developing countries delayed by ten years. The Protocol also contained provisions for periodic review and modification of controls based on advances in understanding of the scientific, technical and economic issues. By early 1988, focused and extensive scientific studies initiated after the discovery of the seasonal declines in stratospheric ozone over Antarctica, the Antarctic ozone hole, in 1985 had established a link between CFCs and other compounds and ozone depletion. This link and other continuing advances in scientific understanding as well as the development of technical options for eliminating the use of CFCs and other ozone-depleting substances led to a series of increasingly stringent controls under the Protocol. Every major ozone-depleting substance is now controlled under the Protocol. Except for exempted uses, production of CFCs for use in developed countries ceased at the end of 1995. Production of CFCs for use in developing countries will cease by 2010.

These regulations have led to the development and implementation of a wide range of alternative fluids and technologies to replace CFCs. Hydrofluorocarbons (HFCs) and hydrochlorofluorocarbons (HCFCs) replaced CFCs in most refrigerant applications with hydrocarbons and ammonia playing a relatively minor role. Hydrocarbons and alternative dispensing technologies such as pump sprays were the primary alternatives for CFCs used as aerosol propellants.

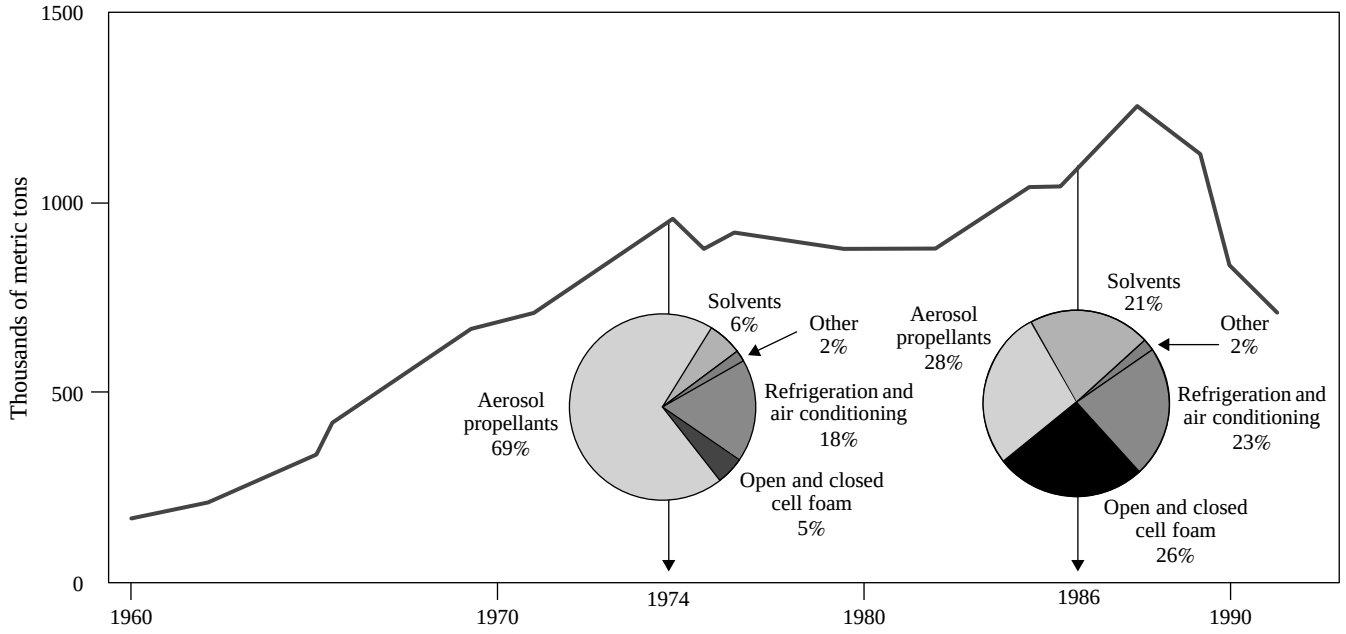

Figure 1 Estimated global CFC consumption. (Reprinted from McFarland (2000) with kind permission from Kluwer Academic Publishers)

HCFCs, water and carbon dioxide were the primary replacements for insulating foams. A wide range of technologies including water, hydrocarbons and changes in production techniques such that no cleaning was required displaced CFC use as cleaning agents.

Production of CFCs peaked at about 1.2 billion kg year^{-1} in 1988 before beginning to decline as a result of the internationally agreed phase-out. The cumulative atmospheric concentration of these compounds peaked at a level below 1 ppb around the year 2000.

CLIC (Climate and Cryosphere)

CLIC is a coordinated study of the role of all components of the cryosphere in the global climate system. The principal scientific questions being considered include:

- change in global sea level;
- energy and water cycles in regions with sea ice;
- land-ice and frozen ground;
- the role of polar fresh water in the ocean thermohaline circulation;
- the interactions of snow cover, sea ice and seasonally frozen ground with other climate processes;
- albedo feedback.

A CLIC Science and Co-ordination Plan has now been prepared, with systematic studies in the following areas:

- cryosphere–atmosphere interactions on a global scale;
- cryosphere–ocean interactions on a global scale;
- atmosphere–sea-ice–ocean interactions;
- atmosphere–land-ice–sea-level;
- cryospheric indicators of climate change.

Under CLIC, the World Climate Research Programme Arctic Climate System Study (ACSYS) will also be completed (*see* ACSYS (Arctic Climate System Study), Volume 1). Since 1993, ACSYS has been assembling a series of comprehensive Arctic climate data sets, including Arctic Ocean hydrography, sea-ice characteristics, the Arctic atmosphere and hydrological cycle. Efforts are also being made to improve representation in models of the physical processes dominant in Arctic climate. Another primary objective is the estimation of the Arctic freshwater budget in order to assess the role of the Arctic in driving the ocean thermohaline circulation. An extensive field program is involved with a range of Arctic Ocean hydrographic and shelf surveys, and an extensive historical Arctic Ocean climate data base has been compiled.

CLIMAP (Climate: Long-range Investigation, Mapping, and Prediction)

The CLIMAP project was an international research project funded by the United States National Science Foundation s International Decade of Ocean Exploration program in 1971. The original goal of the project was to reconstruct the history of the North Pacific and North Atlantic during the last 700 000 years (the Brunhes Normal magnetic epoch). This research resulted in developing the link

between changes in orbital insolation and the glacial cycles by examining the oxygen isotope ratios from ocean cores and proving that changes in oxygen isotope ratios mostly record ice volume rather than ocean temperature. In 1973, the objective expanded to map the surface of the Earth during the Last Glacial Maximum (LGM) (*see* Last Glacial Maximum, Volume 1), and to measure oscillations of the Pleistocene climate. One of the better-known products of CLIMAP was the mapping of LGM sea surface temperatures (SSTs) from planktonic assemblages in ocean cores. The CLIMAP (1981) results showed that SSTs were only a couple of degrees colder than present, which has recently been questioned by newer data showing even colder SSTs. In the final stages, the group also tried to map the Eemian (*see* Eemian, Volume 1) world. CLIMAP was originally composed of researchers from Lamont-Doherty Geological Observatory of Columbia University, Brown University, and Oregon State University, and later included the University of Maine and Princeton University. Eventually nearly 100 researchers from throughout the world were involved (Imbrie and Imbrie, 1986).

Climate

In popular usage, *climate* is the term used to describe the average of the weather during a long period of time at a particular location or over a particular region. In traditional climatological studies for the period when instrumental records are available, averages are usually taken over a designated 30-year period, although sometimes the lack of observational data requires the use of other time intervals. For pre-instrumental periods, efforts are made to reconstruct at least some of the variables defining the climate by use of proxy variables that are responsive to climate, such as tree ring width, pollen distribution, snow amount or other variables, always attempting to consider the representativeness of the measure. In more technical usage, and particularly in connection with modeling, climate is the set of statistics characterizing the state of the atmospheric, oceanic, cryospheric and land surface components of the physical climate system over any period of time longer than about one month. This definition thus includes a description of the variability, the seasonal cycle, and other statistical measures of the system, but is often restricted to the mean values characterizing the atmosphere.

Climate Agenda

Michael Coughlan
World Meteorological Organization, Geneva, Switzerland

The Climate Agenda was jointly developed by a number of international organizations carrying out signi cant climate-related activities in response to the requirements stated in Agenda 21. It is a comprehensive integrating framework for cooperation in climate data collection and application, climate system research and studies of socio-economic impacts of climate variability and their effects on ecosystems.

The *Climate Agenda* is a comprehensive integrating framework for international cooperation on climate-related programs, especially those relating to data collection and application, climate system research and studies of socio-economic impacts of climate variability and their effects on ecosystems.

The Climate Agenda was jointly developed by a number of organizations carrying out significant climate-related activities in response to the requirements stated in Agenda 21 and the United Nations (UN) Framework Convention on Climate Change (*see* United Nations Framework Convention on Climate Change and Kyoto Protocol, Volume 4). The international organizations are: Food and Agriculture Organization, the International Council for Science, UN Environment Programme, UN Educational, Scientific and Cultural Organization and its Intergovernmental Oceanographic Commission, World Health Organization and World Meteorological Organization (WMO).

The Climate Agenda is designed to enable governments, and international governmental and non-governmental organizations to coordinate their contributions to national and international climate programs. This is to be done in a way that allows the participating bodies to benefit from complementary activities of the global effort. International climate-related activities under the Climate Agenda concentrate on the following areas, called *thrusts*:

- new frontiers for climate science and prediction;
- climate services for sustainable development;
- studies of climate impact assessments and response strategies to reduce vulnerability;
- dedicated observation of the climate system.

The principal international programs comprising the Climate Agenda include the World Climate Programme (WCP), the International Geosphere–Biosphere Programme, the International Human Dimensions Programme for Climate Change and the Global Climate Observing System. The periodic assessments carried out by the Intergovernmental Panel on Climate Change are also considered major contributions to the Climate Agenda. Further information can be obtained from the WCP Department of the WMO in Geneva.

Climate Analogues

Climate analogues are past climates that may be similar to possible future climates. Typically the term refers to past climates analogous to a 21st century climate influenced by global warming due to human-produced greenhouse gases such as carbon dioxide. The Russian climatologist M I Budyko argued that a study of climate analogues would lead to more reliable predictions of global warming than can be made with climate models. To develop the analogues, he drew upon paleoclimatic results from warm periods from 6000 to 100 million years ago to characterize the geographic patterns of warm climates. Among the periods he focused on were times characterized by high atmospheric concentrations of carbon dioxide (e.g., the mid-Cretaceous era) or when warming had been induced by changes in the orbital characteristics of the Earth about the Sun. More recently, it has been recognized that the rapid pace of human-induced climate change limits the applicability of analogs from past climates and thus makes a detailed agreement between past and future climatic conditions unlikely (Crowley, 1990). However, there may be some validity in deducing the long-term global-mean climate sensitivity to greenhouse gases and other forcing factors using analogs (Hansen *et al.*, 1993; Hoffert and Covey, 1992). When this is done, the results are in reasonable agreement with the range of estimates developed using climate models.

Climate Change

Traditionally, *climate change* is defined as a local, regional or large-scale change in the long-term average regime of temperature, precipitation, circulation and related weather variables characterizing the climate. For the period since 1860 with instrumental records, the definition is usually applied over a designated 30-year period. For the pre-instrumental record, changes in climate can usually only be resolved on multi-decadal to millennial time scales. More recently, and particularly in the context of modeling, climate change is the change in the statistics characterizing the physical state of the atmosphere, ocean, cryosphere and land surface over a specified region over a specified period of time. This definition thus includes changes of the mean values, variability and other statistical properties of the physical variables describing the climate, and one can speak, for example, of a change in the January climate at a specific site, a change in the decadal climate over Europe, or the change in the global climate over a century.

W LAWRENCE GATES *USA*

Climate Change, Abrupt

Frank Oldfield and Keith Alverson
PAGES (Past Global Changes) International Project Office, Bern, Switzerland

Some of the most exciting new insights into the nature of global change have arisen from the growing body of evidence for rapid changes in the climate system. Recent evidence from ice cores and elsewhere shows that global climate, together with the other aspects of the Earth System to which it is intimately linked, has undergone repeated oscillations in the geologically recent past. Moreover, the emerging evidence indicates that the most dramatic of these switches in climate occurred within a matter of decades and was at least hemispheric in extent, with major consequences for temperatures, hydrological regimes, plants and animals. The new evidence is also providing insights into the climatic backdrop for the development of human societies in the past. Abrupt change also raises major challenges for projecting future climate change. If the potentially disastrous impacts of climatic surprises like the ones that have already occurred are to be avoided in the future, research devoted to deepening our understanding of abrupt changes in the past is of paramount importance.

INTRODUCTION

Any definition of abrupt climate changes is necessarily somewhat subjective, because it depends in large measure on the sample interval used in a particular study and on the pattern of longer-term variation within which the sudden shift is embedded. Here, we avoid any attempt at a general definition but focus attention on four types of rapid transition found in the paleo-record from the geologically recent past:

- On the time-scale over which Milankovitch forcing is recognizable, the evidence from marine, polar ice core and terrestrial records spanning the last 800 kyr, all highlight the sudden and dramatic nature of glacial terminations, the shifts in global climate that occurred as the world passed from dominantly glacial to interglacial conditions.
- Within the glacial periods themselves, and especially the most recent, spanning the period from around 70–11.6 kyr ago, there are very large climate oscillations recorded in archives from the polar ice caps, high to middle latitude marine sediments, lake sediments and loess sections. These oscillations occur on millennial time-scales and are usually referred to as Dansgaard–Oescheger (D/O) cycles (*see* Dansgaard- Oescheger Cycles, Volume 1).
- During the first half of the Holocene period, from 11.6 kyr to around 6 kyr, evidence from lower latitudes especially points to rapid shifts in climate during the period when ice volume, sea level and vegetation were changing in the wake of the last glacial termination and the latitudinal and seasonal distribution of incoming solar radiations differed significantly from that experienced today (*see* Holocene, Volume 1).
- Over the last 6 kyr, the patterns of solar and volcanic forcing are thought not to have differed greatly from the conditions prevailing over the last few centuries. Evidence for rapid changes within this period is therefore of critical interest as context for projecting future climate change.

GLACIAL TERMINATIONS

Figure 1 shows the record of paleo-temperature and atmospheric trace gas concentrations over the last 450 thousand years as recorded in the Vostok ice core from Antarctica (Petit *et al.*, 1999). That glacial terminations are much more rapid than glacial onsets is immediately evident. Trace gas concentrations closely track, but do not lead, the evidence for warming. These data suggest that under natural conditions, greenhouse gases have played a crucial role at the end of each glacial cycle, probably through feedback effects rather than as initiators of change.

The glacial termination for which we have most information is the last one, beginning some 16 kyr ago and ending around 11.6 kyr BP with the beginning of the Holocene (Figure 2). Two features tend to qualify any simple view of the termination as a single, rapid, globally coherent, monotonic process. When the inferred temperature changes in Antarctica and Greenland are synchronized on the basis of their records of changing atmospheric methane concentrations, it is clear that during the course of the warming trend from Glacial to Holocene, the record from Antarctica leads that from Greenland. Moreover, during the period of warming, the sharp fluctuations in temperature that mark the Greenland record in particular, are largely in anti-phase with the changes in much of Antarctica. Recent high resolution U–Th dating reinforces the idea of an Antarctic lead, since it suggests that the penultimate glacial termination occurred 135 ± 2.5 kyr ago (Henderson and Slowey, 2000). This date precedes the Northern Hemisphere insolation peak by nearly 10 kyr; thus, although consistent with primary deglaciation forcing by insolation levels in the Southern Hemisphere, or the tropics, this new evidence runs counter to the view that Milankovich forcing at high northern latitudes was the initial trigger for deglaciation. Any concept of a rapid shift associated with glacial terminations thus has to be qualified by the realization that the rate

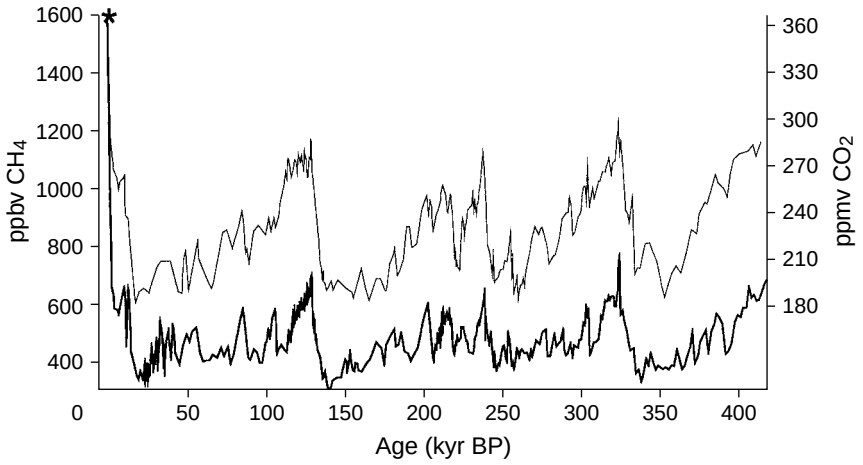

Figure 1 The sequence of changes in the concentration of atmospheric greenhouse gases methane (bold line) and carbon dioxide (narrow line) as recorded in trapped air bubbles in the Vostok ice core over the past four glacial cycles. In this figure, the ice core records have been extrapolated to the modern concentrations of both gases, 365 ppmv and 1600 ppbv for CO_2 and CH_4, respectively, as measured in the atmosphere in Antarctica (indicated by the asterisk). This extrapolation clearly shows that the modern levels are unprecedented over the entire record. (Reproduced with permission from Raynaud *et al.*, 2000)

Figure 2 The termination of the last glacial period was an abrupt climatic change. The associated Younger Dryas cold event some 11.6 kyr ago is, in this record from Central Greenland, manifested as a warming of around 10 °C, accompanied by a doubling in annual precipitation volume, occurring in about a decade. Shown here are accumulation (thick line) and oxygen isotope records (shown as inferred temperature (thin line)) from the GISP2 ice core. (Reproduced with permission from Alley *et al.*, 1993)

of change is not uniform over the whole globe and that the oscillations that are superimposed on the trend are not globally parallel in sign. The rapid oscillations that are superimposed on the warming trend and which tend to emphasize the dramatic nature of the termination are the last of the D/O cycles that are considered in the next section.

MILLENNIAL SCALE CHANGES: THE D/O CYCLES

One of the most unexpected outcomes of the detailed study of Greenland ice cores that began in the 1960s was the discovery that between 70 kyr and 11 kyr ago, all the climate indicators in the cores consistently indicated rapid,

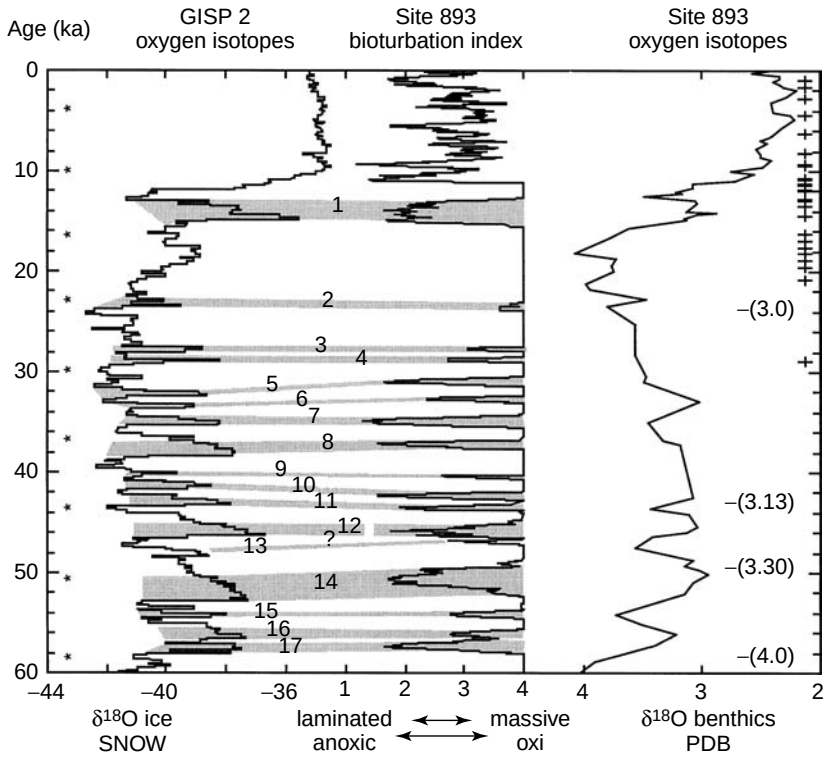

Figure 3 Millennial scale climate variability recorded in the oxygen isotope record from Greenland ice cores (GISP 2) and marine sediments in the Santa Barbara basin (Site 893). The bands linking the two records show the correlations proposed by the authors. The numbers represent the sequence of D/O oscillations identified in the Greenland record. The ice core oxygen isotope record is dominated by past changes in air temperature. The bioturbation index in the marine core reflects the oxygen status of the water column. The apparent coherence of the two widely separated records of environmental change points to climate linkages at least hemispheric in extent. (Reproduced with permission from Behl and Kennet, 1996)

high amplitude switches between full glacial and relatively mild interstadial conditions. Many of these switches appear to have been well over half the amplitude of the temperature change from the glacial maximum to peak Holocene warmth. Corroborating evidence for these oscillations has now come from both marine and continental sediment records (Figure 3). In the North Atlantic, each of the most severe of the cold shifts was associated with evidence for a massive southerly extension of the limit of iceberg extent, confirmed by the presence of ice-rafted detritus (IRD) in sediment cores. Moreover, the events themselves seem to be grouped in cycles (Bond Cycles) beginning with the most severe and gradually declining in amplitude until the next multiple cycle is initiated.

By combining the stratigraphic record of these rapid D/O cycles oscillations with attempts to model the mechanisms responsible, the dominant hypothesis to emerge sees the events as a product of the instability of the ice sheets that girdled the North Atlantic. Rapid discharge of ice into the ocean is thought to have reduced salinity to the point where North Atlantic Deep Water (NADW) formation was inhibited. This cut-off of NADW formation may then have so modified ocean circulation as to have influenced climate on a global scale. Such a hypothesis is consistent with the anti-phase relationship between Greenland and much of Antarctica often referred to as a *bipolar see-saw*.

It seems possible that the variations in amplitude of the cold swings reflect changes between iceberg surges reflecting instability of the Fennoscandian ice sheet, with its relatively more rapid response time, and the Laurentide ice sheet with its longer response time. Surges of the latter are thought to have been responsible for the most extreme events, those that gave rise to the main Heinrich IRD layers. The periodicity of the D/O events is not regular and no credible external forcing mechanism has been proposed. The bipolar anti-phase relationship demonstrated for the major D/O events suggests that they are largely the product of cryosphere–ocean dynamics.

The last of these events, often referred to as the *Younger Dryas*, is by far the best documented (*see* Younger Dryas, Volume 1). It marks the final stage of the last glacial termination, the transition to the Holocene already referred to above (Figure 2). Some sense of the suddenness of this transition in central Greenland may be obtained from

the record of ice accumulation and temperature (Alley *et al.*, 1993). Most of the transition, a near doubling of snow accumulation rate and a temperature shift of around 10 °C, was accomplished within a decade or less. By any standards, this is a truly dramatic, abrupt shift in climate, yet the generally accepted external forcing, an increase in solar irradiance, was relatively modest and certainly gradual. It appears that external forcing pushed the Earth system over some crucial threshold beyond which internal dynamics could generate extremely rapid responses through a range of, as yet poorly understood or quantified, feedback mechanisms.

Over much of the Northern Hemisphere, at least, the period of deglaciation between 16 and 11.6 kyrs ago is marked by a series of rapid shifts in climate, with minor, short-term oscillations superimposed on the major swings from full glacial to the Bolling–Allerod interstadial, the onset of the Younger Dryas and the final termination at the opening of the Holocene. These sharp, lower amplitude changes span decades to centuries and there is increasing evidence that they are spatially coherent and synchronous over large areas, including not only Central Greenland, Eastern Canada and Western Europe, but low latitude sites like the Cariaco Basin off the coast of Venezuela where laminated sediments provide an annually resolved paleoproductivity signal linked to climate changes.

THE FIRST HALF OF THE HOLOCENE

Although the Glacial/Holocene boundary is, over much of the world, a clearly recognizable and apparently synchronous stratigraphic feature, this does not imply that the Earth system as a whole experienced an instantaneous and complete shift. Several of the responses to the rapid changes taking place at the boundary took centuries, even millennia to complete. These include processes like the melting of the continental ice sheets, the recovery of global sea level to something approaching its present height, the recolonization of extensive areas by vegetation adapted to changed thermal and hydrological regimes, and the maturation of soils that goes hand in hand with increasingly stable vegetation cover where this had been absent during glacial times. Hence, it is important to remember that the period was one of transition and readjustment.

This said, it is equally important to dispel the view that the Holocene as a whole was a period of relatively constant climate. This proposition, arising from the stable isotope record in Central Greenland, is misleading. Not only is there now clear evidence of climate variability during the Holocene in Greenland itself, but evidence for Holocene climate variability at lower latitudes is also very strong.

Evidence is accumulating from several quite widely spaced sites for a sudden climate anomaly lasting for several hundred years centered around 8.2 kyr BP. This event shows up as a sharp decline in inferred temperature and in methane concentrations in the Greenland Icecore Project (GRIP)/Greenland Ice Sheet Project Two (GISP 2) ice core records from Central Greenland. An almost perfectly parallel change in $\delta^{18}O$ derived temperature can be seen in the evidence from Ammersee, in southwest Germany, based on stable isotope analyses of ostracod remains (Von Grafenstein *et al.*, 1998). Growing numbers of records appear to indicate that this oscillation had a widespread effect. In terms of timing and signature in the Greenland ice cores records, it appears to be in many ways comparable to the preceding, higher amplitude D/O oscillations and some link to ice melt and NADW formation may be involved, but there is also the possibility that the event, especially the methane anomaly, is linked to lower latitude changes in the extent of tropical and subtropical wetlands or the effects of rising sea level. Certainly, the whole of the early Holocene is marked by dramatic shifts in lake level and wetland extent in Africa and Central America.

The records of changing lake levels at a range of sites in central Africa constitute dramatic evidence of the major changes in hydrology that occurred during the early Holocene (Gasse, 2000) (Figure 4a). Equally powerful indications of variability come from reconstructions of the changing extent of wetlands and vegetative cover in the Sahara/Sahel region and from evidence for high altitude lake level variations in the Altiplano of the central Andes. Gasse (2000) summarizes evidence showing strong coherence between salinity changes in the North Atlantic and the lake level variations recorded across central Africa. The dynamics of these dramatic, low latitude hydrological changes are further complicated by the demonstration that the changes in surface hydrology and vegetation themselves have a crucial feedback to the regional climate. Without including this feedback alongside other forcing, including sea-surface temperatures, it is impossible for existing models to come even close to simulating the extent of wetlands and plant cover in the Sahara/Sahel region during much of the early–mid Holocene (DeMenocal *et al.*, 2000).

THE SECOND HALF OF THE HOLOCENE

Before sharpening the focus on the late Holocene, it is useful to consider briefly some of the evidence that has been interpreted as reflecting the persistence of modes of variability throughout the Holocene. For example, the lake level record from central Africa shows evidence for rapid changes after 6 kyr BP. The changes, though no less sudden than those in the early Holocene, become somewhat reduced in overall amplitude. In the North Atlantic there are

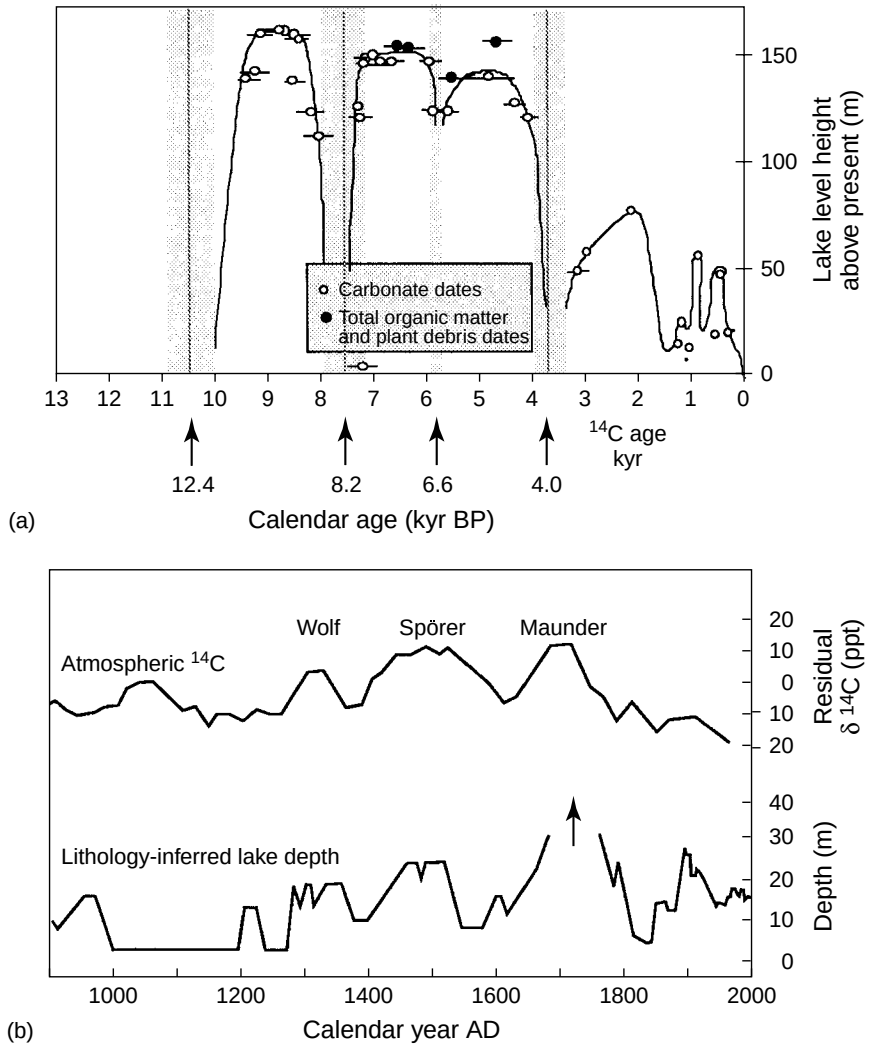

Figure 4 Holocene lake level records from much of Africa show dramatic oscillations well beyond the range of variability captured by the instrumental record. (a) the record from lake Abhe Ethiopia showing periods of extreme drought lasting for centuries with lake level changes of over 100 m occurring on these timescales. (b) A high resolution lake level record for the past millennium from Lake Naivasha, Kenya showing periods of multidecadal drought and lake level variations of over 10 m. Over this time period, lake level is well correlated with atmospheric ^{14}C, a possible proxy for solar activity. (Reproduced with permission from Gasse, 2000 and Verschuren *et al.*, 2000)

also signs that the mode of variability expressed in earlier times successively as D/O events, the Younger Dryas and the 8.2 kyr event persists throughout the Holocene with a somewhat irregular periodicity within the thousand to three thousand year range (Bond *et al.*, 1999). Similar evidence, also indicative of rapid climate shifts, can be cited from many parts of the world, but better chronological control is needed before a clearer picture emerges of the temporal and spatial coherence of these variations.

Turning now to the later part of the Holocene, additional records, many of which have annual resolution, become available. Moreover, the concept of rapid or sudden change becomes something that can be better quantified over large areas and more readily compared with the variations recorded during the recent period of instrumental observations which, for most of the world, seldom exceeds the last 150 years. Attention has focused on the so-called Little Ice Age (LIA) and Medieval Warm Period (MWP) because these are claimed to have had a strong influence on settlements and prosperity especially in Europe. Chronologically constrained evidence for climate changes broadly paralleling but rarely perfectly synchronous with the European MWP–LIA sequence has been identified in records from around the Northern Hemisphere and into low latitudes – for example in the record from the Quelcaya Ice Cap in Peru. Where it has proved possible to analyze high

frequency modes of variability such as El Niño–Southern Oscillation (ENSO) in the time domain, clear evidence is emerging of low frequency abrupt shifts in mode involving both amplitude and periodicity. Increasingly, as detailed chronologies become applicable to a wider range of sites and archives, key time intervals both within and beyond the last two millennia are showing evidence of rapid climatic change with signatures and impacts over a wide area (Mann *et al.*, 1999).

Out of this mix of indications, some generalizations about forcing are beginning to emerge. One of the influences frequently cited is solar variability. In some cases, links between climate and solar variability appear to be present on decadal to century timescales (Verschuren *et al.*, 2000) (Figure 4b) although the precise mechanisms involved are still a matter of controversy. This example is but one of many documenting climate shifts at the regional level and pointing to changes in drought frequency and amplitude well beyond those documented in the instrumental record. However, when archives as well dated as high latitude tree rings are compared across the whole of the Northern Hemisphere for their paleoclimatic response, non-synchroneities are clear. By contrast the brief and transient, but sometimes quite extreme, responses to volcanic eruptions are demonstrably synchronous over wide areas.

IMPLICATIONS FOR THE FUTURE

Growing attention has been paid to the possibility that anthropogenically driven climate change in the future may lead to surprises, major shifts well beyond the range of variability upon which planning and construction schemes are based and even outside the envelope of scenario projections generated by currently available climate models. The paleo-record does not preclude such possibilities, among which major changes to NADW formation have received most attention. Oceanic General Circulation Models raise the possibility that an inflow of sufficient fresh water from additional high latitude precipitation and runoff could have the effect of reducing NADW formation to the point of seriously altering the ocean thermohaline circulation. The climate changes linked to such an event would certainly constitute a surprise and, for many parts of the world, even a catastrophe.

The lessons from the paleorecord for the future are not limited to warnings about potential surprises on the scale of a cessation of NADW formation. Extending the record of climate variability back through time reveals changes, often sudden and sometimes persistent on decadal to century time-scales, which lie outside the range of instrumental records. The concepts of future sustainability, water supply and food security are limited and potentially dangerously short sighted if they fail to accommodate the evidence from the longer-term record.

Climate Change, Detection and Attribution

Myles R Allen
Rutherford Appleton Laboratory, Didcot, UK

Research in the detection and attribution of climate change addresses two basic questions. First, is the climate changing by more than we would expect from internally generated variability (the detection problem)? Second, can we assign this change to a speci c external cause (such as human activity) or combination of causes (the attribution problem)? The main challenge is that we can only observe climate change in the real world once: controlled, repeatable experimentation on the planet being infeasible (not to mention unethical). Hence detection and attribution involve detailed comparisons of multiple model simulations with the observed record, comparing modeled and observed patterns of change to build a statistical picture of what is going on. Formal statements of causal attribution, in any eld, will always be subject to some level of uncertainty: the goal is to be as quantitative as possible in establishing the level of uncertainty and reducing it as far as possible.

Although human activities have been changing atmospheric composition for two centuries, prior to the mid-1990s most scientists were reluctant to attribute observed large-scale changes in climate specifically to human influence. The Second Assessment Report (SAR) of the Intergovernmental Panel on Climate Change (IPCC), (Santer *et al.*, 1996a), broke significant ground in concluding that the balance of evidence suggests a discernible human influence on global climate (*see* Intergovernmental Panel on Climate Change (IPCC): an Historical Review, Volume 4). While a major step forward in building confidence in overall scientific understanding of the problem, this statement was still very cautious. In particular, the SAR did not attempt to quantify the magnitude of this human influence, and it also avoided attributing all or even part of the observed change to a specific forcing agent, such as anthropogenic greenhouse gases.

CORRELATIONS BETWEEN MODELED AND OBSERVED CHANGES

The reason for this caution was that the SAR statement was primarily based on the evidence provided by correlations between observed and model-simulated patterns of trends in near surface (Santer *et al.*, 1994) and zonal mean atmospheric temperatures (Santer *et al.*, 1996b; Tett *et al.*, 1996) over the past 30–50 years. These correlations were found to be significantly higher than would be expected by chance due to internal climate variability as simulated by control integrations of a range of climate models. Although attractively simple to implement and explain to non-specialists, the pattern correlation approach had two acknowledged shortcomings. First, correlations are insensitive to the relative magnitude of observed and model simulated changes, so they do not convey any information about the size of the observed change or whether the models are over- or underestimating it. Second, a positive correlation between an observed change and a single model simulated response pattern does not necessarily preclude some other external influence, which happens to generate a similar pattern of response, confounding the picture.

For example, the combination of an increase in solar activity causing warming of the troposphere and depletion of stratospheric ozone causing cooling of the stratosphere (Ramaswamy *et al.*, 1996) might, together, generate a pattern of atmospheric temperature change rather similar to that expected from the anthropogenic increase in greenhouse gas levels. Stratospheric ozone depletion is itself primarily anthropogenic, so this possibility does not bring into question the conclusion of human influence of some form. Nevertheless, because ozone depletion is expected to reverse over the coming decades while greenhouse gas increases are expected to dominate anthropogenic change over the 21st century, the evidence for anthropogenic greenhouse influence is of greater practical significance than the evidence for human influence *per se*.

In summary, the evidence available at the time of the SAR was sufficient to conclude that a significant climate change was occurring that could be explained by human influence. Nevertheless, both the size of the contributions from different anthropogenic agents, notably greenhouse gases, sulfate aerosols and stratospheric ozone depletion, and the extent of other natural influences, such as changes in solar or volcanic activity, remained uncertain. Thus, as was noted at the time, the IPCC statement in the SAR allowed for the possibility of a statistically significant anthropogenic climate change that was too small to have any practical importance.

NEW DEVELOPMENTS IN DETECTION AND ATTRIBUTION

Five years on, the situation has changed considerably, and we are in a position to make a more quantitative assessment of the extent to which recent observed climate changes are attributable to human influence, particularly the impact of anthropogenic greenhouse gas emissions.

The first new development is an apparently strengthening signal in the observational record: the 1990s was the warmest decade, and 1998 the warmest year, almost certainly over the past century and very possibly over the past millennium (Mann *et al.*, 1998). The availability of reconstructions of past temperatures using indirect proxy indicators extending the temperature record back beyond the 140 years of reasonably global direct measurements is an important new development, because it places recent changes in the context of a longer record. Individual years or decades should not, however, be over-interpreted: in particular, an unusually strong El Niño occurred in 1998. Confidence in detection and attribution of human influence on climate only emerges as model-based predictions are borne out over a much longer period.

A second important development is increased confidence in estimates of internal climate variability. These proxy climatic records also provide a check on the realism of model simulated internal variability. In general, the more up-to-date models generate internal variability similar in magnitude to that observed once changes attributable to natural and anthropogenic external factors are taken into account (Hegerl *et al.*, 1996; Allen and Tett, 1999; Crowley, 2000; Stott *et al.*, 2000b; Allen *et al.*, 2001). None of these models generates warming trends as large as that observed over the past century through internal variability alone, even when run for several thousand years.

A third important development since the SAR is the wider availability of comprehensive model simulations of the climate response to a range of different external forcing scenarios, including various combinations of anthropogenic forcing agents and natural external influences such as variations in solar and volcanic activity (e.g., Tett *et al.*, 1999). A crucial element of any quantitative assessment of the extent to which an observed change can be attributed to a particular external factor is an estimate of the expected change due to that factor, together with estimates of expected changes due to physically plausible alternatives. In simple terms, to assess whether a signal is there, we need to know both what we are looking for and what we need to discriminate against.

Finally, we are now using a wider range of quantitative tools for model–data comparison that take into account the relative magnitude of model simulated and observed changes, allowing us to assess whether models over- or underestimate the observed response. These tools are primarily based on the *ngerprinting* approach of Hasselmann (1979, 1993), also referred to as *optimal averaging* (Bell, 1986) or *optimal ltering* (North *et al.*, 1995). The first applications of the fingerprinting approach (Hegerl *et al.*, 1996) considered only a single pattern of anthropogenic influence, and were therefore subject to the problem of confounding signals mentioned above. More recent studies, from Hegerl *et al.* (1997) onwards, allow for multiple uncertain contributions to recent climate change, assuming that the observed change consists of the sum of a set of model simulated changes, including the response to greenhouse gases, sulfate aerosols, and solar and volcanic activity, for example. Allen and Tett (1999) discuss the physical interpretation of this multi-fingerprinting algorithm in some detail. In essence, the parameters being estimated are the factors by which it is necessary to scale model-simulated signals to reproduce observed climate changes. A scaling factor consistent with zero implies that this particular model-simulated signal is not detectable in the observed climate record using the data set under consideration, while a scaling factor consistent with unity implies the model simulated amplitude could be correct. In a very similar vein, Leroy (1998) reformulated the approach of North and Stevens (1998) in terms of Bayesian estimation theory, a more flexible framework that allows multiple lines of evidence to be drawn together in a formal manner. The algorithms of Allen and Tett (1999) and Leroy (1998), are identical in the absence of any prior expectation about (or equivalently, given infinite prior variance in) scaling factors to be applied to individual signals.

EVIDENCE FROM PATTERNS OF SURFACE TEMPERATURE TRENDS

Hegerl *et al.* (1997) concluded that both anthropogenic greenhouse gas and sulfate influences were required to account for the observed spatial pattern of boreal summertime warming trends over the past fifty years, while cautiously noting that some influence of solar variability might be required to account for the warming observed in the early decades of the 20th century. In a number of follow-up papers (Barnett *et al.*, 1999; Hegerl *et al.*, 2000), the authors have examined the sensitivity of this result to the model used to simulate the characteristics of anthropogenic signals and internal climate variability, finding that their original conclusions regarding sulfate influence on climate were particularly sensitive to the model used and assumptions made in the analysis.

EVIDENCE FROM THE TIME-HISTORY OF RECENT CHANGES

Tett *et al.* (1999) applied a similar approach to observed spatio-temporal patterns of surface temperature change

(Hegerl *et al.* (1996) and subsequent papers focused on spatial patterns of linear temperature trends) and also concluded that both greenhouse and sulfate influences are required to account for observed near-surface temperature changes in the latter half of the 20th century, with a possible role for solar variability in the warming that occurred over the period 1910–1940. With ensemble simulations of the response to natural external forcing agents at their disposal, they were able to draw stronger conclusions than previous authors regarding the difficulty of accounting for observed changes in exclusively natural terms.

Stott *et al.* (2001) show that the inclusion of seasonal information strengthens the evidence for solar influence on the early part of the 20th century. In contrast, Delworth and Knutson (2000), using a different model to estimate internal variability which displays greater variance on 50–80 year time scales, conclude that the warming that occurred early in the century can be accounted for through a combination of anthropogenic influence and internal variability. There is no inherent inconsistency between these two results: Stott *et al.* (2001) were using a more powerful analysis, in that they included both seasonal information and a model based estimate of the spatio-temporal pattern of response to solar forcing (not available to Delworth and Knutson (2000), because their model had not yet been run with estimates of changing solar forcing). It is not surprising that a more powerful analysis detects a weak signal when a less powerful one fails, but this sensitivity to the diagnostic and/or model used indicates that the evidence for a solar role in early 20th century warming remains weaker than the evidence for anthropogenic influence in more recent decades.

The earliest attribution studies, such as Hegerl *et al.* (1996) and Hegerl *et al.* (1997), used signals based either on the equilibrium response of a climate model to a particular forcing or on the transient response over some period in the future. In both cases, the forcing would be sufficiently strong that sampling uncertainty in the model-simulated response would be negligible: if the experiment were repeated, essentially the same model-simulated signal would be obtained. In contrast, more recent studies, beginning with Tett *et al.* (1996), have used signals based on model-simulated responses to forcing changes over the same period as the observations used in the comparison. This approach simplifies interpretation of results, but introduces the complication that climate forcing is not as strong over the 20th century, so model-simulated signals are themselves contaminated by internal variability. This contamination can be reduced through the use of ensemble simulations, as in Tett *et al.* (1999), or through the use of noise free-climate models, as in North and Stevens (1998). The ensemble approach is expensive, so ensembles are not available for all models, while any climate model that is free of internal variability is also likely to be lacking key non-linear feedback processes that may affect the model simulated signal.

Allen *et al.* (2000) and Stott *et al.* (2000a) describe and test a modification to standard fingerprinting that accounts explicitly for the presence of sampling noise in model simulated signals based on single member or small size ensembles. They follow the standard total least squares (TLS) estimation procedure documented in detail by van Huffel and Vanderwaal (1994). Stott *et al.* (2000a) demonstrate that this revised algorithm is particularly important if small (one or two member) ensembles are used in climate model simulations, although it can still make a significant difference even if larger ensembles are available, particularly on upper bounds of uncertainty ranges and when considering relatively weak model-simulated signals (such as the response to natural external influences). Allen *et al.* (2001) apply this procedure to a wide range of model simulations of recent near-surface temperature change, while Stott *et al.* (2000b) and Tett *et al.* (2001) investigate the most up-to-date and comprehensive set of model simulations available to date for detection and attribution studies.

CONCLUSIONS OF KEY RECENT STUDIES

1. When the spatio-temporal patterns of change are taken into account, recent changes cannot be accounted for as internal variability even if the amplitude of model-simulated variability is increased by a factor of two or more.
2. Natural external forcing (solar and volcanic activity) cannot account for the observed acceleration in warming between the 1960–1970s and 1980–1990s, even if amplified by unknown feedback mechanisms, because solar forcing leveled off over this period and volcanic activity was acting as a cooling influence.
3. Solar activity may have contributed significantly to the warming observed in the early 20th century, but uncertainties in the reconstruction of past forcings make this only a tentative conclusion.
4. There is evidence for anthropogenic sulfate and ozone influence on recent near-surface and stratospheric temperature changes, respectively, but the estimated size of this influence depends acutely on the models used to estimate both forcing and response.
5. By far the strongest and clearest signal in the recent climate record is the influence of the anthropogenic increase in greenhouse gas concentrations, with the warming trend attributable to greenhouse gases being at least half and possibly up to three times the total observed warming, depending on the diagnostic used and period considered.

Drawing this information together, the *IPCC Third Assessment Report* (Mitchell *et al.*, 2001) concludes there

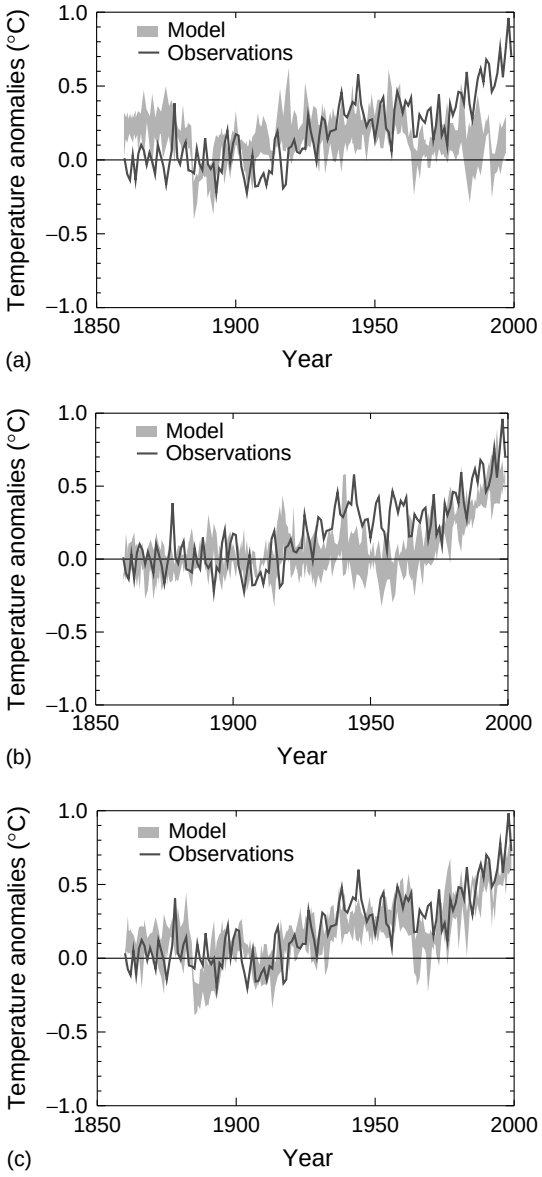

Figure 1 Global mean temperature from 1861 to the present as observed (solid lines) and as simulated by the HadCM3 climate model from the UK Met Office (gray bands, with the width of the bands representing internal model variability within four-member ensembles): (Stott *et al.*, 2000b). In panel (a), the model is forced with the main natural influences on climate, namely solar variability and volcanic activity: the model clearly fails to reproduce the rapid warming over the past three decades. In panel (b), the model is forced with anthropogenic influences alone, particularly greenhouse gases, sulfate aerosols, and stratospheric and tropospheric ozone: the model now fails to simulate the observed early-century warming. In panel (c), all forcings are imposed, and the agreement between model and data is remarkably good. (Figure as published in the Summary for Policymakers of the IPCC Third Assessment Report, prepared by Peter Stott of the UK Met Office and Paul van der Linden of the IPCC WGI Technical Support Unit, and used by permission)

is new and stronger evidence that most of the warming observed over the past 50 years is attributable to human activity, specifically the influence of anthropogenic greenhouse gases.

Figure 1, from Stott *et al.* (2000b), summarizes this evidence: panel (a) shows that the model-simulated response to natural forcings alone cannot explain the warming trend since 1980, panel (b) shows that anthropogenic influence alone can explain the most recent warming but leaves some discrepancies earlier in the century, while panel (c) shows that a combination of natural and anthropogenic influences account, to a remarkably high degree, for observed large-scale temperature changes over the full 20th century.

While much progress has been made in the detection and attribution of temperature changes on continental and global scales, attribution of regional changes and of changes in non-temperature variables remains much more speculative. Changes have been observed that are consistent with those we would expect to result from anthropogenic climate change, including in particular a 10–20 cm rise in sea level over the past century, a significant fraction of which is attributable to an increase in global ocean heat content. Other changes that may be partly due to human influence include a 10% decrease in snow cover since the 1960s; substantial declines in Arctic sea ice thickness and extent; widespread retreat of mountain glaciers; over land a decrease in the temperature difference between night time and day time, and between winter and summer; and, possibly, some increase in the frequency and intensity of heavy rain and snowfall events over Northern Hemisphere temperate regions.

The lack of long observational records or reliable model-based estimates of internal variability in these non-temperature indicators makes it impossible formally to quantify the probability that any of these changes, taken individually, is human-induced rather than natural. Taken together, however, they present a collective picture of a changing global climate increasingly under the influence of human activity.

Climate Feedbacks

L D Danny Harvey
University of Toronto, Toronto, Canada

Climate can change for a variety of reasons, including changes in the composition of the Earth's atmosphere, changes in the energy output from the Sun, changes in the Earth's orbit around the Sun, or changes in the position and area of continents or in the nature of the land surface. These factors cause the climate to change by upsetting the balance between the absorption of solar energy by the sun and the emission of infrared radiation to space by the earth and atmosphere. The change in the net radiation at the tropopause in response to some perturbing factor is called the radiative forcing, and has units of $W\,m^{-2}$ *(watts per square meter), and is what drives changes in the surface climate. The radiative forcing is translated into a temperature change by a variety of feedbacks which either amplify or diminish the initial radiative forcing. A positive climate feedback adds to the initial radiative perturbation and so increases the eventual change in climate, while a negative feedback subtracts from the initial perturbation and so reduces the eventual change in climate.*

The temperatures of the atmosphere and surface tend to adjust themselves such that there is a balance between the absorption of energy from the sun and the emission of infrared radiation to space. If, for example, there were to be an excess of absorbed solar energy over emitted infrared radiation (as occurs with the addition of greenhouse gases to the atmosphere), temperatures would increase but, in so doing, the emission of infrared radiation to space would increase. This would reduce the initial imbalance, and eventually a new balance would be achieved, but at a new, higher temperature. The more rapidly that infrared emission to space increases with increasing temperature, the less that the temperature must increase in order to restore balance.

However, as temperatures increase, other quantities would also change, which would further alter the net emission of radiation to space. For example, an increase in the amount of water vapor as temperature increases would tend to counteract the effect of warmer temperatures in increasing the emission of infrared radiation to space, since water vapor absorbs infrared radiation. As a result, infrared emission would increase more slowly and a greater temperature increase would be required to restore radiative balance. A reduction in the amount of solar energy reflected to space would also tend to offset the effect of increasing infrared emission to space. The resulting rate at which the net emission of radiation to space increases is called the *radiative damping*, λ. The term damping is used because it is the increase in net emission to space as temperatures warm that limits or dampens the increase in temperature. A larger radiative damping results in a smaller temperature increase.

This discussion can be succinctly summarized by the equations

$$\Delta T = \frac{\Delta R}{\lambda} \tag{1}$$

and

$$\lambda = \frac{\mathrm{d}F}{\mathrm{d}T} - \frac{\mathrm{d}Q}{\mathrm{d}T} \tag{2}$$

where ΔT is the eventual change in global average temperature, ΔR is the global average radiative forcing, F is the global average emission of infrared radiation to space, Q is the global average absorption of solar radiation, and T is the global average temperature (strictly speaking, F should be evaluated at the tropopause and Q should be based on the absorption of solar radiation by the surface and troposphere only, since we are interested in surface temperature change).

In the absence of any feedback except the increase in temperature itself, the only way that the emission of radiation to space increases is through the direct dependence of emission on temperature through the Stefan–Boltzman Law. In this case, $\lambda = 3.76\,\mathrm{W\,m^{-2}\,K^{-1}}$. Since a doubling of atmospheric CO_2 (carbon dioxide) causes a global mean radiative surplus ΔR of $3.5–4.0\,\mathrm{W\,m^{-2}}$, the temperature increase required to restore radiative balance in this case would be $\Delta R/\lambda = 1.0\,\mathrm{K}$ (a warming of $1.0\,^{\circ}\mathrm{C}$). However, as noted above, the very change in temperature would cause other atmospheric and surface properties to change, which would lead to further alterations in the energy balance and require further temperature changes through a series of feedback processes.

MAJOR CLIMATE FEEDBACKS

Feedbacks translate a radiative forcing into a change in temperature by altering the radiative damping. Among the feedbacks that have to be considered are the following:

- *Water vapor amount*: in a warmer climate the atmospheric concentration of water vapor will increase. Because water vapor is a greenhouse gas, this is a positive feedback – that is, it amplifies the initial change.
- *Water vapor distribution*: if, as the total water vapor amount increases, the percentage increase is greater at higher altitudes than at lower altitudes, this will result in a greater climate warming than if the water vapor amount increases by the same percentage at all altitudes, as explained later. The case where the percentage increase in water vapor is greater at higher altitude is equivalent to increasing the water vapor amount by the same percentage at all altitudes, then shifting the distribution upward. This serves as a positive feedback. Conversely, a downward shift in the water vapor distribution as the climate warms would serve as a negative feedback.
- *Clouds*: changes in clouds can serve as a positive or negative feedback on climate. Clouds have a cooling effect by reflecting sunlight, but they also exert a warming effect by absorbing the infrared radiation emitted by the surface and re-emitting a smaller amount of radiation due to the fact that the cloud top is colder than the surface. The net feedback of changes in clouds depends on the details of when and how clouds change, so even the sign of the feedback is uncertain (*see* Clouds, Volume 1).
- *Atmospheric temperature structure*: changes in the rate of decrease of tropospheric temperature with height (or lapse rate) will alter the relationship between surface temperature and infrared emission to space, thereby exerting a feedback effect on climate.
- *Areal extent of ice and snow*: a reduction in the area of sea ice and seasonal snow cover on land as climate warms will reduce the surface reflectivity, thereby tending to produce greater warming (a positive feedback). However, concurrent changes in cloud cover that could be induced by the change in ice or snow cover could significantly alter the net feedback, as explained later.
- *Vegetation*: changes in the distribution of different biomes or in the nature of vegetation within a given biome can also lead to changes in the surface reflectivity, thereby exerting a feedback effect on climatic change.
- *The carbon cycle*: the effect of climate on the terrestrial biosphere and the oceans is likely to alter the sources and sinks of CO_2 and CH_4 (methane) leading to changes in their atmospheric concentrations and hence causing a radiative feedback.
- *The sulfur cycle*: changes in climate or associated changes in the vertical mixing of nutrients in the ocean are likely to lead to changes in the production of dimethyl sulfide (DMS) by bacteria in the ocean, which in turn could lead to changes in the optical properties of clouds (*see* Dimethylsul de (DMS), Volume 1).
- *Atmospheric chemistry*: changes in climate will also lead to changes in the chemistry of the atmosphere, in turn indirectly affecting the concentration of a number of greenhouse gases and thereby altering the emission of infrared radiation to space. In particular, in a warmer climate there will be a greater concentration of water vapor and hence of the hydroxyl radical (which is formed by dissociation of water vapor by ultraviolet radiation). The hydroxyl radical in turn determines the life-span and hence atmospheric concentration of methane, and influences the concentration of tropospheric ozone.

Of these feedbacks, those involving water vapor, the lapse rate, atmospheric chemistry, and clouds respond essentially instantaneously to climatic change, while those involving sea ice and snow respond within a few years. These feedbacks are therefore referred to as fast feedbacks. Some vegetation and carbon cycle processes are relevant on a time-scale of decades. Other feedbacks, such as dissolution of carbonate sediments in the ocean and enhanced chemical weathering on land (both of which tend to reduce the atmospheric CO_2 concentration), require hundreds to thousands of years to unfold. Feedbacks involving continental ice sheets occur over periods of thousands of years.

The term *climate sensitivity* refers to the ratio of the long term (steady-state) increase in the global and annual mean surface air temperature to the global and annual mean radiative forcing (*see* Climate Sensitivity, Volume 1). It is standard practice to include only the feedbacks due to water vapor, seasonal ice and snow, and clouds – all of which are fast feedback processes – in the calculation of climate sensitivity using computer climate models. Feedbacks involving DMS and clouds have been excluded because they are too uncertain, while atmospheric chemistry feedbacks have not yet been included because coupled climate–chemistry models have only recently been developed (atmospheric chemistry feedbacks are not expected to be large). In the long-term, a warming of the climate might induce increases in the atmospheric concentration of CO_2, but these and other slow feedback processes are not included in the conventional definition of climate sensitivity. To calculate these feedbacks requires the use of coupled climate–carbon cycle models, with a representation of the geographical distribution of different ecosystems and of biological and chemical processes affecting the cycling of carbon in the oceans. Unlike the fast feedback processes, which are driven by overall climatic change independently of how fast the change occurs, many potential

climate–carbon cycle feedbacks depend to some extent on the rate of change as well as on the absolute change, and thus depend on the particular future human emissions of greenhouse gases and aerosols. Thus, there are distinct advantages in restricting the term climate sensitivity to the fast feedback processes while recognizing the potential for further, longer term feedback effects.

EVALUATION OF THE FAST FEEDBACK PROCESSES USING CLIMATE MODELS

The only models with the potential to reliably simulate the individual feedback processes are three-dimensional (3D) atmospheric general circulation models (AGCMs) with high spatial resolution and a diurnal cycle. However, the complexity of the processes involved in these feedbacks and the need for rather coarse resolution in AGCMs means that results obtained from AGCMs are still rather uncertain.

For example, the amount and distribution of water vapor depends on evaporation of surface water, horizontal and vertical transport of moisture by large-scale winds and small-scale eddies, upward movement by dry convection and within convective clouds, detrainment of moisture from cloud tops, dissipation of non-precipitating clouds, partial re-evaporation of precipitation, and the downward movement of dry air between rising convective columns at low latitudes. At present, only simplified representations of these processes are included in AGCMs, due mainly to the relatively coarse resolution of these models (from many tens to several hundred kilometers) compared with the scales of the most important processes (micrometers to kilometers).

Another example of difficult but important processes to simulate involves clouds. The initiation of clouds in nature depends on large scale motions, the coupling of these motions to the surface layer of the atmosphere (which feeds moisture into the overlying air), and the spatial distribution and intensity of surface–air fluxes of heat and moisture. Once clouds have been initiated in a model, a number of cloud properties and processes need to be simulated, including:

- the liquid and ice water content of clouds and their horizontal variability within model grid cells;
- the mean water droplet or ice crystal sizes and the distribution of sizes around the mean size;
- the optical properties of clouds for a given mean particle size and distribution – something that is complicated by the potential presence of impurities (such as soot) and is particularly difficult to predict for ice crystals because of their irregular shape;
- the fall velocity and hence life-span of water droplets and ice crystals;
- the cloud geometry (thickness, patchiness);
- the detrainment of cloud moisture and mixing with surrounding air, which is especially important to the formation of cirrus anvils from cumulus clouds;
- the formation of precipitation and the partial re-evaporation of falling precipitation, and;
- convective-scale downdrafts and their interaction with the surface layer of the atmosphere.

Most of these processes and properties have been incorporated in 3D climate models, but they are treated in a highly simplified and in some cases a rather *ad hoc* manner because most of them occur at scales well below the resolution of global models. This introduces the potential for substantial error in the simulated changes in cloud properties, locations, and amounts.

Clear-sky Feedbacks

The combination of changes in the amount of water vapor, in the vertical distribution of water vapor, and in the lapse rate in cloud-free regions is referred to as the clear-sky feedback. Analyses with a variety of climate models indicate that the clear-sky feedback is positive and sufficient to increase the climate sensitivity by 50–100% (Cess *et al.*, 1990; Harvey, 2000a, b). That is, the expected warming for a doubling of the atmospheric CO_2 concentration ranges from about 1.5 to 2.0 °C, rather than 1.0 °C (as in the case with no feedbacks other than a spatially uniform increase in temperature). The water vapor feedback is positive in these models due to the simple fact that the amount of water vapor in the atmospheric increases as the climate warms. The lapse rate feedback is negative at low latitudes and positive at high latitudes.

To understand the lapse rate feedbacks, suppose that there is an initial heating perturbation (such as a CO_2 increase) that begins to warm the climate. At low latitudes the lapse rate decreases as the climate warms, meaning that temperature begins to fall less rapidly with increasing height as the climate warms. This results in a larger increase in temperature in the upper troposphere than if the lapse rate were constant. This in turn causes a faster increase in the emission of infrared emission to space as surface temperature increases, which is the same as saying that the radiative damping is larger. As a result, the surface temperature does not need to warm up as much in order to restore radiative balance, which means that the climate sensitivity is smaller. At high latitudes, the opposite changes occur – the lapse rate increases as the climate warms (temperature falls more rapidly with increasing height), so there is less warming of the upper troposphere and less increase in the emission of infrared radiation to space, so a larger surface warming can occur.

The reason the lapse rate tends to decrease at low latitudes as the climate warms is that, in a warmer climate, there is more upward transport of water vapor by

convective clouds and a greater release of latent heat in the upper troposphere through condensation. In current models, some of the extra upward moisture transport leads to greater moistening of the upper transport, rather than immediate condensation and rainout. Thus, greater moistening of the upper troposphere (a stronger positive water vapor feedback) is correlated with greater warming of the troposphere through condensational heating (a stronger negative lapse rate feedback), which reduces the variation in the overall feedback between model versions in which these processes are parameterized in different ways (Zhang *et al.*, 1994).

The increase in the amount of water vapor in the upper troposphere is particularly important to the overall water vapor feedback and hence to climate sensitivity. This is so for two reasons: (1) the effect on an atmospheric layer s emissivity (its ability to absorb and re-emit infrared radiation) for a given increase in water vapor amount is greater the smaller the initial amount of water vapor (layers in the upper troposphere have less water vapor than layers of equal mass in the lower troposphere). (2) The effect of a given increase in emissivity on the emission of infrared radiation to space is larger the colder the layer in which the emissivity increases (the upper troposphere is colder than the lower troposphere). In most AGCMs, the amount of water vapor in the upper troposphere increases as the climate warms, but by less than what would be expected if the relative humidity (RH) were constant: in the Hadley Centre AGCM, RH decreases by 2–3% of the saturation value between 550 and 250 mb (Mitchell and Ingram, 1992); in the (National Center for Atmospheric Research (NCAR), Boulder, CO) AGCM, RH decreases throughout the tropical troposphere by up to 20% of the initial RH, but increases in the upper troposphere outside the tropics (Zhang *et al.*, 1994; Figure 16). Qualitatively similar behavior occurs in the (Geophysical Fluid Dynamics Laboratory (GFDL), Princeton, NJ) AGCM in response to a quadrupling of atmospheric CO_2, at least over continents (Wetherald and Manabe, 1995; Figure 6). Finally, Colman *et al.* (1997) report decreases in upper tropospheric RH in the (Bureau of Meteorology Research Centre (BMRC), Melbourne, Australia) AGCM in regions where strong increases in convection occur. However, in the (Goddard Institute for Space Studies (GISS), New York, USA) AGCM, RH is constant near the surface but increases in the global mean by 5% of the saturation value at the 200 mb level (Del Genio *et al.*, 1991). The reason that the GISS model gives an increase in upper tropospheric RH as climate warms, while the other models give a decrease, appears to be because greater sublimation of ice crystals that are detrained from cumulus anvils occurs in the GISS model. As noted above, more water is pumped into the upper tropical troposphere by convection in a warmer climate. In all models, a new steady state balance will be achieved in which essentially all of the extra upward moisture transfer will eventually fall out as precipitation. In the GISS model, the new steady state requires a greater increase in upper tropospheric moisture than in other models. In the other models, the required increase in upper tropospheric moisture is smaller because more of the anvil water immediately falls as precipitation.

The fraction of upward moisture transfer by convective clouds that immediately falls as precipitation is referred to as the precipitation efficiency (the rest detrains from convective columns and moistens the upper troposphere). This is an important consideration at low latitudes especially. In most AGCMs, the precipitation efficiency is not explicitly considered but would need to be diagnosed; in many cases it seems to be constant. This in turn explains why, in current models, an increase in moisture pumping leads to an increase in both condensational heating and moistening of the upper troposphere, causing variations in the strength of the positive water vapor feedback and the negative lapse rate feedback to partly cancel. However, if, as upward moisture pumping increases, a smaller fraction goes into moistening the upper troposphere and more into immediate precipitation, then the net effect will be a less positive change in upper tropospheric humidity and a more negative lapse rate feedback. That is, the difference in the strength of the two feedbacks would reinforce each other, and reduce climate sensitivity, rather than partly cancel each other. Calculations by Sun and Lindzen (1993; Figure 20) indicate that the time required for raindrops to form decreases as temperature increases, which implies that the precipitation efficiency should increase. This in turn might mean that the water vapor feedback at low latitudes (where convective processes are important) is somewhat too strong and the lapse rate feedback somewhat too weak.

Outside the tropics, the increase in water vapor as the climate warms is more directly related to the increase in the surface vapor pressure and in the atmosphere s ability to hold water, which in turn are directly related to the increase in temperature through the dependence of saturation vapor pressure on temperature as measured in the laboratory.

In summary, the water vapor feedback in climate models is strongly positive (sufficient to increase climate sensitivity by 50–100%), but in low latitudes is partly linked to the lapse rate feedback. The effect on climate sensitivity of changes in upper tropospheric water vapor and temperature, when both increase as overall water vapor pumping increases, is minimal because such changes have opposing effects. This diminishes the importance of changes in upper tropospheric water vapor due to changes in moisture pumping. However, if the precipitation efficiency increases as moisture pumping increases, there will be less cancellation of the negative lapse rate feedback by the positive water vapor feedback. Thus, the clear sky radiative feedbacks in AGCMs depend critically on the way in which cloud processes are treated, and are thus coupled to the cloud processes and associated radiative feedbacks.

Table 1 Qualitative effect of various changes in cloud characteristics that could occur as the climate changes[a]

Cloud property change	Effect on climate	Example reference
Decrease in amount of low cloud	Warming	Le Treut and Li (1991)
Increase in amount of high cloud	Warming[b]	Wetherald and Manabe (1988)
Increase in cloud height	Warming	Mitchell and Ingram (1992)
Increase in water content of stratus clouds	Cooling	Somerville and Remer (1984)
Increase in water content of cirrus clouds	Warming or cooling	Lohmann and Roeckner (1995)
Increase in ratio of water droplets to ice crystals	Cooling through enhanced reflectivity	Senior and Mitchell (1993)
	Warming through increased particle fall velocities	Senior and Mitchell (1993)

[a] Also given are references where the indicated effect is quantitatively assessed or included in climate simulations. The actual changes in cloud property that occur as the climate warms may be different from indicated here, and sometimes differ from model to model (from Harvey, 2000a).
[b] This assumes that high clouds have a net heating effect. However, Del Genio *et al.* (1996) calculate a net cooling effect for high tropical cirrus clouds.

Role of Cloud Feedbacks

Another important source of uncertainty concerning climate sensitivity is the role of cloud feedbacks. Table 1 lists the feedback effect of various cloud changes, if they were to occur in association with a warming of the climate. Clouds reflect solar radiation, which has a cooling effect. This effect depends on the difference between the cloud and surface albedo (reflectivity), and on the amount of incident solar radiation. The smaller the underlying albedo and the greater the incident solar radiation, the greater the increase in the reflection of solar radiation to space due to clouds. The cooling effect thus depends on where and when the clouds occur. Clouds also absorb infrared radiation emitted from the surface and re-emit their own radiation, but the amount re-emitted is smaller than the amount absorbed because the tops of clouds are colder than the underlying surface. The higher the cloud, the colder the cloud top and the greater the reduction in net infrared emission to space. High clouds thus tend to have a net warming effect because the reduction in infrared emission to space is greater than the extra reflection of solar radiation. Low clouds, in contrast, have a net cooling effect. Thus, an increase in the amount of high cloud as the climate warms usually serves as a positive feedback, while an increase in the amount of low cloud serves as a negative feedback. Similarly, an increase in the height of existing clouds, because this makes them colder and reduces the emission of radiation to space, has a warming effect on surface climate. Stratus clouds have an emissivity of 1.0 and so absorb all of the radiation emitted from the surface. An increase in the water content of these clouds increases the albedo but has no effect on infrared emission to space, so there is a net cooling effect. Cirrus clouds, on the other hand, have an emissivity less than 1.0. An increase in water content increases the albedo and the emissivity, so both the cooling and heating effects of the clouds increases. Thus, an increase in the water content of cirrus clouds can have a net warming or a net cooling effect. Ice crystals tend to be much larger than water droplets and so are less reflective, but they also have greater fall velocities. Thus, a transition from ice crystal to water droplet clouds makes clouds more reflective (a cooling effect) but presumably decreases the life-span of clouds which, in most cases, will be a warming effect.

The directions of the cloud changes listed Table 1 are given for illustrative purposes only. In some cases the direction of change that would occur in reality is unknown, as illustrated in the following examples: First, Senior and Mitchell (1993; Figure 18) show that the direction and magnitude of the changes in cloud fraction depend on the way in which cloud amounts are parameterized. Second, we are reasonably confident that convective clouds will rise to greater heights in a warmer climate, but the extent to which this occurs depends on the choice of convective parameterization scheme (Cunnington and Mitchell, 1990). Third, Sinha and Shine (1994) show that implementation of a feedback between temperature and ice water content in cirrus clouds changes the sign of the feedback due to increasing cloud height from positive to negative. For fixed cloud height and for clouds cold enough to remain as ice crystal clouds, warmer temperatures lead to a greater ice water content, which serves as a positive feedback. However, if cloud height increases, this feedback is greatly weakened because there is a smaller increase in cloud ice content due to the fact that the cloud hardly warms at all. Fourth, it was widely believed that the optical thickness of liquid water clouds would increase as climate warms, due to an increase in cloud droplet size (Somerville and Remer, 1984). Now it appears that concurrent changes in cloud thickness – which depend on changes in atmospheric vertical stability in regions of subsiding motion – can override the relationship between temperature and optical depth that one would otherwise expect (Del Genio, 1996). Thus, the direction of the feedback between climate and cloud optical thickness is also uncertain.

Table 2 lists the changes in cloud amount and height that occurred in response to an increase in CO_2 in a number of simulations with AGCMs or coupled atmosphere–ocean

Table 2 Changes in cloud amount and cloud height in response to a warming of the climate, as simulated by various AGCMs (from Harvey, 2000a)[a]

Model	References	Change in cloud amount			Mean cloud height	Type of experiment
		Total or low	Mid	High		
ARPEGE	Timbal *et al.* (1997)	Total and mid-level clouds decrease (with magnitude dependent on forcing, generally around 1–2%)		Positive except at ITCZ	Increased	Forced with $2 \times CO_2$ SST anomalies from ECHAM1 and UKMO models
BMRC	Colman and McAvaney (1995)	Low = +0.23%	−3.7%	−2.1%	High clouds occur higher	$2 \times CO_2$ equilibrium
BMRC	Colman and McAvaney (1997); Colman *et al.* (1997)	Total clouds = −0.45% for 0–2 K Δ SST		−1.2% for 0–2 K Δ SST Mainly in tropics	Increased by about 30 m	Perpetual July, ± 2 K SST
CCC	Boer *et al.* (1992)	Total = −2.2% (−1.9% winter, −2.4% summer)		Positive except between ±30°		$2 \times CO_2$ equilibrium
GFDL	Wetherald and Manabe (1988)	Cloud cover decreases in the upper troposphere at mid and low latitudes, except for an increase near the tropopause, especially at high latitudes. Low cloud cover increases at high latitudes				$2 \times CO_2$ equilibrium
GISS	Rind *et al.* (1995); Cess *et al.* (1996)	−2.3% global average; +0.1% polar		−0.3% global average; +0.4% polar		$2 \times CO_2$ equilibrium
LMD	Le Treut and Li (1991)	Cloud cover decreases almost everywhere at all heights, except that it increases near the tropopause at most latitudes				Perpetual July, ± 2 K SST
NCAR	Zhang *et al.* (1994)	−0.5%	−3.5%	−3.5%		Perpetual July, ± 2 K SST
NCAR	Washington and Meehl (1989, 1996)	Increase at high latitudes		Increase		Transient $2 \times CO_2$
UKMO	Murphy and Mitchell (1995)	NH = −0.2% SH = +1.1 Increase in Arctic	NH decrease	NH = +0.3% SH = −0.7%		Transient $2 \times CO_2$, values given after 75 years

(GCMs) atmosphere–ocean general circulation model (AOGCMs). There is a general tendency for cloudiness to decrease everywhere, except for low clouds at high latitudes and for clouds near the tropopause at most latitudes. There are, however, many exceptions.

In order to accurately simulate cloud feedbacks, at least four conditions need to be satisfied: (i) the relevant feedback processes must be incorporated in the cloud parameterization; (ii) these processes have to be incorporated in a way that mimics nature; (iii) changes in the

large-scale factors that influence clouds must also be correctly simulated, and this depends on the fidelity of all the other processes in the climate model; and (iv) the present-day distribution and characteristics of clouds must be accurately simulated. Because conditions (i) and (ii) must both be satisfied, the incorrect incorporation of a feedback process could result in worse results than if the feedback were neglected altogether. An example might be the incorporation of a strong temperature– optical depth feedback, when the true feedback is much weaker. Thus, more complex cloud parameterization schemes are not necessarily better than simpler schemes, unless the individual processes added to the complex scheme are separately validated against observations.

An analysis of cloud feedbacks published by Cess *et al.* (1996) indicates that the effect of cloud feedbacks in recent models ranges from a 27% reduction in climate sensitivity to a doubling of climate sensitivity, compared with the sensitivity expected based on the clear-sky radiative damping alone. In this analysis, a globally uniform increase in sea surface temperature (SST) was imposed and the changes in radiative fluxes with fixed and variable clouds were determined. From this, the radiative damping λ, and the contribution of clouds to λ, can be computed. If the calculated feedbacks are applicable to a CO_2 doubling perturbation, then the expected global average climatic response ranges from 1.3 to 3.3 °C.

However, the magnitude and even the sign of the net cloud feedback depends in part on the spatial *pattern* of temperature change. In the afore-mentioned analysis of cloud feedbacks published by Cess *et al.* (1996), a globally uniform increase in SST was imposed. In reality, the surface warming will vary with latitude and with longitude, and both variations can cause a markedly different cloud feedback than for the cause of globally uniform warming. With regard to east–west variations, the critical region appears to be the tropical Pacific Ocean. Today, the eastern Pacific is relatively cold due to the upwelling of deep water, while the western Pacific is relatively warm. This temperature contrast drives an east–west circulation known as the Walker circulation, with rising motion over the western Pacific and sinking motion over the eastern Pacific. In the GFDL AOGCM, greater warming occurs in the eastern than in the western tropical Pacific Ocean when CO_2 is increased, thereby reducing the temperature contrast and weakening the Walker circulation (Knutson *et al.*, 1997). In experiments in which a globally uniform change in SST is imposed, Del Genio *et al.* (1996) found that the global mean cloud feedback was slightly negative. However, when greater warming in the eastern than in the western Pacific Ocean was allowed, the cloud feedback was positive. This is because the weakening of the Walker circulation in the latter case resulted in less anvil cloud in the western Pacific, which otherwise has a cooling effect. The warming effect of less anvil cloud in the western Pacific Ocean was only partly offset by increased anvil cloud in the eastern Pacific Ocean. Another instance where the spatial patterns of temperature change could determine the sign of the cloud feedback is in the relative difference between Northern Hemisphere (NH) and Southern Hemisphere (SH) warming (Murphy and Mitchell, 1995). An additional factor complicating the picture is that both the east–west difference in warming in the tropical Pacific Ocean, and the inter-hemispheric difference in warming between the two hemispheres, could be quite different from the equilibrium patterns during the transition to a new climate (Harvey, 2000a). Thus, the sign and strength of the cloud feedback in some regions could very well change over time.

FEEDBACKS INVOLVING LAND SNOW COVER

A reduction in the extent of snow cover on land as climate warms is widely expected to serve as a positive feedback, contributing to a greater warming than in the global average in high latitude regions. This is because snow tends to have a higher albedo (reflectivity) than snow-free land, so a reduction in snow cover leads to an increase in the amount of solar radiation that is absorbed at the surface. This will lead to further warming and thus acts as a positive feedback. However, analyses by Cess *et al.* (1991) and Randall *et al.* (1994) indicate that a number of competing changes come into play when snow cover changes, and these changes can substantially weaken the positive snow cover feedback that would otherwise occur or even change the snow cover feedback into a weak negative feedback.

First, changes in snow cover can induce changes in the amount, location, or optical properties of clouds. In particular, cloudiness tends to increase over snow-free regions, so the reduction in albedo at the top of the atmosphere (the planetary albedo) is much smaller than the reduction in surface albedo. It is even possible for the planetary albedo to increase if the clouds are more reflective than the former snow cover. Second, once the snow melts away, the surface temperature is free to rise above 0 °C, so the emission of infrared radiation from the surface and thence to space can increase. This serves as a negative feedback. Third, the atmospheric lapse rate tends to increase after snow retreats (due to greater surface heating), and this serves as a positive feedback. Finally, the drying of the surface after the snow all melts reduces the water vapor content of the overlying atmosphere, which serves as a negative feedback. Overall, the shortwave feedback tends to be positive, while the longwave feedback tends to be negative. Either feedback can be stronger, so the net feedback due to retreat of snow cover can be positive or negative.

Cess *et al.* (1991) analyzed the snow cover feedback in 17 different AGCMs, and they found that the effect of

snow cover feedback ranged from a reduction in climate sensitivity by 10% to almost doubling the climate sensitivity, based on the calculated radiative damping for experiments in which the models continuously simulate the month of April (a perpetual April experiment). That is, the global mean temperature response can as much as double, with even larger changes (by up to a factor of 3–4 or more) in regions where snow retreats. However, snow cover feedbacks are expected to be strongest during transitional seasons, so the mean annual climate feedback in these models is certainly smaller than indicated by the perpetual April experiments.

Feedbacks Involving Sea Ice

Changes in the areal extent of sea ice can also exert a strong feedback effect on climate by changing the radiative balance. As well, changes in the area and thickness of sea ice alter the fluxes of latent and sensible heat between the ocean and atmosphere, which has a strong effect on the seasonality of temperature change at high latitudes. However, except through possible interactions with cloud amount, these changes will not significantly alter the planetary radiative balance and so will not noticeably affect the climate sensitivity.

The simulation of sea ice in global-scale climate models is a particularly challenging problem (Randall *et al.*, 1998). Sea ice involves vertical growth (at the base of the ice), lateral growth (into cracks or leads created by divergent ice motions), surface and basal melting, and lateral melting (from leads in summer). The surface albedo of sea ice depends on its thickness and the possible presence of snow cover or surface melt ponds; the way in which the surface albedo is computed generally has a dramatic effect on the simulation of sea ice for the present climate (Shine and Henderson-Sellers, 1985), and on the sensitivity of sea ice to changes in climate (Meehl and Washington, 1990). Ice motions, caused by surface winds and ocean currents, have a significant effect on the distribution of ice thickness within a given region, on the occurrence of leads and larger areas of open water, and on the spatial extent of sea ice. There are a number of important interactions between the thermodynamics of sea ice (processes related to freezing and melting) and the dynamics of sea ice (processes related to ice motions). However, only six of the 16 coupled climate models discussed in Gates *et al.* (1996) included sea ice dynamics; in the other 10, only sea ice thermodynamics is explicitly considered, with dynamical effects included only through the specification of a minimum lead fraction.

Pollard and Thompson (1994) found that, in simulations with ice dynamics, the ice was less compact for the control simulation than for the case without sea ice dynamics. Thus, the total area of sea ice was smaller, and because of this, the temperature–albedo feedback was weaker. This reduced the global mean equilibrium warming for a doubling of CO_2 from 2.27 to 2.06 °C, with much larger effects at high SH latitudes in winter and spring. Watterson *et al.* (1997) also found that the introduction of sea ice dynamics reduces the global mean climate sensitivity, in their case from 4.8 to 4.3 °C using the Commonwealth Scientific and Industrial Research Organization (CSIRO) AGCM. The reduced sensitivity with sea ice dynamics is consistent with the more general result that the climate model sensitivity tends to be smaller, the smaller the initial amount of sea ice, all else being equal. The weaker high-latitude feedback in the presence of ice dynamics implies a smaller polar amplification of the response, with important implications for the change in soil moisture in mid-latitudes (Harvey, 2000a; Chapter 10.2).

The simulated high-latitude climatic change and hence the global mean climate sensitivity are also quite sensitive to the initial ice thickness. The initial sea ice thickness in turn is very sensitive to the heat flux from the underlying water to the base of the ice, which is related to the poleward oceanic heat flux simulated for the present climate. Rind *et al.* (1995) found that, when the GISS model was adjusted so that the sea ice thickness (which were initially too great) matched observational estimates, the global mean warming for a CO_2 doubling increased from 4.17 to 4.78 °C. This was due to the fact that, when initial ice thicknesses in the model match those observed for the present climate, it is easier for the ice to retreat when the CO_2 concentration is increased.

INTERACTIVE EFFECT OF FAST FEEDBACK PROCESSES IN AGCMS COUPLED TO MIXED LAYER-ONLY OCEAN MODELS

The effect of any given feedback on the climate sensitivity to a radiative perturbation depends on what other feedbacks are already present (Harvey, 2000a; Chapter 3). This is because there is a synergistic or multiplicative effect between the different feedbacks. Thus, if there is a positive cloud feedback, this will increase the warming at high latitudes, thereby increasing the effect of the positive snow and ice feedback, which in turn will amplify the effect of the positive cloud feedback. These interactions can be simulated with climate models.

As previously noted, the strength of the cloud feedback depends in part on the spatial patterns of climatic change. These in turn depend on regional variations in the heat uptake or release by the oceans (during the transition from one climate to another) and in changes in ocean currents. Ideally, coupled AOGCMs should be used to compute the patterns of climatic change and from these, the feedback strengths and climate sensitivity. However, these models are not practical for evaluating the steady state (long-term) response to an increase of CO_2. This is because integrations on the order of 1000 years are required to reach close

to steady state, and this is prohibitively expensive. Since the feedback processes that determine climate sensitivity operate in the atmosphere or at the surface, an alternative is to couple the AGCM to an ocean model consisting of the mixed layer only. This permits steady state changes to be attained after only a few decades simulation. The disadvantage is that horizontal heat transport in the oceans, which depends on the 3D overturning circulation, cannot be simulated. Instead, the oceanic heat transports required to give the present day variation of temperature with latitude are prescribed. These are then held constant as the climate changes. Spatial variations in the warming can develop, in response to regional variations in the feedback strengths, but the spatial patterns in the new steady state climate would undoubtedly have been different in an AOGCM simulation due to changes in the horizontal transport of heat by the oceans. Not only would this affect regional patterns of climatic change, it would also likely affect cloud feedbacks and hence the global mean climate responsiveness to a doubling of atmospheric CO_2.

Table 3 lists the steady state, global mean change in surface air temperature obtained with coupled AGCM-mixed layer models for a doubling of atmospheric CO_2. In most cases, the global mean warming for a CO_2 doubling is 2.0–4.0 °C. This is consistent with the discussion of feedbacks presented above.

Table 3 Global mean change in surface air temperature (ΔT, K) for a doubling of atmospheric CO_2 as obtained by various AGCMs coupled to a slab ocean[a,b]

[g] Model version in which sea ice thickness for the present climate matches observational estimates.

DIRECT OBSERVATIONS OF THE WATER VAPOR FEEDBACK

The preceding discussion has highlighted the complexity of the feedback processes that determine climate sensitivity in nature, and of the difficulties and uncertainties associated with trying to simulate these processes – and their interactive effects – in computer climate models. The increase in the amount of water vapor in the atmosphere as climate warms is projected to be the single largest feedback, and to be strongly positive. Cloud feedbacks could also be important, but the net feedback could be either positive or negative. However, the importance of cloud (and surface albedo) feedbacks depend on the overall strength of the water vapor feedback, due to the synergistic effects mentioned above. The primary factors driving the overall increase in atmospheric water vapor are the global mean warming and its latitudinal distribution. The primary factors governing the vertical distribution of changes in water vapor at low latitudes are likely to be how the intensity and height of convection changes as the climate warms, and how the partitioning of convective moisture pumping between upper tropospheric heating and humidification changes as convection changes. At middle and high latitudes, the changes in the vertical moisture transport by large-scale eddies (i.e., storms) are likely to be the dominant control on the vertical distribution of changes in water vapor.

The amount of water vapor and its vertical distribution can be directly observed at present. This provides the possibility of directly inferring the strength of the feedback between temperature and water vapor from observations. There are three different kinds of observations that shed light on the water vapor feedback: the relationship between surface temperature and the total amount of water in the atmospheric column (the precipitable water); the relationship between surface temperature and the vertical distribution of water vapor; and the relationship between specific processes (such as deep convection) that influence water vapor and the greenhouse trapping (GHT) of infrared radiation.

Variations in the Total Amount of Water Vapor

There is no doubt that the total amount of water vapor in the atmosphere will increase as the climate warms. This follows from very fundamental principles involving the fact that the driving force for evaporation from the ocean – the difference between surface and atmospheric vapor pressures – tends to increase as the surface temperature increases, combined with the fact that the atmosphere s ability to hold water increases as the air warms. Observations made during recent decades indicate that the atmospheric water vapor content has indeed increased as the climate warmed (Harvey, 2000a; Chapter 5). The relationship between surface temperature and precipitable water in

the tropics is weak at the monthly and annual time scales, where concurrent changes in atmospheric dynamics complicate the picture, but is stronger at the decadal time scale (Gaffen *et al.*, 1992).

Interannual Variations in the Amount and Vertical Distribution of Water Vapor

Available balloon-based observations are not reliable for determining long-term trends in the amount of water vapor in the upper troposphere, while satellite observations have not been available for long enough to determine long-term trends. However, the available datasets are adequate for assessing the spatial distribution of inter-annual changes in water vapor and their correlation with inter-annual changes in surface temperature. Much of the inter-annual variability is related to the El Niño oscillation, which involves large-scale oscillations in surface temperatures in the tropical Pacific Ocean and a shift in the main region of convection between Indonesia and the eastern Pacific Ocean. Since the changes in surface temperature are associated with major shifts in the tropical circulation that are unique to the El Niño oscillation, the local correlation between temperature and humidity will not be applicable to long-term, large-scale climatic change unless long-term climatic change happens to involve some circulation changes.

Sun and Oort (1995) have attempted to circumvent this problem by examining the correlation between atmospheric water vapor and surface temperature averaged over the entire tropics (30 °S–30 °N). Using balloon-based data for the period May 1963 to December 1989, they found that the amount of water vapor in the tropical atmosphere increased with increasing temperature as follows:

- by 70–75% of the increase that would occur with fixed RH in the 1000–900 mb layer;
- by only 15% of the increase expected with fixed RH at 700 mb, and;
- by 70% of the increase expected with fixed RH at 300 mb.

In the planetary boundary layer (1000–900 mb), the change in water vapor is most directly tied to the thermodynamically-driven increase in the rate of evaporation. There is also a sizeable relative increase in the upper troposphere, related no doubt to an increase in the rate of detrainment of moisture from the tops of cumulus cloud columns. However, in the middle troposphere there is almost no increase in the amount of water vapor, which can be explained by an increase in the rate of subsidence of relatively dry air from the upper troposphere (even though this air becomes moister, it is still much drier than the air below).

Since AGCMs simulate close to constant RH at all heights as the climate warms, the results of Sun and Oort (1995) – assuming that they are applicable to long-term climatic change – imply that the water vapor feedback is too strong in AGCMs. This is turn could be due to the convective coupling between the moist surface layer and the middle troposphere being too strong, so that water vapor increases enough at all heights to keep RH constant as temperatures increase (Sun and Held, 1996). Sun and Oort (1995) compared the effect of their observed water vapor variation on the outgoing emission of infrared radiation with that assuming constant RH. Their results imply that the assumption of constant RH increases $|\mathrm{d}F/\mathrm{d}T|$ by about $0.8\,\mathrm{W\,m^{-2}\,K^{-1}}$ compared with the observed water vapor variations. Since this error is applicable only to cloud-free regions in the tropics, the error in the global mean $\mathrm{d}F/\mathrm{d}T$ is about $0.2\,\mathrm{W\,m^{-2}\,K^{-1}}$. This in turn implies that the total water vapor feedback strength as computed by AGCMs is about 10% too strong.

Direct Observations of Processes Governing Upper Tropospheric Water Vapor

An alternative to examining the correlation between changes in surface temperature and atmospheric water vapor is to examine the relationship between specific processes and atmospheric water vapor. In particular, one would like to know how the upper tropospheric humidity, averaged over the entire tropics, changes through time as the frequency of deep convection, averaged over the entire tropics, changes. Unfortunately, currently available data are not reliable enough to answer this question clearly.

An alternative (and more physically meaningful) approach is to directly examine the relationship between clear-sky GHT and SST, where GHT is simply the difference between the surface emission (σT^4) and the outgoing emission for clear skies at the top of the atmosphere (which can be easily measured by satellite). For the period April 1985 to December 1987, Soden (1997) found that the tropical-mean GHT increased in association with an increase in tropical-mean SST, as conditions changed from La Niña to El Niño. This is illustrated in Figure 1. GHT increased in regions where deep convection increased, and decreased elsewhere (due to the drying effect on the middle troposphere of an increase in subsidence). There were marked intra-annual variations in GHT that are not reflected in changes in the tropical-mean SST. This must be related to changes in the spatial patterns of SST, which are known to be as important to the occurrence of deep convection as absolute temperatures (Zhang *et al.*, 1994). Since it is not clear how the spatial patterns of SST will change as the climate warms or whether the patterns of temperature change will resemble El Niño patterns, the correlation seen over the course of a La Niña–El Niño transition might not apply to a warmer climate.

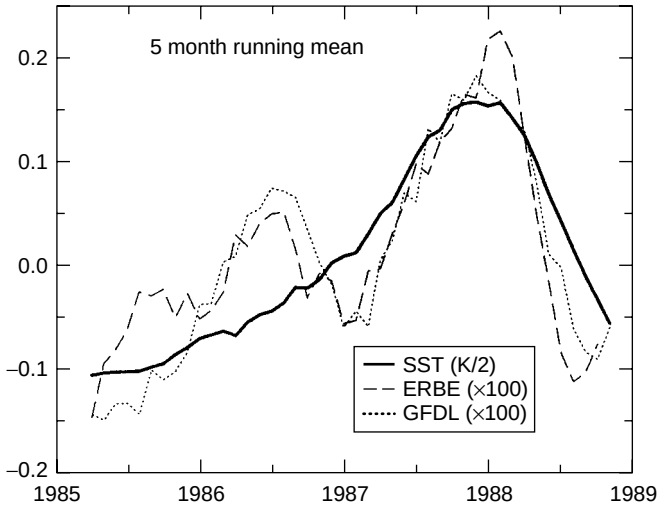

Figure 1 Variation (times 100) from 1985 to 1989 in the GHT ($W M^{-2}$) as measured by the Earth Radiation Budget Experiment (ERBE) satellite observations and as computed by the GFDL AGCM when driven by observed SST variations. Results are averaged over the entire region from 30°S to 30°N. Also given are the average SST variations divided by two. (Reproduced from Soden, 1997)

However, the GFDL AGCM has successfully simulated the overall variation in tropical-mean GHT from 1985 to 1989, in tropical-mean intra-annual fluctuations, and the local patterns of increasing and decreasing GHT when given the observed changes in SST. The tropical-mean variations are shown alongside the observed variations in Figure 1. This model, like all AGCMs, produces a positive long-term water vapor feedback. Thus, although observations of intra-annual, longer term, and spatial patterns of GHT do not directly tell us anything about the multi-decadal water vapor feedback, they can be used to test the fidelity of convective process embedded in AGCMs, the same processes that give rise to the long-term feedback in AGCMs. This test indicates that, given the correct patterns of SST change, current AGCMs should do a reasonable job in simulating the water vapor feedback in tropical regions.

Outside the tropics, Del Genio *et al.* (1994) find that, in AGCMs, synoptic-scale storms and the east–west averaged motions are the dominant factors influencing moisture in the upper troposphere. Although their analysis is based on model simulations rather than on nature (for which adequate observations are lacking), the processes in question are fully resolved by AGCMs. This is in contrast to convective processes, which must be parameterized because they occur at scales smaller than the model grid resolution. Thus, we can have more confidence in these results than in model results concerning the role of convection. The analysis of Del Genio *et al.* (1994) indicates that the moistening effect of storm systems and average motions would both increase as the climate warms.

Thus, the evidence based on observations in the tropics, where convection is an important process, and diagnoses of model behavior outside the tropics (where we have more confidence in the models) supports the conventional wisdom that the water vapor feedback is positive. Observations indicate that total precipitable water increases as the climate warms, which will exert a positive feedback. Observations of inter-annual variability indicate that the amount of water vapor also increases in the upper troposphere, although the increase in the middle troposphere is probably less than simulated by current AGCMs. Observations also show that the clear-sky GHT, averaged over the tropics, increases as tropical average SST increases during the course of the La Niña–El Niño cycle. Although this particular change might not be a valid analogue for long-term climatic changes, the GFDL AGCM does an excellent job in simulating this correlation. This serves as a validation of key water vapor processes in this AGCM, an AGCM that, like other models, simulates a significant positive water vapor feedback for long-term climatic change.

SLOW FEEDBACK PROCESSES

The above discussion has focused on the fast feedback processes that determine climate sensitivity, as traditionally defined. These feedback processes are relevant if one were to imagine a prescribed and fixed increase in greenhouse gas concentrations (other than water vapor), and if one wanted to know the eventual climatic response to the prescribed concentration changes. In reality, the change in climate would induce further changes in greenhouse gas concentrations, on a variety of time scales ranging from a decade to several centuries. The major potential climate–greenhouse gas concentration feedbacks involving CO_2 and CH_4 – the two most important gases directly affected by human activities – are outlined below. A more detailed discussion and extensive references can be found in Harvey (2000a; Chapter 8).

A warming of the climate would alter the uptake by or release of CO_2 from both the terrestrial biosphere and the oceans. First, a warmer climate will lead to changes in the rate of photosynthesis (generally an increase). Second, a warmer climate will generally lead to increased rates of respiration by plants and of soil organic matter by micro-organisms. Climate-induced changes in the rate of respiration of soil organic matter depend on the concurrent changes in soil moisture. If soils are saturated, a partial drying would facilitate greater decomposition (respiration) of soil organic matter, while if soil moisture is already limited, further drying could reduce rates of decomposition. Another potential terrestrial biosphere feedback could arise if climatic zones shift substantially faster than the rate at which forests can migrate

(as is likely under business-as-usual scenarios). As the ocean surface warms, the solubility of CO_2 in the surface layer will decrease, thereby reducing the ocean s ability to absorb anthropogenic CO_2. A change in the ocean circulation would alter the upwelling of nutrients to the surface layer, thereby altering the intensity of marine photosynthesis and the downward transfer of carbon.

A warming of the climate would alter the production of CH_4 from wetlands – the largest natural source – in two ways. First, it would change the productivity of wetland ecosystems and hence of the supply of organic matter, a portion of which is anaerobically decomposed and converted to CH_4. Second, a change in temperature would alter the rate of decomposition of the available organic carbon. A warmer climate would also increase the rate of removal of CH_4 from the atmosphere since, under a warmer climate, more hydroxyl radicals would be created through the splitting of water molecules by ultraviolet radiation, due to the greater water vapor content of a warmer atmosphere (reaction with hydroxyl is the main removal process for atmospheric CH_4). There is also the possibility that a warmer climate could provoke the decomposition and release of methane clathrates – ice–methane mixtures found in continental slope sediments worldwide and in permafrost regions on land. This latter possibility has been investigated by Harvey and Huang (1995) and found not to be a significant except for scenarios leading to very large climate change even in the absence of methane clathrate destabilization. The methane released in this way would be converted to CO_2 on a time scale of 10 years, which would then be gradually removed from the atmosphere in the same way as direct anthropogenic emissions (*see* Methane Clathrates, Volume 1).

Climate Model Simulations of the Geological Past

André Berger

Institut d'Astronomie et de Géophysique G. Lemaître, Louvain-la-Neuve, Belgium

The accumulating amount of information on the Earth's climatic history can be greatly augmented by carrying out climate model simulations of periods in the geological past. Such model simulations have been extensively used to better understand the in uence on the climate of tectonic uplift, movement of the continents, and changes in atmospheric composition, land-surface properties, the intensity of solar radiation, and the seasonal and latitudinal distribution of solar radiation caused by cyclic variations in the shape and timing of the orbit of the Earth around the Sun. By accounting for changes in these factors, major changes in the Earth's climate history can be simulated with some success. During the early life of the planet, high levels of atmospheric carbon dioxide are believed to have kept the Earth's temperatures reasonable even with lower luminosity of the Sun. Over the last one billion years, changes in the locations of continents caused by plate tectonics have modulated the global climate and were likely the origin of the late Ordovician and Permo-Carboniferous Ice Ages. The very warm climate of the Cretaceous (~100 Myr ago) and the Miocene (~17 Myr ago) were likely due to very high concentrations of greenhouse gases and large poleward heat transport by the oceans. The onset of the Quaternary Ice Age about three million years ago is most probably due to the uplift of the Tibetan Plateau, a decrease of the carbon dioxide level, and some important changes in continental con guration. The glacial- interglacial cycles during this Ice Age result from cyclic changes in the Earth's orbit around the Sun; and the more rapid changes of the Late Glacial period are likely to be associated with complex interactions between the ice sheets, the ocean circulation and the hydrological cycle.

INTRODUCTION

The Earth s climate has always been changing and will undoubtedly continue to change. The Earth s history indicates that quite large variations in climate can occur (*see* Earth System History, Volume 1). For example, when the dinosaurs dominated the planet during the Mesozoic (250–65 Myr BP), the climate was very warm with tropical-like conditions in high latitudes. There is extensive evidence from the Mid-Cretaceous (120–90 Myr BP) indicating that the Earth was ice-free with a significant poleward displacement of many types of warm climate flora and fauna.

However, at the time of the last glacial maximum (LGM) 20 kyr ago, the climate was very different, with surface temperature likely being about 5 °C lower than at present. At this time, sea level was about 110 m below the present-day level, the North American and Eurasian ice sheets were much larger (reaching about 45×10^6 km^3 of ice), and the carbon dioxide concentration in the atmosphere was only about 200 parts per million by volume (ppmv) (against 367 in 1999).

In the future, climate will surely continue to change, driven by natural causes such as fluctuations in the Earth s orbit (*see* Orbital Variations, Volume 1) and in solar activity (Rind *et al.*, 1999; Bertrand *et al.*, 1999). But future climate will also be influenced by human activities (Houghton *et al.*, 1996), which even might interfere with the natural evolution of the climate (Loutre and Berger, 2000).

Observations indicate that climate has fluctuated at many different time scales, ranging from seasonal to the tens of millions of years associated with the tectonic evolution of the Earth. New observational techniques, accurate dating methods and comprehensive program of climate reconstruction are leading to an improved understanding of the past evolution of the atmosphere and the oceans, the shift of continents, the waxing and waning of the ice sheets, and the growth and retreat of forests and deserts.

The study of the past climate of the Earth provides a useful time perspective for viewing the present climate and projecting future climate change. The first goal of paleoclimate research is to describe variations in climate that occur over intervals well before the availability of instrumental records. The ultimate objective is to identify the physical causes of past climate variations and to understand the complex behaviour of the whole climate system. This is a key problem because past climatic conditions are not thought any more to be good analogs of future climate changes, future climate forcing and boundary conditions going likely to be largely different from those of the past. Finally, the need to verify models of climate change has stimulated study of the Earth s history in order to reap the potential benefits of testing models of differing complexity at many different time scales and conditions.

MODELING PAST CLIMATES WITH GENERAL CIRCULATION MODELS

General Circulation Models

Paleoclimates are being studied using a wide range of types of models (*see* Models of the Earth System, Volume 1). Climate models are frequently divided into three very broad categories:

1. General circulation models (GCMs);
2. Statistical–dynamical models that include a two-dimensional (2D) representation of the Earth (either latitude–vertical or latitude–longitude) and;
3. Thermodynamic and energy balance models.

Three-dimensional (3D) GCMs include, in the most explicit form, processes that depend on details of the atmospheric flow. They are primarily generally used for simulating geographic features of paleoclimates. However, because of the large computational costs that are involved, coupled ocean–atmosphere GCMs are generally used for time spans not exceeding a few thousands of years (Von Storch *et al.*, 1997). Most of the time these models are only able to provide snapshot views of the climate in equilibrium with specific boundary conditions. These boundary conditions include the seasonal and latitudinal changes of solar radiation at the top of the atmosphere (resulting from variations in the Earth s orbit about the Sun and in its axis of rotation) as well as variations in sea-surface temperature (SST), in major ice sheets, in atmospheric composition and opacity, in land-surface properties, and in location of continents for simulations distant enough in the past.

Most of these modeling experiments have focused on extreme climates of the Quaternary and Cretaceous periods.

Cretaceous (*see* Cretaceous, Volume 1)

Early modeling studies of the ice-free climates of the mid-Cretaceous focused on understanding the effects of the significant changes in continental positions that occurred during this time (the break up of the supercontinent of Pangaea). To explain the global average temperature during the mid-Cretaceous, including estimated Cretaceous global temperatures 6–14 °C above the present temperature and very high temperatures in polar regions, it is however necessary to increase the poleward heat transport by the ocean and to invoke higher atmospheric CO_2 levels (up to 6–8 times the present level, Barron *et al.*, 1993) which might have resulted from increased sea floor spreading rates and volcanism. Sellwood *et al.* (1994) have however, challenged the evidence for such Cretaceous warmth, which further questions the role of atmospheric carbon dioxide in determining Cretaceous climate.

Pliocene

Although cooler than the Cretaceous, the Pliocene (about 5–2 Myr BP) may be the best example of a climate that was significantly warmer than now over large areas. In addition to a CO_2 concentration that was about twice its present-day value, changes in oceanic heat transport seem to have been needed to explain the magnitude of high latitude warming in the winter, especially for the last 40 Myr. Recent evidence suggests indeed that warmer temperatures are not necessarily always linked to higher CO_2 levels and vice versa. Pagani *et al.* (1999), for example, presented evidence, later contested, for surprisingly low CO_2 levels of about 180–290 ppmv through the warm Miocene (17–12 Myr BP), invoking an increase of other greenhouse gas concentrations (like water vapor and methane) or changes in continental geography in order to explain the climate of those times.

Entering the Quaternary Ice Age (*see* Quaternary, Volume 1)

There is strong evidence that the Quaternary Ice Age began to develop in the Northern Hemisphere around 2.7 Myr BP. Simulations in the Eurasia sector (Kutzbach *et al.*, 1993) show that surface uplift of the Tibetan Plateau produced marked increases in the intensity of the summer and winter monsoons over Asia and a general cooling in northern polar latitudes. Thus, the Tibetan uplift could therefore have contributed significantly to the late Cenozoic climate change. However, some other mechanisms are needed to explain the full range of the observed trend toward the Quaternary Ice Age. These might include a decrease of atmospheric carbon dioxide, which could result from increased global chemical weathering and erosion, and a change of continental configurations with openings and closings of oceanic gateways and consequent impacts on ocean heat transport.

Last Interglacial (*see* Eemian, Volume 1)

During the last interglacial, 125 kyr ago (called the *Eemian interglacial*), the atmospheric CO_2 concentration was above pre-industrial levels, and sea level was somewhat higher than now. The Greenland ice sheet was perhaps smaller and orbital parameters favoured greatly enhanced Northern Hemisphere seasonality. In agreement with geological reconstructions, modeling experiments suggest warmer conditions, especially in high latitudes. Reduced sea-ice extent, enhanced northern tropical monsoons, and poleward displacement of the tundra and ta ga biomes (Harrison *et al.*, 1995) are other indications of the sign of the change. This warm interglacial ended around 115 kyr ago with a major transition to cooler conditions. Although orbital parameters induced a strong cooling at these times, it does not seem to be sufficient to initiate glaciation when other components of the climate system are kept as present. Actually, it is the southward migration of the boreal forest/tundra limit which helps to create favourable conditions for continental ice-sheet growth (de Noblet *et al.*, 1996). These results support the fundamental role that biogeophysical feedbacks play in initiating glaciation: if the climates were to cool initially and the boreal forests were to retreat, then feedbacks, associated in the model with albedo differences between forest

and bare ground-tundra during the season of snow cover, might cause additional cooling.

Abrupt Climatic Changes of the Late Glacial

Deep-sea cores from the Atlantic (Heinrich, 1988) and ice cores from the Greenland ice cap (Dansgaard *et al.*, 1993) suggest that many major abrupt century-scale warm–cold oscillations have occurred through the Late Glacial over the last 60 kyr (*see* Climate Change, Abrupt, Volume 1). The so-called *Dansgaard- Oeschger events*, clearly recognized in both types of cores, represent a climate system oscillating between significantly different states (*see* Dansgaard- Oescheger Cycles, Volume 1). These events, apparently related to reorganization of the ocean–atmosphere system, also seem to group into larger oscillations, each terminating in a massive discharge of icebergs into the North Atlantic. These discharge events, known as *Heinrich events* (*see* Heinrich (H-) Events, Volume 1), appear to be related to instabilities in the glacial ice sheets, particularly the North American Laurentide ice sheet, and result in abrupt changes in oceanic circulation and North Atlantic climate.

Modeling experiments seeking to understand these abrupt climatic changes have so far been carried out using low-order dynamical systems models. These studies have focused on simulating the Dansgaard–Oeschger oscillation (Sakai and Peltier, 1999) and Heinrich events (Verbitsky and Saltzman, 1994) and their relation to the thermohaline circulation (Stocker, 1999). These model experiments confirm that abrupt climate changes appear to be caused by changes in the freshwater balance of the ocean s sea surface, but suggest also that the response of the ocean circulation depends on the amplitude and temporal evolution of the perturbation. The coupled ocean–atmosphere model developed at the National Oceanic Atmospheric Administration s Geophysical Fluid Dynamics Laboratory develops a reversal in the normal thermohaline circulation (i.e., with no deep water formation in the North Atlantic Ocean) resulting from a massive discharge of freshwater into the high North Atlantic latitudes. The simulation shows that the ocean circulation transforms back to the original direct thermohaline circulation as soon as the fresh water discharge into the North Atlantic Ocean is terminated (Manabe and Stouffer, 1999). Moreover, this inactive mode of the reverse thermohaline circulation is not a stable equilibrium for a large coefficient of vertical subgrid scale eddie mixing.

The *Younger Dryas* event is another example of a rapid climatic change that occurred during the Late Glacial period (*see* Younger Dryas, Volume 1). The Younger Dryas terminated the relative warmth of the Bolling/Allerod period in the middle of the last deglaciation. It lasted about 1300 years before there was a rapid change from glacial to interglacial conditions at about 11.5 kyr BP. The Younger Dryas event could have been triggered by rapid insertions of glacial ice or melt water into the North Atlantic, which might have induced changes in the thermohaline circulation. However, based upon paleoceanographic evidence, Manabe and Stouffer (1999) suggested that the stable state of the reverse thermohaline circulation mentioned above, did not prevail during the cold periods of the Younger Dryas. Instead it is likely that the thermohaline weakened temporarily, but reintensified before it fully reached the state of the reverse phase.

The Last Glacier Maximum (LGM)

Several GCMs have been used to simulate the climate of the LGM (*see* Last Glacial Maximum, Volume 1). These simulations have helped to clarify the relative roles of changes in continental ice sheets, CO_2 concentration, sea ice, ocean temperature, and land albedo in producing major changes in atmospheric circulation, surface temperature, and precipitation patterns. An early model simulation by Broccoli and Manabe (1987) demonstrated the sensitivity of glacial-age climate simulations to the lowered level of the glacial-age atmospheric CO_2 concentration. The movement of wind blown dust and the cycling of water isotopes have also been simulated by models with tracer capabilities (Jouzel *et al.*, 2000).

Changes in ocean circulation associated with the LGM have been simulated using dynamical ocean models forced by surface wind, temperature and salinity information from atmospheric models. Using this procedure, Lautenschlager *et al.* (1992) found a much reduced thermohaline circulation in the Atlantic and an increased one in the Pacific during this extreme phase of the Late Glacial.

Mid-Holocene (*see* Holocene: Climate Changes and Society, Volume 3)

Experiments with climate models show that a significant fraction of the widespread warmth and enhanced northern summer monsoon circulation of the mid-Holocene can be simulated correctly by including the seasonal and latitudinal changes of solar radiation (Kutzbach, 1999). The northward shifts of the main regions of monsoon precipitation over Africa and India are also well reproduced in the 18 simulations conducted for the Paleoclimate Modeling Intercomparison Project (PMIP) (Joussaume *et al.*, 1999). However, all the models underestimate the magnitude of the monsoon increase over northern Africa.

This increase in precipitation in a warm climate changed the vegetation cover significantly. Paleobotanic evidence indicates that during the early to middle Holocene, boreal forests extended north of the modern treeline. Foley *et al.* (1994) demonstrated that this northward expansion of forest itself, triggered by changes in the Earth s orbit, likely

amplified the initial warming; however, this vegetation-climate interaction needed to be tested using coupled atmosphere-vegetation models (Claussen, 1994). These model simulations also confirmed an earlier suggestion that the vegetation snow-albedo feedback is positive. The importance of the synergism between terrestrial and marine feedbacks has already been demonstrated by Ganopolski *et al.* (1998a) using a lower order coupled atmosphere–ocean-vegetation model.

The same biospheric feedback also operates in subtropical latitudes. Climate reconstructions indicate that North Africa was much greener in the mid-Holocene than today (Jolly *et al.*, 1998). This was more or less well simulated by Claussen and Gayler (1997), who found a strong feedback between vegetation and precipitation due to an interaction between high albedo of Saharan sand deserts and atmospheric circulation. In Ganopolski *et al.* (1998a), the biospheric feedback dominates and its synergism with an increase in monsoon precipitation owing to increased SST results in only a little further amplification (see also Berger, 1999). It also appears that multiple equilibria exist in the atmosphere-vegetation system, mainly in the subtropical areas of North Africa. The existence of these would be important as they could explain the abrupt transitions in vegetation structure, such as occurred at the end of the mid-Holocene wet phase in North Africa around 5 kyr BP (Claussen *et al.*, 1999).

TRANSIENT SIMULATIONS

Due to the length of the needed simulations, the time-dependent behavior of the fully coupled climate system over geological time scales has only been able to be simulated with simplified models. These models incorporate the slow-response climate processes involving changes in ice volume, bedrock depression, deep-ocean temperature, and the atmospheric concentrations of greenhouse gases (Saltzman, 1990).

Most of the simulations with such models have examined Quaternary climatic variations. Some studies have focused on understanding the forced response of the coupled climate system to changes of astronomical parameters, while other have demonstrated that the coupled systems themselves exhibit free oscillatory behavior. Many long, time-dependent integrations have been performed with such models of intermediate complexity (Berger, 1995; Berger and Loutre, 1998; Ganopolski *et al.*, 1998b; Peltier and Marshall, 1995).

In particular, the Louvain-la-Neuve (LLN) 2D model is an altitude–latitude model that links the Northern Hemisphere atmosphere, ocean mixed layer, sea-ice, ice sheets and continents. In each latitudinal belt, the surface is divided into at most seven oceanic or continental surface types, each of which interacts separately with the subsurface and the atmosphere. The oceanic surface can be ice-free or sea-ice covered, while the continental surfaces can be covered by snow and includes Northern Hemisphere ice sheets. This model is actually able to simulate long-term variations of the Northern Hemisphere ice volume using either a constant CO_2 value or the CO_2 record reconstructed from the Vostok ice core (Jouzel *et al.*, 1993). The model also simulates successfully the initiation of glaciation at around 2.75 Myr BP, the late Pliocene–early Pleistocene 41 kyr cycle, the emergence of the 100 kyr cycle around 900 kyr BP, the glacial–interglacial cycles of the middle and late Pleistocene and the importance of CO_2 in shaping the climate of isotopic stages 11 and 1 (our present Holocene interglacial).

This model confirms the hypothesis of Hays *et al.* (1976) that the orbital forcing acts as a pacemaker for the glacial–interglacial cycles. However, changes in the CO_2 concentration are also shown to play an important role in the amplification of the climatic response to orbital forcing. The other important processes that need to be accounted for in the model simulations are albedo-temperature feedback (in particular related to the snow covered ta ga versus tundra in high polar latitudes), water vapor–temperature feedback, altitude and continental effects on snowfall over the ice sheets, the snow aging process, and isostatic rebound.

Due to its ability to simulate the past climate, the LLN 2D model has also been used to project the climate of the next 130 kyr making different assumptions about the chemical composition of the atmosphere (Loutre and Berger, 2000). Most of the natural scenarios indicate that the present interglacial is likely to last several tens of thousands of years, which is significantly longer than previous interglacials. In addition, according to the modeling experiments and as a result of human activities, the Greenland ice sheet might start to melt significantly within a few thousands of years, its return to a natural behavior not being expected before 35 000 years from now.

CONCLUSIONS

In summary, many of these modeling experiments indicate an acceptable agreement between their results and geological reconstructions. This validation of models has increased confidence in scientific understanding of the behavior of the climate system in the model simulations of the changes of the climate under the forcing of human activities.

Climate Sensitivity

Michael E Schlesinger and Natalia Andronova
University of Illinois at Urbana-Champaign, Urbana, IL, USA

The importance of human-induced climate change depends critically on the temperature sensitivity of the climate system, measured by the change in global-average near-surface temperature resulting from a doubling of the preindustrial carbon dioxide (CO_2) concentration, denoted by ΔT_{2x}. If ΔT_{2x} is small, then the problem of human-induced climate change may not be acute. If ΔT_{2x} is large, then human-induced climate change may be one of the most severe problems of the 21st century.

Estimates of the value of ΔT_{2x} *have been based on mathematical climate models, instrumental measurements of temperature since about the mid 19th century, and surrogate indicators of temperature prior to the instrumental record. Based predominantly on climate model simulations, the Intergovernmental Panel on Climate Change (IPCC) has stated that* $1.5\,^{\circ}C \leq \Delta T_{2x} \leq 4.5\,^{\circ}C$. *However, a recent study based on the instrumental temperature record finds that there is a significant (>50%) probability that* ΔT_{2x} *lies outside this range.*

Progress in reducing the uncertainty in the value of ΔT_{2x} *will require reducing the uncertainty in the anthropogenic factors such as non-sulfate aerosols, and natural factors such as changes in the outputs of the Sun and volcanoes, which may have contributed to the observed temperature changes. It will also require a longer record of instrumentally observed near-surface temperatures to enhance the signal of forced climate change relative to natural climate variations. Thus, it is quite likely that the formulation and negotiation of policies to abate human-induced climate change will, for the foreseeable future, continue to be made against a backdrop of deep uncertainty.*

INTRODUCTION

Imagine that, at some time t_o, the amount of energy given off by the Sun were to instantaneously increase, say by 1%. Such an increase in solar radiation would imbalance the energy budget of the Earth s climate system by causing more solar (shortwave) radiation to enter the system across the top of the atmosphere than the amount of terrestrial (longwave) radiation then being emitted by the system to space. This net energy gain will cause the system to warm. As it does, the longwave radiation emitted to space by the system will increase and the system will thereby eventually achieve a new balance or equilibrium wherein there is no net energy gain or loss by the system. What will be the change in global-average temperature of the air near the surface of the Earth, ΔT_e, when equilibrium is restored? The answer to this question is defined as the climate sensitivity, expressed either as the temperature change, ΔT_e, in degrees Celsius ($^{\circ}$C) for a prescribed radiative forcing F in $W\,m^{-2}$ at time t_o, such as a 1% increase in solar radiation, or as their ratio:

$$G_f = \frac{\Delta T_e}{F} \tag{1}$$

the change in near-surface temperature per unit of radiative forcing, in units of $^{\circ}C/W\,m^{-2}$. For convenience, F is usually taken not at the top of the atmosphere, but instead at the tropopause – the boundary between the lowest layer of the atmosphere, the troposphere, and the overlying atmosphere. In this case, F is called the adjusted radiative forcing and includes not only the original instantaneous radiative forcing at the tropopause, but also the additional radiative forcing there due to the resulting change in temperatures above the tropopause, with all quantities in the troposphere being held fixed (Andronova *et al.*, 1999).

The change in equilibrium near-surface temperature due to F can be expressed by Equation (1) as:

$$\Delta T_e = G_f F \tag{2}$$

Because G_f is positive, based on the first law of thermodynamics, positive F results in near-surface warming, $\Delta T_e > 0$, as in the example above, and negative F results in near-surface cooling, $\Delta T_e < 0$. The larger the value of G_f, the larger the equilibrium near-surface warming or cooling for a given positive or negative F.

The actual warming or cooling at any time t after t_o, but before the Earth s climate system restores its equilibrium, is the realized temperature change, $\Delta T(t)$, which is smaller in magnitude than the equilibrium temperature change. This occurs because of the thermal inertia of the climate system, principally as a result of the transfer of heat downward into the Earth s oceans. While the initial response of the near-surface temperature to the radiative forcing is rapid, full restoration of equilibrium can take thousands of years to achieve as heat is slowly transferred into the deep ocean from above. Only after this long time does $\Delta T(t) = \Delta T_e$ for a time-independent F.

Imagine now that the amount of energy given off by the Sun were to change not instantaneously, but as a function of time t. Then both F and ΔT_e will change with time, the latter following Equation (2), $\Delta T_e(t) = G_f F(t)$, and:

$$\Delta T(t) = G_f F(\tau) = \Delta T_e(\tau) \quad t_o < \tau \leq t \tag{3}$$

Consequently, the realized global-average temperature change at time t equals the equilibrium global-average temperature change at some earlier time τ and the climate system is continually striving to achieve equilibrium.

Equation (3) shows that the magnitude of the realized global-average temperature change at any time depends on the size of the climate sensitivity, G_f. Accordingly, the larger the value of G_f, the larger the impacts of any radiative forcing will be. For example, through the burning of fossil fuels – coal, gas and oil – which contain carbon, humanity has been increasing the concentration of CO_2 in the Earth s atmosphere since the beginning of the industrial revolution in the mid 18th century. Everything else being equal, this increased atmospheric CO_2 would reduce the amount of radiation emitted by the Earth to space, thereby leading to a time-dependent, positive radiative forcing. In response, according to Equations (2) and (3), both the equilibrium and realized near-surface air temperatures of the Earth would increase.

Several computer models have been developed to assess, in an integrated manner, the economic effects of such

a human-induced warming (e.g., Nordhaus, 1994). These integrated assessment models have taken the cost to the world economy of global warming to be:

$$C(t) = \alpha \left[\frac{\Delta T(t)}{3} \right]^n \tag{4}$$

where $C(t)$ is the costs of climate-change impacts in terms of their percent reduction in gross world productivity (GWP), $n = 2$ or 3, and the value of α – the economic damage for a 3 °C global-average warming – ranges from 0.5–20% of GWP. Although such damage functions can be criticized for their amalgamation into a single metric of the regional and cultural dependencies of climate-change impacts, they do serve to illustrate that such impacts may depend nonlinearly on climate sensitivity, for as given by Equations (3) and (4),

$$C(t) = \alpha G_f^n \left[\frac{F(\tau)}{3} \right]^n, \quad \tau_0 \leq t \tag{5}$$

Accordingly, uncertainty in the value of climate sensitivity G_f translates into an amplified uncertainty in the costs of climate-change impacts.

In view of this result, what is the accepted range in the value of the climate sensitivity G_f, or equivalently,

$$\Delta T_{2x} = G_f F_{2x}, \quad F_{2x} = 3.7\,\mathrm{W\,m^{-2}} \tag{6}$$

the change in equilibrium global-average near-surface air temperature in response to the radiative forcing equivalent to that due to a doubling of the pre-industrial CO_2 concentration, F_{2x}? The range given by the IPCC is $1.5\,^\circ\mathrm{C} \leq \Delta T_{2x} \leq 4.5\,^\circ\mathrm{C}$ (Houghton *et al.*, 2001), which translates into $0.4 \leq G_f \leq 1.2\,^\circ\mathrm{C/W\,m^{-2}}$. By Equation (5), this three-fold uncertainty in climate sensitivity translates into a nine-fold uncertainty in climate costs for $n = 2$ and a 27-fold uncertainty for $n = 3$. Such a large uncertainty in climate costs can confound attempts to develop and agree to policies that abate human-induced climate changes.

Why is there such a large uncertainty in the value of the climate sensitivity? To answer this question it is necessary to understand both the concept of feedbacks in the climate system and the computer models of climate that underpin the IPCC assessment of climate sensitivity.

CLIMATE SYSTEM FEEDBACKS

In the examples above, for the 1% increase in energy emitted by the Sun and the doubling of the pre-industrial CO_2 concentration, the climate system responds to the respective radiative forcing F by changing its near-surface air temperature T and other climate-system properties such as atmospheric water vapor and clouds, which we shall denote by X, to restore the net radiation at the top of the Earth s atmosphere N back to zero. For a small change Δ, this equilibration can be expressed by the linear approximation:

$$F + \frac{\partial N}{\partial T}\Delta T_\mathrm{e} + \left(\frac{\partial N}{\partial X}\frac{dX}{dT} \right) \Delta T_\mathrm{e} = 0 \tag{7}$$

where $(\partial N/\partial T)$ is the change in the net radiation due to the change in near-surface air temperature T alone, and $(\partial N/\partial X)(dX/dT)\Delta T_\mathrm{e}$ is the change in N due to the change in everything else in the climate system. The latter includes, for example, the vertical profile of temperature, the amount of water vapor in the atmosphere, and the amount and radiative properties of clouds. Solving for ΔT_e in Equation (7) yields Equation (2) with the sensitivity (gain) of the climate system with feedback given by:

$$G_f = \frac{G_o}{1 - f} \tag{8}$$

where

$$G_o = -\left(\frac{\partial N}{\partial T} \right)^{-1} = \frac{T}{(1 - \alpha_\mathrm{p})S_o} = 0.3\,^\circ\mathrm{C}\,(\mathrm{W\,m^{-2}})^{-1} \tag{9}$$

is the sensitivity (gain) of the climate system without feedback, with $S_o (= 1370\,\mathrm{W\,m^{-2}})$ the amount of energy from the Sun incident on the top of the Earth s atmosphere, $\alpha_p (= 0.30)$ the reflectivity (albedo) of the Earth, and $T (= 288\,\mathrm{K})$ the global-average near-surface air temperature; and:

$$f = G_o \frac{\partial N}{\partial X}\frac{dX}{dT} \tag{10}$$

is the feedback (Schlesinger, 1985, 1988).

If N were independent of all climatic quantities X, hence $\partial N/\partial X = 0$, or if X were independent of the near-surface air temperature T, hence $dX/dT = 0$, then $f = 0$ by Equation (10). In this zero-feedback case, $G_f = G_o$ by Equations (8) and (9) and $(\Delta T_{2x})_o = 1.1\,^\circ\mathrm{C}$ by Equation (6).

If instead, N depends on one or more climatic quantities, hence $\partial N/\partial X \neq 0$, and they in turn depend on T, hence $dX/dT \neq 0$, then $f \neq 0$ by Equation (10). In this nonzero-feedback case, by Equation (8), G_f will either be larger or smaller than G_o, depending on whether the feedback f is positive (amplifying) or negative (damping).

For example, suppose X represents the amount of water vapor in the atmosphere and that this quantity increases with increasing near-surface air temperature, that is, $dX/dT > 0$. An increase in atmospheric water vapor, which is a greenhouse gas like CO_2, will decrease the amount of terrestrial radiation emitted to space by the climate system; hence the net incoming radiation at the top of the atmosphere will increase, i.e., $\partial N/\partial X > 0$. By Equations (10), (2) and (6), $f > 0$, $G_f > G_o$ and $\Delta T_{2x} > (\Delta T_{2x})_o$. The response of the

climate system with positive feedback is larger than the response without feedback.

In contrast, suppose X represents the amount of cloud cover and that cloud cover increases with increasing T, i.e., $dX/dT > 0$. Increasing cloud cover will allow less solar radiation to enter the climate system and less terrestrial radiation to escape to space. For low and middle altitude clouds, the solar effect dominates, hence $\partial N/\partial X < 0$. Now by Equations (10), (2) and (6), $f < 0$, $G_f < G_o$ and $\Delta T_{2x} < (\Delta T_{2x})_o$. The response of the climate system with negative feedback is smaller than the response without feedback.

As previously stated, the range for ΔT_{2x} given by the IPCC is $1.5\,^{\circ}\mathrm{C} \leq \Delta T_{2x} \leq 4.5\,^{\circ}\mathrm{C}$. To what values of feedback do these limits correspond? To answer this question we can rearrange Equation (8) to be:

$$f = 1 - \frac{G_o}{G_f} = 1 - \frac{(\Delta T_{2x})_o}{(\Delta T_{2x})} \tag{11}$$

the latter by Equation (6). Thus, $\Delta T_{2x} = 1.5\,^{\circ}\mathrm{C}$ and $\Delta T_{2x} = 4.5\,^{\circ}\mathrm{C}$ correspond respectively to $f = 0.27$ and $f = 0.76$. Why is this large range in positive feedback obtained? As shown by Equation (10), f depends on three quantities: G_o, the value of which is known; $\partial N/\partial X$, which can be calculated using a radiative-transfer model; and dX/dT, which can be determined only by a mathematical climate model. As described below, it is the uncertainty in dX/dT that results in the threefold uncertainty in f, and thus in G_f and ΔT_{2x}.

MATHEMATICAL CLIMATE MODELS

The earliest estimate of ΔT_{2x} using a simple mathematical climate model for the temperatures of the Earth s surface and atmosphere was made by Arrhenius in 1896 who found $\Delta T_{2x} = 5.4\,^{\circ}\mathrm{C}$ (Arrhenius, 1896; Houghton *et al.*, 2001).

The IPCC s estimated range of $1.5\,^{\circ}\mathrm{C} \leq \Delta T_{2x} \leq 4.5\,^{\circ}\mathrm{C}$ is based on simulations of climate change by the most comprehensive type of model in the hierarchy of mathematical climate models, namely, the general circulation model (GCM) of the atmosphere and ocean. GCMs are the only type of mathematical climate model that determines the geographical and vertical distributions of an ensemble of climatic quantities, including temperature, wind, water vapor, clouds and precipitation in the atmosphere; soil moisture, soil temperature and evaporation on the land; and temperature, currents, salinity and sea ice in the ocean.

The mathematical equations in GCMs that express the fundamental governing laws of nature, such as conservation of energy, conservation of mass, and Newton s second law of motion, are so complex, however, that they can be solved only at discrete geographical and vertical locations, and only over discrete time intervals. Thus, a typical GCM divides the atmosphere into thousands of three-dimensional volumes, each having dimensions of about 250 km (155 mi) in both the north–south and east–west directions, and 1 km (0.6 mi) in the vertical direction. Reducing these dimensions is severely constrained by the speed of available supercomputers. For example, increasing the horizontal resolution of a GCM 10-fold from 250 km (155 mi) to 25 km (16 mi) would increase the required computer time 1000-fold, from about two weeks to compute a greenhouse-gas induced change in equilibrium climate to more than 30 years.

The constraint on horizontal resolution imposed by available supercomputers also has profound significance for the physical processes that can be included in a GCM. In particular, the Earth s climate system encompasses physical processes ranging in horizontal size from 40 055 km (24 889 mi) for disturbances that span the entire circumference of the Earth, to about one-millionth of a meter (0.00004 in) for the condensation of water vapor onto aerosol particles and dust to form clouds. GCMs using supercomputers explicitly include only physical processes having horizontal sizes of about 250 km (155 mi) and larger. Worse yet, the physical processes smaller than 250 km (155 mi) that are not resolved cannot be ignored because their effects significantly determine climate and climate change. Thus, climate modelers face the dilemma that their models cannot resolve all the important physical processes, but they cannot ignore their effects. This is the major difficulty in modeling the Earth s climate.

The approach taken to overcome the computational limitation on a GCM s spatial resolution is to determine the effects of the unresolved physical processes on the scales resolved by a GCM by using information available only on the resolved scales. This approach is called parameterization (*see* Parameterization, Volume 1). The principal differences among GCMs lie in their different parameterizations of the unresolved subgrid-scale physical processes, particularly those for clouds and precipitation.

The parameterizations used in GCMs have a significant influence on the climate changes simulated by these models, i.e., the different parameterizations used for the unresolved physical processes are the principal cause for the differences in f, G_f and ΔT_{2x} simulated by GCMs. Put another way, the parameterizations can be tuned to yield a wide range of ΔT_{2x} values. This dependency can be eliminated by either increasing the spatial resolution of a GCM such that it resolves all the important physical processes, thereby eliminating the need for parameterizations, or by providing a target value of ΔT_{2x} for a GCM s parameterizations to replicate. While the first option may not be impossible in principle, it is not now possible in practice because it requires a hypercomputer that is many powers of 10 faster than today s supercomputers. The second option requires estimating ΔT_{2x} empirically from observed climate changes.

EMPIRICAL ESTIMATES OF CLIMATE SENSITIVITY

The value of climate sensitivity has been estimated empirically using both the historical record of temperatures measured by thermometers since about the middle of the 19th century, and non-thermometer, surrogate (proxy) indicators of temperature for ancient (paleo)climates. The instrumental record consists of near-surface air temperature measurements obtained at land stations and sea-surface temperature measurements obtained by ships. The pre-instrumental proxy record consists of quantities that are sensitive to temperature, such as the thickness and isotopic composition of the annual growth rings of trees and the annual layers of glacial ice; the relative abundance and isotopic composition of planktonic (living near the sea surface) and benthic (living near the sea floor) foraminifera (shell-covered species) that, after dying, fall to the sea floor where they are covered up by the sedimentary material raining down from above; and the relative abundance of pollen in the annual growth layers of sediment at the bottom of lakes. These proxy data are converted into temperatures using statistical relations that have been developed for the present climate.

The temperature so reconstructed for any paleoclimate gives its temperature difference from the present, ΔT_e. This is used in Equation (2), together with an estimate of the radiative forcing, F, to estimate the climate sensitivity, G_f. This approach was pioneered by Budyko and colleagues using estimates of ΔT_e and F for six paleoclimates – (1) Late Cretaceous, 101–67 million years ago (Mya); (2) Paleocene, 67–58 Mya; (3) Eocene, 58–37 Mya; (4) Oligocene, 37–25 Mya; (5) Miocene, 25–9 Mya; and (6) Pliocene, 9–2 Mya – with the result $2.8\,^{\circ}\mathrm{C} \leq \Delta T_{2x} \leq 3.5\,^{\circ}\mathrm{C}$ (Budyko, 1977); also, see Chapter 6 of (MacCracken *et al.*, 1990). A more recent estimate based on reconstructed temperatures for the Cretaceous and the Last Glacial Maximum, 21 000 years ago, yielded a similar result, $1.4\,^{\circ}\mathrm{C} \leq \Delta T_{2x} \leq 3.2\,^{\circ}\mathrm{C}$ (Hoffert and Covey, 1992).

There are at least three factors that lead to uncertainty in the estimates of ΔT_{2x} by the paleocalibration method. First, the proxy data for temperature are not global in extent, hence their global average is uncertain, and their conversion to temperature is also uncertain. Second, estimation of the radiative forcing for paleoclimates relative to the present climate is difficult and thus uncertain. Third, the sensitivity of paleoclimate temperature changes from the present climate, G_f and ΔT_{2x}, may be different from the sensitivity of future human-induced temperature changes from the present. This is possible because in Equation (8) for G_f, G_o in Equation (9) depends on the state of the climate (T, α_p, S_o) that is being perturbed, and f depends on which feedback processes are active, both of which factors can vary with paleoclimate. Accordingly, it is desirable to estimate G_f and ΔT_{2x} using the instrumental temperature record.

Two approaches have been used to estimate the climate sensitivity from the observed departure of near-surface temperature from a 30-year average temperature, $\delta T_O(t)$, shown by the dashed curve in Figure 1. One method uses a statistical model such as:

$$\delta T_M(t) = \beta_0 + \beta_1 \delta T_M(t-1) + \beta_2 F(t) + \varepsilon(t) \quad (12)$$

where $\delta T_M(t)$ and $F(t)$ are the model s temperature departure and radiative forcing in year t, and $\varepsilon(t)$ is an error term of mean zero. The values of the coefficients β_0, β_1 and β_2, are estimated statistically by fitting $\delta T_M(t)$ to $\delta T_O(t)$ such that the sum over all years of $[\delta T_M(t) - \delta T_O(t)]^2$ is minimized. The climate sensitivity is then given by $G_f = \{[(1-\beta_1)/\beta_2] - k\}^{-1}$ where k characterises the heat transfer from the upper ocean to the deeper ocean and ΔT_{2x} by Equation (6). This approach was pioneered by Miles and Gildersleeves who obtained $\Delta T_{2x} = 1.4 - 2.2\,^{\circ}\mathrm{C}$ (Miles and Gildersleeves, 1977). A major problem with the statistical model arises because we do not have observations

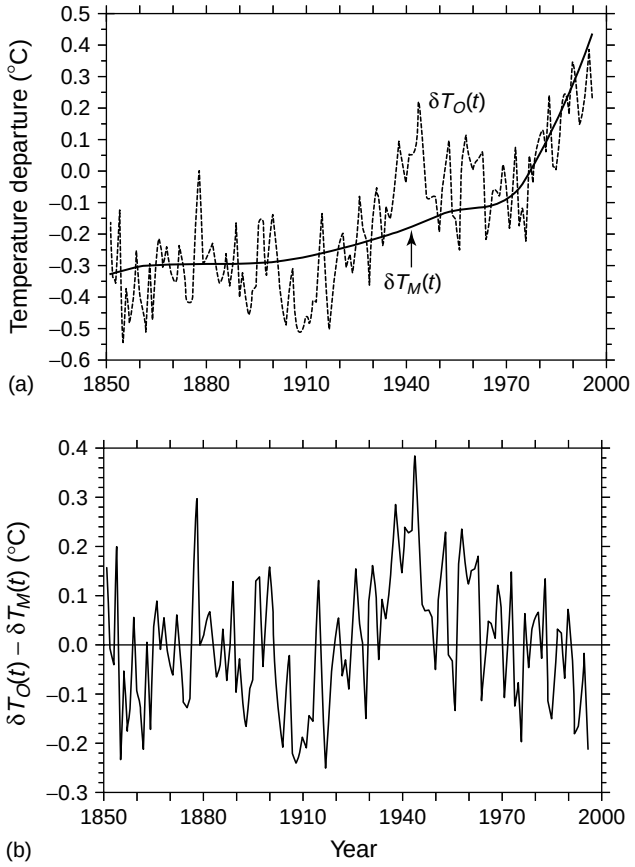

Figure 1 (a) The observed and model-simulated departures of near-surface temperature from the 1961–1990 average temperature, and (b) their difference for the GT radiative-forcing model with greenhouse gases (GHGs) and tropospheric ozone

of the temperature change of the deep ocean. Accordingly, an assumption must be made regarding k, and this assumption strongly influences the estimated value of the climate sensitivity. A way to overcome this problem is to use a simple, physically based mathematical model of the atmosphere/ocean system.

In one such mathematical model (Schlesinger *et al.*, 1997), the temperatures of the atmosphere and ocean are simulated, the latter as a function of depth from the surface to the ocean floor. In the model, the ocean is subdivided vertically into 40 layers, with the uppermost being the mixed layer and the deeper layers each being 100 m thick. Also, the ocean is subdivided horizontally into a polar region where bottom water is formed, and a nonpolar region where there is upwelling. In the nonpolar region, heat is transported upwards toward the surface by the water upwelling there and downwards by physical processes whose effects are treated as an equivalent diffusion. Heat is also removed from the mixed layer in the nonpolar region by a transport to the polar region and downwelling toward the bottom, this heat being ultimately transported upward from the ocean floor in the nonpolar region. The atmosphere in each hemisphere is subdivided into the atmosphere over the ocean and the atmosphere over land, with heat exchange between them. The governing (differential) equations in this model are stepped forward in time from some initial time, circa 1850, in steps of a year or less, to obtain $\delta T_M(t)$, an example of which is shown by the solid curve in Figure 1. The climate sensitivity is determined such that the sum of $[\delta T_M(t) - \delta T_O(t)]^2$ over all years of observations is minimized.

The value of ΔT_{2x} estimated by the simple atmosphere/ocean model is presented in Figure 2 for four different radiative forcing models. The GT model includes the radiative forcing by the GHGs CO_2, methane, nitrous oxide and the chlorofluorocarbons CFC-11 and CFC-12, as well as tropospheric ozone. For this radiative forcing model, $\Delta T_{2x} = 1.1\,^{\circ}\mathrm{C}$, which is the same as $(\Delta T_{2x})_o$, the climate sensitivity with zero feedback.

The GTA model includes the radiative forcing by sulfate (SO_4) aerosol, which is created in the atmosphere from SO_2 gas generated by the burning of coal and oil that contains sulfur. In contrast to the positive radiative forcing by the GHGs, the SO_4 aerosol produces negative radiative forcing by two effects, the enhanced scattering to space of solar radiation incident on the aerosol in the cloud-free atmosphere, and the formation (nucleation) on the aerosol of cloud droplets that are smaller than they would be in the absence of the aerosol, thereby preferentially scattering solar radiation backwards to space and enhancing the longevity of the clouds. For the GTA radiative forcing model, $\Delta T_{2x} = 5.0\,^{\circ}\mathrm{C}$ ($f = 0.78$), which exceeds the upper bound of the IPCC estimate, $\Delta T_{2x} = 4.5\,^{\circ}\mathrm{C}$. This large value of ΔT_{2x} is required

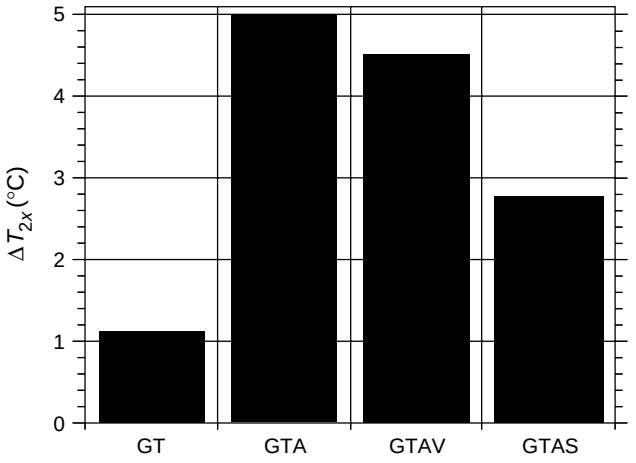

Figure 2 The climate sensitivity for four radiative-forcing models: (1) GT, GHGs and tropospheric ozone; (2) GTA, as in GT, but with sulfate aerosols; (3) GTAV, as in GTA, but with volcanoes; and (4) GTAS, as in GTA, but with solar irradiance variations

for the simulated temperature departure to reproduce the observed temperature departure for the smaller net positive radiative forcing that results from the partial cancellation of the positive GHG forcing by the negative aerosol forcing.

When the negative radiative forcing by volcanoes is included, as in the GTAV radiative forcing model, the estimated value of ΔT_{2x} is reduced slightly to $4.5\,^{\circ}\mathrm{C}$ ($f = 0.76$). This occurs because there was more negative radiative forcing by volcanoes in the 19th century than in the 20th century, and this reduced negative forcing with increasing time is equivalent to a positive forcing during the period of the observed warming, hence the value of ΔT_{2x} needed for the simulated temperature departure to agree with the observed is thereby diminished.

Lastly, the GTAS radiative forcing model shows the effect of conjectured variations in the energy emitted by the Sun. Solar radiative forcing larger than the 0.1% variation of the solar irradiance observed by satellites since 1978 over two 11-year sunspot cycles has been hypothesized to have occurred before 1978, based on the observed variations of other characteristics of the Sun and Sun-like stars. Comparison of the climate sensitivity for the GTAS and GTA radiative forcing models shows that inclusion of the conjectured solar radiative forcing reduces ΔT_{2x} by 46% to $2.7\,^{\circ}\mathrm{C}$ ($f = 0.41$). Clearly, the uncertainty in whether or not the Sun s irradiance has changed by more than the 0.1% observed by satellites is a major uncertainty in the determination of ΔT_{2x}.

Yet another uncertainty in estimating ΔT_{2x} is displayed in Figure 1(b) which shows the difference between $\delta T_O(t)$

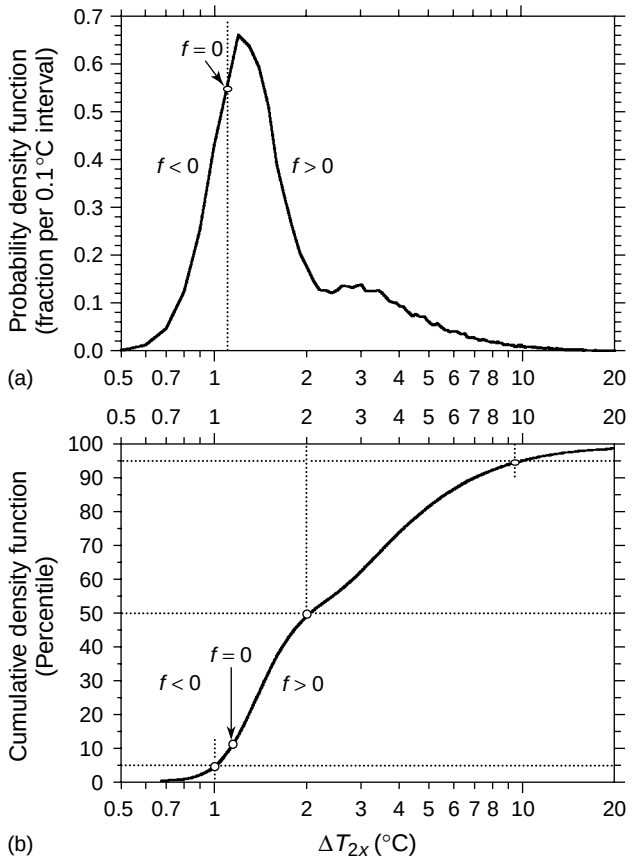

Figure 3 Differential (a) and cumulative (b) density functions for the climate sensitivity

and $\delta T_M(t)$ in Figure 1(a). This temperature difference represents the part of the observed temperature change that is not explained by the radiative forcings described above, hence it represents the natural variability of the climate system, of which we have only the single realization shown in Figure 1(b). If other realizations were available, our estimates of ΔT_{2x} based on them plus the forced temperature changes would likely yield different results. In a recent study we have attempted to quantify this uncertainty by statistically generating 80 000 realizations of the natural variability based on sampling $\delta T_O(t) - \delta T_M(t)$, adding to each the model-simulated forced temperature departures, and then estimating ΔT_{2x} for each of the resulting 80 000 surrogate observed temperature records (Andronova and Schlesinger, 2001). The result is presented in Figure 3 in terms of both the differential and cumulative probability density functions for ΔT_{2x}. The latter shows that there is a 33% probability that $\Delta T_{2x} \leq 1.5\,^{\circ}\mathrm{C}$ and a 79% probability that $\Delta T_{2x} \leq 4.5\,^{\circ}\mathrm{C}$. Accordingly, the combined uncertainties in the radiative forcing model and the natural variability of the climate system yield a 54% $[= 33 + (100 - 79)]$ probability that ΔT_{2x} lies outside the IPCC range of $1.5\,^{\circ}\mathrm{C} \leq \Delta T_{2x} \leq 4.5\,^{\circ}\mathrm{C}$.

THE WAY FORWARD

To reduce the uncertainty in the estimate of ΔT_{2x} requires learning whether or not the energy emitted by the Sun before 1978 varied by more than the 0.1% variation that has been observed by satellites since 1978. It also requires a longer record of instrumentally observed near-surface temperatures to enhance the signal of forced climate change relative to natural climate variations. It is quite likely that a significant reduction in the uncertainty in ΔT_{2x} will take a large part of the 21st century. Thus formulation and negotiation of policies to abate human-induced climate change will continue for the foreseeable future to be made against a backdrop of deep uncertainty. This argues for adaptive climate-change policies, which make midcourse corrections based on what is observed and learned in the future (Lempert *et al.*, 1996). Such adaptive policies can be constructed that are robust against our present uncertainty about the magnitude of the climate-change problem (Lempert and Schlesinger, 2000).

Climatology

F Kenneth Hare
University of Toronto, Toronto, Canada

Climatology is the scienti c eld that focuses on observation and documentation of the climate (generally of the Earth's climate, but it can refer to study of planetary climates as well). Climate, in turn, is the term used to describe the way the atmosphere has been and can be over time scales from days to millions of years, and space scales from kilometers to spanning the Earth. From its beginnings in the 19th century, dependent largely on volunteer observers and on the simplest archiving facilities, climatology has become a richly equipped science, able to draw on a sophisticated observational system using orbiting and geostationary satellites; a world-wide network of free-air soundings by balloons, rockets, and airplanes; state-of-the-art data reduction and storage systems; and, above all, comprehensive climate models that can be used to make predictions of climate change. During the last few decades of the 20th century, study of the climate has become very encompassing, so that it now refers to study of the interconnected system involving the atmosphere, the oceans, the land surface and its vegetation, and the snow and ice surfaces. Over recent decades, studies of the oceans and atmosphere have been brought closer together, and there are emerging collaborative efforts that include consideration of the biosphere. Building on the base of information provided by climatology, full understanding and prediction of how the climate will evolve has become a central objective - perhaps the

ultimate objective - of those studying the Earth and its environment (Manabe, 1998).

The Earth s climate system is composed of the atmosphere, the oceans, the land surface and its vegetation, and the snow and ice surfaces (*see* The Earth System, Volume 1). All climatic activity, however, traces back to the interaction of solar radiation – insolation – with the Earth in ways that create temperature gradients that, in turn, drive the circulation of the lower atmosphere and ocean, and thereby determine the world s climatic zones. A major advance in scientific understanding during the 20th century was to recognize that, in nature, nothing exists in isolation and that all aspects of the climate system are connected. Thus, those seeking to understand the climate must be involved in observing, documenting, and analyzing a wide range of geophysical and biological parameters extending from the Sun to the bottom of the oceans.

Study of the climate system, although it was implicit in the work of such pioneers as Augustin de Candolle and Thomas Blodget in the 19th century, did not really win full recognition until the 1970s, and then in the context of pending climatic change and its consequences (e.g., Gates and Mintz, 1975). The United Nations (UN) Conference on the Human Environment at Stockholm in 1972 was of particular importance in advancing study of the climate system, because it focused major attention on three connected environmental issues: atmospheric pollution, climatic stability and ecosystem health. To advance study of these topics, two parallel initiatives were taken by committees of the International Council of Scientific Unions (now ICSU, the International Council for Science). These initiatives have contributed greatly to advancing understanding of the Earth s climate system, including its physical, chemical, and biological environment. The first was the development of the World Climate Programme by ICSU, the World Meteorological Organization, the UN Environment Programme, and other UN agencies, with a World Climate Research Programme (WCRP) at its core. The second was the development of the International Geosphere–Biosphere Programme (IGBP), which brought Earth scientists and biologists together. Both initiatives, which are still nominally independent (although strong couplings are developing), have dealt squarely with the issue of climatic change: with climate s past, largely in the IGBP area, and its present and future state, largely in WCRP s. The net result has been the emergence of the climatic system as the common object of study.

In the study of the climate system, climatologists are pursuing three key approaches. The first is analysis of climatic archives. The instrumental network began in the 19th century (with a few pioneering efforts reaching back to the 17th century). By the late 19th century, pioneers such as Laplace, Ferrel, Maxwell and von Helmholtz had shown what needed to be observed to understand the Earth s fluid domains – water, air and ice. Observation systems were initiated, and archives of such variables as temperature, air pressure, humidity and precipitation were generated. Not only are individual records analyzed, but connections, correlations, teleconnections, and apparent contradictions are being carefully investigated. The next phase, only just beginning, will be to identify the regularities that have still to be isolated (since most lie unsuspected) in the archives.

The second approach to understanding the Earth s climate system is the validation of the various theoretically based models of the system (*see* Models of the Earth System, Volume 1), of which the most encompassing are the general circulation models of the atmosphere and ocean. These models are large and comprehensive, and give solutions that create model climates that need to be compared with one another, and with the observed climate of today. Validating that the models do a reasonable job of reproducing present and past climates is a key step in building confidence in their use for predicting potential changes in future climatic conditions (*see* General Circulation Models (GCMs), Volume 1).

This is a formidable challenge; the need is to predict the present day mean fields of temperature, precipitation and winds, and also the set of space and time anomalies that are internal to the present-day climate, but which may be greatly changed in the future. These anomalies include such perturbations as the El Niño–La Niña events of the Pacific, which appear to affect much of the globe (McPhaden, 1999); (*see* El Niño/Southern Oscillation (ENSO), Volume 1) and the Arctic oscillation (with its relative the North Atlantic Oscillation) (*see* Arctic Oscillation, Volume 1; North Atlantic Oscillation, Volume 1). In the same category, but lying more in the oceanographic domain, are predictions of changes in ocean currents and in the thermohaline circulation within the oceans, whose bottom water global coldness (below 4 $^{\circ}$C) is dependent on high-latitude processes.

A major international effort has been made in the past 10 years to carry this validation task forward, thanks to the work of the WCRP s Atmospheric Model Intercomparison Project begun in 1989 (*see* AMIP (Atmospheric Model Intercomparison Project), Volume 1). Directed by W L Gates, and based at the US Lawrence Livermore National Laboratory, the very large effort has confirmed (with reservations) the professional confidence in general circulation modeling (Gates *et al.*, 1999). Thirty-one such models have been examined (virtually the entire international effort). No single model has proved superior across all the range of outputs. Modeled seasonal distributions of pressure, temperature and circulations are reasonably close to observed values (apart from the El Niño and the Southern Oscillation (ENSO) anomalies over the Pacific), but precipitation is less so; and cloudiness (for which the observational

basis is poor) is not yet well predicted. Numerical modeling of this sort is, by common agreement, the best form of experiment possible within the observational sciences, where controlled isolation of the object, in this case the Earth s climate system, is unattainable. Years ago, John von Neumann identified the prediction of weather and climate as among the most difficult problems, and chose to put such numerical predictions high on the list of tasks for the digital computers then being launched. Von Neumann s prediction has proved true.

Third in the list of approaches has been focusing on obtaining a close understanding of processes taking place at the Earth s surface. There has been a long-standing interest among geographers, ecologists, and others interested in the climate near the ground, defined since Rudolph Geiger s times as microclimatology, because it deals with local sites. More recently, the students of surface climates have called themselves physical climatologists (especially among geographers), including the specialized group of urban climatologists (e.g., Bailey *et al.*, 1997). In parallel with such efforts, and often independently, there has been long-standing work on the atmospheric and oceanic boundary layers, including the study of turbulence, and of the role of vegetation in modulating exchanges of heat and moisture with the atmosphere (Monteith, 1976). This is territory that has been explored by several different sub-disciplines that have tended to disregard one another, until challenged by the global climatic change problem. Among climatologists, it was Mikhail Budyko (*see* Budyko, Mikhail Ivanovich, Volume 1) and his Russian colleagues who first overcame this arm s-length attitude (Budyko, 1959).

Here again there has been a concerted international effort to reach agreement on the role of the land surface in weather and climate, including the provocative question: does the land surface matter? As wind passes over plant-covered terrain, it encounters roughness elements (trees, shrubs, grass, etc.) that are crudely represented in terms of their roughness length in boundary layer theory. The boundary layer then experiences fluxes of momentum, water (evapotranspiration), sensible heat, carbon dioxide and many other trace gases and particles. Organic processes within the vascular plant cover, also usually parameterized, modulate the fluxes. The immense complexity of the land surface means that all winds, as they pass along their trajectories, must be considered to be interacting with the surface, although the full range of interactions is rarely capable of being specified. Yet this interface is crucial to determining the general circulation of the global atmosphere, for which it acts as a brake, a heating element, a source of trace gases, and a reservoir for major exchanges of water and carbon dioxide. Pitman *et al.* (1999) have reported the results of an IGBP program called Biospheric Aspects of the Hydrological Cycle (*see* IGBP Core Projects, Volume 2). The results are tentative, yet very impressive. The writers conclude that accurate representation of land-use changes will be central to the ability to simulate the climate of the 21st century.

Two other themes for climatological study are also emerging. One is the reconciliation of traditional climatology with hydrology and glaciology. These fields grew up rather separately in most countries, in different government agencies, and often without reconciling, for example, conflicting fields of precipitation and run-off (Hare and Hay, 1970; Hare, 1980). For the reason that the transfer and storage of water substance is at the very center of operation of the climatic system, however, a major effort is underway to unify the treatment of water within an enlarged climatology (or if another term is preferred, simply global system science). The Global Energy and Water Cycle Experiment (GEWEX) of the WCRP has been in progress for some time, and has already produced some landmark syntheses (see, for example, Stewart *et al.*, 1998) (*see* GEWEX (Global Energy and Water Cycle Experiment), Volume 1).

The second theme has emerged as a result of the astonishing findings of paleoclimatology, which have pushed the observational record back very far indeed, although not, as yet, in as great detail as the recent instrumental records. In broadest outline, the world contains numerous sources of laminated material – glacial ice, peat and lake-bottom organic sediments, ocean floor sediments, tree-rings and cave calcite deposits – in which the laminations represent annual, seasonal or longer-term repositories for proxy indicators of climate. These can be dated by a variety of isotope indicators, that can, in addition, offer evidence of the temperature of the past. The written record has also been used to great effect, and the world s volcanoes have helped by spreading ash layers that serve as markers in many deposits. Remarkably detailed reconstructions of climate have thus been created for the Holocene and late Pleistocene epochs, and some indications of past climates are available back into the Proterozoic, that is to say, more than 550 Myr. The relevant sciences are geology, geophysics, geochemistry, paleoecology and many others (not least isotope chemistry). A happy consequence of the global change movement has been to bring these sciences into direct contact with the climatological community.

Based on the results of these various approaches, the findings of climatologists have become of great interest to the world community. Although climate is not alone in causing global change, concerns, even fear, about the potential consequences of global warming, especially after the mid-1970s, have been a primary factor in promoting the global change movement. Through the 1960s and early 1970s, fear arose from early model predictions that rising carbon dioxide concentrations would lead to rising surface temperatures (Callendar, 1938; Plass, 1956; Manabe and Wetherald, 1975). In those decades, global mean temperatures appeared to be stable, or even falling, and there were warnings of

possible reversion to glacial conditions, so it was difficult for society to accept the notion of potential warming. Since 1975, however, increasingly accurate estimates of global surface temperatures have revealed a strong and continued warming even more marked than that between 1920 and 1945. Today, most climate scientists are convinced by the observational evidence that there has been a global average warming of about 0.7 °C since 1900 (*see* The Global Temperature Record, Volume 1), although they are not yet sure how much of the warming is due to human influences. This was the view cautiously expressed by the Intergovernmental Panel on Climate Change (IPCC, 1996), and it has underlain the successive rounds of discussions between governments that are trying to control greenhouse gas emissions. Improving confidence in our understanding of the Earth s climate and helping society to consider how to deal with, and respond to the potential for change, are key activities of climatologists.

CLIVAR (CLImate VARiability and Predictability)

CLIVAR is an international scientific program under the aegis of the World Climate Research Programme (WCRP) to extend the investigation of climate variability and predictability to large geographic regions and longer time-scales and the response of the climate system to anthropogenic forcing.

The specific objectives of CLIVAR are:

- to describe and understand the physical processes responsible for climate variability and predictability on seasonal, interannual, decadal, and centennial time-scales;
- to extend the record of climate variability through paleoclimatic and instrumental data;
- to extend the range and accuracy of seasonal to interannual climate prediction through the development of global coupled predictive models;
- to understand and predict the response of the climate system to increases of radiatively active gases and aerosols, and to compare these predictions to the observed climate record in order to detect the anthropogenic modification of the natural climate signal.

The CLIVAR program is organized into three component programs:

CLIVAR-GOALS examines the variability and predictability of the Global Ocean Atmosphere Land System on seasonal-to-interannual time scales, building on the

successes of the Tropical Oceans Global Atmosphere (TOGA) program, by:

- developing observational capabilities;
- further developing models and predictive skill for SST and other climate variables on seasonal to interannual time scales around the entire global tropics;
- building understanding and predictive capabilities of the interaction of monsoons with the Indian Ocean, El Niño–Southern Oscillation and land surface processes;
- understanding climate variability and predictability arising from the interaction between the tropics and extratropics;
- exploring the predictability of extratropical seasonal to interannual climate variability induced by the interaction of the atmosphere with oceans, land surface processes, and sea-ice processes and developing means to exploit any such predictability.

See GOALS (Global Ocean- Atmosphere- Land System), Volume 1.

CLIVAR-DecCen determines the mechanisms of variability and predictability of climate fluctuations on Decadal-to-Centennial time-scales with a special emphasis on the role of the oceans in the global coupled climate system by:

- describing and understanding the patterns of global decadal-to-centennial climate variability in the instrumental, paleoclimatic, and model records;
- extending the records of climatic variability by concerted efforts of data recovery, reanalysis of existing atmospheric, oceanic and paleoclimatic data, finding new paleoclimatic indices, and instituting new oceanographic monitoring sites;
- developing and implementing appropriate observing, modeling, computing, and data collection and dissemination systems needed to describe, understand, and predict global decadal variability;
- identifying and studying the oceanic regions and processes, such as water mass transformation regions, strong boundary currents and return path choke points, through which the ocean and atmosphere interact to produce decadal-to-centennial climate variability.

CLIVAR-ACC studies the response of the climate system to anthropogenic climate change by:

- developing understanding, modeling and predictive capabilities of the response of the climate system to the anthropogenic increases in radiatively active gases and changes in aerosols;
- identifying the patterns of anthropogenic modification to the mean state and to the variability of the climate system;
- using the understanding of natural climate variability derived from the other two CLIVAR component programs as a baseline for detecting the trends and signatures associated with increases in greenhouse gases and the effects of other anthropogenic changes.

A scientific steering group has oversight of the development of the CLIVAR implementation. Topical workshops and symposia with broad international participation are organized to gather input for these plans and to refine them. CLIVAR implementation is closely coordinated with and builds on national programs and other international climate-related activities. Joint projects are developed, and maximum use is made of existing infrastructure. Two CLIVAR Numerical Experimentation Groups coordinate international modeling studies.

JOHN S PERRY *USA*

Cloud–Radiation Interactions

Richard C J Somerville
University of California, San Diego, CA, USA

Only a few years ago, clouds were regarded as picturesque but minor components of the hydrological cycle. Today, they are believed to be the single most important source of uncertainty in climate model forecasts of future climate change, because their interaction with solar and terrestrial radiation is such an important aspect of the climate system. A current dilemma of climate modeling is that model results are strongly sensitive to the treatment of several poorly understood physical processes, especially cloud- radiation interactions. Thus, different models with alternative plausible parameterizations often give widely varying results. Yet, we typically have had little basis for estimating which parameterization is more realistic, although most of the global differences in results between leading climate models, as measured by their sensitivity to greenhouse gases, can be traced to different model treatments of cloud- radiation interactions.

Cloud- radiation interactions are regarded today as one of the most critical areas in global change research. In particular, when climate models are intercompared, cloud-radiation parameterizations are responsible for most of the global-mean differences in sensitivity to greenhouse gas increases. This fact has become well established through parameterization transplant experiments.

In such computational experiments, transplanting the cloud- radiation algorithm from one model to another typically causes the recipient model to closely replicate the climate sensitivity of the donor model. The uncertainty in model responses is directly due to a lack of fundamental understanding of the physical processes involved. A major research effort is underway worldwide in response to this challenge. Furthermore, closely related research areas, such as the role of atmospheric aerosols in climate, are also beginning to receive the attention they deserve.

On even the simplest theoretical grounds, it is not surprising that climate is extremely sensitive to cloud amount. Similar arguments can be made to show that climate also ought to depend strongly on other cloud properties, such as cloud height and cloud liquid water or ice content. In fact, an easily stated but still unsolved major problem is to understand why the global cloud cover is now about 60% and why the planetary albedo is now about 30%. Were these quantities the same during the ice ages? What mechanisms maintain the system at the present values of these key parameters, and how stable are these mechanisms to perturbations, such as those due to changing greenhouse gas concentrations? We simply do not know. Until we nd out, the con dence limits or error bars on the results of climate model greenhouse simulations will be much too large.

For many years, virtually all global climate model or general circulation model (GCM) treatments of clouds were based on simple algorithms relating cloud amount to relative humidity. Such parameterizations usually produced positive global average cloud–radiation feedbacks in numerical experiments simulating greenhouse-induced climate change. For example, in a typical integration performed with a GCM developed in the 1970s, a climate warming due to increased atmospheric carbon dioxide (CO_2) concentrations would lead to increased average cloud heights and/or decreased average cloud amounts. It is easy to understand qualitatively why such feedbacks were positive. First, higher clouds are colder and so less effective infrared emitters, and they generally have lower albedos than lower clouds, so the cloud-height feedback was positive (i.e., the change in clouds produced by the warming tended to amplify the warming). Second, average model clouds, like average real clouds, contribute more strongly to the planetary albedo than to the planetary greenhouse effect (in technical terms, the shortwave cloud forcing is larger than the longwave cloud forcing by about $20\,W\,m^{-2}$). Hence, a reduction in cloud amount reduces the shortwave effect more than the longwave effect of clouds. Thus, the cloud amount feedback is also positive.

Climate models are now more numerous and more complicated, however, and model responses to increased greenhouse gas concentrations are more varied. GCMs today attempt to take into account a broader range of physical processes involved in cloud–radiation feedbacks. The climate modeling community now realizes clearly that cloud feedback processes are not limited to macrophysical cloud properties, such as cloud amount and cloud altitude. In recent years, many GCMs have begun to include cloud parameterizations, which include explicit treatments of cloud physics.

Clouds have a powerful effect on the radiation budget of the Earth. The reasons are obvious: clouds contribute to both the greenhouse effect, which warms the planet, and to the Earth s reflectivity, or albedo, a competing cooling effect. Studies in which alternative cloud parameterizations can be tested against observations show great promise for improving our understanding of clouds and their influence on climate. Ultimately, this improved understanding will find its way into the representations of clouds used in GCMs.

Improving the realism of this aspect of models is a key to improving the model simulations of climate change. We know that the leading models of today differ by a factor of three among themselves, when they are compared in terms of their simulation of the global average surface temperature increase, due to a prescribed climate forcing, such as doubling the atmospheric concentration of CO_2. Most of this factor of three is due to the different ways in which the models represent clouds and cloud–radiation interactions. We know, for example, that in many climate models, cloud amounts in a warmer climate tend to be somewhat less than in the present-day climate, and cloud altitudes tend to be somewhat greater. These changes lead to positive feedbacks, increasing the apparent sensitivity of the model climate to the imposed forcing which led to the original warming, such as an increase in CO_2. However, the nature and strength and especially the regional aspects of these feedbacks differ greatly from model to model. For this reason, many scientists regard cloud–radiation processes as the most critical area of climate modeling research, deserving highest priority for climate research resources.

Only about 70% of the sunlight intercepted by the Earth is available to drive the climate system. The other 30% (the planetary albedo) is simply reflected to space, mainly by clouds, which cover some 60% of the surface of the planet (*see* Energy Balance and Climate, Volume 1). On average, clouds reduce the global average absorbed solar radiation by about $50\,W\,m^2$. Clouds also help to trap terrestrial radiation, contributing about $30\,W\,m^2$ to the greenhouse effect. The net cloud radiative forcing is the difference, approximately $20\,W\,m^2$. Thus, the albedo effect dominates, and the net effect of clouds at present is to cool the Earth.

Simple blackbody radiative equilibrium calculations suggest that changes in cloud amount by only 1–2% might double or halve the model sensitivity to CO_2. One simple way to appreciate the climatic significance of clouds is

to compare the cloud radiative forcing magnitudes given above with the direct radiative effect of doubling the concentration of atmospheric CO_2, which is only about $4\,W\,m^{-2}$. Thus, if a climate change caused by increased CO_2 were to result in even a small change in the cloud amount, the cloud feedback effect might well be important. Furthermore, even if global average cloud amount did not change appreciably in response to a changed climate, the spatial and temporal distribution of clouds might well be altered, as might other critical quantities, such as cloud altitude and cloud radiative properties. All of these changes in clouds could lead to significant feedback effects.

Until cloud processes are much better understood, and until this understanding is incorporated in our models, the model results will always be subject to major uncertainties. However, the plain fact is that we lack a basic understanding as to why the global cloud amount is about 60%, why the planetary albedo is about 30%, how these and other fundamental quantities may have changed as climate changed over geological time, and how they may change in the future.

Much research is now underway exploring the role that microphysical properties of clouds might play in affecting climate change. These processes might well lead to strong feedbacks. For example, as the climate warms because of an increase in the greenhouse effect, the entire hydrological cycle may accelerate. More water may evaporate from the oceans, and the atmospheric concentration of water vapor may increase. Because of the greater availability of water vapor, some clouds in the warmer climate may have more liquid water or ice than their counterparts in today s climate. In general, a higher liquid water or ice content is thought to lead to a higher albedo, hence a negative feedback. However, for thin clouds, particularly cirrus, the cloud greenhouse effect may also increase. In addition, it is not at all clear that cloud water content will change in any systematic way as climate alters. It may also be too simplistic to look on temperature as a dominant controlling factor for cloud microphysics.

Furthermore, the way in which cloud water or ice content depends on temperature, even in the present climate, is not well understood. Simple theory and aircraft data and some modeling studies support the idea of higher cloud water contents in warmer clouds. Some recent interpretations of satellite data, however, suggest that even the sign of the temperature dependence may be in doubt. It seems unlikely that any simple universal relationship is valid. Additionally, the radiative properties of clouds also depend on factors such as the size distribution of cloud droplets, the shape of ice particles, and other factors. Despite much observational and theoretical work in recent years to explore these issues, we are still far from a comprehensive physical understanding of them.

Nevertheless, several leading atmospheric GCM groups in different countries have now incorporated this class of cloud feedback mechanisms in one way or another. In a typical approach, cloud liquid water or ice content is included in the model as an additional prognostic variable, just like temperature, wind velocity and water vapor. The physical processes that act as sources and sinks for cloud water or ice, such as evaporation, condensation and precipitation, are simulated parametrically. In other words, the effects of these processes on the cloud water and ice budget are represented by simple formulae relating these processes to the large-scale variables that the model predicts explicitly.

The results of climate change simulations with these models confirm the strong sensitivity of climate to cloud microphysics. In one striking set of numerical experiments, a British GCM group (Senior and Mitchell, 1993) produced global average surface temperature changes (due to doubled CO_2) ranging from $1.9-5.4\,^{\circ}C$, simply by altering the way in which these cloud–climate feedback mechanisms were treated in the model. They tested four different parameterizations, successively incorporating relative humidity cloud, prognostic cloud water, phase changes from water to ice, and interactive radiation dependent on cloud microphysics. Their cloud water algorithm was that of Smith (1990). It is somewhat unsettling that the results of a complex model can be so drastically altered by what amounts to changing a few lines of code, essentially replicating the factor of three difference in global sensitivity between GCMs that has been revealed by extensive model intercomparisons (Cess *et al.*, 1989). Clearly, further research is urgently required to understand this class of physical processes better and to incorporate this understanding in models.

One particularly promising avenue of research is to combine process modeling with intensive field observations and with research using GCMs. For too long, research in this field has been characterized by too many plausible cloud–radiation parameterizations and too little effort to test them empirically. Now that appropriate observations and novel modeling tools are at last becoming available, we may anticipate rapid progress in this critical area of climate research.

Recent research has led to a greatly increased understanding of the uncertainties in today s climate models. In attempting to predict the climate of the 21st century, we must confront not only computer limitations on the affordable resolution of global models, but also a lack of physical realism in attempting to model key processes. Until we are able to incorporate adequate treatments of critical elements of the entire biogeophysical climate system, our models will remain subject to these uncertainties, and our scenarios of future climate change, both anthropogenic and natural, will not fully meet the requirements of either policymakers or the public. The areas of most-needed model improvements are thought to include air–sea exchanges,

land surface processes, ice and snow physics, hydrologic cycle elements, and especially the role of aerosols and cloud–radiation interactions.

A serious dilemma of climate modeling today is that model results are extremely sensitive to parameterizations of several poorly understood physical processes. As a result, models with different plausible parameterizations give very different results. Unfortunately, we have no firm basis for knowing which parameterization is more nearly correct. Perhaps the most dramatic example of this dilemma is the mystery of cloud–radiation interactions.

Unfortunately, it is not known which of these parameterizations is the most realistic, or even if any of them captures the essential feedback processes of actual clouds. Furthermore, other GCM groups have obtained different results by trying other ways of incorporating cloud microphysical processes and their radiative interactions (e.g., Le Treut and Li, 1988, 1991; Roeckner *et al.*, 1987), in contrast to the approach that Senior and Mitchell (1993) followed. There is thus a clear need to intercompare these approaches with one another, and, even more importantly, to validate them against observations, so as to evaluate the strengths and weaknesses of each.

It is noteworthy that the sensitivity of model-simulated climates to changes in atmospheric CO_2 concentration has undergone major fluctuations in recent years. The equilibrium global average surface temperature change in response to a CO_2 doubling, based on GCM results from models developed in the mid-1970s, was typically between 2–3 °C. By the middle to late 1980s, the range of typical GCM sensitivities was between 4–5 °C. Nearly all of the increase in sensitivity could be traced to cloud–radiation interactions. More recently, several GCMs incorporating more complex cloud algorithms, including some feedbacks arising from cloud microphysical processes, have shown reduced sensitivity to changing greenhouse gas concentrations (Senior and Mitchell, 1993).

In the earlier models, clouds were treated in a very simplistic way, and their ability to undergo changes, and thus to influence climate variability, was limited. In some GCMs, in fact, clouds and their radiative properties were prescribed once and for all and then held constant, so that no feedbacks were possible. Later models, by contrast, featured clouds that could and did change their absolute amount and their height distribution in response to changes in atmospheric water vapor content (e.g., Slingo, 1987). As the simulated clouds changed, so did their ability to contribute to both planetary reflectivity, or albedo, and to the greenhouse effect.

One type of problem is to characterize clouds, once they are formed in GCMs, i.e., to determine their radiative properties. Many unanswered questions are tied to this type of problem. For example, does carrying cloud liquid water as a prognostic variable offer real advantages in terms of being able to specify cloud radiative properties realistically? Or is it feasible to specify these properties directly from the other large-scale GCM fields? Some recent work (e.g., Tselioudis *et al.*, 1992) suggests that it may be difficult or impossible to infer cloud radiative properties as simple functions of temperature and other variables carried explicitly by GCMs, but much research remains to be done on cloud characterization.

Another class of problems involves cloud formation. Here the goal is to develop parametric treatments that enable GCMs to simulate when and where clouds occur. In current GCMs, typical algorithms relate cloud amount to GCM variables such as relative humidity. Then partial cloud cover is handled by weighting clear-sky and overcast radiative calculations by the predicted cloud fraction. One promising alternative approach is to specify clouds stochastically, i.e., to develop parameterizations that yield probability distributions for variables such as the size and spacing of clouds (e.g., Malvagi *et al.*, 1993).

New theoretical tools have been developed to aid in validating parameterizations against observational data. One such tool is the single-column model (SCM) (Somerville, 2000). An SCM is a computationally efficient and economical one-dimensional (vertical) model, resembling a single column from a GCM grid (e.g., Iacobellis and Somerville, 1991a,b). The model contains a full set of modern GCM parameterizations of subgrid physical processes. To force and constrain the model, the advective terms in the budget equations are specified observationally (Randall *et al.*, 1996).

The trend of increased reliance on observational field programs, which can provide both satellite and *in-situ* data, together with the development of SCMs and other means of using these data, is a powerful combination (e.g., Iacobellis and Somerville, 2000). This trend holds great promise for improving our understanding of cloud–radiation processes and for the future improvement of the treatment of these processes in climate models (e.g., Lee *et al.*, 1997).

Clouds

Marcia B Baker
University of Washington, Seattle, WA, USA

Clouds cover two-thirds of the global surface. They re ect incoming solar radiation and inhibit outgoing longwave radiation at the top of the atmosphere, thus providing strong controls on the global and regional energy balances. The evolution of clouds is strongly in uenced by: (i), the moisture content, roughness, and radiative characteristics of the Earth's surface; (ii), the thermal and humidity structure of the atmosphere; and (iii), atmospheric particles and gases. Each of these factors may change as the Earth's climate changes, and each factor can, in turn, be modi ed by clouds. Thus, clouds and their environments are parts of one coupled system, and the responses of this system to global change must be considered in a uni ed way.

Traditionally, clouds were studied only by observation from the Earth's surface. Instrumented aircraft and balloons launched from the surface and aircraft became useful in directed eld experiments in the 1940s. Radar is now used routinely to monitor the evolution of cloud and precipitation particles, both from aircraft and surface stations. In the last decades, satellites carrying sophisticated sensors have become useful indicators of cloud distributions and temperatures, ice and water distributions, and particles and gases in clear air. These data are used in numerical cloud models that provide a great deal of information on cloud processes and serve as the basis for routine weather prediction. The cloud models consist of dynamic, thermodynamic, and particle evolution equations that are solved on grids, the spacing of which range from several meters to hundreds of kilometers. Cloud-related processes are responsible for large uncertainties in current global climate models, and different representations of these processes lead to quite different predictions of climate evolution.

*Clouds determine and are determined by their exchanges of heat, moisture, and chemical species with their environments. These exchanges can be perturbed through external factors, including land-use modi cation, and perturbations in circulation patterns and surface uxes that accompany changing climate. Due to the fact that few systematic records of cloud parameters over periods longer than about 40 years exist, little is known about the historical evolution of clouds and cloud impacts during the 19th and early 20th centuries. We are now much better equipped to study these processes, but we are at this point unsure what sign and magnitude and what geographical distribution of cloud-related effects to project for the future. We do know that clouds provide some of the dominant feedbacks in determining climate change (*see *Climate Feedbacks, Volume 1).*

CLOUDS AND PRECIPITATION

Figure 1 shows the most important cloud-related processes. Clouds form when moist air rises as a result of mechanical lifting, convergence, or positive buoyancy. The rising air expands and cools, causing the relative humidity to increase. This stage of cloud formation is driven by surface heat and moisture sources, as well as rising motion in the lower atmosphere. At a high enough relative humidity, vapor condenses to form liquid drops (at temperatures $T \geq 0\,^{\circ}\mathrm{C}$) and small ice particles (at lower temperatures). Drops form by condensation on small (submicron) solid and partially liquid particles, termed atmospheric aerosol particles, that are ubiquitous in the troposphere.

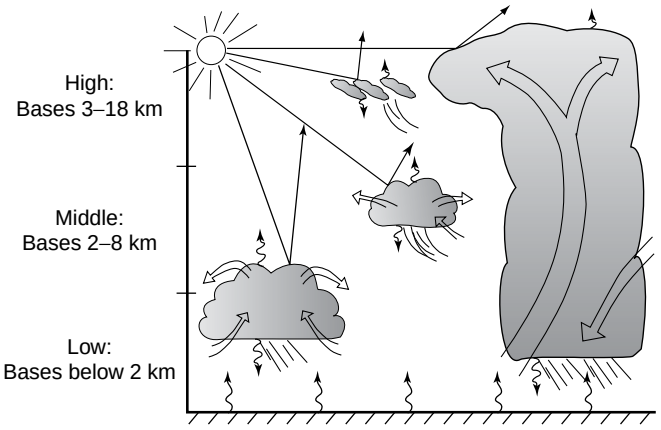

Figure 1 A schematic view of clouds, and of their interactions and environments. Thin lines indicate precipitation and hollow arrows indicate airflow, which brings environmental gases and particles into cloud. Wiggly arrows indicate infrared radiation, which clouds receive from Earth. They reemit this radiation back to Earth and to space. The lengths of the wiggly arrows indicate the relative magnitudes of the radiative fluxes. The thick lines indicate solar radiation, which is reflected by clouds. The lengths of these lines emanating from the cloud top suggest the relative magnitudes of solar reflectivity of different cloud types

The subset of aerosol particles that are large enough and soluble enough to produce cloud drops under normal atmospheric conditions are called *cloud condensation nuclei* or CCN. These are generally larger than $\sim 0.1\,\mu m$ in size, and consist of sulfates, salts, organic materials, black carbon, and minerals, in varying proportions, depending on their origins. In remote regions, typical droplet concentrations are around $10-100\,cm^{-3}$, whereas in polluted regions, the droplet concentrations can be on the order of $1000\,cm^{-3}$.

The $0\,^{\circ}C$ isotherm is normally at an altitude of $2-4\,km$ over much of the Earth s surface. The cloud must rise higher than this level in order to become partially or totally glaciated. Ice formation appears to be facilitated by certain aerosol particles termed ice nuclei (IN). Very little is known about the so-called IN; there are apparently very few of them relative to the number of CCN present in the atmosphere; at $-10\,^{\circ}C$, for example, there are only a few ice particles per liter. IN are thought to be largely composed of minerals (dust), but have been associated with oceanic sources in the Arctic and with biological debris. Anthropogenic processes appear to increase the concentration of IN under some circumstances and decrease it in others. It is possible that adsorption of atmospheric constituents, such as sulfates and aliphatic alcohols, can either *activate* or *deactivate* certain classes of atmospheric aerosols, rendering them more or less efficient as IN.

Both anthropogenic and *natural* modification of the chemical composition and/or concentrations of CCN and IN may modify the development and characteristics of clouds by modifying the evolution of the droplets and ice particles within them.

Precipitation Formation

When some of the droplets in a rising cloudy air parcel become large enough to fall through the updraft, they can collide with smaller, rising droplets below them. This process becomes effective when the droplets reach around $20\,\mu m$ in radius. For a given total amount of water, the droplets are larger and more likely to reach this size if the droplet concentration is relatively low. Coalescence of the colliding drops results in even larger drops that fall as *warm rain*. As a general rule of thumb, something like one million cloud drops must coalesce to form a single raindrop. The rain falls through the cloud and into the subcloud air, where it either evaporates or continues to the surface.

The effect of a few ice particles on precipitation in a supercooled cloud can be large. The equilibrium vapor pressure over ice is lower than that over liquid water at the same temperature, so that when they coexist, vapor flows from liquid to ice; the ice particles grow rapidly and deplete the liquid water. Collisions among these particles lead to precipitation in the form of rain (if the ice particles melt on their way to the surface), snow (aggregates of vapor-grown ice particles), sleet (freezing rain), or hail (rimed ice). Much of the precipitation in middle and high latitudes begins in the ice phase, although the hydrometeors can melt on the way down and fall to the surface as rain. Cloud lifetime is, in general, shortened by the development of ice, which removes water substance rapidly.

It is evident from the above that precipitation increases as a result of increasing uplift (through local surface heating, or convergence in the lower atmosphere, or orographically forced rise over mountains), increasing moisture content in the air (and thus, proximity to surface water, as well as increasing surface and atmospheric temperatures), relatively low concentrations of CCN (so the liquid water is divided among a few relatively large drops), and relatively high concentrations of IN (so that ice particles can form at midtropospheric temperatures and grow, sedimenting out of cloud base). Modification of the thermodynamic, chemical, or dynamic properties of the air in the cloud can have dramatic influences on precipitation formation. In turn, the formation of clouds and precipitation modifies the circulations, atmospheric temperatures, relative humidities, and the radiative fluxes below and above the clouds.

CLOUDS AND RADIATIVE FLUXES

Clouds and Shortwave Radiation

The fraction of downwelling solar radiation that is reflected back to space by clouds is called the *cloud albedo* (A_{cl}). The

A_{cl} generally ranges from about 0.4 to 0.8 for low stratiform clouds, increasing with cloud thickness, cloud liquid water content, and the number concentration of cloud drops. The albedo is usually assumed to be higher for water clouds than for ice clouds, all other parameters remaining constant, but if the ice particles are very small, the opposite is true. Thus, the cooling impact of clouds, which stems from the reflection of incoming solar radiation, increases with all the factors that increase cloudiness and with drop concentrations, and can decrease or increase with increasing ice fraction (for constant total condensate). Increased concentrations of anthropogenic aerosol particles and precursor gases can increase drop concentrations in warm clouds, and possibly, the concentrations of ice particles in colder clouds. This effect would increase the cloud albedo; however, in reality it is very difficult to quantify the anthropogenic effects on cloud albedo from large-scale observations because of the complexity of the clear air to cloudy air transition. However, in plumes and downwind of large population centers, the effect is clearly seen in satellite and aircraft measurements. There is some indication that the mean droplet size in low clouds in the Northern Hemisphere is around 1 μm smaller than that in the Southern Hemisphere, and models suggest that this difference would give rise to a net cooling of the Earth–atmosphere system on the order of $1\,W\,m^{-2}$ (about 25% of the magnitude of the warming due to the increase in CO_2 since the industrial revolution).

Clouds and Longwave Radiation

While the reflection of solar radiation by clouds cools the surface under the clouds, absorption and the subsequent reemission of terrestrial radiation by clouds warms the underlying surface, and lessens the flux of outgoing radiation at the top of the atmosphere. The impacts that clouds have on downwelling longwave radiation at the surface are felt by anyone who goes camping on cool nights; the approach of a cloud signals a rise in surface temperature.

The longwave radiative properties of a cloud can be expressed in terms of its emissivity, a number between 0 and 1 that depends on cloud properties and the wavelength of the radiation. The higher the emissivity, the more efficiently the cloud can absorb and emit radiation. The emissivities of clouds depend largely on the cloud temperature and total column water substance, and for thin clouds, the emissivity decreases as the mean dropsize increases, all other factors remaining equal.

Thick liquid water clouds tend to have emissivities near 1 at all wavelengths in the infrared; therefore, small perturbations in their properties do not change their longwave radiative impacts. On the other hand, the emissivities of thinner clouds (such as those that form in very cold regions and at higher levels) can be much less than 1. High CCN concentrations in these clouds could result in smaller drops for the same amount of condensed water; this might lead to increased cloud emissivities, thus increasing the greenhouse effect.

Clouds reflect downwelling solar radiation and emit infrared radiation to space, as well as back to the surface; therefore, they alter the fluxes of radiation at the top of the atmosphere, and they also modulate the fluxes of shortwave and longwave radiation at the Earth s surface. These cloud–radiation interactions determine the present climate and are subject to change as the climate changes (*see* Cloud- Radiation Interactions, Volume 1).

PRECIPITATION CHEMISTRY: ACID RAIN

In remote locations, the chemical composition of cloud water is dominated by the chemical content of the CCN and the absorption of atmospheric gases, such as CO_2 and NH_3. The predicted average pH of background cloud water is thus not 7, but approximately 4.5–6 i.e., it is slightly acidic. Atmospheric gases, such as SO_2, HNO_3, NO_x, and NH_3, and gaseous organics are all taken up to some extent by liquid water, which is the most efficient solvent known. In general, these decrease the pH of the cloud water further. The chemical composition of the rainwater produced exclusively by warm rain processes is usually dominated by the same ions as those in cloud water. The acidity of rain falling in and downwind of urban and industrial areas is often as low as 3–4. A general downward trend in the pH of rainwater in the north-east US, Eastern Canada, and Scandinavia appears to have ceased in the 1980s, possibly due to the control of emitted particles and SO_2 (which reacts with water to produce condensed sulfate). Contamination of rainwater by industrial emissions and by biomass burning remains a problem in many areas of the world.

The ice lattice, unlike liquid water, does not readily accept most non-water molecules. Therefore, the composition of precipitation formed in the ice phase is largely dominated by the *impurities* present in drops that freeze, and it has been shown in both urban and remote areas that the composition of snow that falls to the ground depends on the extent of riming. The composition of precipitation on the ground at any location depends on the trajectories of the air masses prior to precipitation; significant contamination from sulfates and trace metals has been found in newly fallen snow in the remote Alps and even in the high Caucasus Mountains.

CLOUDS IN URBAN AND AGRICULTURAL REGIONS

Anthropogenic effects on cloud and cloud processes have been observed for centuries over urban regions and those

intensively used for agriculture and grazing. In the last century, these effects have increased markedly. While the strictly urban effects are of limited importance globally, due to their small coverage of the planet, they give an indication of the kinds of impacts on cloudiness to be expected as the fraction of the Earth s surface modified by human activities continues to grow.

There are many (often conflicting) reports, based on surface measurements, of large changes in cloud-related quantities near urban areas. For example, low cloud cover, F_{cloud}, increased by 16.5% over Moscow in the years 1958–1993, together with surface temperature (increase by 1.3 °C), and a decrease of 6–7% in downwelling shortwave radiation. Recent satellite observations also suggest an urban effect on low cloud cover. The effect is due, in part, to perturbations in water or heat fluxes from the surface and partly to perturbations in the nature and concentrations of the aerosol particles in the air. There have been several studies that suggest increasing convective rainfall, thunderstorm activity, and hail production over and just downwind of highly urbanized areas during the 20th century. On the other hand, there are also a number of reports indicating decreased ice formation efficiency in polluted air masses. These changes in cloud properties are likely to be due to the anthropogenic modification of one or more of the parts of the cloud–environment system defined in the introduction.

Surface Moisture, Temperature, Albedo, and Roughness

Estimates of the impact of overgrazing alone suggest an increase of roughly 0.1 in the mean surface albedo due to overgrazing over the past 6000 years. This increase would have lowered the mean surface temperature by around 0.8 °C; larger effects have been reported in local and regional areas due to changes in land use. The reduction in surface moisture in these areas means that the surface heats more than in the damp surrounding countryside, a situation that enhances convergence and uplift over the dry area and subsidence outside it.

The results from mesoscale numerical models generally indicate that the accurate inclusion of heterogeneous soil moisture is of first-order importance in simulating cloud structures and movement over land surfaces. Agriculture, particularly when accompanied by surface irrigation and/or grazing, and deforestation modify surface heat and moisture fluxes, surface albedo, surface roughness, boundary-layer temperature structure, and the air chemistry. Gradients in vegetation type are thought to produce gradients in surface moisture and heat fluxes that modulate the mesoscale circulations associated with summer thunderstorms over the central US.

Stability of the Lower Atmosphere

While the air over cities tends to be drier, and therefore, the cloud bases tend to be higher than those over more moist surfaces, the convergence and enhanced updrafts over the city compensate for this effect, and cloudiness and rain often increase over and downwind of urban areas.

Chemical Composition of the Air

Emissions of pollutant gases and liquids modify the growth of droplets from the haze to the cloud droplet stage. Adsorption of such materials can change the droplet/vapor surface energy and droplet composition (i.e., equilibrium vapor pressure). These effects may increase droplet concentrations under some circumstances and decrease them in others. The rate of ice formation may also be sensitive to trace amounts of organic solutes or thin films on aerosol particles that modify the ice nucleating efficiencies. One possible mechanism for urban enhancement of storm activity might be the enhancement of ice formation by increased production of large CCN, and therefore, large drops, in urban boundary-layer clouds, or by enhanced IN activity. (Ice formation accelerates upward motion and precipitation evolution in general.) On the other hand, if CCN concentrations rise, the cloud droplets might be smaller, and the frequency and intensity of precipitation might decrease. Thus, it is not possible to make general predictions about the impacts of future anthropogenic changes in the atmospheric chemistry on cloudiness.

CLOUDS IN POLAR REGIONS

Clouds in polar regions are white like the underlying surface, and they tend to be associated with atmospheric temperature inversions so that their longwave emissivity (and not just their shortwave reflectivity) tends to be similar to that of the underlying surface. These properties make them very difficult to identify from satellite measurements. Nevertheless, the apparently small cloud-induced changes in both the reflected solar radiation and the emitted terrestrial radiation can have enormous impacts in polar regions. The Arctic is particularly susceptible to any perturbation of surface temperature, because the ensuing modifications in ice cover can then drive changes in cloud cover. Due to the complexities of these multiple interactions, the largest disagreements in models of global circulation are found in their predictions of cloud properties in the polar regions.

Surface Properties

Arctic clouds increase the downwelling longwave radiation and decrease the downwelling shortwave radiation at the surface, while they have opposite effects on the fluxes of

radiation leaving the system at the top of the atmosphere. Model results indicate that the sea-ice cover increases with increasing low cloud cover, and it increases with increasing cloudiness in summer, presumably because the clouds increase the system albedo. The predicted sea-ice cover also increases with high liquid to ice ratio in the clouds because, in general, liquid clouds have higher albedos than ice clouds. (On the other hand, as we have pointed out, if the ice particles are numerous and small, they may increase cloud albedo.) Also, the sea-ice cover decreases with increasing coverage by high clouds, the main radiative impact of which is to inhibit outgoing longwave radiation. Modifications in precipitation and in the cloud radiative fluxes can modify the temperature structure and stability of the ice, which, in principle, can modify the thermohaline circulation in the oceans by perturbing the freshwater flow to the sea. Moreover, the surface albedo decreases when sea ice melts, causing more heat to be absorbed by the surface. This amplifies the temperature increase. Model simulations of climate change due to increased greenhouse gas emissions indicate that, because of the response of the sea ice, the zonal mean temperature rise in the Arctic will be 2–3 times larger than the global temperature rise.

Structure of the Lower Atmosphere

The ice thickness and surface ice coverage determine the fluxes of heat and moisture from the surface into the lower atmosphere. These, together with fluxes from lower latitudes, determine the atmospheric temperature and humidity profiles to which the cloud cover responds.

In the winter, clouds are sparse in the Arctic, but the low-level atmosphere tends to hold *clear air ice precipitation*. This consists of ice crystals that apparently form at fairly low relative humidities, often in the plumes of moisture emanating from leads or cracks in the ice that expose liquid water to the air. The ice particles sediment to the surface, dehydrating the lower atmosphere. Although the clear air precipitation appears visually thin, it can contribute up to $80\,W\,m^{-2}$ to the downwelling longwave flux at the surface, which is equivalent to a heating rate of a few degrees per day.

Chemical Composition of the Air

Arctic clouds persist in summer and tend to be mainly liquid [for temperatures over $\sim 255\,K$ ($-18\,^{\circ}C$)]. It is thought that the CCN on which spring and summer Arctic cloud drops form are derived from sulfate aerosols. Some of the particles are produced photochemically from dimethyl sulfide emitted at the ocean surface. However, chemical analysis, showing that these particles contain black carbon and other elements typical of pollution sources, suggests that most are advected from midlatitudes in spring and summer. The advected aerosol particles are apparently inefficient at promoting ice formation, perhaps because sulfate particles coagulate with and deactivate dust or other potential ice nucleants; perhaps some other deactivation mechanism is present in the advected air masses. During winter, circulation patterns do not move air into the Arctic from lower latitudes as efficiently as in summer; the clouds tend to be completely glaciated. When a few ice particles form, they grow rapidly. Growth is faster at lower temperatures, causing the particles to fall from the clouds, taking most of the condensed phase water with them. Thus, cloud lifetime (and thus, cloud-related fluxes of heat and moisture, and therefore, the response of the underlying surface) depends sensitively on the ice/water ratio, which in turn depends on the particles and gases in the environment.

The results of these observational and modeling studies suggest that, if the mean surface temperature increases in the Arctic, the cloud cover and cloud lifetime might increase.

Continental Drift

Naomi Oreskes
University of California, San Diego, CA, USA

Continental drift is the motion of the Earth's continents over geological time. Since the 17th century, cartographers have noticed the jigsaw puzzle fit of the continental edges; in the 19th century, paleontologists discovered that some fossil plants and animals were extraordinarily similar across the globe. Some rock formations in distant continents were also surprisingly similar. To account for these similarities, Austrian geologist Eduard Suess proposed the theory of Gondwanaland: a giant supercontinent that had once covered the entire Earth surface before breaking apart to form continents and ocean basins. In the early 20th century, German meteorologist Alfred Wegener suggested an alternative explanation: continents drift. The paleontological patterns could be explained if the continents migrated, sometimes joining together, sometimes breaking apart.

Continental drift was not accepted when first proposed, but in the 1960s it became a cornerstone of the theory of global plate tectonics. Continental drift is now explained as a consequence of moving plates. The continents are embedded within the lithospheric plates that comprise the upper 80–100 km of the Earth, and are carried along with the plates as they migrate at average rates of 3–10 cm year^{-1}. As a result, the global configuration of continents and oceans is constantly changing. For several hundred million years during the late Paleozoic and the Mesozoic eras, the continents were united into a supercontinent called Pangea. The breakup of Pangea produced the configuration of the continents we have today.

Continental drift is a fundamental natural cause of global change. The major geological processes (earthquakes, volcanoes, mountain building) are caused by plate motions and interactions. These processes control the large-scale physiography of the globe, and with it, the distribution of habitat. In addition, many facts of evolution are explained as effects of continental drift. With the breakup of Pangea, previously unified populations began to diverge and speciate in response to their new environmental conditions. Other types, such as South American emus and African ostriches, retained obvious similarities even while physically segregated. A major part of paleoclimate change is also explained by continental drift, as the direct result of continents moving passively through climate zones, and the indirect impact of the reconfiguration of continents and oceans on oceanic circulation and climate patterns.

The development of the theory of continental drift and plate tectonics illustrates the tortuous process by which new scientific knowledge is established. The idea of globally moving continents was adamantly rejected when first widely debated in the 1920s, then established as scientific fact only 40 years later. Studying this history illuminates some of the reasons why scientific communities resist new ideas.

HISTORICAL BACKGROUND: THE ORIGIN OF MOUNTAINS AND CONTRACTION THEORY

One of the central scientific questions of 19th century geology was the origin of mountains. How were they formed? What process squeezed and folded rocks like putty? What made the Earth's surface move? Most theories invoked terrestrial contraction as a causal force. It was widely believed that the Earth had formed as a hot, incandescent body, and had been steadily cooling since the beginning of geological time. Because most materials contract as they cool, it seemed logical to assume that the Earth had been contracting as it cooled.

In Europe, Austrian geologist Edward Suess (1831–1914) popularized the image of the Earth as a drying apple: as the Earth contracted, its surface wrinkled to accommodate the diminished surface area. Suess assumed that the Earth's initial crust was continuous, but broke apart as the Earth's interior shrunk; the collapsed portions formed the ocean basins, the remaining elevated portions formed the continents. With further cooling, the continents became unstable and collapsed to form the next generation of ocean floor; what had formerly been ocean now became dry land. The interchangeability of continents and oceans explained the presence of marine deposits on land (which had long before puzzled Leonardo Da Vinci), and the extensive interleaving of marine and terrestrial materials in the stratigraphic record. Suess's theory also explained the widely known similarities of fossil assemblages in parts of India, Africa, and South America by attributing

them to an early geological period when these continents were still contiguous. He called this ancient supercontinent Gondwanaland.

In North America, a different version of contraction theory was developed by James Dwight Dana (1813–1895). Dana suggested that the Earth s continents had formed first, when minerals with relatively low-fusion temperatures such as quartz and feldspar had solidified. Then the globe continued to cool and contract, until the high temperature minerals such as olivine and pyroxene finally solidified: on the moon, to form the lunar craters, on Earth, to form the ocean basins. As contraction continued after the Earth was solid, it induced surface deformation. The greatest pressure was experienced at the boundaries between the oceanic and continental blocks, explaining the concentration of mountains along continental margins. Because continents and oceans were viewed as globally permanent features, Dana s account came to be known as permanence theory.

In North America, permanence was linked to the theory of geosynclines (subsiding sedimentary basins along continental margins) developed by Dana and James Hall (1811–1889), state paleontologist of New York and the first president of the Geological Society of America (1889). Hall noted that the Appalachian Mountains mostly consisted of folded sequences of shallow water sedimentary rocks, thousands of meters thick. How did thick sequences of shallow water deposits form? How were they folded and uplifted into mountains? Hall suggested that materials eroded off the continents and accumulated in the adjacent marginal basins, causing the basin to subside. Subsidence allowed more sediments to accumulate, causing more subsidence, until finally the weight of the pile caused the sediments to be heated, lithified, and then uplifted into mountains. Dana modified Hall s view by arguing that thick sedimentary piles were not the cause of subsidence but the result of it. Either way, the theory provided a concise explanation of how thick sequences of shallow water rocks could form, but was vague on the question of how they were transformed into mountain belts.

CONTINENTAL DRIFT AS AN ALTERNATIVE TO CONTRACTION THEORY

In the early 20th century the contraction theory was refuted by three independent lines of evidence. First, field mapping in the Swiss Alps and the North American Appalachians demonstrated hundreds of kilometers of shortening of strata. This would require impossibly huge amounts of terrestrial contraction to explain. Second, geodesists studying the problem of surface gravitational effects showed that the surface mass associated with mountains was counterbalanced by subsurface mass deficit. Mountains were held aloft not by their internal strength, but by floating: a concept called isostasy. Contra Suess, continents and oceans were not interchangeable. Third, physicists discovered radiogenic heat, which refuted the basis of contraction theory. With contraction no longer axiomatic, Earth scientists were motivated to search for other driving forces of deformation. Many did; Alfred Wegener (1880–1930) is the most significant, for his theory was the most widely discussed (*see* Wegener, Alfred, Volume 1).

Primarily known as a meteorologist and author of a pioneering textbook on the thermodynamics of the atmosphere, Wegener realized that paleoclimate change could be explained if continents had migrated across climate zones, and the reconfiguration of continents and oceans altered the Earth s climate patterns. However, continental drift was more than just a theory of paleoclimate change. It was an attempt to unify disparate elements of Earth science: on the one hand, paleontological evidence that the continents had once been connected; on the other, geodetic evidence that they could not be connected in the way European contractionists had supposed. Wegener s answer was to reconnect the continents by moving them laterally.

Wegener s theory was widely discussed in the 1920s and early 1930s. It was also hotly rejected, particularly by geologists in the United States who labeled it bad science. The standard explanation for the rejection of continental drift is the lack of a causal mechanism, but this explanation is false. There was a spirited and rigorous international debate over the possible mechanisms of continental migration. Much of it centered on the implications of isostasy: if continents floated in a denser substrate, then this substrate had to be plastic or fluid and continents could at least in principle move through it. The Fennoscandian rebound (the progressive uplift of central Scandinavia since the melting of Pleistocene glacial ice) provided empirical evidence that they did, at least in the vertical direction and at least in the Pleistocene period. However, in Scandinavia the cause of motion was generally agreed upon, first the weight of the glacial ice, then the pressure release upon its removal. What force would cause horizontal movement? Would the substrate respond comparably to horizontal as to vertical movement? Debate over the mechanisms of drift concentrated on the long-term behavior of the substrate and the forces that could cause continents to move laterally.

In the United States, the question was addressed by Harvard geology Professor Reginald A Daly (1871–1957), that country s strongest defender of continental drift. Daly argued that the key to tectonic problems was to be found in the Earth s layered structure. Advances in seismology demonstrated that the Earth contained three major layers: crust, substrate (or mantle) and core. The substrate, he suggested, might be glassy, and therefore could flow in response to long-term stress just as old plates of glass gradually thicken at their downward edges and glassy lavas flow downhill. Continents might do the same. Building on the geosyncline concept of Dana and Hall, Daly suggested

that sedimentation along the continental margins resulted in subtle elevation differences, which in turn produced isostatic instabilities. Eventually, the continent could rupture, sliding down over the glassy substrate under the force of gravity. The sliding fragment would then override the other half (an early suggestion of subduction) and, over time, the accumulation of small increments of sliding would result in global continental drift.

Daly admonished his American colleagues to take up the question of drift, but few did. Reaction in Europe was more favorable. Irish geologist John Joly (1857–1933) linked the question to discoveries in radioactivity. Trained as a physicist, Joly had demonstrated that pleochroic haloes in mica were caused by radiation damage from tiny inclusions of U and Th-bearing minerals, such as apatite. Radioactive elements were therefore ubiquitous in rocks, suggesting that radiogenic heat was also ubiquitous. If it were, then it could be a force for geological change. Joly proposed that as radiogenic heat built up, the substrate would begin to melt. During these periods of melting, the continents would move under the influence of small forces (such as small gravitational effects) that would otherwise be ineffectual. These were the periods of global orogeny (i.e., periods of mountain formation), such as the Appalachian/Caledonian that crossed Europe and North America in the Paleozoic and the Alpine/Dinaric era that crossed Europe in the Cenozoic age.

Joly s theory responded to a geophysical complaint against a plastic substrate: that the propagation of seismic waves indicated a fully solid and rigid Earth. He pointed out that although the Earth was solid now, it might not always have been. More widely credited was the suggestion of British geologist Arthur Holmes (1890–1965) that the substrate was partially molten or glassy. Underscoring arguments made by Wegener, Holmes emphasized that the substrate did not need to be liquid, only plastic, and that it might be rigid under high strain rates during seismic events yet still be ductile under the low strain rates that prevailed under most geological conditions. If it were plastic in response to long-term stress, then continents could move within it. Holmes s driving force was convection currents in the mantle. He argued that radiogenic heat would generate convection currents: the mid-ocean ridges were the sites of upwelling convection currents, where continents had split, and the ocean deeps (geosynclines) were the sites of downwelling currents, where continents were deformed as the substrate descended. Between the ridges and the trenches, continents were dragged along in conveyor-like fashion.

THE REJECTION OF CONTINENTAL DRIFT

Arthur Holmes s papers were widely read and cited; many geologists thought he had found the cause of continental drift. However, opposition was none the less strong, particularly in the United States, where reaction to Wegener s theory was vitriolic. More was at stake than a matter of scientific fact.

Three factors contributed to the American animosity to continental drift. One, Americans were widely committed to the method of multiple working hypotheses, and Wegener s work was interpreted as violating it. For Americans, the right scientific method was empirical, inductive, and required weighing observational evidence in light of alternative explanatory possibilities. Good theory was also modest, holding close to the objects of study. Most closely associated with the University of Chicago geologist T C Chamberlin (1843–1928), who named it, the method of multiple working hypotheses reflected American ideals expressed since the 18th century linking good science to good government: Good science was anti-authoritarian, like democracy. Good science was pluralistic, like a free society. If good science provided an exemplar for good government, then bad science threatened it. To American eyes Wegener s work was bad science: It put the theory first and then sought evidence for it. It settled too quickly on a single interpretive framework. It was too large, too unifying, too ambitious. In short, it was seen as autocratic. Features that were later viewed as virtues of plate tectonics were attacked as flaws of continental drift.

Second, continental drift was incompatible with the version of isostasy to which Americans subscribed. In the late 19th century, two accounts of isostatic compensation had been proposed: John Henry Pratt (1809–1871) attributed it to density variations, George Biddell Airy (1801–1892) attributed it to differences in crustal thickness. Until the early 20th century, there had been no empirical confirmation of the concept beyond the original evidence that had inspired it, nor any means to differentiate the two explanations. Then American geodesists John Hayford (1868–1925) and William Bowie (1872–1940) used Pratt s model to demonstrate that isostatic compensation was a general feature of the crust. By making the assumption of a uniform depth of compensation, they were able to predict the surface effects of isostasy to a high degree of precision throughout the United States. At first, their work was hailed as proof of isostasy in general, but in time it was viewed as confirmation of the Pratt model in particular. However, if continental drift were true, then the large compressive forces involved would squeeze the crust to generate thickness differences. Continental drift seemed to refute Pratt isostasy, which had worked for Americans so well. Rather than reject Pratt isostasy, they rejected continental drift.

Third, Americans rejected continental drift because of the legacy of uniformitarianism. By the early 20th century, the methodological principle of using the present to interpret the past was deeply entrenched in the practice of

historical geology. Many believed this was the only way to interpret the past: that uniformitarianism made geology a science because, for without it what proof was there that God hadn t made the Earth in seven days, fossils and all? Historical geologists routinely used faunal assemblages to make inferences about climate zones, but according to drift theory, continents in tropical latitudes did not necessarily have tropical faunas, because the reconfiguration of continents and oceans might change matters altogether. Wegener s theory raised the spectre that the present was not the key to the past: that it was just a moment in Earth history, no more or less characteristic than any other. This was not an idea American scientists were willing to accept.

In North America, the debate over continental drift was quelled by an alternative account of the faunal evidence. In 1933, geologists Charles Schuchert (1858–1942) and Bailey Willis (1857–1949) proposed that the continents had been intermittently connected by isthmian links, as the isthmus of Panama presently connects North and South America and the Bering Land Bridge recently connected North America to Asia. The isthmuses had been raised up by orogenic forces, then subsided under the influence of isostasy. This explanation was patently *ad hoc*: there was no evidence of isthmian links other than the paleontological data that they were designed to explain (away). Nevertheless, the idea was widely accepted, and a major line of evidence of continental drift undercut. In 1937, South African geologist Alexander du Toit (1878–1948) published *Our Wandering Continents*, a comprehensive synthesis of the geological evidence of continental drift, but it had little impact in North America. The matter rested there for two decades, until the debate was reopened on the basis of entirely new evidence.

FROM CONTINENTAL DRIFT TO PLATE TECTONICS

In the 1950s, continental drift was revived by British geophysicists studying rock magnetism as a means to understand the Earth s magnetic field, one group at Imperial College led by P M S Blackett (1897–1974), and one at Cambridge (later at Newcastle) led by S K Runcorn (1922–1995). Both groups found evidence that rocks had moved relative to the Earth s magnetic poles, so either the continents or the poles had moved. Initially geophysicists were more receptive to the idea of polar wandering, but by the late 1950s comparative evidence from India and Australia pointed in the direction of moving continents. Inspired by these results, American geologist Harry Hess (1906–1969) revived the idea earlier proposed by Arthur Holmes: that convection currents drove continental motions.

Hess suggested that mantle convection drives the crust apart at mid-ocean ridges and downward at ocean trenches, forcing the continental migrations in their wake. He interpreted the oceanic crust as a hydration rind on a serpentinized mantle; Robert Dietz (1914–1995) modified this to generate an oceanic crust by submarine basalt eruptions, and gave it the name it holds today: sea floor spreading. Dietz s interpretation was later confirmed by direct examination of the sea floor. Meanwhile, geophysicists had demonstrated that the Earth s magnetic field has repeatedly and frequently reversed its polarity. Magnetic reversals plus sea floor spreading added up to a testable hypothesis, proposed independently by Canadian Lawrence Morley and British geophysicists Frederick Vine and Drummond Matthews. If the sea floor spreads while the Earth s magnetic field reverses, then the basalts forming the ocean floor will record these events in the form of a series of parallel stripes of normal and reversely magnetized rocks. Since World War II, the United States Office of Naval Research had been supporting sea floor studies for military purposes, and large volumes of magnetic data had been collected. American and British scientists examined the data, and by 1966 the Vine and Matthews hypothesis had been confirmed. In 1967–1968, the evidence of drifting continents and the spreading sea floor was unified into a global framework. Working independently, Daniel P McKenzie and Robert L Parker at the Scripps Institution of Oceanography, and Jason Morgan at Princeton University, showed that existing data could be used to analyze crustal motions as rigid body rotations on a sphere. The result became known as *plate tectonics* (*see* Plate Tectonics, Volume 1); by the early 1970s it was the unifying theory of the Earth sciences.

Continental drift is now subsumed into global plate tectonics, but the problems it was designed to explain (global physiography, disjunctively distributed fauna, and paleoclimate change) are still explained by the same basic idea: Continents drift. So faunal assemblages are divided or united, climate patterns are altered, and the Earth s physiography is transformed.

LESSONS FROM CONTINENTAL DRIFT: THE TORTUOUS DEVELOPMENT OF SCIENTIFIC KNOWLEDGE

Most people believe that when the weight of evidence becomes sufficiently great, scientists will accept the reality of new phenomena and the truth of new theories. The case of continental drift suggests that reality is more complex. Scientific theories are not judged only in the light of evidence, but also in the light of methodological standards and epistemic preferences. Because these standards and preferences are forged prior to the onset of any theoretical debate, the legacies of past intellectual debates may weigh heavily in the outcomes of new ones.

The problem with continental drift was not a lack of evidence, nor a lack of causal explanation. The evidence presented by Wegener and du Toit has been largely confirmed by global plate tectonics, and Holmes s causal account (mantle convection) is now generally accepted as the cause of plate tectonics. The problem with continental drift was a conflict with prior intellectual commitments. Between the 1920s and the 1960s, these earlier commitments (to Pratt isostasy, to the method of multiple working hypothesis, to uniformitarianism) were loosened, modified, or abandoned altogether. With this, the debate could be reopened on the basis of new evidence, and a previously discarded idea resurrected.

Convection

Roger A Pielke, Sr

Colorado State University, Fort Collins, CO, USA

The term convection refers to vertical mixing through the exchange of mass that is driven by buoyancy forces. This buoyancy occurs when the density of a uid parcel is different from the surrounding uid. In the oceans, for example, cold and saline water is denser than warm and fresh water. As a result cold water above warm water will vertically mix. Similarly, salty water over less saline water will vertically mix. In the atmosphere, a warm air parcel will rise and a cold air parcel will sink. In an unsaturated atmosphere, this convection is called dry convection*; while in an atmosphere that is partially or completely saturated it is referred to as* moist convection*. A third type, called* forced convection*, occurs when air blows over a rough surface or up a slope.*

Dry convection occurs in a dry atmosphere when the vertical decrease of temperature with altitude exceeds in magnitude the dry adiabatic lapse rate (1 °C per 100 m), the rate at which a rising parcel of dry air cools due to expansion (*see* Lapse Rate, Volume 1). When the ambient lapse rate is greater than this, a rising air parcel is warmer, and thus less dense than its surrounding air, and buoyancy forces accelerate its upward motion. In a saturated atmosphere, *moist convection* happens when the release of latent heat in a rising air parcel, combined with the effect of expansion, is sufficient to make it warmer than the surrounding air at the same altitude. This occurs when the temperature change with altitude outside the parcel (referred to as the environmental *lapse rate*) decreases more rapidly than the cloud cools as it ascends. The cloud cools less rapidly than a dry air parcel, since condensation of water vapor into liquid water, the freezing of liquid water, and the deposition of water vapor into ice introduce the heat of condensation, freezing and deposition, respectively.

This lapse rate, called the moist adiabatic lapse rate, is always smaller than the dry adiabatic lapse rate. At very cold temperatures, where the actual amount of water vapor in the air must be small, the moist and dry lapse rates become nearly identical. Moist convection is also often referred to as *cumulus convection*. The specific lapse rate of a real cloud as it ascends depends on its initial temperature, the actual amounts of water vapor in the air, and the amount of lateral mixing with the surrounding cooler and drier air. This lateral mixing is called *entrainment*.

Downward convection in the atmosphere can be initiated when rainwater evaporates. If the cooling by evaporation produces air parcels that are cooler than the surrounding air, vertical mixing will occur. When rainwater remains within the parcel, this downward convection is referred to as a *wet microburst*. The term *downburst* has also been used. If the rainwater is completely evaporated, yet the parcel remains colder than the environmental air, the term *dry microburst* is used. These microbursts are a hazard to aircraft landing and takeoffs, since the wind shear created as the convection reaches the surface can be quite large.

Clouds formed through convective processes are referred to as cumuliform clouds (*see* Clouds, Volume 1). Shallow cumulus clouds, as often occur on otherwise sunny days, are called *cumulus humulis*. They are also known as fair weather cumulus. Towering cumulus clouds that extend upwards to several kilometers or more are called *cumulus congestus*. Cumulus clouds, which extend to the tropopause, and have an anvil shape at their top, are referred to as *cumulonimbus*. The anvil forms as the cloudy air becomes colder or is of the same temperature as the surrounding clear air, as it impinges into the lower levels of the stratosphere. Cumulonimbus clouds are also called thunderstorms, since these clouds are electrified enough to produce lightning. Downward bubbles of cloud that often form below the anvils of thunderstorms are called *mammatus* clouds. These clouds are actually elevated wet downbursts.

Convection occurs in the atmosphere, lakes and the oceans. Changes in the atmospheric temperature lapse rate associated with environmental change would directly affect the intensity of both dry and moist convection. Alterations in the amount of fresh water inflow from rivers would change the intensity of convection in the oceans. The Younger Dryas period (which occurred early in the Holocene), for example, was a period of brief return to glacial climate conditions, as massive inflows of fresh water from melting glaciers caused suppression of vertical mixing in the North Atlantic, since the fresh water had a lower density than the underlying ocean water (*see* Younger Dryas, Volume 1). This reduced vertical mixing caused much colder temperature in the region, which subsequently cooled the entire Northern Hemisphere.

Atmospheric convection is strongly controlled by the energy and water balance at the Earth s surface. As a result, alterations in land surface conditions; such as due to landscape changes (deforestation, overgrazing, etc.) will directly influence dry and moist convection. Examples of studies that have explored these effects include Pielke *et al.* (1998); Pitman *et al.* (1999); Xue (1996); and Polcher and Laval (1994).

Coriolis Effect

Anders Persson

European Center for Medium-range Weather Forecasts (ECMWF), Reading, UK

As a consequence of the Earth's rotation, wind and ocean currents are de ected to the right in the Northern Hemisphere and to the left in the Southern Hemisphere. This de ection is attributable to a Coriolis force, a so-called ctitious force, which, like the equally ctitious centrifugal force, is essentially a consequence of inertia. The Coriolis de ection is always at right angles with the motion, which means that it cannot change the velocity and kinetic energy of a body (do work). Still the Coriolis force has a decisive in uence on many atmospheric and oceanic ow patterns of almost all scales, from the diurnal turning of the sea breeze circulation and the drifting of icebergs, to large-scale circulation systems like the Indian monsoon and the Gulf Stream.

THE HISTORY OF THE CORIOLIS FORCE

That the motion of the Earth has a profound effect on the motion of the atmosphere has been recognized since the 17th century, most famously by George Hadley (1685–1768). A general mathematical expression for the apparent motion within a rotating system was derived around 1800 by Pierre Simon Laplace (1749–1827), but he did not understand the implications for the atmospheric circulation. In the 1830s, the French mathematician and physicist Gaspard Gustav Coriolis (1792–1843) wanted to calculate the centrifugal force on a body that was not fixed to the rotating system, but moving within it. The

total centrifugal force C, or *compound* centrifugal force as Coriolis called it, could be calculated by adding to the normal centrifugal force ($C_0 = m\omega^2 R$), an extra force, the Coriolis force $m^2\omega V_r$ (where ω is the angular velocity of the rotation, R the distance to the axis of rotation, V_r the relative motion with in the rotating system and m the mass). This means that physically the Coriolis force is just an extra component of the centrifugal force for a body moving at the same time it is taking part in a rotation.

The relevance of the Coriolis effect to Earth sciences was not realized by Coriolis and his contemporaries. This recognition only came in the wake of the famous pendulum experiment by Jean Bernard Léon Foucault (1819–1868). Inspired by this experiment and Laplace s work, the American William Ferrel (1817–1891) concluded in 1856 that the direction of the wind is parallel to the isobars, and that its speed is dependent on the latitude and the horizontal pressure gradient. At the same time, but independently of Ferrel, the Dutch meteorologist C H D Buys-Ballot (1817–1890) published his empirical rule according to which low pressure is to the left if the wind is blowing into one s back. Neither Foucault, nor Ferrel and Buys-Ballot had read Coriolis 1835 paper. The first time his work was brought into Earth Sciences was in 1859 at the French Academy in a comprehensive discussion of the deflective force in relation to the problems associated with water currents in channels or rivers. But it took many years before Coriolis name started to appear in the meteorological literature. When meteorologists in the second half of the 19th century discussed the effects of the rotation of the Earth, it was the findings of Foucault, Ferrel and Buys-Ballot that were referenced. The name Coriolis force was not used until the early 1920s, and then was simply attached to a mechanical effect that had been explored by others.

BASIC MECHANISM

A quantitative measure of the horizontal deflection is fV_r where V_r is the velocity of the body and $f = 2\Omega \sin\varphi$, the so called Coriolis parameter, where Ω is the angular velocity of the Earth s rotation and φ the latitude. The horizontal deflection is strongest at the poles, zero at the equator. At 43° latitude, where $f = 10^{-4}\,s^{-1}$, a body moving with a speed of $10\,ms^{-1}$ will in less than a minute have deviated 1 m from its original course. Because the Coriolis force is always perpendicular to the motion, it tries to bring back the moving body from where it came by forcing it into a circular orbit (Figure 1). The role of the Coriolis force on the global system is presented in Atmospheric Motions, Volume 1; Ocean Circulation, Volume 1.

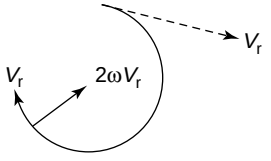

Figure 1 A body (of unit mass) moving with a velocity V_r in a system rotating with an angular velocity ω under no other force than the Coriolis force $2\omega V_r$ will follow a circular path with a radius of curvature $V_r/2\omega$

THE CORIOLIS FORCE ON A TURNTABLE

To acquire a physical understanding of the Coriolis force, consider a body m in a curved motion, like a vehicle taking a sharp bend. In the driver s frame of reference there will be (per unit mass) a centrifugal force C (Figure 2a) (Equation 1).

$$C = \frac{V^2}{R} \tag{1}$$

where V and R are the velocity and radius of curvature of the trajectory, both viewed from the fixed frame of reference.

A special, but common, case is a body, fixed to a rotating system, moving with a constant angular velocity ω under a central force in a circle with a radius R_0. In this case the total centrifugal force agrees with what is normally referred to as the centrifugal force C_0 (Figure 2b) (Equation 2).

$$C_0 = m\omega^2 R_0 \tag{2}$$

The next step is to consider the total centrifugal force on a body that is not fixed to the rotating system, but moving within it with a relative velocity V_r. The trajectory seen from the fixed frame of reference will then not necessarily be a circle (where Equation (2) applies), but a curved path (where the more general Equation (1) applies).

If the body moves radially *inwards* the trajectory, seen from the fixed frame of reference, it will follow an inward spiral with $R < R_0$, with R and C pointing in a different direction than R_0 and C_0 (Figure 2c). If the body moves radially *outward*, the trajectory in the fixed frame of reference will be an outward spiral with $R > R_0$ with R and C_0 pointing in a different direction to R_0 and C_0 (Figure 2d). The difference between the centrifugal force C for a moving body and C_0 for a fixed body, will in both cases be in the same direction relative to V_r (to the right for anticlockwise rotation) (Equation 3)

$$C - C_0 = 2\omega V_r \tag{3}$$

This is also true if the body moves tangentially. If the motion is in the direction of the rotation, the centrifugal force C will increase; if the body moves against the direction of the rotation, the centrifugal force C will decrease (Figure 2e). The difference $C - C_0$ will again for both

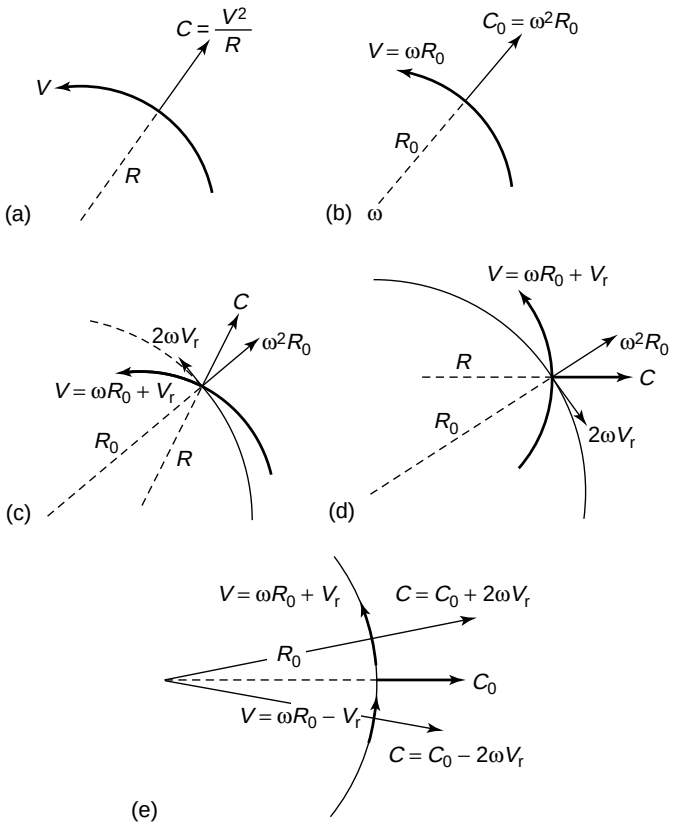

Figure 2 (a) The total centrifugal force is always directed perpendicularly to the trajectory of the body moving in a curved path in a fixed frame of reference; (b) for a body stationary in a rotating system, the trajectory in a fixed frame of reference is a circle and the total centrifugal force is directed radially out from the center of rotation; (c) for a body moving inward with velocity V_r, the trajectory is an inward spiral and the total centrifugal force is pointing outward but not exactly radially; (d) for a body moving outward with velocity V_r, the trajectory is an outward spiral and the total centrifugal force is pointing outward but not exactly radially; (e) for a body moving tangentially, the total centrifugal force is pointing radially outwards, but is weakened or strengthened, respectively, depending on whether the motion is against or with the rotation

cases be in the same direction relative to V_r (to the right for anticlockwise rotation). On a turntable any body will be accelerated away from the center of rotation more or less independent of whether the body is moving on it or not. This does not happen to air, water or any other mass element on the Earth, because the Earth s gravitation acts as a balancing force.

THE CORIOLIS FORCE ON A ROTATING PLANET

During the formation of the Earth, the centrifugal force due to the Earth s rotation shaped it into an oblate ellipsoid. A balance was reached when the combination of the centrifugal force C and the gravitational force g^* became perpendicular to the Earth s surface. The resultant of C and g^* is the weight of a body, g, called the effective gravity (Figure 3a). We can also consider the vertical and horizontal components of C and g^*. The vertical components C_V and g_V^* make up the effective gravity g, whereas the horizontal components C_H and g_H^* balance each other (Figure 3b).

However, this balance $C_H + g_H^* = 0$ with g perpendicular to the Earth s surface is only valid for stationary bodies; a non-stationary object will, due to its motion, change the total centrifugal force C in the way discussed above: east–west motions (relative to the rotating system) will change it through a change of the absolute velocity, a south–north motion will change it because of a change of the radius of curvature (both in magnitude and direction). Thus, the resultant of g^* and C will no longer be perpendicular to the Earth s surface but have components in the vertical and horizontal directions.

The modification of effective gravity g in magnitude and direction of a body due to its motion relative to the Earth s surface is the physical mechanism behind the Coriolis effect on a rotating planet. For motion westward, it is g_H^*, the horizontal component of gravitation, which has become stronger than the horizontal component of the centrifugal force C_H, that will physically displace the body towards the poles, to the right of the relative motion V_r. A body

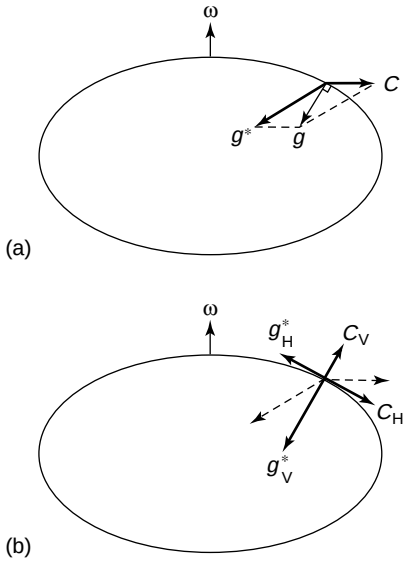

Figure 3 (a) The combined effect of the centrifugal force C and gravitational force g^* affecting a stationary body, results in the force of gravity g which is perpendicular to the earth's surface. (b) The earth's centrifugal force C and gravitational force g^* decomposed into horizontal and vertical components. C_V and g_V^* constitute effective gravity. The horizontal components C_H and g_H^* balance each other provided the body is stationary

moving westward also becomes heavier, moving eastward lighter, due to the vertical Coriolis deflection. This so-called *Eötrös effect*, named after the Hungarian physicist Lorand Eotros (1848–1919), has long been known to geodesists measuring the Earth s gravitational field.

The Coriolis force in vector form is $-2\omega \times V_r$ where the cross multiplication reflects the fact that the Coriolis force is strongest for motions perpendicular to the axis of rotation and is zero for motions parallel to it (Figure 4).

The angular velocity ω for the Earth s angular velocity should not relate to the solar day (24 hours) but the sidereal day (23 hours and 56 minutes) because this represents the rotation versus the fixed stars. By using the sidereal day instead of the solar day, we take effectively into account the Coriolis effect due to the orbiting of the Earth around the Sun!

Due to the latitudinal variation of the Coriolis force, a body moving under inertia will therefore not follow a perfectly circular but a slowly westward translating spiral (Figure 5). This is because the radius of curvature is shorter at higher latitudes than at lower ones. This so-called *beta-effect* plays an important role in the dynamics of the atmosphere and oceans.

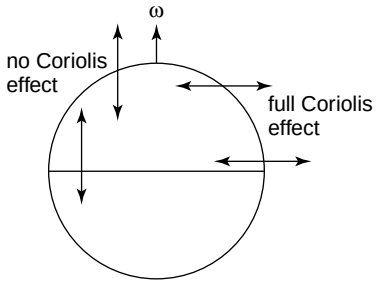

Figure 4 The Coriolis force affects all motions with maximal strength when they are perpendicular to the Earth's axis. When the motion is parallel to the axis there is no Coriolis deflection

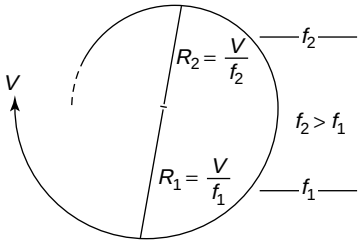

Figure 5 The variation of the Coriolis force makes an inertial motion slowly spiral westward (the beta-effect). A body moves with a velocity V and is deflected at a northerly latitude where the Coriolis parameter is f_2 with a radius of curvature R. Arriving at a southerly latitude with Coriolis parameter $f_1 < f_2$ the radius of curvature. $R_1 > R_2$ and the body will not exactly follow a circular path

Cretaceous

The *Cretaceous* is the last of three geologic periods in the Mesozoic Era (225–65 Ma), lasting 71 million years from 136 to 65 Ma, and is the final period of the existence of the dinosaurs. The Cretaceous Period follows the Jurassic Period and is followed by the Tertiary Period in the Cenozoic Era, which follows the Mesozoic (*see* Earth System History, Volume 1). The origin of the name, originally coined by William D Conybeare (1787–1857) and William Phillips (1775–1828), is the clay (*creta* in Latin) found in the White Cliffs of Dover and throughout Northern Europe (Prothero, 1990). The beginning of the Cretaceous period is marked by the separation of North America from Eurasia (Laurasia), and South America from Africa (Gondwanaland), while the uplift of the Rocky Mountains began towards the end of the Cretaceous. Sea level was, on average, over 300 m higher than present, mainly due to global tectonic processes (Southam and Hay, 1981). The resulting paleogeography led to a near-equatorial current in the so-called Tethys Sea, covering large parts of western Europe and North Africa, as well as a large, shallow interior sea in western North America, extending from the Gulf of Mexico throughout the western US and Canada (Crowley and North, 1991). The end of the Cretaceous, known as the K–T (Cretaceous [C stands for Carboniferous]–Tertiary) boundary, occurred catastrophically with an asteroid impact that is thought to have wiped out the dinosaurs and 75% of all living species. Geological evidence shows that the mid-Cretaceous was warmer than present in high latitudes and possibly ice-free. Modeling studies have explored various reasons for this enhanced high latitude warmth, including land–sea configuration, ocean heat transport, land–surface processes such as vegetation, and CO_2 levels. In all of the simulations, higher CO_2 levels are needed to produce the required warmth. There is some evidence that higher CO_2 levels in the mid-Cretaceous may be the result of greater volcanism due to enhanced sea-floor spreading and reduced continental area, which leads to less weathering and therefore less uptake of CO_2 (Crowley and North, 1991).

Crutzen, Paul J

(1933-)

Paul J Crutzen was born in Amsterdam, The Netherlands, in December 1933. He first studied civil engineering and worked at the Bridge Construction Bureau in his native city between 1954 and 1958. He then moved to Sweden where he received a degree in Meteorology (1968) and a few years later his doctoral degree (1973). His thesis work was performed in part at Oxford University in the UK. In 1974, Paul Crutzen moved to the United States and became a research scientist at the National Center for Atmospheric Research (NCAR) in Boulder, CO, and at the Aeronomy Laboratory of the National Oceanic and Atmospheric Administration, also in Boulder. In 1977, he was appointed as the Director of the Air Quality Division of NCAR. In 1980, he returned to Europe and became a member of the Max Planck Society for the Advancement of Science, and the Director of the Atmospheric Chemistry Division at the Max Planck Institute for Chemistry in Mainz, Germany. Crutzen held several part-time teaching positions including a professorship at the universities of Chicago (1987–1991), Stockholm (1991–1992), California at San Diego (since 1992), Mainz (since 1993), and Utrecht (since 1997).

Paul Crutzen has made a large number of innovative contributions in many areas of atmospheric chemistry. In the 1970s, he studied the photochemical mechanisms affecting ozone in the stratosphere and established that the most efficient ozone destruction mechanism is provided by a catalytic cycle involving the presence of nitrogen oxides (*see* Stratosphere, Chemistry, Volume 1). This discovery led H Johnston at the University of California to suggest that the emission of nitrogen oxides by a projected fleet of high-altitude aircraft would destroy large amounts of stratospheric ozone.

Crutzen also showed that the presence of ozone in the troposphere was not due only to the intrusion of ozone-rich stratospheric air masses or the formation of ozone in urban areas, but that on the global scale, the photooxidation of methane and carbon monoxide catalyzed by the presence of nitrogen oxides could produce substantial quantities of background tropospheric ozone. This finding suggested that photochemical pollution was not limited to industrial areas, but was potentially global in nature. Crutzen suggested that an important source of ozone precursors (including carbon monoxide and nitric oxide) was provided by biomass burning in the tropics during the dry season.

Together with John Birks at the University of Colorado, Crutzen pointed out that a large number of intense fires could be triggered by the explosion of nuclear bombs, should a nuclear war occur. Such perturbation would not only alter dramatically the chemical composition of the atmosphere, but it would considerably modify the climate and produce for the entire population of the Earth what Crutzen and Birks named a *nuclear winter* (*see* Nuclear Winter, Volume 3). In the 1980s, Crutzen contributed to the understanding of the chemical mechanisms involved in the formation of the Antartic ozone hole (*see* Ozone Hole, Volume 1).

Paul Crutzen has received honorary doctoral degrees from several universities: York (Canada), Louvain (Belgium), East Anglia (UK), San José (Costa Rica), Liège (Belgium), Tel Aviv (Israel), Oregon State (US), Burgundy (France), and Athens (Greece). He is a member of the Royal Swedish Academies of Sciences and of Engineering, a foreign Associate of the US National Academy of Sciences, a Foreign member of the Italian Academy of Sciences, a corresponding member of the Royal Netherlands Academy of Science, and a founding member of the Academia Europaea. Crutzen is the recipient of numerous prestigious awards including the Tyler Prize for the Environment (1989), the Volvo Environmental Prize (1991), the German Environmental Prize of the Federal Foundation for the Environment (1994), and the United Nations Environment Program (UNEP) Global Ozone Award (1995). In 1995, together with Drs M Molina (*see* Molina, Mario J, Volume 1) and F S Rowland (*see* Rowland, F Sherwood, Volume 1), Crutzen was awarded the Nobel Prize in Chemistry for their contributions to understanding the stratospheric ozone layer and the cause of ozone depletion.

GUY BRASSEUR *Germany*

Cryosphere

The term *cryosphere* traces its origins to the Greek word *kryos* for frost or icy cold. It is used collectively to designate regions of the Earth s surface where water is in a solid form. The components of the cryosphere include: sea ice, lake ice, river ice, snow cover, glaciers, ice caps and ice sheets, and seasonally frozen or perennially frozen (permafrost) ground. Seasonally, snow and ice cover between 8 and 15% of the Earth s surface. Snow cover has the largest areal extent of any component of the cryosphere, with a mean maximum areal extent of

approximately 47 million km^2 in January–February, mostly located in the Northern Hemisphere. Sea ice covers much of the polar oceans and some adjacent seas. In the Arctic Ocean there is perennial ice cover (*see* Arctic Climate, Volume 1), whereas around Antarctica the ice is mostly seasonal. Sea ice has highly variable thickness, as new ice forms in openings and level ice is compressed into pressure ridges (*see* Sea Ice, Volume 1). Freshwater ice forms on rivers and lakes in response to seasonal cooling. Ice on rivers may form ice jams that block the flow and cause flooding prior to spring breakup. Ground seepages and springs in northern land areas commonly freeze to form surface icings. Permafrost (perennially frozen ground) may occur where mean annual air temperatures (MAAT) are less than -1 or $-2\,^{\circ}$C and is generally continuous where MAAT are less than $-7\,^{\circ}$C. It underlies 24% of exposed Northern Hemisphere land areas. Thicknesses exceed 600 m along the Arctic coast of northeastern Siberia and Alaska, but toward the margins, permafrost becomes thinner and horizontally discontinuous. Land ice occurs in the two large ice sheets of Greenland and Antarctica, smaller ice caps and mountain glaciers (*see* Greenland, Volume 1; Antarctica, Volume 1). The ice sheets hold approximately 77% of global freshwater, corresponding to 80 m of world sea-level equivalent. Of this, Antarctica accounts for 90%, Greenland nearly 10%, other ice bodies and glaciers less than 0.5%. In Antarctica, large ice streams extend out into the ocean, forming floating ice shelves that are the primary source of Southern Ocean icebergs. The cryosphere is an integral part of the global climate system with important linkages and feedback generated through its influence on surface energy and moisture fluxes, clouds, precipitation, hydrology, and atmospheric and oceanic circulation. Deep permafrost also contains methane gas hydrates trapped in the ice lattice (clathrates) which could be a significant long-term source of additional greenhouse gas burden for the atmosphere.

D

Dansgaard–Oescheger Cycles

Dansgaard-Oescheger (*D-O*) *cycles* are rapid warm–cold cycles that occurred on millennial time scales during the last glaciation, which began in earnest around 75 000 years ago, and reached its maximum extent about 21 000 years ago. The D-O cycles are sawtooth-shaped cooling cycles comprised of long cold periods (*stadials*) followed by abrupt warming (*interstadials*) of up to 5 °C. Most, but not all of the cool events were terminated by what is called a Heinrich event (Bond *et al.*, 1993) (*see* Heinrich (H-) Events, Volume 1).

Deserts

Martin Williams
Adelaide University, Adelaide, Australia

The word desert comes from the Latin verb deserere, meaning to forsake or abandon, as in the expression deserted. The Arabic word Sahara also implies a vast and empty wilderness, bereft of life. A subtle and hidden implication of the term desert is that these now dry areas have been deserted, but were once able to support more abundant life. There is growing concern today that human actions are contributing to the spread of desert-like conditions in previously fertile and well-vegetated land, a process termed desertization or deserti cation. The causes of deserti cation are complex and include droughts, human mismanagement, and the aftermath of war. Two thousand years ago (ka), the great Roman historian, Tacitus, wrote caustically of the scorched earth policies favored by some of the Roman emperors and their generals: "Ubi solitudinem faciunt pacem appellant (They create a desert, and call it peace)." Once again, the use of the Latin word solitudinem *(solitude) in this context connotes emptiness and an absence of life.*

WHAT IS A DESERT?

A desert is a region where the rainfall is too little and too erratic and the evaporation too high to allow many plants and animals to survive except in a few favored localities. Over very long intervals of time the plants and animals living in desert areas have become well adapted through their physiology and behavior to using scarce water efficiently. The sparse human populations in deserts have also evolved long-term behavioral adaptations to the harsh extremes of desert climate, particularly through a nomadic life style designed to make optimum use of sporadic rains and ephemeral grazing. However, low precipitation is a necessary but not a sufficient cause of aridity. In certain cold areas of the world the rates of evaporation may be low enough to compensate for the low rates of precipitation, allowing a relatively dense plant cover and sometimes even a wetland flora to exist in spite of low overall amounts of annual precipitation. In such instances, the effective precipitation is said to be high.

Some definitions of a desert are essentially economic, with a desert being defined as a region where viable agriculture is not possible without irrigation. If we accept this working definition, then roughly 36% of the land area of the globe is either arid or semi-arid. Despite their aridity, these

lands provide a home for about 15% of the world s present human population. It is also worth noting that, although deserts share a number of common attributes or diagnostic characteristics, each desert is unique, and reflects the subtle interplay between local biophysical influences, including rock type, tectonic history, climate, and biota. This account will deal with desert conditions in all continents except Antarctica.

WORLD DISTRIBUTION OF DESERTS

The distribution of the world s major deserts (Figure 1) is closely linked to latitude and to distance from the sea. The great deserts of the Sahara and Arabia and the Rajasthan Desert of India with its counterpart the Cholistan Desert of Pakistan lie astride or close to the Tropic of Cancer. The deserts of Australia, the Kalahari and the Atacama are likewise traversed by the Tropic of Capricorn. The deserts of Central Asia, including the Taklimakan and Gobi Deserts of China and Mongolia, are situated in the interior of mid-latitude continental regions. A number of deserts are also located in the rain-shadow of high mountain ranges such as the Andes, the Rockies, the Himalayas and the Altai, Tien Shan and Kunlun Ranges in Central Asia. Why is this so?

CAUSES OF PRESENT-DAY ARIDITY

There are four main reasons why deserts have such little rain (Abrahams and Parsons, 1994). The two most important factors are location in latitudes dominated by dry subsiding air and location inland far from sources of moist maritime air. The remaining two factors are location in the rain-shadow of high mountain ranges and location on a coast flanked by cold ocean currents or cold upwelling ocean water. The first and fourth factors are a direct product of the global atmospheric circulation system. Atmospheric circulation is determined by solar radiation modulated by latitude, by the distribution of land and sea, and by the topography of the land.

Solar radiation is greatest at the equator because the sun is almost directly overhead there for much of the year. Away from the equator, progressively more incoming radiation is reflected or absorbed by the earth s atmosphere since the sun s rays travel ever more obliquely through the atmosphere as a result of the curvature of the earth. Because of the tilt of the earth s axis, the sun is directly over the Tropic of Cancer/Capricorn once a year, at the summer solstice. If the axial tilt were greater, the sun would appear to travel farther from the equator during summer, and the converse would apply if the tilt were less.

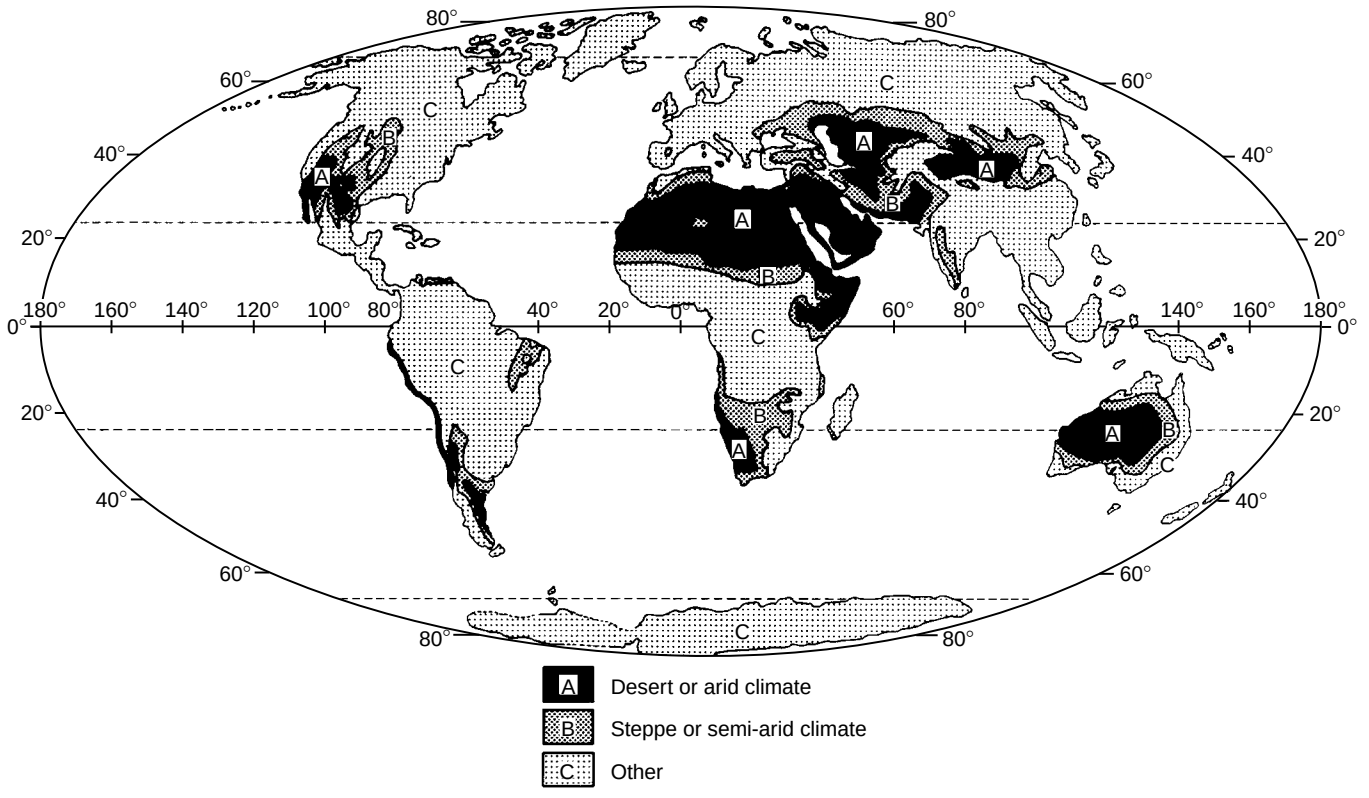

Figure 1 Present-day distribution of tropical and temperate deserts and semi-deserts. (Reproduced from Williams *et al.*, 1998)

Hot tropical deserts like the Sahara and Arabia are in latitudes where the air aloft is dry and subsiding, and the atmospheric pressure is high for much of the year. The surface winds in deserts are therefore generally directed outwards, towards areas of lower atmospheric pressure, so that there is minimal inflow of moisture from surface winds. As the air over the deserts subsides it is compressed and becomes warmer, so that its capacity to absorb additional water vapor is increased. The result is that the relative humidity of desert air is usually very low. The dew point (100% relative humidity) is only reached when the night temperatures fall sufficiently for desert dew to precipitate on chilled rock surfaces. This ephemeral dew allows some desert antelopes to survive despite the lack of surface water. Shortly before sunrise small herds of gazelle may sometimes be seen licking the dew from the surface of small piles of desert rocks in North Africa and Arabia, a behavioral strategy that enables them to survive in otherwise waterless conditions.

The tropical anticyclonic deserts are a direct result of the atmospheric circulation cells (often termed Hadley cells) located between the equator and the Tropics of Cancer and Capricorn, so that their location is determined by latitude rather than by the regional distribution of land and sea. The two polar deserts also come under the influence of semi-permanent anticyclones and of cold dry subsiding air. Because the distribution of high pressure cells (anticyclones) is closely related to latitude, the oceans in both polar and strictly tropical latitudes receive very little precipitation, and are the arid marine counterparts of the continental deserts.

The second major cause of aridity is a geographical location sufficiently far inland to be away from the influence of moist maritime air masses. Rainfall decreases rapidly away from the coast in all parts of the world except those close to the equator. Distance inland is sometimes described as *continentality*, and naturally applies to all big deserts, including the great tropical deserts of Arabia, Australia and the Sahara. In the case of these hot tropical deserts, the effects of continentality accentuate those of latitude. Other examples of continental interior deserts are the great mid-latitude deserts of central Asia, Mongolia and Western China. Bitterly cold in winter, with temperatures falling as low as minus 40 °C, summer temperatures can rise to 50 °C, which is nearly as hot as the southern Libyan Desert in July and August.

Two other factors may often enhance the aridity resulting from latitude and continentality, or may be the direct and dominant cause of reduced precipitation. These two factors are the proximity of cold oceanic water immediately offshore, and the rain-shadow effect generated by high mountains. They may operate individually or together.

The presence close offshore of cold upwelling water or a cold ocean current is an effective cause of coastal aridity in tropical and even in equatorial latitudes such as the arid Horn of Africa. The cold Peru current flows north parallel to the coast of the Atacama Desert in northern Chile and the coastal desert of Peru, and the cold Benguela current flows north parallel to the Namib Desert in southern Africa. The cold West Australian current likewise flows north parallel to the arid west coast of Australia, but the situation here is more complex, with the warm Leeuwin current flowing somewhat erratically from the Indonesian Warm Pool to the north, to counteract the desiccating effect of the cold West Australian current. In fact, the western borders of all the great tropical or trade wind deserts in both hemispheres are washed by cool ocean currents associated with the oceanic circulation cells or gyres which flow clockwise in the Northern and anticlockwise in the Southern Hemisphere. If cool moist maritime air blows onshore, it often meets a land surface that is warmer than the adjacent ocean surface, at least in summer and during the day. The cool maritime air mass becomes warmer on contact with the warm surface of the land. The relative humidity of this air mass is therefore decreased, and its ability to absorb additional moisture from surface evaporation is increased. The air therefore has a desiccating effect upon the land. This situation is only reversed if the land temperatures become significantly cooler than those of the adjacent ocean or if the sea surface temperatures become periodically warmer, as happens off the coast of Peru during El Niño years. Otherwise, the major source of moisture in these often quite narrow coastal deserts are the coastal fogs that blow inland in winter when the land has cooled down relative to the sea surface temperatures. Coastal fogs are quite common in deserts where mountain ranges like the Andes or the Rockies or uplands of more moderate elevation like the Red Sea Hills run parallel to and close to the shore. For example, Erkowit in the Red Sea Hills of the eastern Sudan is a mist oasis and supports a spectacular flora of tall *Euphorbia candelabra* trees in the dry valleys between its rocky granite hills.

The fourth and final general cause of aridity is the rain-shadow effect, which is a global phenomenon linked to topography and is not restricted to deserts. Wherever ranges of hills or mountains lie close to the coast, forming a physical barrier to onshore winds, the incoming moist maritime air will be forced upwards. Moist air cools adiabatically as it rises, attains vapor saturation, and sheds its condensed water vapor as rain or snow. The air then passes over the coastal ranges and flows downhill, becoming warmer and drier. The country inland of the coastal ranges is said to be in the *rain-shadow* of the ranges, a somewhat poetic term for lack of rain. The inland-facing slopes of high mountains are almost invariably drier than the coastal foothills, hence the great aridity of the Tibetan Plateau in contrast to the extreme wetness of the Assam foothills of the Himalayas. The wind-swept upland plains of the Bolivian Altiplano

and of Patagonia lie in the rain-shadow of the Andes. The rain-shadow deserts of New Mexico and Arizona are situated downwind of the Rockies. Other examples are the very gently undulating semi-arid western plains of Queensland and New South Wales inland of the Eastern Highlands of Australia, and the exceptionally hot, dry and rugged Afar Desert bounded by the Ethiopian highlands to the south and west. Both the Afar Depression and the Dead Sea Rift are flanked by very high mountainous escarpments and occupy low-lying fault-troughs or rifts that in places descend as much as 150 m below sea level. If the region inland of the coastal mountains contains high mountains, these will be a focus for some additional orographic or relief rain, but if the area is lacking in relief, there will be no opportunity for any such precipitation. The high gravel plains of the southern Libyan desert (serir) and the sandstone plateaus (hamada) of the central Sahara, the Gobi plains of northern China and Mongolia and the gibber plains of central Australia are all good examples. On these stony desert surfaces, rainfall and runoff are at a minimum and plants and animals are exceedingly rare, even by desert standards.

EVIDENCE OF FORMERLY WETTER CLIMATES IN NOW ARID AREAS

After considering why deserts are arid it is pertinent to ask whether they have always been so. The answer is unequivocally no. Scattered across the Sahara Desert are the silicified trunks of tall trees that once grew in abundance in the forests that covered the Sahara over 100 million years ago. The prehistoric hunters who roamed the Sahara at intervals during the last million years made good use of this silicified fossil wood to fashion the stone tools they used to hunt the great herds of savanna animals that also inhabited this now empty region. Later still, Neolithic pastoralists grazed their brindled herds of cattle, sheep and goats at numerous localities throughout the Sahara (Frostick and Reid, 1987). They left behind them an enduring legacy of superbly executed color paintings and engravings on the smooth rock faces of the Tassili sandstone plateau in Algeria, the A r mountains in Niger and the sandstone plateaus and granite massifs of the Libyan and Egyptian deserts. Another indication of formerly wet climates in the drier parts of Africa, Asia and Australia is the ubiquitous presence of deeply weathered and chemically altered bedrock. To achieve such a degree of intense leaching and new mineral formation requires considerable rainfall, a relatively dense vegetation cover, and very low rates of physical denudation – conditions more akin to the wet tropics than the arid tropics.

Perhaps the most striking evidence of previously wetter conditions are the remains of the once integrated river systems that used to flow through every major modern desert, providing the sandy alluvium that was later fashioned by wind into the imposing sand seas and associated dunes popularly considered synonymous with deserts. Indeed, one of the most characteristic features of all deserts is their lack of a perennial and integrated system of drainage (Cooke *et al.*, 1993). Desert streams are ephemeral. They flow episodically, for variable distances, depending upon the intensity and duration of sporadic rainstorms in their upper catchments. Even great rivers like the Nile, the Tigris and the Euphrates, which flow through deserts, originate in well watered uplands far beyond those deserts. All rivers that flow through deserts constantly lose water by evaporation and by seepage to the local aquifers. Most desert rivers never reach the coast and flow into closed depressions like the Tarim basin in China or the Lake Eyre basin in Australia. Such rivers are termed endoreic, in contrast to exoreic rivers like the Nile.

The fossil river valleys of the Sahara (Figure 2), the Gobi and Western Australia have long provoked the curiosity of geologists. Today they are broad linear depressions filled with Cenozoic alluvium that is often cemented with iron, silica or calcium carbonate. Some of these former valleys now form low erosional remnants or even extensive sheets of resistant ferricrete, silcrete or calcrete. In Mauritania, Namibia and Western Australia these valley-fill calcretes may also contain variable amounts of secondary uranium minerals precipitated out of slowly moving groundwater originating from the Pre-Cambrian host rocks, which form the valley interfluves.

EVIDENCE OF PREVIOUSLY GREATER ARIDITY AND DESERT EXPANSION

Just as now-arid areas retain evidence of once wetter climates, so is the converse equally true. Along the now-vegetated and stable margins of all the great deserts there is abundant evidence of former aridity including former desert dunes, salt lake and evaporite deposits, and now vegetated mantles of desert dust. Some care is needed in using such evidence to reconstruct past aridity, particularly in the case of desert dunes.

Desert dunes currently occupy about one-fifth of the Sahara and nearly two-fifths of the Australian arid zone. In North Africa, the 150 mm isohyet is a good indicator of the boundary between active and vegetated dunes (Figure 3), although precipitation is not the only factor responsible for dune mobility. Sand supply, wind velocity, surface roughness and evaporation rates also have an important influence on the movement of sand grains, as the presence of active coastal dunes in relatively wet areas with strong winds and abundant sand attests. Another exception to the general rule that dunes cease to be mobile once the rainfall exceeds about 150 mm are the source-bordering dunes that form downwind of sandy channels in semi-arid areas. There are three main prerequisites for the formation of

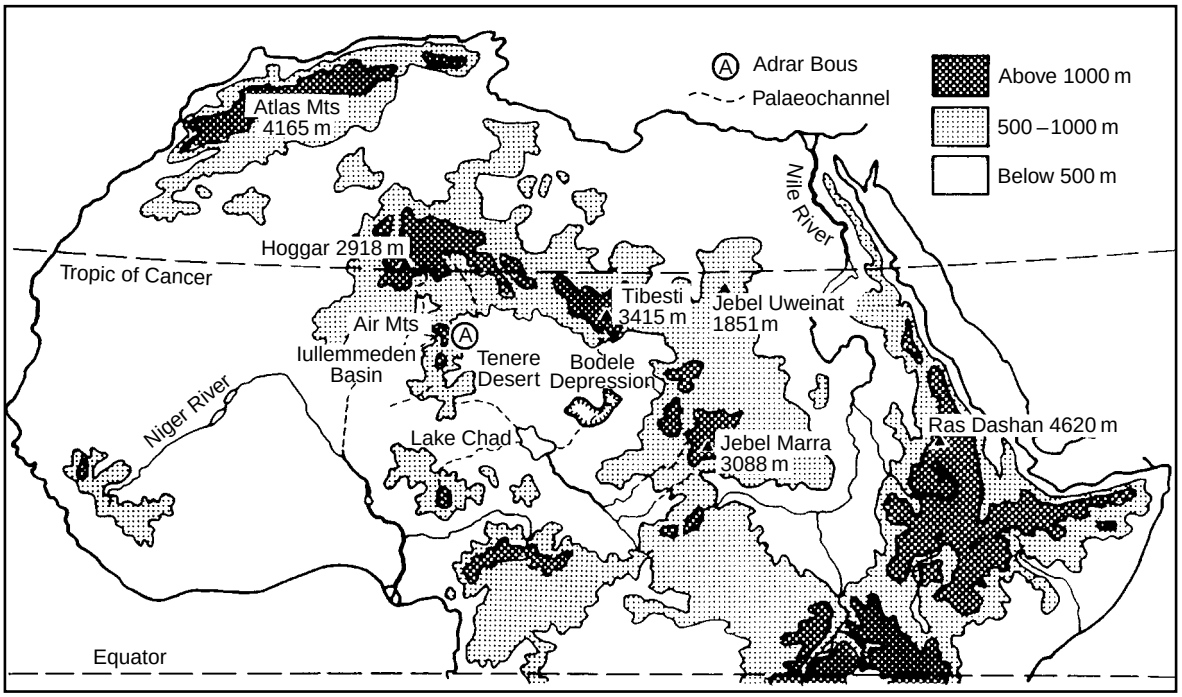

Figure 2 Distribution of major uplands in the Sahara

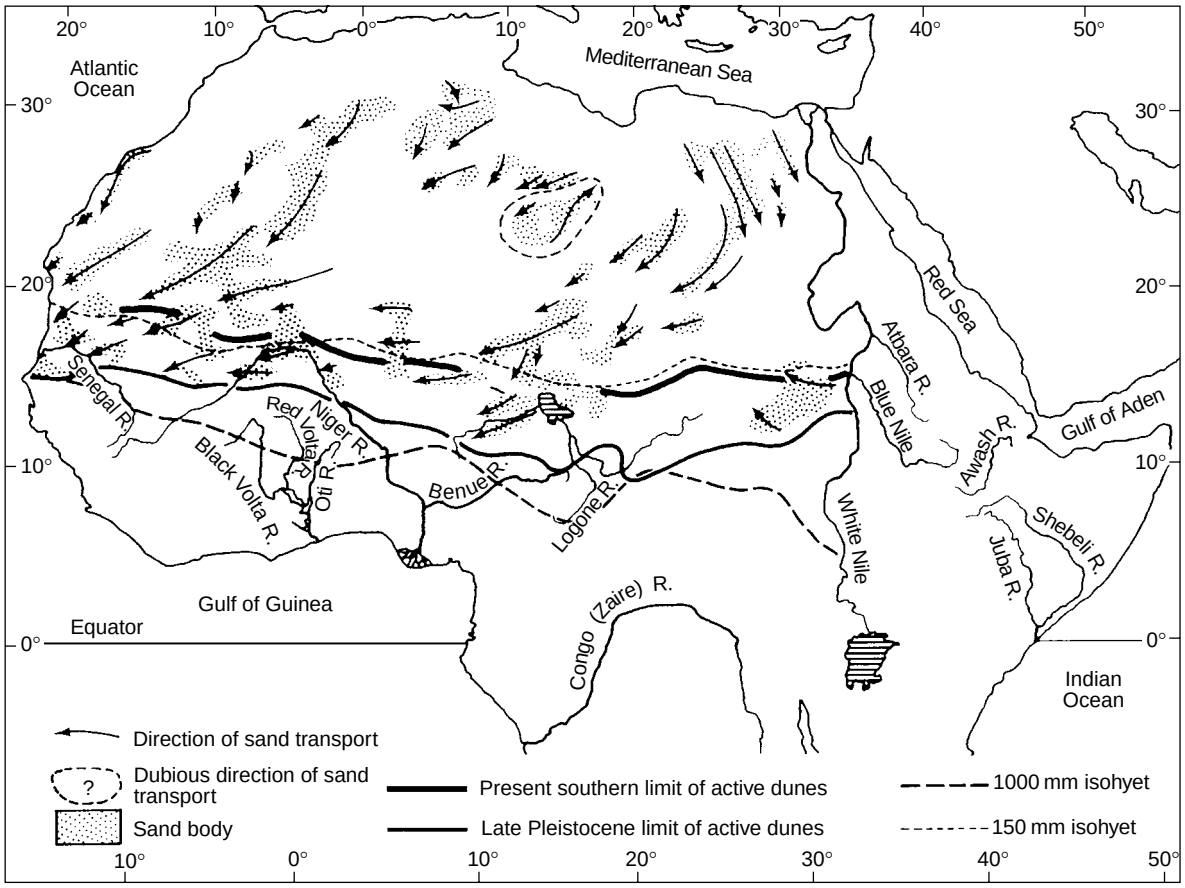

Figure 3 Distribution of active and stable sand dunes in the Sahara and its southern margins. (Reproduced from Williams *et al.*, 1998)

source-bordering dunes. First is a regular, usually seasonal replenishment of river channel sands or sandy beaches by long-shore drift in deep lakes. Second is a strong seasonal unidirectional wind and third a lack of riparian or lake-margin vegetation. The first prerequisite, a regular renewal of the sand supply from seasonally active rivers, precludes a fully arid climate.

Bagnold s classic observations in the Libyan desert and his detailed experimental work demonstrated that the volume of desert sand transported by wind increased exponentially with wind velocity above a certain threshold value (Pye and Tsoar, 1990; Cooke *et al.*, 1993; Lancaster, 1995). Where sand supply and wind velocity are not limiting factors, dune mobilization will increase as vegetation cover decreases. Rainfall and evapotranspiration are the primary controls over plant cover in arid areas. There is therefore a close relationship between the amount of rainfall and the average outer limit of active dunes in such deserts as the Great Indian Desert or the Sahara, where the southern limit of presently mobile dunes coincides remarkably closely with the 150 mm isohyet (Figure 3). The belt of fixed and vegetated dunes along what are now the semi-arid margins of these two deserts has been mapped in detail from air photographs and satellite imagery. Assuming that the relationship between rainfall and dune mobility held in the recent past, then the presence of these fixed dunes indicates that the effective range of the Sahara once extended 400–600 km farther south and that of the Rajasthan Desert some 350 km to the southeast.

ANTIQUITY OF DESERT LANDFORMS

Desert landscapes are made up of very young depositional landforms and very old erosional landforms (Frostick and Reid, 1987; Abrahams and Parsons, 1994; Thomas, 1997).

Figure 4 Ténéré desert dunes from summit of Air Mountains, Republic of Niger. (Photo: J Desmond Clark, January 1970)

Figure 5 Jebel Kassala, a desert inselberg or monolith, NE Sudan. (Photo: Martin Williams, December 1971)

The young landforms include dunes (Figure 4), alluvial fans, salt lakes and alluvial channels. The old landforms include mountains, hills and plateaus. It would be misleading to assume that the landform assemblage that is found in deserts had developed entirely under arid conditions. Most of the major erosional landforms formed under previously wetter climates and have been preserved from further erosion by the onset of aridity. Many desert landforms are exceedingly old. The vast desert plains of the central Sahara and Western Australia have been exposed to subaerial denudation for well over 500 million years. Desert monoliths such as Ayers Rock (Uluru) in Central Australia, or the granite inselbergs of the Sahara (Figures 5 and 6), far from being diagnostic of aridity, owe their present morphology to prolonged and repeated phases of weathering and erosion under a succession of former climates, few of which were particularly arid.

The abrupt juxtaposition of very ancient erosional landforms and very young depositional landforms gives desert landscapes their peculiar and somewhat paradoxical character, together with the absence of vegetation and the sharp breaks of slope. These young landforms and sediments, whether aeolian or fluviatile or lacustrine, contain the best record of past environmental changes, most notably the rapid climatic fluctuations of the last few million years.

LINKS BETWEEN CENOZOIC TECTONISM, GLOBAL COOLING AND DESICCATION

The onset of late Cenozoic aridity some 10–15 million years ago and the resultant slow emergence of the deserts were a result of global tectonic events that led to changes in global atmospheric circulation linked to changes in the global distribution of land and sea. For example, the origin of the Sahara as a desert was associated with several independent tectonic events. Slow northward movement of

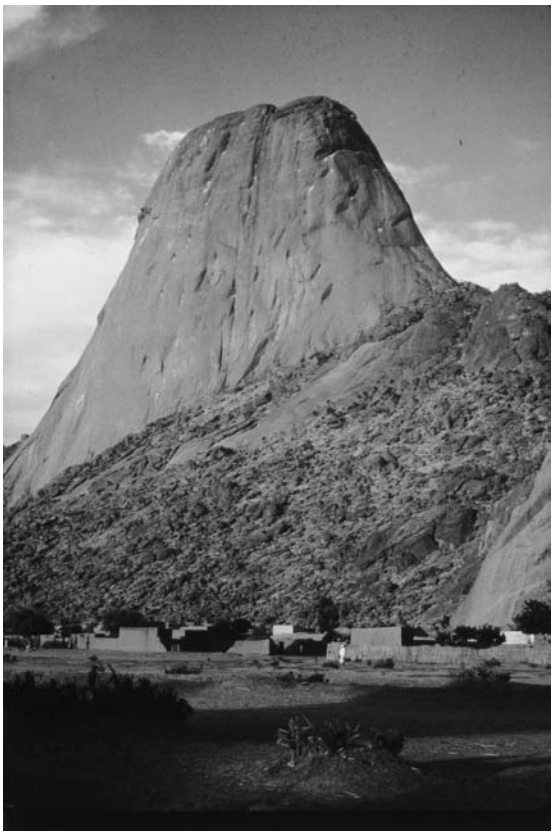

Figure 6 Jebel Kassala, a desert inselberg or monolith, NE Sudan. (Photo: Martin Williams, December 1971)

the African plate during the last 100 million years (late Mesozoic and Cenozoic) resulted in the migration of North Africa from wet equatorial into dry tropical latitudes. A slight clockwise rotation of Africa began over 60 million years ago (60 Ma) and continued through the Miocene and Pliocene, bringing Africa into contact with Europe. This displacement was accompanied by crustal deformation and rapid uplift in the Atlas region, and by volcanic eruptions and gentle updoming in Jebel Marra (3042 m), Tibesti (3415 m), the Hoggar (2918 m) and the A r Mountains (Figure 2). Owing to their altitude, the high mountains of the central and southern Sahara have always been wetter than the surrounding desert plains and so may have served as refugia for plants, animals and humans throughout the Quaternary.

Two additional factors were responsible for the late Cenozoic desiccation of North Africa. One was the gradual expansion of continental ice in high latitudes associated with the cooling of the Southern Ocean. The separation of Australia from Antarctica some 45 Ma ago culminated in the establishment of a large ice cap on Antarctica by 15 Ma ago. Closure of the Panama Isthmus and diversion of warm water into the North Atlantic allied to high northern latitude cooling provided the impetus for a sudden increase in the volume of Northern Hemisphere ice caps towards 2.5 Ma ago. One effect of the progressive build-up of high latitude ice sheets was to steepen the temperature and pressure gradients between the equator and the poles, resulting in increased trade wind velocities. Faster trade winds were better able to mobilize the alluvial sands of an increasingly dry Sahara and to fashion them into desert dunes. For example, the first appearance of wind-blown quartz sands in the Chad basin is towards the end of the Tertiary, when they occur interstratified among late Pliocene to early Pleistocene fluviatile and lacustrine sediments. The associated lacustrine diatom flora indicate temperatures cooler than those now prevalent in this region. The combined evidence suggests that the late Pliocene was both cooler and drier along the tropical borders of the Sahara. The diatom and pollen evidence from a large late Pliocene lake in the south-eastern uplands of Ethiopia is also consistent with the inference that intertropical cooling and desiccation may have been closely bound up with the expansion of Northern Hemisphere ice caps towards 2.5 Ma ago.

A further influence contributing to the drying out of the Sahara was late Cenozoic uplift of the Tibetan plateau and the ensuing creation of the easterly jet stream which brought dry subsiding air to the incipient deserts of Pakistan, Arabia, Somalia, Ethiopia and the Sahara. Isotopic analysis of fossil soils and fossil herbivore teeth collected from the Potwar Plateau of Pakistan indicates a major change in flora and fauna between 7.3 and 7.0 Ma ago. Until about 7.3 Ma ago, forest and woodland dominated the landscape. After 7.0 Ma ago, there was a rapid expansion of tropical grassland at the expense of forest. This change in vegetation may indicate the inception (or strengthening) of the Indian summer monsoon 7 Ma ago.

Other factors have probably contributed to intertropical cooling and desiccation during the past 30 Ma. One was the progressive shrinkage of the Paratethys Sea. This warm shallow sea once stretched across Eurasia but shrank gradually during the Oligocene and Miocene. As the once extensive sea shrank, the rainfall that was previously well distributed throughout the year became progressively more seasonal.

A further agent of late Cenozoic cooling was the decrease in atmospheric carbon dioxide (CO_2) associated with increased erosion, weathering and associated consumption of CO_2 caused by the late Cenozoic uplift of the Himalayas, the Rockies, the Andes, the Ethiopian uplands and perhaps also the Transantarctic Mountains. The global increase in plants using C_4 photosynthesis (*see* C_3 and C_4 Photosynthesis, Volume 2) and the reduction in C_3 plants between about 8 and 6 Ma ago is certainly consistent with a decrease in the concentration of atmospheric CO_2. The threshold for C_3 photosynthesis is higher at warmer latitudes, and so it is not surprising that the initial change from C_3 to C_4 plants was in the lowland tropics first. Climatic cooling was

probably also triggered by the eruption of the voluminous Ethiopian flood basalts over a period of no more than a million years towards 30 Ma ago.

Changes in the Cenozoic flora and fauna of the Sahara show a similar trend to that inferred for the Himalayan foothills of Pakistan. During the Palaeocene and Eocene much of the southern Sahara was covered in equatorial rainforest, and there was widespread deep weathering at this time. During the Oligocene and Miocene, much of what is now the Sahara was covered in woodland and savanna woodland, but by Pliocene times many elements of the present Saharan flora were already present. Pollen preserved in scattered localities in northern Africa shows that replacement of tropical woodland by plants adapted to aridity was already under way during the late Miocene and early Pliocene, a conclusion consistent with the pollen evidence preserved in deep sea cores off the north-west coast of Africa.

From about late Pliocene times onwards, the great tropical inland lakes of the Sahara, Ethiopia and Arabia began to dry out. The formerly abundant tropical flora and fauna of the well-watered Saharan uplands became progressively impoverished as entire taxa became extinct, and a once integrated and efficient network of major rivers became increasingly obliterated by wind-blown sands. In the Chad basin there is good evidence of wind-blown desert dune sands deposited between alluvial and lacustrine sediments that were laid down well over two million years ago. Farther north, in the Tibesti and Hoggar mountains of the central Sahara, the evidence from fossil pollen grains shows that some of the plants growing in this region were already adapted to aridity at about the time that the desert sands made their first appearance in the Chad basin. In Central China the first appearance of wind-blown desert dust has been reliably dated to *circa* 2.4 Ma ago. In Central Australia the inception of aridity seems to have started much later, with major inland lakes persisting until at least a million years ago before giving way to desert playa lakes and dunes fashioned from wind-blown quartz and gypsum sand-sized particles. Farther afield, in the present Congo/Za re basin of Central Africa, there are much older deposits of red desert sands that pre-date the oldest sands of the present Kalahari desert. Allowing for local differences in timing linked to regional climatic and tectonic factors, a similar sequence of events is also true of the deserts of China, India, Australia and southern Africa.

Three conclusions may be drawn from this brief survey. First, the aridity of the Sahara, northern China and Central Australia pre-dates any human presence in those regions and so humans cannot be considered the cause of these deserts, as some have claimed. Second, the inception of aridity was not everywhere synchronous, suggesting that local influences need to be considered. Third, in some presently humid areas there is evidence of former aridity just as some previously wetter areas are now arid.

DESERTS AS GEOMORPHOLOGICAL, ARCHAEOLOGICAL AND PALAEOCLIMATIC MUSEUMS

Deserts contain superb evidence of past climatic events. The very aridity to which they owe their existence also promotes the preservation of landforms, soils and sediments formed under quite different climatic conditions. Many desert landforms reflect the influence of weathering and erosional processes that are seldom active today. Every desert contains dry or saline lakes that once belonged to major exoreic river systems. The salt lakes of Western Australia are all that remain of the great rivers that flowed when Australia was joined to Antarctica over 45 Ma ago. Likewise, the fossil fauna of great deserts like the Sahara and the Gobi evoke distant echoes of a time long gone when dinosaurs roamed these once luxuriantly vegetated lands. In more recent times, the Sahara was host to great herds of elephants and giraffes, and a widespread aquatic fauna of turtles, hippos, crocodiles and Nile perch. The contrast with the present waterless wilderness could hardly be more stark. Some elements of this savanna fauna survive rather precariously. In sheltered valleys in the rugged A r massif in Niger, near the southern margin of the Sahara, there are remnant populations of baboons (*Papio anubis*) and patas monkeys (*Cercopithecus patas*), which must have reached these desert mountains during times of wetter climate when the West African savanna woodland was more extensive than it is today. They probably made use of riparian forest corridors that grew along once permanent rivers flowing south from the mountains. The Awash River that flows from the Ethiopian highlands down into the Afar Desert is a possible modern analogue. The dwarf crocodiles that lived in some of the permanent waterholes in the Tibesti Mountains of the south-central Sahara in the 1950s but have since been hunted to extinction were part of this palaeoclimatic legacy.

INTERACTIONS BETWEEN PREHISTORIC PEOPLES AND THE DESERTS

Scattered throughout the Sahara are abundant remains of the stone tools left behind by the Early, Middle and Late Stone Age peoples who once roamed the Sahara during wetter climatic intervals. The Late Stone Age hunters preyed upon the savanna herbivores and were also gifted artists, leaving behind them an enduring legacy of rock engravings and rock paintings depicting the animals they knew so well.

With the onset of plant and animal domestication by small groups of Neolithic herders and farmers some

10 000 years ago, the focus of the paintings changed. Cattle camps showing herds of brindled cattle guarded by men with bows and arrows and dogs were painted on suitable smooth rock faces in mountainous areas throughout the Sahara. Some of these paintings show women in their finery, riding oxen just as they do today among the Baggara cattle-owning Arabs of the western Sudan during the summer migrations north into the desert. Others show papyrus or reed canoes similar in design to those still made and used on Lake Tana near the Ethiopian headwaters of the Blue Nile. The plains adjacent to high mountains were preferred occupation sites for these Neolithic pastoralists. Small lakes and permanent springs were a guarantee of survival in years when the summer rains failed. The cattle herders ranged as far as Jebel Uweinat in south-east Libya, the Tassili sandstone plateau in southern Algeria and the A r massif in Niger (Figure 2). The nature of the interactions between prehistoric peoples and their environment remains the subject of enduring archaeological enquiry. Given the former presence of domesticated cattle, sheep and goats in areas no longer able to sustain them, it is tempting to speculate that they themselves may have accelerated their exodus from the desert. An obvious question to ask is to what extent did Neolithic overgrazing by large herds of hard-hoofed cattle, sheep and goats accelerate soil erosion by wind and water, and initiate humanly induced processes of desertification, especially in the drier second half of the Holocene?

GLACIAL ARIDITY OR GLACIAL PLUVIAL?

Nineteenth century geologists working in the semi-arid inter montane basins in the US identified and mapped the shorelines of a series of former very large lakes. The close association between glacial moraines and high-level shorelines or strandlines showed that the lakes were high during glacial episodes. The notion, that glacial climates were wetter than today, was quickly adopted in Europe. During the first half of the 20th century former high lake levels discovered by European and American geologists in the deserts of Asia and Africa were regarded as pluvial lakes formed during glacial times. The notion of glacial pluvial climates became solidly entrenched and the so-called pluvial chronology was even used to provide a relative chronology for prehistoric sites in East Africa, with each alleged pluvial being equated with one of the glaciations identified in the European Alps. The far-traveled coarse alluvial deposits of great rivers like the Nile were also interpreted as having originated during glacial pluvial climates.

Although there were dissenting voices, it was not until the high strandlines of the East African Rift lakes and the abundant remnants of former lakes scattered across the Sahara were directly dated in the late 1960s, that the glacial pluvial concept was finally abandoned for the arid and semi-arid tropics. The African high lake levels were found to be 9000 rather than 18 000 radiocarbon years old, that is, of early Holocene rather than of Last Glacial Maximum age. The alternative hypothesis, glacial aridity, was rapidly adopted and by 1975 there was growing acceptance that late Pleistocene intertropical aridity had been synchronous in both hemispheres.

It is now widely accepted that during times of maximum glaciation the tropical deserts were even drier than they are today and during the interglacial phases they were somewhat wetter. For example, during the last glacial maximum, dunes were active well beyond their present limits, and considerable volumes of desert dust were deposited downwind of the desert margins in Central Asia and China, northern India, northern Nigeria and south-eastern Australia (Pye and Tsoar, 1990; Williams *et al.*, 1998). These dust mantles are now vegetated and relatively stable. Maximum concentrations of desert dust in deep-sea cores from the equatorial Atlantic, coincide with glacial maxima during the last half a million years, and probably for far longer. Such dust is easily recognized by its high degree of sorting.

A similar pattern of glacial aridity is evident also in the Gulf of Aden and the Red Sea. The isotopic composition of planktonic foraminifera from deep-sea cores in this region shows that during the last 250 ka, at least, glacial maxima were times of extreme aridity, with increased sea-surface salinity reflecting even higher rates of evaporation than prevail there today. We can therefore conclude that in many of the world s hot deserts, the dominant climate during the last glacial maximum (18 ± 3 ka) was drier, windier and colder than today, although the summers may still have been very hot. In addition, the desert lakes that had been full and fresh until about 18–20 ka dried out or became hyper-saline, previously perennial desert rivers became seasonal, and seasonal rivers became intermittent or ephemeral streams. With glacially lowered sea levels, land areas were greater and so the aridity associated with enhanced continentality was accentuated. Stronger trade winds associated with steeper pressure gradients between equator and pole caused increased upwelling of cold water close offshore, further accentuating the aridity of coastal deserts.

The early Holocene climates of the tropical deserts were wetter than today, with highest lake levels towards 9 ka. Similar climatic conditions occurred in the last interglacial towards 125 ka. The desert environments no doubt oscillated between these two extremes, with the interglacials slightly warmer and very much wetter than today, and the glacial maxima colder and mostly drier. However, not all arid phases coincide with glacial maxima, nor do all humid phases coincide with interglacial times. For instance, Lake Chad in the southern Sahara and Lake Abhe in the Afar desert of Ethiopia were both very high for at least

10 000 years before 18 ka, when they fell rapidly. They were then intermittently dry (Lake Chad) or dry (Lake Abhe) until 12 ka, rising rapidly thereafter to reach peak levels at 9 ka. Since about 4.5 ka both lakes have remained low apart from occasional brief transgressions. The $>30-18$ ka phase of high lake levels could be regarded as a humid glacial phase, and the $18-12$ ka regression as an arid glacial phase. Similarly, the early Holocene transgression represents a humid interglacial phase; and the late Holocene interval of low lake levels a dry interglacial phase. This simplified four-fold subdivision ignores local hydrological and geomorphic controls over rainfall, runoff, evaporation, seepage losses and groundwater inflow, but is probably closer to reality than the simple dichotomy between arid glacial and humid interglacial climates.

AQUIFER RECHARGE AND FOSSIL GROUNDWATER

The contrast between the terminal Pleistocene aridity of the Sahara, the Gobi and the Namib Deserts and their well-vegetated and well-watered early Holocene condition had an enormous impact on the Late Stone Age and early Neolithic peoples who benefited from these changes. As the great continental ice sheets melted, temperatures and sea levels rose around the world. Evaporation from the intertropical oceans increased once sea surface temperatures became warmer. The summer monsoons of tropical Australia, India and Africa brought reliable rainfall to the seasonally wet margins of the tropical deserts. Aquifers were replenished and groundwater levels rose, sometimes feeding springs and small lakes. Formerly dry lakes refilled. The mobile late Pleistocene dunes became vegetated and stable. Savanna woodland and grassland re-occupied what are today the semi-arid regions of the world. Rivers flowed once more in many parts of the Sahara and Arabia. Countless small freshwater lakes supported communities of Upper Palaeolithic or Late Stone Age hunter-fisher-gatherer communities who left behind their middens and hearths as enduring testimony of these brief episodes when the deserts were green once more.

Some groundwater recharge also took place during previous interglacial periods. However, since each interglacial episode was of relatively short duration, or roughly one-tenth of each glacial-interglacial cycle, the duration of these recharge intervals was quite short. The consequence of all this is that the groundwater in major aquifers like the Great Artesian Basin in Central Australia or the Nubian Sandstone aquifers in North Africa may be up to a million years old. Current use of the fossil groundwater in Australia, Arabia and in some of the North American deserts is well in excess of current recharge rates. In essence, we are mining a non-renewable resource.

AMBIGUOUS QUALITY OF THE EVIDENCE FOR CLIMATIC CHANGE

Early studies of desert regions tended to focus upon specific desert landforms such as dunes, alluvial fans, river terraces, playa lakes, and deflation hollows. In the last 30 years, particularly since the widespread use of radiocarbon dating, palaeoclimatic research in deserts has focused upon using alluvial and lacustrine deposits and their associated plant and animal fossils to reconstruct the history of desert lakes and rivers (Cooke *et al.*, 1993; Abrahams and Parsons, 1994; Thomas, 1997). One of the problems inherent in using high lake levels as evidence of formerly wetter climates lies in the complex hydrology of many desert lakes. Some are fed primarily from groundwater, and may respond slowly to local changes in climate. Others may be fed solely from surface runoff. If the rivers that flow into these lakes originate in some distant well-watered uplands, the lake levels will fluctuate in response to distant changes in rainfall and may again not accurately reflect local conditions. Where the lakes are full and overflowing, and merely enlarged portions of a through-flowing river system, they will also tend to be highly insensitive to local climatic fluctuations. Finally, is a lake high because of high rates of precipitation over the lake basin or because of much lower rates of evaporation related to colder or cloudier conditions? Interpreting river terraces is equally fraught with ambiguity. Does widespread sedimentation reflect a river no longer able to transport its load because of aridity in the headwaters and reduced discharge? Or does it reflect an increase in the supply of sediment from increased erosion in the headwaters, perhaps related to glaciation? Or might it represent a change from regular perennial flow to a more seasonal flow regime? To use a river terrace to infer a particular climate and then use the inferred climate to interpret other river terraces is to indulge in circular argument. None of these questions is easy to answer. Each requires accurate dating and careful scrutiny of many independent lines of evidence for its proper resolution. An excellent example of this approach is the loess record from China.

THE LOESS RECORD IN CHINA

The loess sequence in China illustrates how accurate dating and careful evaluation of different lines of evidence are essential in reconstructing environmental change in deserts. Fine-grained wind-blown dust accumulated at intervals throughout the Quaternary on the downwind margins of deserts in Africa, Australia, South America and Asia. In terms of their sorting and mineral composition, they are virtually identical to the central European and North American loess mantles, which accumulated downwind of the fluvioglacial outwash plains, so that the term *loess* is used

here for any fine-grained aeolian deposit irrespective of its original provenance. The aeolian dust deposits in the Loess Plateau of Central China are the thickest and most extensive loess deposits in the world (Liu, 1991; Pye, 1987). They cover an area of 275 000 km^2 and attain thicknesses commonly in excess of 100 m and more than 300 m near the city of Lanzhou. Detailed studies over the past three decades have made the Chinese loess sequence with its alternation of unweathered loess and fossil soils one of the most informative sequences covering the last 2.5 Ma that exists on earth (Liu, 1991).

Detailed sampling of stratigraphic sections located on a set of west-east and north-south transects has revealed a sequence of 37 loess-soil couplets spanning the past 2.5 Ma. Each couplet represents a cold and dry phase of rapid dust accumulation and an ensuing wet and warm phase of weathering and soil formation. A soil is defined as weathered loess if it shows at least as much pedological organization as the widespread early Holocene soil at the top of the loess sequence. Interpretation of the loess-soil couplets is based on high-resolution sampling and detailed analyses of grain size, magnetic susceptibility, organic carbon (C), sediment micromorphology and mineralogy, calcium carbonate content and mollusc species. The soils are thought to indicate a weaker winter monsoon and a stronger summer monsoon. Conversely, the coarser-grained unweathered loess with generally much weaker magnetic susceptibility values is regarded as evidence of a stronger and more extensive winter monsoon and a weaker summer monsoon.

Chronological control is based on the palaeomagnetic timescale, cross-correlation with the marine oxygen isotope record and a combination of radiocarbon and thermoluminescence dates for the more recent part of the sequence. Comparison of the Chinese loess record with evidence from deep sea cores and the Greenland and Antarctic ice cores strongly confirms the climatic interpretation of the loess-soil couplets, with glacial maxima synchronous with times of maximum dust deposition and interglacials with times of maximum weathering and soil development.

INFLUENCE OF DESERT DUST ON LOCAL AND REGIONAL CLIMATE

In general, glacial maxima were drier than today and interglacial maxima were as wet or wetter. The deserts of North Africa, Arabia, Central Asia, China, Patagonia and Australia all display evidence of more vigorous aeolian dust flux during glacial maxima. Nor should it be forgotten that aeolian dust could have an influence upon local and regional climates. In tropical West Africa from 15 ka to about 7 ka the rivers were mainly depositing clays and after 7 ka they mostly carried sands. French research has attributed this abrupt hydrological change to a change in the size of raindrops. Abundant atmospheric dust would provide the nuclei for many small raindrops to form, resulting in gentle, non-erosive rains. Conversely, a reduction in atmospheric dust load would result in large, highly erosive drops. The momentum of a falling raindrop is the product of its mass and velocity, so that this interpretation is physically plausible (see also Tucker *et al.*, 1991).

Other workers have noted that the very high inputs of aeolian dust to Central Antarctica and Greenland during the Last Glacial Maximum, which are clearly evident in the Antarctic and Greenland ice cores, are consistent with shorter dust washout times and a weaker global hydrological cycle. It is also possible that a high concentration of atmospheric dust may in itself have contributed to the lowering of sea surface temperatures evident in the tropical western Pacific, especially in the warm shallow seas or Warm Pool immediately to the north of Australia. Given the growing recognition of the interactions between present-day desertification processes, dust generation, and the impact of dust particles in scattering incoming solar radiation, it seems highly plausible that wind-blown dust would be both a cause and an effect of Quaternary climatic fluctuations.

MODERN MYTHS RELATING TO DESERT ENCROACHMENT AND DESERTIFICATION

The great African droughts of the 1930s and the 1970s triggered considerable speculation as to the respective role of climatic fluctuations and human influences on land degradation along the margins of the Sahara. Many observers blamed the destruction of the vegetation and the mobilization of hitherto fixed and stable dunes entirely on human mismanagement in the form of overgrazing and clearing of forest and woodland for arable land. Some even argued that the Sahara Desert was itself at least in part a product of adverse human impact. Phrases like desert encroachment or the advancing desert were bandied about with more enthusiasm than accuracy. Such sensationalism took no account of the long geological history of the deserts, nor of the inconvenient fact that the deserts pre-date human origins. While the deserts may have helped to shape the prehistoric cultures of the occasional desert dwellers, there is scant evidence that the reverse applies, at least until more recent times.

The prolonged drought that afflicted the Sahel region of Africa as well as Ethiopia from 1968 onwards led to renewed debate about the role of humans in accentuating normal climatic variability and helping to prolong severe drought. The argument may be summarized thus. Destruction of the vegetation through overgrazing increases the surface albedo (*see* Albedo, Volume 1). If albedo increases, the surface will become cooler. A cooler surface will mean less convection and hence less instability in the lower atmosphere. The result will be a reduction in convectional rain. Less rain will mean less plant growth, and so a vicious spiral of degradation or desertification will ensue along the

desert margins. Although plausible, the albedo hypothesis fails to account for the globally synchronous pattern of major floods and droughts in both hemispheres. Nor does it account for even more severe historic droughts in Africa well before population increase and overgrazing were evident. The current consensus is that sea surface temperature anomalies control the global incidence of floods and droughts. The El Niño/Southern Oscillation (ENSO) events are perhaps the best known of these phenomena.

ENVIRONMENTAL CHANGE IN DESERTS AS AN INTEGRAL ASPECT OF GLOBAL CHANGE

In a number of areas bordering deserts, including Southern and Eastern Africa, North-east Brazil, New Mexico, Eastern and Northern Australia, Central India, and North-eastern China, the incidence of wet and dry years is strongly influenced by the incidence of ENSO events. Many of the rivers in these areas are sensitive to small changes in rainfall, and ENSO events will amplify their already highly variable flow regimes. The sensitive hydrological response of desert rivers to global sea surface temperature anomalies is an integral part of global environmental change, and is likely to remain so in the future.

This immediately raises the question of how the various deserts are likely to respond to global warming over the next 50–100 years. Williams and Balling (1996) have examined this issue in some detail in their book on *Interactions of Deserti cation and Climate*. They evaluated a number of numerical climate models and concluded that desert regions were likely to warm substantially over the next century, particularly in the higher latitudes. Increases in evaporation associated with temperature increases were likely to cause a reduction in soil water content, which could in turn lead to a reduction in vegetation cover, leaving the desert margins even more vulnerable to accelerated erosion by wind and water. The precipitation predictions for individual arid and semi-arid areas are even less certain than the temperature predictions, but overall the models suggest greater aridity and an increase in extreme climatic events for the temperate and tropical deserts and their borders. It is worth noting that the broad trends of temperature and aridity in most but not all desert areas over the past century are generally consistent with the predictions of the models.

Detection and Attribution of Climate Change

see Climate Change, Detection and Attribution (**Volume 1**)

Dimethylsulfide (DMS)

Meinrat O Andreae
Max Planck Institute for Chemistry, Mainz, Germany

The presence of dimethylsul de (DMS, $(CH_3)_2S$) in the oceans and atmosphere was discovered in the early 1970s by James Lovelock (Lovelock et al.*, 1972). Subsequently, DMS was identi ed as the most abundant biogenic sulfur compound in the oceans and as the dominant natural source of*

sulfur to the atmosphere (Andreae, 1990). DMS is produced from dissolved sulfate by the marine plankton community, and to a lesser extent also by terrestrial plants (Bates et al.*, 1992). Based on these observations, Charlson, Lovelock, Andreae and Warren (CLAW) (Charlson* et al.*, 1987) proposed a biospheric climate feedback, in which DMS is released by marine phytoplankton, enters the troposphere and is oxidized to sulfate particles, which then act as cloud condensation nuclei (CCN) for marine clouds. Changes in CCN concentration affect the cloud droplet number concentration, which in uences cloud albedo and consequently climate. Initial estimates have suggested that the effect of a 33% increase in CCN production from DMS would be of the same order of magnitude, but opposite direction, as that associated with present-day greenhouse gas forcing. Large-scale climate change, in turn, affects the phytoplankton in the oceans and thereby closes the feedback loop. In spite of considerable research effort, fundamental gaps remain in understanding the key issues in this biosphere-climate interaction. Critical information is missing regarding the processes which regulate the concentration of DMS in seawater, the rate of transfer across the air/sea interface, the mechanism and rate of CCN production from DMS oxidation, and the effect of climate on DMS production in the sea.*

The concentration of DMS in the surface ocean is regulated by a complex set of interactions, shown schematically in Figure 1 (Bates *et al.*, 1994; Kiene *et al.*, 1996). DMS is produced from a metabolic precursor, dimethylsulfoniopropionate (DMSP), the intracellular concentration of which varies between different phytoplankton species over a range of five orders of magnitude. DMSP is released into the water column predominantly as a result of senescence or grazing by viral, bacterial, and zooplankton. The subsequent breakdown of DMSP to DMS, which occurs with turnover times on the order of hours to days, is microbially mediated and has a highly variable DMS yield (10–70%). Once produced in the marine mixed layer, DMS is lost again by a number of mechanisms including bacterial and photochemical decomposition, emission to the atmosphere, and downward mixing, with a total turnover time of one to a few days. The removal rates by these sink mechanisms are highly variable as a function of ecological and meteorological conditions, but are of comparable overall importance for the removal of dissolved DMS. Because of this complexity, attempts to predict the concentration of DMS in surface waters by a process model have been successful only on a regional scale. As a result of this limited understanding at the process level, current estimates of the global DMS concentration and emission field are based on an heuristic extrapolation scheme (Kettle *et al.*, 1999). This precludes prediction of the distribution of DMS in the oceans and its emission to the atmosphere under scenarios of future global change.

The ocean-to-atmosphere flux of DMS is estimated from the air/sea concentration gradient and an empirically determined exchange coefficient. The different formulations for the wind speed dependence of this coefficient, based on wind tunnel, radiocarbon, and tracer measurements, range in their predictions by about a factor of two. At present, there is no objective way to select one formulation over the

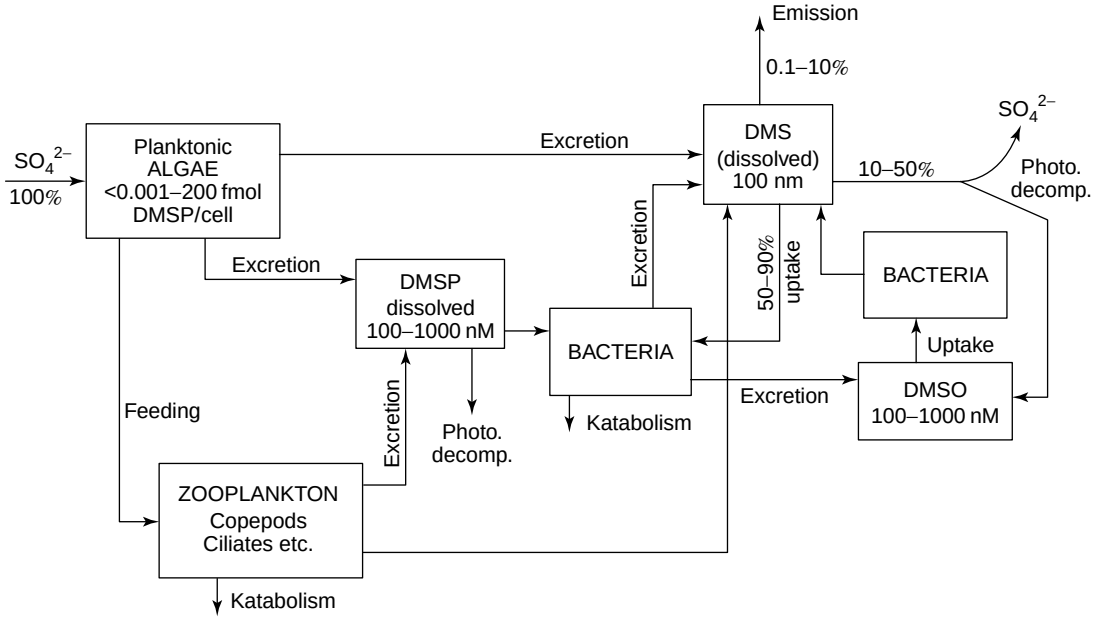

Figure 1 Model of DMS cycle in surface ocean

others, and it appears that parameters other than windspeed, e.g., the coverage of the water surface with organic films, must also be considered. Largely as a consequence of this uncertainty, current estimates of global annual sea/air flux of DMS range from 16 to 40 Tg S year^{-1}, with frustratingly little improvement in the width of this range over the last decade.

The main oxidant in the atmospheric photo-oxidation of DMS is the OH radical, initiating a reaction sequence leading to the production of SO_2 and lesser amounts of methanesulfonic acid (MSA), dimethylsulfoxide and dimethylsulfone (Davis *et al.*, 1999). Under some circumstances, the NO_3 radical can also play an important role, especially in winter. This could explain the observed seasonal cycle in the MSA/non-seasalt-sulfate ratio, which shows a pronounced minimum in winter. Recent modeling studies suggest that reactions with halogen radicals in the marine boundary layer (MBL), such as BrO, Cl, and Br, may also contribute to the oxidation of DMS. Such additional sinks and the observed large diel (24-hour) amplitude of DMS would imply sea surface emission fluxes near the higher end of the range of estimates.

Present evidence from field measurements, laboratory studies, and model calculations suggests that SO_2 is the dominant oxidation product of DMS under most environmental conditions and that this SO_2 is the main source of non-seasalt sulfate aerosol in the unpolluted MBL. In order to be relevant to climate forcing under the CLAW hypothesis, however, DMS oxidation must increase the number concentration of CCN, i.e., particles that can nucleate droplets in clouds. This can either be achieved by the creation of new particles from the gas phase, or by growth of existing smaller particles beyond the minimum diameter necessary for cloud droplet nucleation (ca. 0.05 μm diameter, assuming the particles are completely soluble).

The formation of new particles from gaseous H_2SO_4 molecules is a highly non-linear process, which is strongly influenced by the levels of H_2O and NH_3 present. Since deposition of H_2SO_4 molecules on existing aerosol surfaces competes with nucleation, it has been argued that nucleation of sulfate aerosol can only take place in the MBL if the normally present aerosol population has been depleted (Clarke *et al.*, 1998a). Recent measurements of newly formed particle concentrations over the remote Southern Ocean provide strong evidence that, at least in this region, most of the formation of new particles does indeed take place in the free troposphere around the detraining regions of clouds, at altitudes from 2 to 6 km (Clarke *et al.*, 1998b). These new particles are initially too small to act as CCN, but can be entrained from the free troposphere into the MBL and subsequently grow either by gas-to-particle deposition or by cloud processes. By this mechanism, DMS oxidation can lead to the formation of new CCN both by providing the starting material for the nucleation of new particles in the free troposphere, and subsequently by supporting the growth of smaller particles into CCN.

Given the strong predicted climate response to even relatively modest changes in the DMS-derived CCN number concentration (Charlson *et al.*, 1987), it would be important to know how DMS emission and CCN production might change over the next 100 years (*see* Aerosols, Effects on the Climate, Volume 1). If we assume that DMS levels in the ocean remain constant, the climate change predicted over the next century would only result in a slight increase ($\ll$10%) in the marine DMS emission. It is quite likely, however, that changing ecological conditions in the oceans will influence the concentration of DMS. Unfortunately, in the absence of a process-based model of the regulation of DMS concentrations in the surface ocean, we are presently unable to predict by how much, and even in which direction, this change would be. Since the rate of sulfate aerosol production depends strongly on the amount of OH radical in the atmosphere, changes in UV radiation and the oxidizing properties of the atmosphere may also influence the climate forcing due to DMS in ways that are difficult to predict at the present state of knowledge.

Downscaling

Brad Bass
University of Toronto, Toronto, Canada

Climate change is a global phenomenon, yet many of the impacts will differ substantially between regions and between speci c locations within regions. Due to the computer time required to simulate the climate, it is necessary to ignore variations at higher resolutions. Downscaling offers a means to derive higher-resolution climate scenarios in order to assess the impacts of climate change at a regional or local scale. The major approach to downscaling is stochastic or empirical linking of the large-scale atmospheric circulation with site-speci c observations in a manner similar to the perfect prognosis (PP) method used in weather forecasting. An alternative dynamic approach uses the outputs from a global climate model as boundary conditions for regional climate models (RCM) or higher-resolution mesoscale atmospheric models, which simulate the physics and dynamics of the atmosphere over a smaller area. Even though both approaches have their drawbacks, downscaling has been recognized as having a valuable role to play in providing input for assessing the risks of climate variability and change.

Many of the impacts of climate change will be experienced as changes in a broad range of biophysical or socio-economic systems such as agriculture, hydrology, forestry and health. Biophysical and social impacts often occur on the order of tens of kilometers in response to weather events that range in size from a few to hundreds of kilometers and last a few hours to a few days. Simulations of future climates, such as produced by global climate models (components of which are general circulation models (GCMs)) (*see* General Circulation Models (GCMs), Volume 1), are not able to represent these smaller scale atmospheric events. Downscaling offers one approach to providing data for climate impact assessment that are more representative of the scales at which the impacts will be observed (Giorgi and Mearns, 1991). Downscaling approaches provide higher resolution data through quantifying the links between synoptic scale patterns and site-specific observations and using those links to translate the large, atmospheric patterns from the GCM to site-specific climate variables.

The major approach to downscaling is stochastic or empirical (Bárdossy and Plate, 1992; Cubasch *et al.*, 1996; Wilby *et al.*, 1998). In this approach, the large-scale atmospheric circulation is empirically linked with site-specific observations in a manner similar to the PP method used in weather forecasting. PP assumes that numerical simulations are able to provide an accurate representation and forecast of the large-scale atmospheric circulation. The variables that characterize this larger-scale circulation, typically free atmospheric variables, for instance geopotential heights and/or surface variables such as sea surface temperature, are related in an empirical manner to site-specific observations, such that site-specific variables can be derived from these more reliably simulated variables.

Downscaling applications can proceed in the same manner, either for monthly or daily data. Although linear methods are commonly used, good results have been achieved with non-linear methods for variables that are considered to be difficult such as wind (Faucher *et al.*, 1999). In some applications, the variables that characterize the large-scale circulation are used to classify the atmospheric circulation into regular patterns. Each pattern is associated with a specific probability distribution of temperature, precipitation or other climatic variables. The classification and association can occur at daily or monthly time steps.

One proposed extension of downscaling has been to the integrated assessment of multiple air issues, specifically climate change, ultraviolet radiation, smog, acid rain, suspended particulates and the transport of hazardous pollutants (Bass and Brook, 1997). It is very difficult to assess the integrated risk of multiple issues because the risks are not additive as the occurrence of one may affect the occurrence of another. However, these atmospheric issues are sensitive to a similar suite of climatic variables, and if these can be downscaled, it may be possible to develop a set of integrated scenarios for these issues under current climate conditions and under climate change.

These stochastic approaches have been acknowledged as being quite valuable for producing high-resolution data sets under current atmospheric conditions. When used to

produce climate change scenarios, they have been criticized with respect to the basic underlying assumption – the stochastic parameters are invariable under a climate change scenario. In those applications that rely on classified circulation patterns, it is further assumed that the patterns do not change, but their frequency of occurrence may change. Thus, climate change becomes defined as the change in the frequency of atmospheric circulation patterns, but this assumption has also been criticized (Wilby *et al.*, 1998). An alternative is to embed a higher resolution atmospheric model into the GCM or to use a dynamic approach to downscaling by coupling the GCM to a higher resolution model (Bass and Brook, 1997).

The dynamic approach uses the outputs from a GCM as boundary conditions for regional climate models (RCM) or higher-resolution mesoscale atmospheric models at scales ranging from 5 to 50 km (Mearns *et al.*, 1999). These models simulate the physics and dynamics of the atmosphere over a small area. Statistical models, called weather generators, can be used with stochastic downscaling to create long multiple-year scenarios. Dynamic approaches are often used over shorter time periods due to the demanding computational requirements, but are especially useful in applications where stochastic approaches are unreliable due to an inability to classify an atmospheric pattern, sparseness of data or complex terrain. In addition, there are several variables for which initial values must be provided in order to run an RCM and a mesoscale model (Bass and Brook, 1997).

Stochastic approaches are also useful in conducting risk assessments due to the large amounts of data and the multiple realizations that can be generated through the use of Monte Carlo techniques. However, any other errors or uncertainties that are inherent in the GCM will be translated into the new higher-resolution climate data sets. In fact, with respect to the accuracy of the GCM in simulating the future, all downscaling approaches will most likely increase the uncertainty of the scenario.

An international research program, the Weather Generator Project, was created to evaluate different approaches to downscaling conducted under the auspices of the International Geosphere-Biosphere Programme – Biospheric Aspects of the Hydrological Cycle (BAHC). One of the conclusions that emerged from the Weather Generator Project is that an exclusive focus on high-resolution climate change scenarios would only allow for a limited assessment of the risks to important biophysical systems. A more comprehensive approach has been proposed in BAHC based on a vulnerability assessment (Box 1). Methods such as downscaling, and in particular stochastic downscaling, have been recognized as having a valuable role in vulnerability assessment, particularly in providing input for assessing the risks of climate variability and change (Hutjes *et al.*, 1998).

Box 1 Vulnerability assessment

Vulnerability assessment refers to the evaluation of the sensitivity of a particular ecosystem, resource or activity to a broad range of environmental and socioeconomic stresses. Depending on the particular case, the assessment could be conducted through determining critical thresholds of different stresses and risks associated with those thresholds. Stochastic downscaling is a suitable method for evaluating the risks associated with climatic thresholds. For a definition of vulnerability, *see* **Precautionary Principle**, Volume 5.

Dust

Irina N Sokolik
University of Colorado, Boulder, CO, USA

Mineral aerosols, or dust, are airborne mineral particles that range in size from about 0.01- 100 μm *and are a dominant component of the total atmospheric aerosol burden. Most dust particles are lofted into the atmosphere by aeolian (wind) erosion of arid and semi-arid lands, which cover*

approximately 33% of the global land area. However, any type of land surface can be a potential source of dust particles. Current estimates of global annual mean dust burden are in a range from 1000 to 5000 Tg year^{-1}. With an average lifetime of up to several weeks, mineral particles can be transported long distances downwind from the source. Each year, large plumes of dust are transported from sources in North Africa across the Atlantic Ocean, reaching the Caribbean and the southeastern United States, as well as across the Mediterranean into Europe. Large quantities of dust, originating in Central Asia, are also carried out over the North Paci c to the west coast of the United States.

Dust particles are not only of natural origin, but they are also produced as a result of human activities. Various human activities, e.g., road construction, can extend the geographical area of dust sources and increase dust loading into the atmosphere. This portion of dust is called anthropogenic dust, and it is of special interest in climate change studies. Recent estimates show that the anthropogenic fraction of dust could be as much as 30- 50% of total dust production, but this remains uncertain (Tegen et al., *1996). The dependence of dust emissions on climatic parameters, such as wind speed and rainfall, strongly suggests that the atmospheric dust load could be signi - cantly affected by any climatic change that may result from human activities. This fraction of the mineral dust particles is considered as anthropogenic dust too, but it is largely unquanti ed.*

Once lifted into the atmosphere, both anthropogenic and natural components of mineral aerosols play an important role in air quality, atmospheric chemistry, ecology, remote sensing, Earth's radiation budget, and, hence, regional and global change (Duce, 1995).

DUST IMPACTS

The direct radiative effects of mineral particles are due to their ability to scatter and absorb ultra-violet (UV), visible, and infrared (IR) radiation (Sokolik and Toon, 1996). To quantify the effects of aerosols on the Earth s radiative balance, the concept of direct radiative forcing is often employed. Dust can cause either positive or negative radiative forcing, leading to heating or cooling of the climate system. The sign of the direct radiative forcing is determined by the optical properties of the dust as well as atmospheric conditions and surface reflectance. For instance, dust plumes over dark surfaces such as the ocean result in negative forcing because reflection reduces the amount of solar radiation absorbed, while their radiative forcing is positive over bright surfaces such as snow and ice because aerosols darken the surface–troposphere system and increase the amount of solar radiation absorbed.

Moreover, the presence of dust alters the surface radiation budget, thereby affecting surface temperature and various surface–air exchange processes. In addition, radiative heating or cooling occurring within the dust layer itself affects the temperature profile and, hence, atmospheric dynamics. Overall, the radiative impact of mineral aerosols is important relative to that of other types of aerosols, such as sulfates and smoke particles, due to their widespread distribution and large optical depth.

The direct radiative impact of dust is augmented by indirect radiative effects. Aerosol-induced variations of clouds, followed by the alteration of the radiative budget, are referred to as indirect radiative forcing of aerosols on climate. Some mineral particles are able to take up water and can act as cloud condensation nuclei, altering cloud properties and amount. The insoluble fraction of dust may serve as ice forming nuclei.

In addition, dust can alter atmospheric chemical processes and air composition by a variety of means: altering UV radiative fluxes, and, hence, the photochemistry of the atmosphere; influencing the partitioning of semi-volatile trace species; providing additional reaction pathways for reactions involving H_xO_v, nitric oxides (N_xO_v), sulfur dioxide (SO_2), ozone (O_3) and semi-volatile organics (VOCs) (Denterner *et al.*, 1996). In turn, chemical processes occurring on the surfaces of dust particles may result in the formation of multicomponent aerosols that can have drastically different properties and, hence, radiative impact, from those at the dust source.

Dust also has a significant impact on the chemical and biological processes in the oceans. For instance, aeolian mineral dust deposited in the oceans provides soluble iron, which is essential for the growth of plankton (Duce, 1995). As a result, iron may affect the biogeochemical cycle of sulfur-stimulating planktons to grow and produce more dimethyl sulfide, DMS. The transport of micronutrients (such as phosphate and potassium) associated with dust particles also can be important for terrestrial systems.

The degradation of visibility and health problems caused by dust make it an important air quality issue (Wilson and Spengler, 1996). During a heavy dust storm, the visibility might be as low as a few meters. Some dust particles are toxic or can act as the transport mechanism for toxic species that can be inhaled and pose a health threat.

The fundamental problem in estimating the diverse impacts of dust comes from its complex nature. Mineral aerosol is a collective term referring to widely varying mixtures that may include many constituents such as quartz, various clays, calcite, gypsum, hematite and others. These minerals have very different physical and chemical properties (e.g., size distribution, particle shape, density, spectral refractive index, solubility, chemical reactivity, etc.).

In addition, dust sources and sinks are not uniformly distributed, and the lifetime of mineral dust in the atmosphere is relatively short, ranging up to a few weeks. Consequently the dust burden has a complex spatial and temporal pattern. Moreover, the physical and chemical characteristics of dust, originally determined by a given source and production mechanism, may vary during transport. Individual particle analysis of samples collected at various locations reveals that dust particles often occur as irregular aggregates of minerals and/or other aerosol species.

Therefore, the quantification of dust impacts must include various processes governing the changes of the physical and chemical properties of dust along with dust emission and atmospheric transport.

DUST EMISSION

Mineral dust is injected into the atmosphere mainly during sporadic events of high intensity. Strong winds capable of entraining dust particles occur under different meteorological conditions and at a variety of spatio–temporal scales (Pye, 1996). It has been demonstrated that the amount of uplifted dust is proportional to:

$$(u - u^*)u^2 \tag{1}$$

where u is the surface wind speed, and u^* is the threshold friction velocity required to initiate particle motion (Gillette, 1978). However, the threshold friction velocity depends on several factors and can vary from a few tens to a few hundreds of cm s^{-1}. The main factors influencing dust production are wind stress, surface roughness, the presence of non-erodible elements (such as rocks), soil mineralogy, size of erodible particles, vegetation, and soil moisture. Both natural and anthropogenic changes to any of these factors can drastically alter dust production.

In recent decades, the dramatic increase in the human population has had a crucial impact on Earth s drylands, causing their degradation, and desertification has been a result. At present, desertification threatens about one-third of the world s land surface, spreading over every continent with an estimated rate of about 6×10^4 km^2 $year^{-1}$ (*see* Deserti cation, Volume 3). Over-cultivation of poor soils, inappropriate irrigation practices, human-induced wind erosion, severe trampling and heavy grazing, deforestation, urbanization, building and road construction; mining and industry, off-road vehicle use, and tourism are among the major factors that contribute to anthropogenic dust loading. For example, the presence of Saharan dust is thought to be an indicator of desertification of the Sahel region in Africa. In the United States, the highest dust production occurs in regions where the soil has been disrupted by cultivation and other intensive land uses. Although there are many examples of humans altering the environment, thereby causing an additional dust burden, it is a challenging problem to separately quantify the dust emission rates from natural and anthropogenic (disturbed) sources with the pertinent temporal and spatial resolution.

EVOLUTION OF DUST PROPERTIES DURING ATMOSPHERIC TRANSPORT

Once mobilized, the suspended dust particles can be vertically mixed in the atmosphere and transported downwind from the source. Measurements made at the surface often show a bimodal dust particle size distribution, with the larger particle mode composed primarily of quartz and the small particle mode consisting of smaller quartz grains and clay minerals. Because of size-dependent removal processes, the relative importance of these smaller particles increases with increasing distance from the source. Some particles are deposited back to the surface due to aerodynamic resistance (referred to as dry deposition) (*see* Deposition, Dry, Volume 2). Larger particles fall out rapidly near the source region due to gravitational settling. Rain can also remove some or all dust particles from the atmosphere (referred as wet removal). Depending on specific meteorological conditions, dust can be transported downwind for thousands of kilometers, e.g., across the Atlantic Ocean from West Africa to the Caribbean. Long-lived dust particles that are transported long distances are typically characterized by one size mode with median mass diameter of about 1–3 μm. Particle concentration generally decreases rapidly with distance from the source. At the source, particle concentrations can be as high as a few thousands particles per cubic centimeter, but the concentration normally drops to a few tens of particles per cubic centimeter over distances of several thousand kilometers.

Along with concentration and size distribution, composition of dust particles may evolve during transport. Observations indicate that dust particles are often internally mixed with other aerosol species. Dust particles coated by sulfate, nitrate, sea-salt or carbonaceous matter have been measured by both ground-based and aircraft measurements. This can occur as a result of coagulation of dust with other aerosols, uptake of gases on dust particle surfaces followed by heterogeneous chemistry, and/or cloud processing of dust particles. Whereas the mechanism for coagulation is well understood, it is not clear how heterogeneous chemistry and cloud processing are accomplished.

The evolution of dust particles also depends on the prevailing physical and meteorological characteristic of a particular dust source, as well as transport route. For instance, some plumes of Asian dust can travel through large urban areas that are heavily polluted by anthropogenic sulfates and soot aerosols. By the time Asian dust reaches the marine environment, it can have drastically different properties from those at the source.

Many studies demonstrate that dust may be transported in one or several layers located at different altitudes in the atmosphere. Normally, long-range transport of dust by strong winds occurs above the boundary layer but below 10 km. Due to stratification of the atmosphere, dust layers can have drastically different properties depending on the history of the air mass found at a given altitude. If there were to be significant changes in atmospheric circulation due to natural climate variability or climate change, the atmospheric transport and, hence, the evolution of dust plumes and their spatial distribution could be very different.

MEASUREMENTS AND MODELING OF DUST PROPERTIES

Various experimental and modeling studies have been conducted to characterize the properties of dust and evaluate its impacts. However, most observations that exist are from short-duration ground-based studies at a limited number of locations. As a result, the diverse impacts of dust cannot be fully quantified from existing measurements.

Recently considerable progress has been made in employing satellite observations to characterize dust properties and transport on a global scale. For instance, since 1978, the Advanced Very High-Resolution Radiometer (AVHRR) on board National Oceanic Atmospheric Administration (NOAA) satellites has been used to derive long-term climatologies of aerosol amount over the oceans. Data from the National Aeronautics and Space Administration (NASA) Total Ozone Mapping Spectrometer (TOMS), operating at UV wavelengths, have been used to monitor dust production and transport over land as well as over the ocean since 1979. Several new space sensors that have been explicitly designed for aerosol study are becoming available (King *et al.*, 1999).

Satellite observations confirm that mineral dust is a major aerosol component over many marine and continental areas and reveal a complex structure of the spatial and temporal distribution of dust plumes. Satellite imagery, providing global-scale aerosol distributions, can be used to guide the development of models of dust sources, transport, and deposition.

Process-oriented models (such as climate models, global circulation models (GCMs), and atmospheric chemical transport models) have become the most comprehensive tools available for predicting the diverse impacts of dust. A common approach to simulate dust fields employing an atmospheric transport model includes several steps:

1. characterize the dust source;
2. use a dust production scheme to simulate dust emission; and
3. use transport and dust removal schemes to predict the size-resolved concentration fields or total mass concentration fields as a function of time and space depending on the resolution of a given model.

Because of the complexities involved and the lack of understanding of the interactions between dust and the chemistry and physics of the atmosphere, model predictions typically rely on oversimplified parameterizations of dust processes. Nevertheless, the estimated global-mean radiative forcing by anthropogenic dust is in the same range as that due to anthropogenic sulfate aerosols and smoke from biomass burning. Models predict that the presence of dust will affect surface temperature, rainfall, and tropospheric winds.

Modeling studies further demonstrate that the diverse effects of dust may induce various feedbacks on the climate system. Several competitive feedbacks have been suggested; for example, reduction of the surface winds is likely a negative feedback, whereas a decrease in rainfall would likely lead to a positive feedback. However, an understanding of the overall response of the climate system to the diverse impacts of mineral aerosols is still incomplete.

Eemian

The *Eemian* refers to the last interglacial period, which began about 127 000 years ago at the end of the previous glaciation. The onset of the last glacial cycle followed at 115 000 years ago. The Eemian is also known as the Riss-Wurm interglacial (Berggren and Couvering, 1977) and corresponds to oxygen isotope stage 3 from ocean sediments. The transition from full interglacial to full glacial conditions has generally been relatively slow (taking tens of thousands of years), while the transition from glacial-to-interglacial conditions is more rapid (taking thousands of years). This asymmetric timing creates a sawtooth-shaped pattern, with the entire process occurring in cycles that have averaged about 100 000 years. The glacial-interglacial cycles are thought to be related to changes in the Earth s orbit (*see* Orbital Variations, Volume 1) that regulate the amount of solar radiation reaching different latitudes of the Earth during different seasons (there is little overall change in the annual, global integral of incoming radiation). The most recent maximum in the Northern Hemisphere, summertime solar insolation, occurred about 10 000 years ago (the start of the Holocene). During the Eemian interglacial, the insolation maximum during July at high northern latitudes was even greater than 10 000 years ago, suggesting

that the Eemian could have been warmer than the beginning of the Holocene. Paleogeologic proxy data do indeed indicate that land temperatures in some locations were a couple degrees warmer than present, even though sea surface temperatures seem to have been similar to present. Sea level, on average, is estimated to have been 6 m higher than at present, possibly due to melting of some or all of the West Antarctic or Greenland ice sheets. Crowley and North (1991) summarize the results from many studies.

El Niño

El Niño is a warming of the tropical Pacific that occurs roughly every 3–7 years and typically lasts for 12–18 months. It is dynamically linked to the Southern Oscillation, a seesaw in surface atmospheric pressure between the Australian–East Asian region and the eastern tropical Pacific. During El Niño, the trade winds weaken along the equator as atmospheric pressure rises in the western Pacific and falls in the eastern Pacific. Weakened trade winds allow warm surface water, normally confined to the western Pacific, to migrate eastward. Wind-driven upwelling, a process which brings cold water to the surface along the equator and along the west coasts of North and South America, is also greatly reduced, causing sea surface temperatures to rise. Upwelled waters are rich in nutrients that support biological productivity, so that reduced upwelling adversely affects marine ecosystems and economically valuable fish stocks.

In the atmosphere, deep cumulus clouds and heavy rains typically occur in the western Pacific over the warmest surface waters. As these waters migrate eastward during El Niño, so does the heavy rainfall. Condensation of water vapor into liquid water releases heat into the middle and upper troposphere. This heat provides a source of energy to drive global wind fields that extend El Niño s influence to remote parts of the planet. Altered circulation patterns produce droughts, floods, unusual storminess, heat waves, and other weather extremes that have serious social, economic, and public health consequences. However, El Niño can also have a positive influence on weather, such as bringing milder winters to North America and suppressing Atlantic hurricane formation.

El Niño in Spanish means the child, with specific reference to the Christ child. It was the name given by fishermen to a warm southward flowing coastal ocean current that occurred around Christmas time off the west coast of Peru and Ecuador. These coastal warmings are linked to the much more extensive ocean warmings that occur across the width of the tropical Pacific Basin. Thus the term El Niño has now become synonymous with these extensive ocean warmings because of their impacts on global climate. El Niño is sometimes also referred to as the warm phase of the El Niño/Southern Oscillation (ENSO) cycle (*see* El Niño/Southern Oscillation (ENSO), Volume 1).

El Niño and La Niña: Causes and Global Consequences

Michael J McPhaden

National Oceanic and Atmospheric Administration, Seattle, WA, USA

El Niño is a warming of the tropical Paci c that occurs roughly every three to seven years and lasts for 12- 18 months. It is dynamically linked to the Southern Oscillation, a see-saw in surface atmospheric pressure between the Australian- East Asian region and the eastern tropical Paci c. During El Niño, the trade winds weaken along the equator as atmospheric pressure rises in the western Paci c and falls in the eastern Paci c. Weakened trade winds allow warm surface water, normally con ned to the western Paci c, to migrate eastward. Wind-driven

upwelling, a process that brings cold water to the surface along the equator and along the west coasts of North and South America, is also greatly reduced, causing sea surface temperatures to rise. Upwelled waters are rich in nutrients that support biological productivity, so that reduced upwelling adversely affects marine ecosystems and economically valuable fish stocks.

In the atmosphere, deep cumulus clouds and heavy rains typically occur in the western Pacific over the warmest surface waters. As these waters migrate eastward during El Niño, so does the heavy rainfall. Condensation of water vapor into liquid water releases heat into the middle and upper troposphere. This heat provides a source of energy to drive global wind fields that extend El Niño's influence to remote parts of the planet. Altered circulation patterns produce droughts, floods, unusual storminess, heat waves, and other weather extremes that have serious social, economic, and public health consequences. However, El Niño can also have a positive influence on weather, such as bringing milder winters to North America and suppressing Atlantic hurricane formation.

La Niña is a climatological phenomenon akin to El Niño, but with opposite tendencies in the tropical Pacific Ocean and atmosphere. La Niña is characterized by stronger than normal trade winds and colder than normal tropical Pacific sea surface temperatures. It is also characterized by unusually high surface atmospheric pressure in the eastern tropical Pacific and low surface pressure in the western tropical Pacific in association with the Southern Oscillation. La Niña's effects on global weather are roughly opposite to those of El Niño. As a result, El Niño, La Niña and Southern Oscillation are often referred to collectively as El Niño/Southern Oscillation (ENSO), a cycle that oscillates year-to-year between warm, cold and neutral states in the tropical Pacific.

After the disastrous 1982-1983 El Niño, which was neither predicted nor even detected until nearly at its peak, a 10-year international scientific research program was undertaken between 1985-1994 to improve the understanding, detection, and prediction of ENSO-related variability (see TOGA (Tropical Ocean Global Atmosphere), Volume 1). New networks of moored and drifting buoys, island and coastal tide gauges, and ship-based measurements were initiated. Satellites provided global observations of the ocean and the atmosphere. Computer models were developed to forecast El Niño and La Niña events with lead times of up to one year. Scientific progress in these areas was highlighted during the 1997-1998 El Niño, which by some measures was the strongest on record. This El Niño was monitored day-by-day at a level of detail never before possible. In addition, early warning impending impacts, made possible by new data and forecasting techniques led to planning efforts in some parts of the world that helped to reduce the toll the El Niño, might otherwise have taken.

The strength of the 1997-1998 El Niño, the tendency for more frequent El Niño events and less frequent La Niña events in the past 25 years, and the prolonged 1991-1995 El Niño have raised questions about the possible influence of global warming on the ENSO cycle. Some recent computer model simulations suggest that the ENSO cycle may be more energetic in a warmer world. However, no firm conclusions can be drawn at present because models used to simulate the interaction between global warming and ENSO are limited in their ability to accurately represent key physical processes. Also, available data are insufficient to unambiguously establish that recent changes in the ENSO cycle are outside the range of natural variability.

HISTORICAL BACKGROUND

El Niño in Spanish means *the child*, with specific reference to the Christ child. It was the name given by fishermen to a warm southward flowing coastal ocean current that occurred every year around Christmas time off the west coast of Peru and Ecuador. The term was later restricted to unusually strong warmings every few years that disrupted local fisheries, led to massive bird die offs, and brought torrential rains to the region. These coastal warmings and episodes of heavy rainfall have been linked by researchers over the past 40 years to much more extensive ocean warmings that occur across the width of the tropical Pacific basin (Figure 1). The term El Niño has now become synonymous with these extensive ocean warmings because of their impacts on global climate (Philander, 1990).

El Niño is coupled to an atmospheric phenomenon known as the Southern Oscillation, first defined by Sir Gilbert Walker in the early 20th century. Walker was an Englishman who was appointed director general of observatories in India in 1904. He arrived in the wake of a devastating drought and famine that claimed more than a million lives in 1899–1900. Most of the rain in India falls during the summer monsoon. When the monsoons fail, the results can be disastrous for Indian agriculture. Walker believed that summer monsoon rainfalls might be predictable, so he set out to find possible precursors, gathering weather information from all over the world. In the 1920s and 1930s, he published a series of papers describing a year-to-year see-saw in surface atmospheric pressure between the Eastern and Western Hemispheres (Figure 2). He found that when pressure was unusually low over the Indian Ocean region and the western tropical Pacific, it was high east of the international date line in the southeastern tropical Pacific. This situation corresponded to periods of good monsoon rains in India. When this pressure pattern was reversed, with low pressures east of the date line and high pressures west of the date line, rainfall was deficient not only in India,

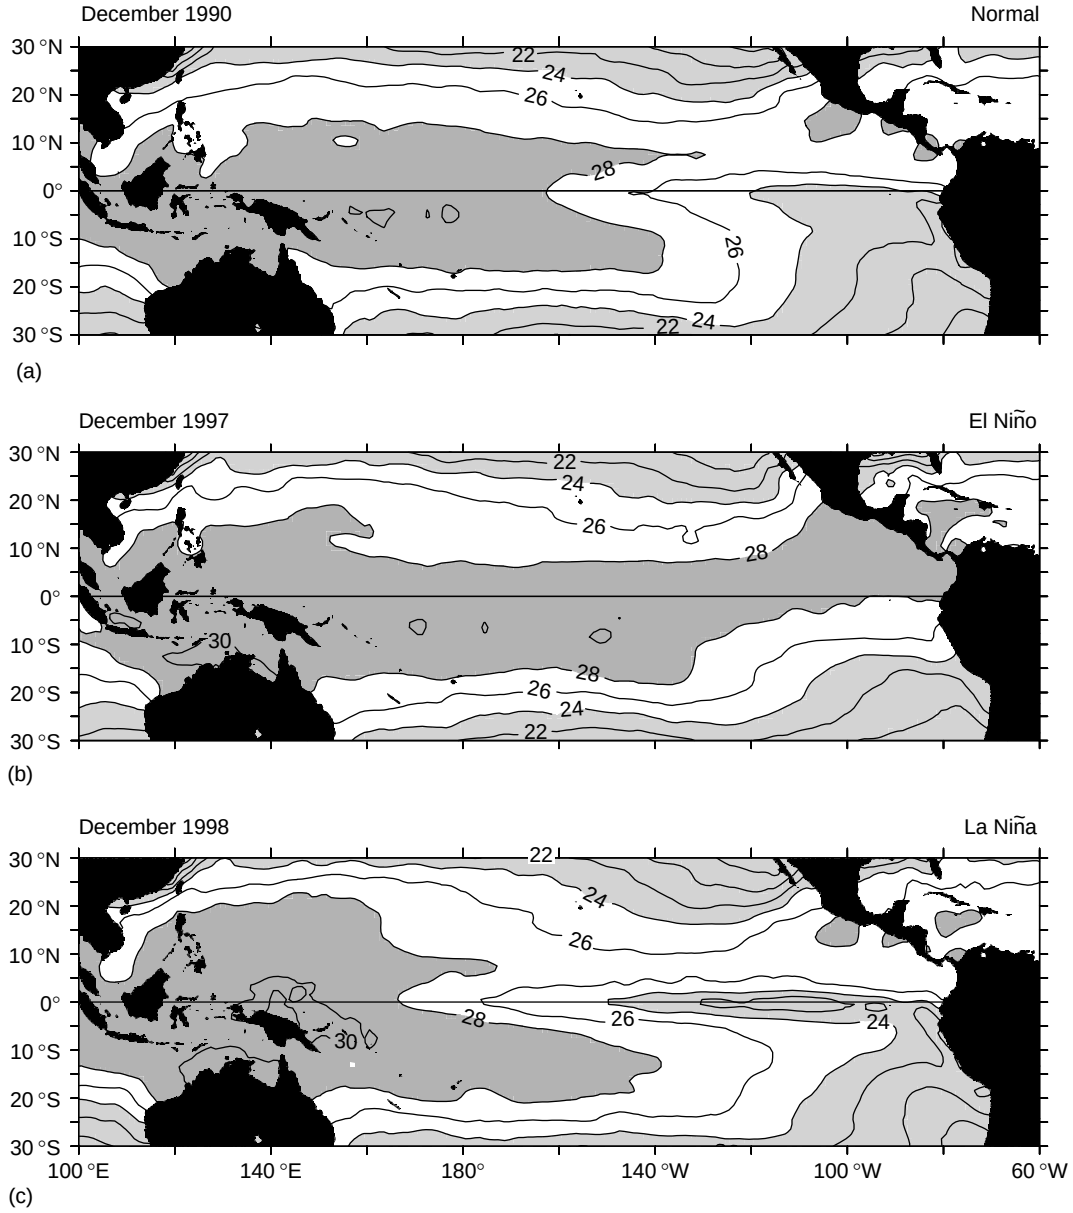

Figure 1 Monthly averaged sea surface temperature (in °C) illustrating normal conditions in December 1990 (a), El Niño conditions in December 1997 (b), and La Niña conditions in December 1998 (c)

but also in neighboring countries such as Australia and Indonesia.

Unfortunately, for Walker, variations in the Southern Oscillation lagged rather than led those associated with Indian summer monsoon rainfall, so that his index was not useful for monsoon predictions. Curiously, he also found that the low index phase of the Southern Oscillation was correlated with warm winters over Canada and dry conditions in parts of South Africa. His work was met with a great deal of skepticism though because he could not provide a physical explanation for the observed connections between the Southern Oscillation and climatic variations in widely separated parts of the globe. This skepticism was evident in his obituary, published in the *Quarterly Journal of the Royal Meteorological Society* (1959, p. 185):

> Walker s hope was presumably not only to unearth relations useful for forecasting but to discover sufficient and sufficiently important relations to provide a productive starting point for a theory of world weather. It hardly seems to be working out like that.

Ironically, Walker died in 1958 during the 1957–1958 International Geophysical Year (IGY), the first truly international scientific study of the global oceans, atmosphere, and

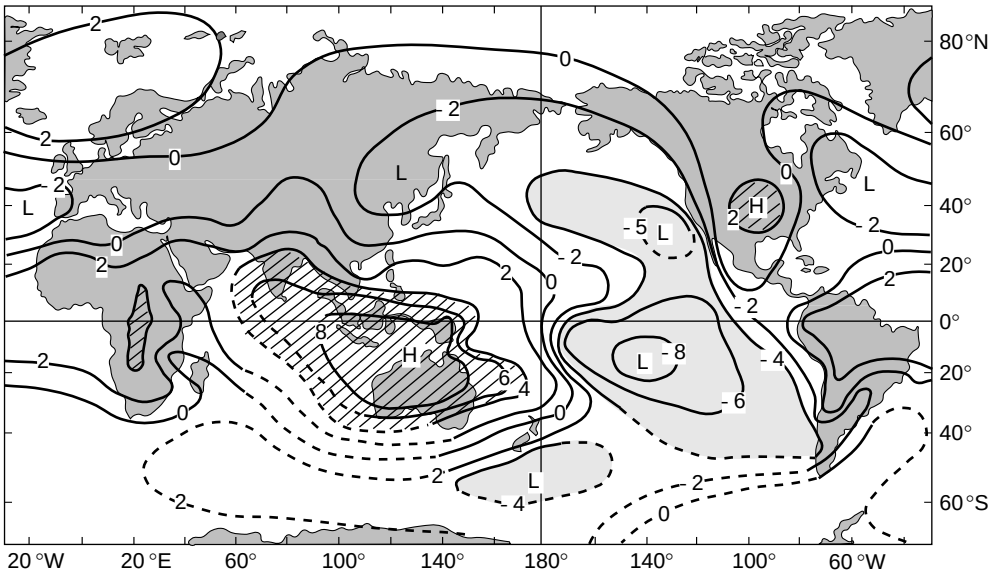

Figure 2 Spatial pattern of annual mean sea level pressure anomalies associated with the Southern Oscillation. Solid cross hatching indicates regions where sea level pressure varies in phase with Darwin, Northern Australia, and light shading indicates regions where sea level pressure varies out of phase with Darwin. Units are in correlation coefficient ($\times$10), for which large absolute values indicate a more consistent relationship with Darwin (Trenberth and Shea, 1987)

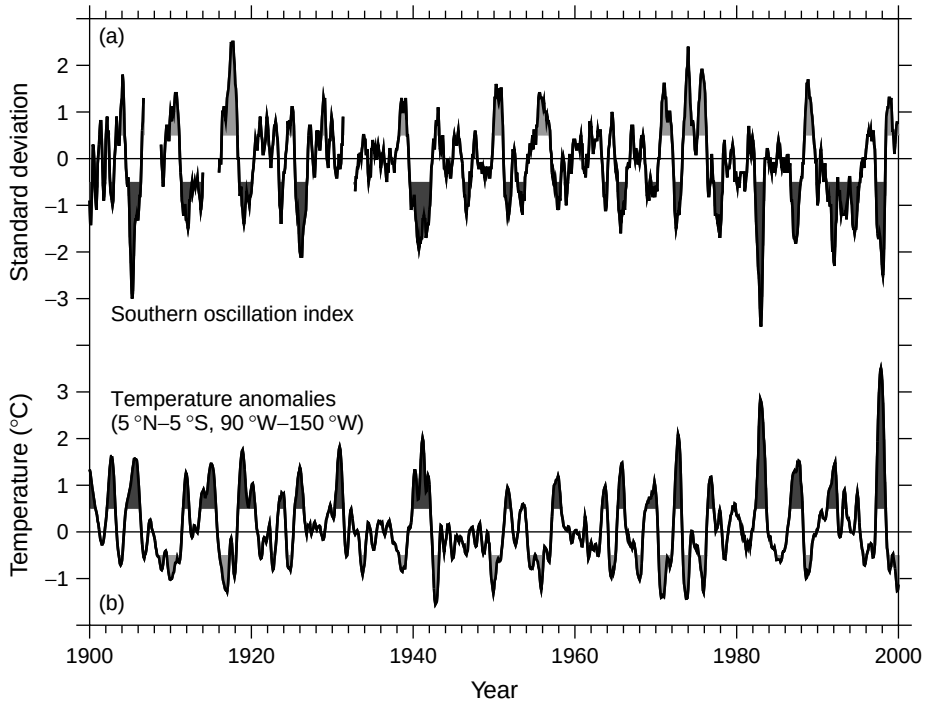

Figure 3 (a) SOI, which is a normalized difference between Tahiti, French Polynesia minus Darwin, Australia surface air pressure, after typical seasonal variations have been subtracted out. Periods of SOI greater in magnitude than 0.5 are shaded to emphasize the relationship with El Niño and La Niña episodes. Low SOI is associated with warm sea temperatures (El Niño), and high SOI with cold sea temperatures (La Niña). (b) Sea surface temperature anomalies (that is, deviations from normal) for the region 5 °N–5 °S, 90 °W–150 °W from 1900–1999. Positive anomalies greater than about 0.5 °C indicate El Niño events. Negative anomalies less than about −0•5 °C indicate La Niña events

solid earth (*see* IGY (International Geophysical Year), Volume 1). Intensive measurements were being undertaken in a coordinated effort to better understand the processes involved in shaping the global environment. As fate would have it, 1957–1958 coincided with a strong El Niño event. Measurements from the various observing systems deployed during the IGY stimulated Jacob Bjerknes to examine how interactions between the ocean and the atmosphere in the tropical Pacific could affect weather patterns (*see* Bjerknes, Jacob, Volume 1). Bjerknes was a Norwegian meteorologist who emigrated to the US just before World War II. He had established his reputation in the early part of the century by making fundamental contributions to the understanding of fronts and weather systems at middle and high latitudes. Using IGY data in the 1960s, Bjerknes would be the first to identify the relationship between El Niño and the Southern Oscillation, to propose physical mechanisms by which they might interact, and to describe some of the effects of El Niño on North American weather.

The close connection between El Niño and the Southern Oscillation over the past 100 years can be seen in the strong inverse relationship between two commonly used indicators (Figure 3). The Southern Oscillation index (SOI) is based on departures from normal of surface atmospheric pressure at Tahiti, French Polynesia, and Darwin, Northern Australia. The difference of Tahiti minus Darwin pressure provides a measure of the pressure force that drives the trade winds across the Pacific basin. When this index is negative (low pressure at Tahiti relative to Darwin), the trade winds are weak. When the index is positive, the trade winds are strong.

A commonly used index for El Niño is the areal averaged sea surface anomaly (i.e., deviation from normal) in the region 5 °N to 5 °S, 90 °W to 150 °W. Large positive values of this index define warm El Niño conditions, while large negative values indicate cold La Niña conditions. It is evident that the warm surface temperatures are strongly linked to weak trade wind (negative values of the SOI) and vice versa. These indices show that the 1982–1983 El Niño and the 1997–1998 El Niño were the strongest of the 20th century.

El Niño events exhibit some common characteristics (such as unusually warm sea surface temperatures and weak trade winds in the tropical Pacific) that allow them to be classified as a distinct phenomenon (see Box 1). However, they often differ among themselves in duration, intensity and in the details of their development. No two El Niños are exactly alike, and the same is true of La Niña events. Thus, the ENSO cycle displays a degree of irregularity for which there is yet no simple explanation.

Box 1 El Niño and La Niña, Past and Present

El Niño and La Niña events generally last 12–18 months, and tend to be most fully developed during the Northern Hemisphere winter season. Thus, they often span two calendar years. Commonly used indices like those in Figure 3 show that El Niño events over the past 50 years occurred in 1951, 1953, 1957–1958, 1963, 1965–1966, 1969, 1972–1973, 1976–1977, 1982–1983, 1986–1987, 1991–1995 and 1997–1998. La Niña events of the past 50 years occurred in 1949–1950, 1955–1956, 1964, 1970–1971, 1973–1975, 1988–1989, 1995–1996 and 1998–2000. Weak cold events also occurred in 1967–1968 and 1984–1985, but these were not accompanied by positive values of the SOI.

Instrumental records available for identifying El Niño and La Niña years prior to the mid-19th century are very limited. However, it has still been possible to identify El Niño events in the distant past using anecdotal historical information from the reports of early explorers and settlers in those areas bordering the Pacific where in modern times El Niño consistently affects weather and climate. Quinn *et al.* (1987) produced a chronology of El Niño events going back to 1525 using historical reports of conditions from the coastal region and adjacent waters of northwestern South America. Their work suggests, e.g., that Francisco Pizarro's conquest of the Incas in 1531–1532 coincided with an El Niño event. Heavy rains and swollen rivers, which typically occur only during El Niño years in Peru, delayed Pizarro's advance through the countryside. On the other hand, the same rains produced abundant vegetation, providing plentiful fodder for his horses, which were one of the chief tactical advantages (along with swords) that his small contingent of soldiers had over the natives.

Quinn (1992) extended this El Niño chronology back to 622 AD using maximum yearly Nile River flow data at Cairo, and related historical information on African droughts, floods, plagues and famines. Careful records of Nile stream flow were kept because it formed the basis of Egyptian agriculture for thousands of years. The stream flow records reveal year-to-year changes that can be related to variations in summer monsoon rains over the highlands of Ethiopia. These rains, and the stream flows they feed, are typically reduced in El Niño years.

It is possible to extend the record of ENSO time scale variations even further back in time by developing climate reconstructions using proxy data from tree rings, laminated lake sediments, glacier ice cores and tropical Pacific corals. These proxies preserve year-by-year records of environmental parameters related to physical climate, such as temperature, precipitation, or rainwater runoff. The relevant climate information is encoded in the chemical and isotopic composition of coral skeletons, the water content and chemistry of ice cores, the thickness and grain sizes of sediment layers, and the thickness and density of tree rings. Properly calibrated against modern instrumental records, proxy data allow investigations on ENSO-related climate variability to extend many thousands of years into the past.

EL NIÑO PHYSICS AND THE ENSO CYCLE

To understand El Niño, we must first understand what is considered normal. Sunlight reaching the Earth s surface is more intense in the tropics than at higher latitudes, so that the warmest ocean temperatures are found near the equator. Air masses over warm tropical waters extract heat and moisture from the ocean, expand, become less dense than surrounding air, and ascend to higher altitudes. The rising air cools and condenses, producing towering cumulus clouds and heavy precipitation through a process referred to as deep convection. At upper levels of the troposphere (the lowest 10–12 km of the atmosphere affected by weather) these air masses flow poleward, then sink in regions of high surface pressure over the subtropical oceans of the Northern and Southern Hemispheres. The rising tropical air masses in turn are fed by air drawn in towards the equator near the surface from the subtropical high-pressure zones. This circulation cell on the meridional plane is called the Hadley circulation in honor of George Hadley, an 18th century British meteorologist who was the first to provide a theoretical explanation for it (*see* Hadley Circulation, Volume 1).

The equatorward flowing surface air masses are deflected westward because of the rotation of the Earth about its axis (the Coriolis effect). The result is easterly tradewind systems in the Northern and Southern Hemispheres. The northeast and southeast trade winds meet in the Intertropical Convergence Zone, situated on average about five to ten degrees of latitude north of the equator in the Pacific. This is a region of deep convection, cumulus cloud formation, and heavy rainfall that comprises the ascending branch of the Hadley circulation. A second zone of converging surface winds, the South Pacific Convergence Zone, is on average located several degrees south of the equator in the western tropical Pacific.

Along the equator, the trade winds normally drive surface flow westward in the south equatorial current (Figure 4). This current piles up the warm surface water in the western Pacific, and drains it from the eastern Pacific. The thermocline, which is the sharp vertical temperature gradient separating the warm surface layer from the cold deep ocean, is pushed down to a depth of 150 m in the west, but shoals to 50 m depth in the east. Sea level tends to mirror thermocline depth since water expands when heated. Thus, while the thermocline tilts downward towards the west along the equator, sea level rises to the west where it stands about 60 cm higher than in the eastern Pacific.

The relative shallowness of the thermocline in the eastern Pacific facilitates the upward transport of cold interior water by the trade winds, and a cold tongue develops in sea surface temperature from the coast of South America to near the international date line. The east–west surface temperature contrast reinforces the easterly trade winds, since low atmospheric surface pressure is associated with

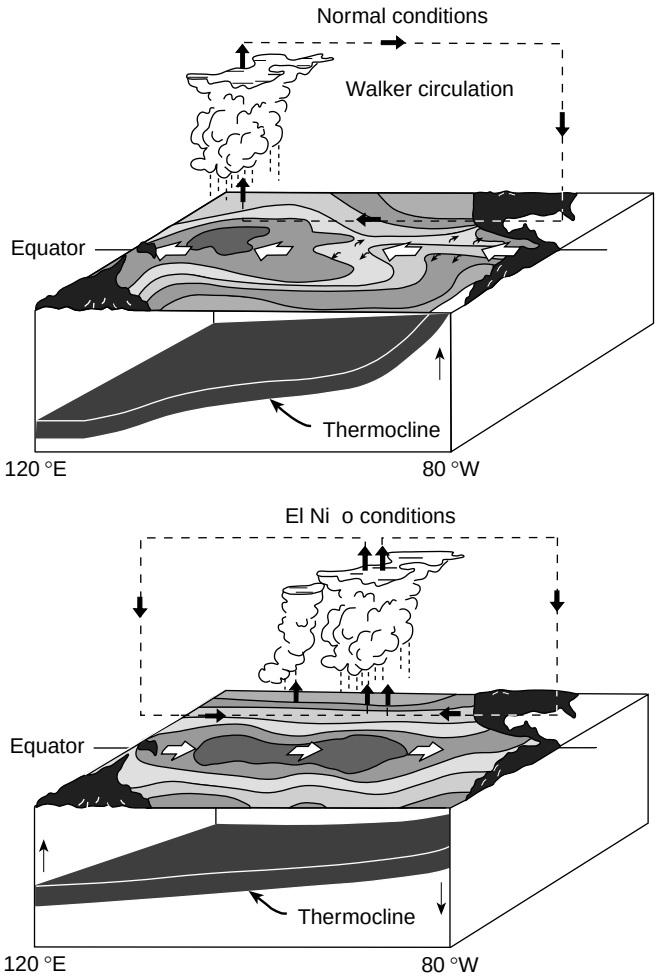

Figure 4 Schematic of normal and El Niño conditions in the equatorial Pacific

warm water in the west and high surface pressure with cooler water in the east. Also, as the trade winds flow from east to west, they pick up heat and moisture from the ocean. The warm, humid air mass becomes less dense and rises over the western Pacific warm pool where deep convection leads to towering cumulus clouds and heavy precipitation. Ascending air masses in this region of deep convection return eastward in the upper levels of the troposphere, then sink over the cooler water of the Eastern Pacific. Bjerknes labeled this atmospheric circulation pattern on the equatorial plane the Walker circulation in honor of Sir Gilbert Walker (*see* Walker Circulation, Volume 1).

Upwelling is a key oceanic process that regulates sea surface temperatures along the equator and along much of the west coast of the Americas. Wind-driven surface currents flow to the right of the winds in the Northern Hemisphere and to the left of the winds in the Southern Hemisphere because of the Coriolis force. Easterly trade wind-driven currents therefore flow poleward in opposite directions near the equator in the Northern and Southern

Hemispheres. This divergent surface flow is fed from below by upwelled thermocline water to create the equatorial cold tongue (Figure 1). A similar process operates off the west coasts of the Americas. Equatorward winds on the eastern flanks of subtropical high-pressure systems drive surface waters offshore. These offshore flows are fed from below by cooler thermocline waters, which then lower coastal sea surface temperatures.

During El Niño, the trade winds weaken in the western and central equatorial Pacific as atmospheric pressure rises in the west and falls in the east (Figure 4). Weakened trade winds generate waves in the ocean interior, which radiate along the equator both to the east and to the west away from the region of wind forcing (see Box 2). Over the course of a few months, these waves elevate the thermocline in the west and push it down in the east. In the cold tongue region, depression of the thermocline leads to surface warming as equatorial upwelling can no longer efficiently tap into the cold water reservoir below. Westward flow in the south equatorial current also weakens and reverses when the trade winds relax, allowing the western Pacific warm pool to migrate eastward. Sea level drops in the west and rises in the east in response to the redistribution of warm surface waters.

As sea surface temperatures warm east of the date line, the pattern of deep convection and precipitation also shifts eastward. This reinforces the reduction in trade wind intensity, because westerly winds flow into the convective center from the west. Pressure continues to fall in the east and rise in the west as the region of convection and rainfall migrates eastward. The system becomes locked in a positive feedback loop, with warming surface temperatures leading to weakened trade winds and vice versa. This positive feedback is eventually broken when the oceanic waves that elevated the thermocline in the western Pacific at the onset of the event bounce off the land masses bordering the western Pacific and reflect back toward the east. As the reflected waves propagate eastward along the equator, they elevate the thermocline and initiate surface cooling. Cooler surface waters in the eastern Pacific increase the east–west atmospheric pressure gradient and the strength of the trade winds, which in turn reinforces surface cooling through intensified upwelling. These interactions between the ocean and the atmosphere terminate El Niño typically 12–18 months after its onset. The ocean returns to near normal conditions, or it may overshoot into a cold La Niña state.

While El Niño involves an intimate coupling of the atmosphere and the ocean, the two fluids respond to each other on very different time scales. The atmosphere is a thousand times less dense than the ocean, and therefore responds almost immediately to forcing from the ocean surface. The ocean is massive by comparison, so its dynamical response to atmospheric forcing is relatively sluggish. For example, thermocline depths may take many months to adjust to changing winds in the tropics, whereas atmospheric convection can develop within hours over warm surface water. It is the slow evolution of the upper ocean thermal field that provides the memory for the climate system in the tropical Pacific, and it is this thermal inertia that provides the basis for predictability of ENSO time scale variations.

Box 2 Equatorial Waves

One early theory for El Niño postulated that the winds blowing equatorward off the west coast of South America weakened during an El Niño event, so that coastal upwelling would be reduced and sea surface temperatures would rise. However, Klaus Wyrtki, an oceanographer at the University of Hawaii, demonstrated in the mid-1970s that winds along the coast of South America actually strengthened during El Niño (Wyrtki, 1975). He found instead that weakening of the tradewinds thousands of kilometers to the west in the central Pacific was related to the development of El Niño along the coast of South America some months later. Based on these results, Wyrtki suggested that large scale equatorial ocean waves were the mechanism by which wind variations in the central Pacific could lead to the onset of El Niño in the eastern Pacific.

Two classes of oceanic waves are important for understanding the cycle of El Niño and La Niña variations. One class is referred to as Kelvin waves, named after Lord Kelvin (William Thompson), a 19th century British physicist who was the first to theoretically predict such waves in rotating fluids. The other class is referred to as Rossby waves, named after Carl-Gustaf Rossby, a Swedish-born meteorologist who in the 1930s first discovered this kind of wave in the atmosphere (*see* **Rossby Waves**, Volume 1; **Rossby, Carl-Gustaf**, Volume 1). Both types of wave are generated in the equatorial ocean by large-scale variations in surface winds.

Kelvin waves propagate eastward along the equator and Rossby waves propagate westward. They are evident below the surface as undulations of the thermocline, causing it to rise and fall by tens of meters as the waves pass by. Equatorial waves also affect sea level and the intensity and direction of ocean currents. The Earth's rotational forces trap these waves within several hundred kilometers of the equator in the open ocean, so they transfer energy very efficiently over many thousands of kilometers in the east–west direction.

Kelvin waves take about two months to cross the Pacific basin and Rossby waves take about six months to cross. When they reach the landmasses at the eastern and western boundaries of the ocean, they reflect back into the interior and, in the case of Kelvin waves, leak energy to higher latitudes along the west coasts of the Americas. The life cycle of these waves, evolving over many months and seasons in response to changing winds, are a critical aspect of ocean dynamics controlling the evolution of El Niña and La Niña events.

EL NIÑO WEATHER IMPACTS

One impact of the eastward shift in rainfall along the equator during El Niño is that drought develops in Australia, Indonesia and neighboring countries. On the other hand, the island states of the central Pacific and the west coast of South America are inundated with heavy rains. Heavy rainfall bands normally situated north and south of the equator in the Intertropical Convergence Zone and the South Pacific Convergence Zone also shift equatorward as surface waters warm. These latitudinal shifts contribute to unusually heavy rains near the equator in the central and eastern Pacific, and to drought conditions at higher latitudes in regions such as New Caledonia and Fiji to the south, and Hawaii to the north.

Heat released into the troposphere from deep tropical convection is one of the principal driving forces for the global atmospheric circulation. Changes in the location of tropical heat sources during El Niño therefore lead to widespread changes in wind and weather patterns outside the tropical Pacific. These remote effects of El Niño are referred to as teleconnections. In the extratropics, teleconnections are usually most pronounced during the winter season, though they are detectable in other seasons as well.

Anomalous tropospheric heating in the central tropical Pacific during El Niño generates quasi-stationary atmospheric wave trains that radiate poleward and eastward. In the Northern Hemisphere, these waves set up the Pacific North American Teleconnection Pattern, or (PNA) pattern, which is a series of high- and low-pressure centers extending from the central North Pacific to North America (Figure 5). During El Niño, the Aleutian low pressure center over the North Pacific deepens, high pressure develops over western North America, and low pressure prevails over the southeastern US. These pressure changes steer warmer air masses from southern latitudes into the Pacific Northwest and southern Canada, so that much of Canada and the northwestern US tend to experience mild winters. Low pressure in the southeastern US associated with the PNA pattern brings wetter, cooler conditions to the

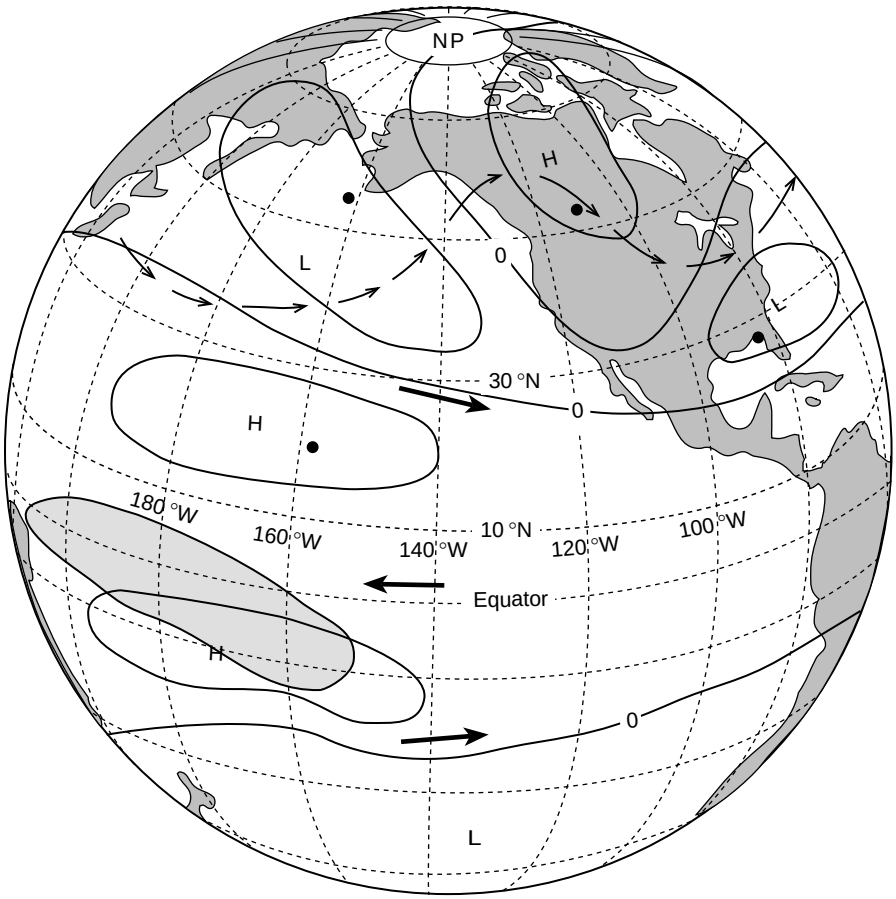

Figure 5 Schematic diagram of the PNA pattern of middle tropospheric pressure anomalies during Northern Hemisphere winter coinciding with an El Niño event. Dark arrows indicate strengthening of the subtropical westerly jet streams and, along the equator, weakening of the upper branch of the Walker circulation. Lighter arrows depict mid-tropospheric flows as distorted by the anomalous high and low pressure patterns. Rainfall and cloudiness are enhanced over the shaded region near the equator (Horel and Wallace, 1981)

states bordering the Gulf of Mexico. Similar wave trains are excited in the Southern Hemisphere, but they are weaker and more variable than those in the north.

Teleconnections also affect the subtropical jet streams which are swift air flows girdling the Earth at altitudes centered between about 10 000 m and 12 000 m (*see* Teleconnection, Volume 1). The eastward migration of deep convection during El Niño causes the core of these jet streams to intensify and shift southeastward in the central and eastern Pacific (Figure 5). The jet streams are a major influence on the location of storm tracks, so that southern California and northern Chile typically experience stormier and wetter weather in their respective winter seasons during El Niño.

Teleconnections affect surface conditions over land masses and the ocean. At extratropical latitudes of the North and South Pacific, for example, sea surface temperatures cool in response to intensified surface wintertime westerlies. Over land, changes in temperature and precipitation can affect soil moisture and evapotranspiration. These changes in surface conditions can feed back to the atmosphere, affecting the overall climatic response to El Niño forcing.

A global composite of typical rainfall and air temperature anomalies associated with El Niño is presented in Figure 6. In addition to effects already mentioned, El Niño years generally bring drought in northeastern Brazil, southern Africa, and the western Pacific, and wetter conditions to southern Brazil, Uruguay, Peru, and equatorial East Africa (Ropelewski and Halpert, 1987). Indian monsoon summer rains tend to be weaker during El Niño events, consistent with the strong relation between the Southern Oscillation and Indian monsoon rainfall noted by Walker.

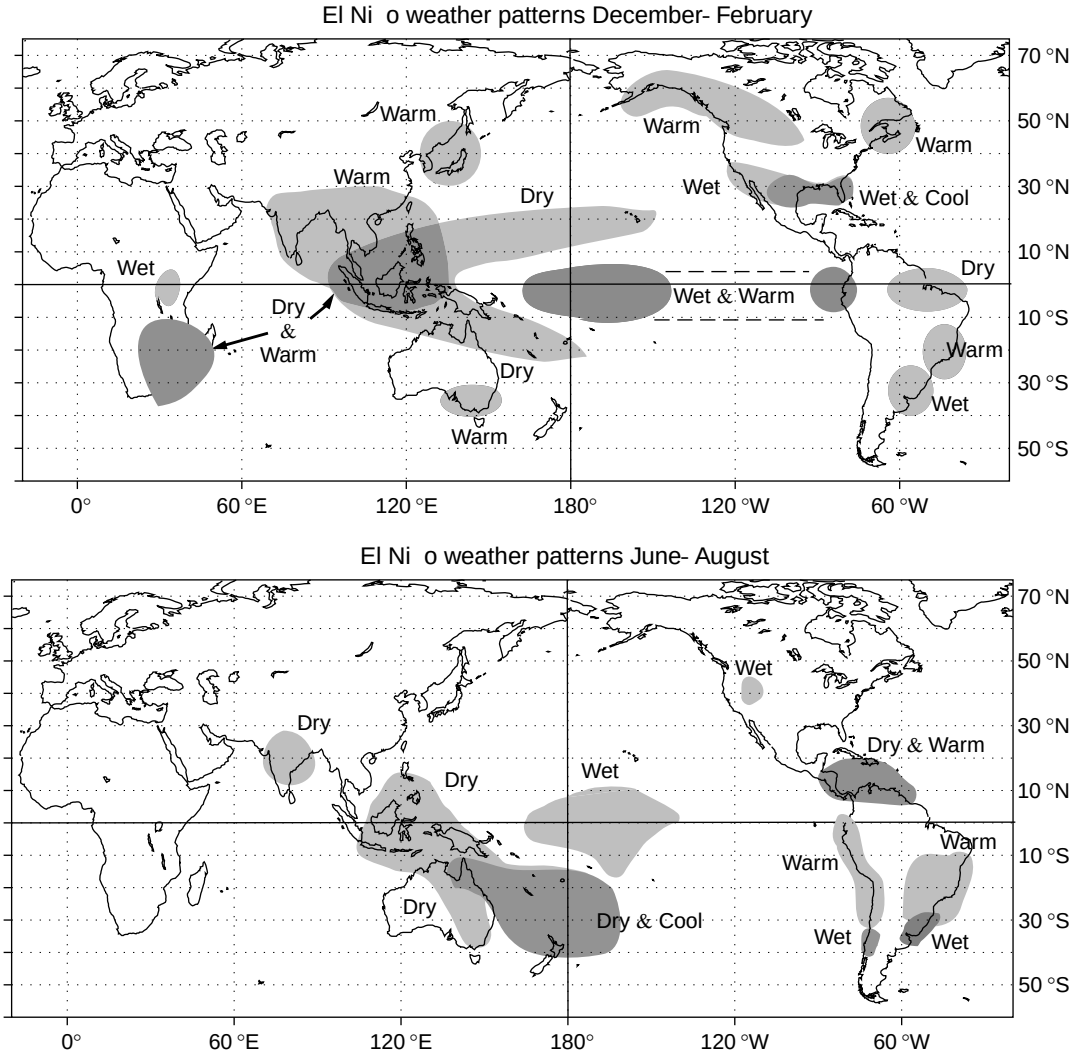

Figure 6 Schematic diagram showing temperature and precipitation anomalies associated with El Niño. To a first approximation, the impacts of La Niña are similar, but with opposite sign (Ropelewski and Halpert, 1987 and Halpert and Ropelewski, 1992)

El Niño also affects tropical storm frequency, intensity, and spatial distribution (Gray, 1984). In the Atlantic, 10 named tropical storms, of which six reach hurricane intensity (wind speeds greater than 33 ms^{-1}), form during a typical June to November hurricane season. However, during El Niño, an intensified subtropical jet stream shears off the top of fledgling storms before they fully develop. Thus, fewer tropical storms and hurricanes form, and those that do form tend to be weaker and shorter lived. The summer of 1997 was a particularly striking example of reduced Atlantic hurricane activity during El Niño. Only seven named storms formed, three of which reached hurricane intensity.

Intense tropical storms in other regions (referred to as hurricanes in the northeastern Pacific, typhoons in the northwestern Pacific, and cyclones in the Indian ocean and Southern Hemisphere) are affected more in terms of their spatial distribution and intensity than in terms of total numbers (*see* Hurricanes, Typhoons and other Tropical Storms - Descriptive Overview, Volume 1; Hurricanes, Typhoons and other Tropical Storms - Dynamics and Intensity, Volume 1). Heat from the underlying ocean surface is a major source of energy for intense tropical storms, which are almost always generated over waters warmer than 26 °C. Therefore, extensive warming of the eastern Pacific during El Niño allows hurricanes to travel farther westward and northward and, in some cases, attain greater strength. Similarly, the eastward extension of warm tropical surface waters along the equator during El Niño expands the area over which typhoons and cyclones may spawn. Changes that can occur in tropical storm activity in the eastern Pacific during El Niño are exemplified by the 1997 season when hurricane Linda grew to record strength and hurricane Nora tracked far to the north, bringing heavy rains to normally arid northern Mexico and the southwestern US. In the South Pacific during the 1982–1883 El Niño, ocean surface warming allowed six cyclones to strike French Polynesia, a region not usually prone to experiencing intense tropical storms (Canby, 1984).

El Niño affects the coastal zones of the Americas all the way to Alaska in the Northern Hemisphere and at least to central Chile in the Southern Hemisphere. When eastward propagating oceanic waves generated by weakening of the trade winds at the onset of El Niño reach the coast of South America, part of the wave energy is reflected back into the open ocean, but part also radiates northward and southward along the coasts. The coastal waves push the thermocline down and reduce the upwelling of cool water as they progress poleward. Within one to two months after the first equatorial waves reach South America, sea surface temperatures rise all along the coast to the north and south. North of central California, southerly surface winds related to the PNA pattern also contribute to coastal warming (Ramp *et al.*, 1997). These winds both bring warm subtropical air northward, and also drive on-shore ocean currents that converge at the coast to push the thermocline down.

The unusually thick layer of warm surface water along the west coast causes near shore sea levels to rise by 15–30 cm during El Niño. In addition, offshore winter storms associated with intensified jet streams in the subtropics can generate unusually high ocean swells and storm surges in coastal zones. Storm-generated surface waves and currents, and high tides, can add to already elevated sea levels high tides to cause severe coastal erosion. In communities with major shoreline development such as in southern California, the combined assault from high seas and heavy rains can lead to significant loss of property and life.

The impacts of El Niño on weather are most consistent from event to event in the tropical Pacific and bordering areas. Impacts are prominent, but less consistent, at higher latitudes and in other ocean basins where regional influences can become important. Thus, although El Niño increases the probability of a particular kind of weather pattern occurring in particular regions of the globe, actual impacts may vary from those expected for any given event (Trenberth *et al.*, 1998).

ECOSYSTEMS IMPACTS

Narrow coastal and equatorial upwelling zones account for much of the biological productivity in the world s oceans. One-celled plants known as phytoplankton are at the base of the aquatic food chain in these regions, and all higher organisms depend directly or indirectly on them as a food source. Upwelling ecosystems are rich in species diversity and abundance, including many types of phytoplankton, zooplankton, shellfish, crustaceans, fish, marine mammals, and sea birds. Many of the fish and shellfish species such as tuna, anchoveta, sardines, squid, and shrimp are valuable commercially.

Primary productivity is the rate at which carbon is taken up by phytoplankton via photosynthesis. Nutrient limitation controls primary productivity in tropical and subtropical regions where sunlight is plentiful. The principal source for nutrients, away from river outflows and areas of significant coastal runoff, is the thermocline. Small organisms that have died near the surface decay and remineralize as they slowly sink out of the euphotic zone (the well lit upper layer of the ocean). Fecal pellets from larger organisms likewise sink and decompose at depth. These processes create a pool of nutrients and remineralized carbon in the thermocline which, when upwelled into the euphotic zone, are available for uptake by phytoplankton. Lateral flows in the thermocline may bring nutrients and carbon from great distances before they are upwelled, concentrating primary production in narrow equatorial and coastal zones.

During El Niño, ocean dynamical processes depress the thermocline in the eastern and central equatorial Pacific, and along the coasts of North and South America. The supply of nutrients to the euphotic zone drops or may be cut off entirely. Primary production decreases, with effects that ripple through the entire food chain (Barber and Chavez, 1984). Zooplankton that feed on phytoplankton decrease in abundance. Fish, sea birds and marine mammals die off or migrate to more productive regions in search of food. Undernourished sea birds and marine mammals may experience reproductive failures or abandon young when food becomes scarce. In extreme cases, decimated populations may require one or more years to fully rebound.

El Niño can also cause bleaching of tropical corals when water temperatures become too warm (Strong *et al.*, 2000) (*see* Coral Reefs: an Ecosystem Subject to Multiple Environmental Threats, Volume 2 and Coral Bleaching (1997- 1998), Volume 2). Corals thrive in a narrow range of temperatures between about 18 and 28 °C. At temperatures above the upper threshold, they expel symbiotic algae that reside in their polyps. The algae add color to healthy corals, and their metabolic by-products are essential for coral survival. Coral can recover from bleaching unless water temperatures remain too high for too long. The concern over lethal bleaching is that it threatens the vitality of coral reef ecosystems, which support local fisheries and provide tourist income. Massive and widespread coral bleaching occurred during 1998 in the Galapagos Islands, off the coast of Panama, in the Great Barrier Reef of Australia and elsewhere in the tropics in response to the exceptionally strong 1997–1998 El Niño. Decadal warming trends in tropical ocean temperatures contributed to this bleaching, by elevating background temperatures on which El Niño warming was superimposed. These decadal trends, possibly related to global warming, have raised concerns about prolonged deterioration in the health of coral reefs.

El Niño can also dramatically affect fisheries, a particularly striking example of which was the collapse of the Peruvian anchoveta fishery following the 1972–1973 El Niño (Glantz, 2001). In the late 1960s and early 1970s, Peru was the most productive fishing nation in the world. The annual catch of anchoveta was over 10 million metric tons, one fifth of the global total. Most of the catch was exported for use as a feed supplement in poultry farms, with the exports accounting for nearly one third of Peru s foreign exchange earnings. Concerns were voiced at the time that overfishing might be depleting the stocks from sustainable levels. Those concerns proved to be well founded. Intense fishing pressure and extraordinarily high mortality rates during the 1972–1973 El Niño caused the fishery to crash. Effects were long lasting. For at least 10 years following the 1972–1973 El Niño, anchoveta landings ranged between only 1/10–1/3 the catch of 1970.

It was the collapse of the Peruvian anchoveta fishery that focused international attention on the socio-economic consequences of El Niño. A reduction in the supply of fishmeal caused many farmers in the US to switch from planting wheat to planting soybeans. Soy is an alternative source of poultry feed supplement and more lucrative than wheat as a cash crop. However, wheat harvests had declined in many nations, particularly the Soviet Union, because of widespread droughts in 1972. Staple food shortages developed in some regions and prices steeply increased for basic commodities in others. These events highlighted the role of climate in affecting global economies, and specifically focused attention on the need for a better understanding of the El Niño phenomenon.

DEVELOPMENT OF ENSO OBSERVING AND FORECASTING SYSTEMS

Research efforts in both oceanography and meteorology in the decade following the 1972–1973 El Niño gathered momentum, motivated by heightened awareness of El Niño s global socio-economic consequences, and the prospect that it might be predictable. It was recognized that advance warning of an impending El Niño would potentially be extremely valuable for either disaster preparedness or for exploiting opportunities created by altered environmental conditions. Thus, in the early 1980s, the international research community began mobilizing resources for a major 10-year study of El Niño. This study, called the Tropical Ocean-Global Atmosphere study, or (TOGA), took place from 1985–1994.

The 1982–1983 El Niño, the strongest in over 100 years, occurred as plans for TOGA were being formulated. This El Niño left a global swath of devastation in its wake. It had not been predicted because El Niño forecasting capabilities had not yet been developed. Even more stunning to the research community, however, was that it was not even detected until nearly at its peak. At the time, most oceanographic data were available for analysis only months, or in some cases years, after they had been collected. A handful of scattered but more readily available ocean and weather data from islands and volunteer observing ships suggested the development of unusually warm conditions in mid-1982, but these reports were discounted as erroneous. One reason was that the 1982–1983 El Niño developed differently than expected from conventional wisdom. There had been no prior strengthening of the trade winds, and no warming off the west coast of South America in early 1982, both considered at the time to be necessary precursors of an impending El Niño. To complicate matters, eruptions of the Mexican volcano El Chichón in March–April 1982 injected a massive cloud of aerosols (dust, soot, and other fine particles) into the lower stratosphere, where prevailing winds spread it around the globe at low latitudes within

weeks. This cloud of volcanic aerosols produced undetected cold biases of several degrees Celsius in satellite measurements of sea surface temperature. It was only after definitive reports were received from a research cruise in the eastern equatorial Pacific that the scientific community realized to what extent existing data sources and simplistic notions of El Niño evolution had misled them.

The lessons from this experience were clear: there was urgent need for improved monitoring, detection, and understanding of El Niño, as well as an urgent need to develop reliable El Niño forecast models. Observational requirements were met in part by utilizing data from a constellation of satellites viewing the Earth from space. However, satellites require Earth-based measurements for calibration and verification. Also, satellites do not see below the ocean surface, where critical oceanic processes operate to produce El Niño events. An ocean observing system specifically designed for El Niño was therefore developed under the auspices of the TOGA program (McPhaden *et al.*, 1998) (*see* TOGA (Tropical Ocean Global Atmosphere), Volume 1). It included an extensive network of moored buoys, drifting buoys, volunteer observing ships, and tide gauges (Figure 7). One of the most important attributes of this system was that most of the data were transmitted via satellite relay to shore stations within hours of collection. The observing system was implemented through an international collaborative effort spanning the full 10 years of TOGA, and was completed only in the last month of the program (December 1994). Continued after TOGA, it is now called the ENSO Observing System. The 1997–1998 El Niño was the first for which the ENSO Observing System was in place from start to finish, so that this event was not only among the strongest on record, but also the best ever documented (McPhaden, 1999).

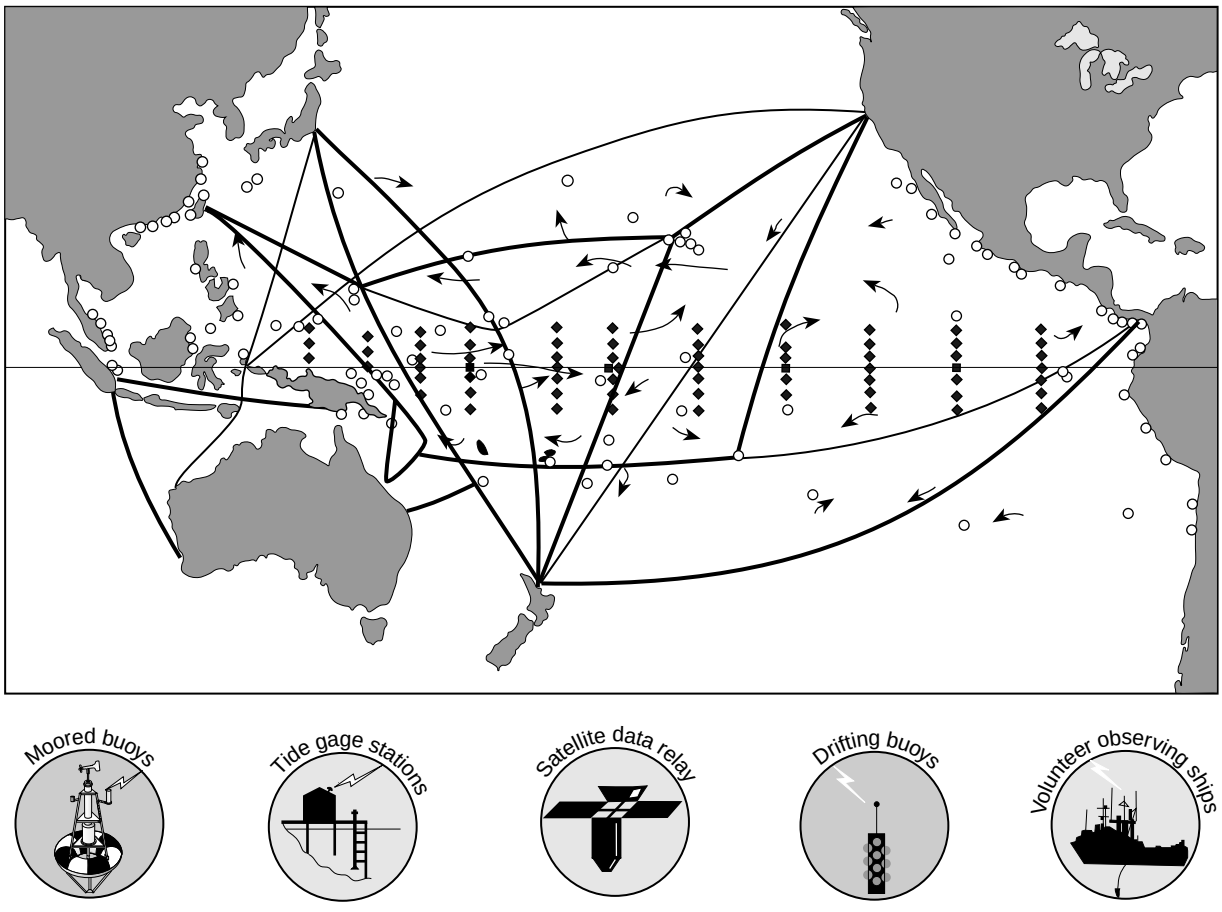

Figure 7 The ENSO Observing System. The four major elements of this observing system are; (1) a volunteer observing ship program for surface marine meteorological observations and ocean temperature profiles (shown by schematic ship tracks); (2) an island and coastal tide gauge network for sea level measurements (circles); (3) a drifting buoy network for sea surface temperatures and ocean currents (shown schematically by curved arrows); (4) a moored buoy array for wind, ocean temperature, and ocean current measurements (squares and diamonds). Thick ship tracks indicate repeat transects 11 or more times per year; thin ship track indicate repeat transects six to ten times per year. One schematic drifting buoy arrow represents 10 actual randomly distributed drifters (McPhaden *et al.*, 1998)

Progress in the development of the ENSO Observing System has been paralleled in the development of ENSO forecast models (National Research Council, 1996). These models range from statistical approaches based on the average behavior of previous ENSO variations, to complex dynamical models that explicitly represent the physical processes at work in the coupled ocean-atmosphere system. The 1986–1987 El Niño was the first to be successfully predicted with these techniques, which have since undergone continual refinement and improvement. As one measure of success, many ENSO forecast models predicted that 1997 would be unusually warm in the tropical Pacific at least one to three seasons in advance (Barnston *et al.*, 1999). Long-range weather forecasting schemes that included information about tropical Pacific conditions during the 1997–1998 El Niño likewise had success in predicting surface air temperature and precipitation patterns in widely disparate parts of the globe months in advance. For instance, the forecast for wintertime precipitation and temperature issued by the National Centers for Environmental Prediction in Washington, DC, in the fall of 1997 were among the most accurate ever for the continental US.

Successful seasonal forecasts, unprecedented high definition ocean measurements from the ENSO Observing System, and record warmth in the tropical Pacific all combined to capture the attention of the public in 1997–1998. Media coverage was so intense that El Niño became a household word all over the world. As a result of the heightened public awareness about El Niño and its consequences, many individuals, municipalities, businesses, and in some cases national governments mobilized resources in an effort to prepare for El Niño s onslaught. It is likely that without the advance warning made possible by new measurement and forecasting capabilities, the toll in terms of lives, property damage, and economic losses due to the 1997–1998 El Niño would have been much higher.

SOCIO-ECONOMIC IMPACTS OF THE 1997–1998 EL NIÑO

The 1997–1998 El Niño affected the lives of tens of millions of people around the globe. Significant disruptions were experienced in agriculture, forestry, fisheries, transportation, communications, power generation, public health and other climate-sensitive areas of human endeavor. Weather-related disasters and disease outbreaks during this El Niño claimed over 22 000 lives worldwide and caused US$36 billion dollars in economic losses (Sponberg, 1999).

The 1997–1998 El Niño brought torrential rainfalls and flooding to parts of California, the southeastern US, equatorial East Africa and Chile. It was also responsible for severe droughts in Papua New Guinea, Indonesia, Central America, and northeastern Brazil (Supplee, 1999; WMO, 1999). Many regions experienced extensive crop failures and livestock losses due to these droughts and floods. Life-threatening food and drinking water shortages developed in New Guinea, prompting international relief efforts. In some drought-stricken regions, forest fires raged for months, devastating the countryside. The drought and fires in Indonesia produced deadly smog that covered an area one half the size of the continental US, causing widespread respiratory ailments, and contributing to airline and shipping disasters. Unusually low water levels in the lakes that feed the Panama Canal forced officials to restrict traffic through the waterway for the first time in 15 years.

Flood-contaminated water supplies in some regions contributed to outbreaks of cholera and dysentery. Stagnant pools of floodwater also provided ideal breeding grounds for mosquitos and other insects that spread infectious diseases like malaria and dengue fever. Public health emergencies developed in Southeast Asia, South America, and Africa as these diseases afflicted thousands of people.

Heavy rains and flooding from El Niño damaged or destroyed roads, bridges, buildings and phone and power lines in many parts of the globe. Thousands of individuals and families lost homes and personal property due to storms, floods, mud slides and land slides. Hydroelectric energy generation was curtailed in regions of severely reduced rainfall and stream flow. Many business lost income as a result of weather-related closures, commodity shortages or shifts in market demand for consumer goods. Tourism was affected because of extreme weather in areas such as southern California and Florida. The catch of Peruvian anchoveta fell sharply as in previous El Niño years, and the fishery was briefly closed by government decree as a precautionary measure to limit further depletion of the remaining stock. Economic hardship followed severe declines in catch experienced in three of the four major fisheries (tuna, squid, sardine) off the west coast of Baja California.

Despite losses of life, property, and income, 1997–1998 El Niño produced some benefits as well (Changnon, 1999). Losses from Atlantic hurricanes were greatly reduced, as only one of three hurricanes that formed made landfall. Parts of the US Midwest and the Great Lakes region experienced the mildest winter in over 100 years, as temperatures warmed to record highs between November 1997 and February 1998. The milder than normal winter reduced heating bills, weather-related travel delays for the transportation industry, and deaths from exposure. It has been estimated that for the US as a whole, the 1997–1998 El Niño produced a net economic gain of about $16 billion dollars and resulted in 650 fewer deaths than would have otherwise occurred.

Similarly, not all fisheries were hit hard by the 1997–1998 El Niño. Though severe declines in most

commercial fisheries were experienced off the west coast of Baja California, these declines were partially offset by an eight-fold increase in the catch of more lucrative shrimp. Likewise, shrimp catch increased off the coast of Ecuador, with export revenues rising by 40% in 1997 (WMO, 1999). Northward migration of warm water fish species such as marlin, tuna and mahi-mahi was also a boom to the sport-fishing industry off the west coast of the US.

The 1997–1998 El Niño highlighted societal sensitivities and vulnerabilities to year-to-year climate fluctuations on a global scale. It also demonstrated that losses and gains are inherently unevenly distributed across economic sectors and national boundaries. Spurred in part by the dramatic consequences of this El Niño, new areas of interdisciplinary research are emerging to examine the use of El Niño-related climate information in economic planning and policy decisions. These efforts involve both social and physical scientists, with a focus on not only how forecasts are generated, but also how they are disseminated, interpreted, and acted upon.

LA NIÑA

La Niña is the cold phase of the ENSO cycle (Philander, 1990). It is characterized by stronger than normal trade winds, colder tropical Pacific sea surface temperatures, and positive values of the SOI (Figure 3). It represents a situation in which oceanic and atmospheric processes which give rise to normal conditions illustrated in Figure 4 are exaggerated, with deep convection and heavy rainfall along the equator shifted even further to the west and confined to a narrower range of longitudes. The term La Niña (*the girl*) was coined in the mid-1980s by scientists investigating the year-to-year oscillations between warm and cold conditions in the tropical Pacific. La Niña has also been referred to as anti-El Niño, ENSO cold event, and El Viejo (the old man). Like El Niño, La Niña typically lasts 12–18 months.

La Niña s effects on global weather variability are roughly (though not exactly) opposite to those of El Niño (Halpert and Ropelewski, 1992). The atmospheric response to weak-to-moderate cold and warm tropical Pacific sea surface temperature anomalies tends to be similar in magnitude, but opposite in sign. However, the atmospheric response to strong La Niña events tends to be weaker than the response to strong El Niño events. This difference arises because tropical rainfall (which translates into atmospheric heating and associated teleconnection patterns) has a lower limit of zero, regardless of how cold the tropical Pacific may get. On the other hand, the upper limit for rainfall and hence atmospheric heating during strong El Niño events is not as rigidly constrained.

Examples of La Niña weather impacts include an increased probability of unusually rainy conditions in southern Africa and northeastern Brazil, and in the monsoon regions of India, Indonesia and Northern Australia. La Niña is often linked to drier than normal conditions over equatorial East Africa, southern Brazil and Uruguay. The subtropical jet streams over the Pacific weaken, shift poleward, and become more variable in strength during La Niña winters. Blocking highs tend to develop in the eastern North Pacific, accompanied by more frequent cold polar air outbreaks over western North America. These changes in atmospheric pressure patterns and circulation result in winters that tend to be colder and stormier than normal over Alaska, western and central Canada, and the northern US. Conversely, the northward shift in the subtropical jet stream leads to warmer and drier than normal conditions in the southeastern US, and drier than normal conditions in the southern plains of the US.

La Niña, like El Niño, affects tropical storm frequency, intensity, and geographical distribution through changes in sea surface temperature and atmospheric circulation. Pacific hurricanes, typhoons and cyclones are more restricted in their geographical extent because of colder underlying sea surface temperatures. On the other hand, Atlantic hurricanes tend to increase in number as the subtropical jet stream shifts northward, reducing the shear between upper and lower level tropospheric winds where hurricanes form. The 1995 Atlantic hurricane season is a good example of what can happen during La Niña. That year witnessed a bumper crop of 19 named tropical Atlantic storms, including 11 hurricanes, almost double the usual number.

La Niña s socio-economic impacts can be as impressive as those resulting from El Niño. La Niña-related drought and heat waves in the US Midwest during the summer of 1988 constituted one of the worst natural disasters in US history, causing US$40 billion in agricultural and other losses, and claiming approximately 7500 lives from heat stress. Also, with more and stronger Atlantic hurricanes during La Niña, their destructive potential and probability of making landfall in populated regions increases. For the US, it is three times more likely that an intense hurricane will make landfall during a La Niña than during an El Niño. Hurricane Mitch, one of the strongest Atlantic hurricanes on record and the deadliest in 200 years, was spawned during the 1998 La Niña. Mitch devastated Central America, claiming 10 000 lives, leaving over three million homeless, and causing US$6 billion in damage.

La Niña can also be beneficial to some regions of the globe. For instance, higher monsoon rainfall totals over the Indian subcontinent, the western Pacific, and northeastern Brazil can support greater agricultural production and economic growth. Enhanced winter snowpack

in the mountains of the Pacific Northwest provide for extra hydroelectric power production, ample summer water supplies, and improved freshwater habitat for salmon. In terms of marine ecosystems, primary productivity, driven by more intense equatorial and coastal upwelling, is generally enhanced. Higher-level marine organisms tend to thrive under these conditions, and severe disruptions in fisheries, like those during El Niño, are not so evident.

DECADAL VARIATIONS AND GLOBAL WARMING

The frequency and amplitude of El Niño and La Niña events are modulated on decadal and longer time scales. The 1930s to the early 1950s, for example, was a period of relatively few El Niños, while the period since 1976 has witnessed more frequent, stronger, and in the case of 1991–1995, longer lasting El Niños. In addition, the magnitude of the strongest El Niños over the past 50 years seems to be increasing while at the same time there has been a trend toward fewer La Niña events (Figure 3).

Variations in the ENSO cycle may simply be a result of random or chaotic fluctuations in the Earth s highly complex climate system. However, there may be other factors at work as well. Temperatures have been elevated in the tropical Pacific since the mid-1970s in association with a recently discovered, naturally occurring phenomenon known as the Pacific Decadal Oscillation, or (PDO) (Mantua *et al.*, 1997) (*see* Paci c- Decadal Oscillation, Volume 1). This oscillation alternates between phases of warm and cold tropical Pacific sea temperatures lasting 20–25 years. The physical mechanisms that account for the PDO are at present poorly understood. However, the PDO affects the background oceanographic and atmospheric conditions on which ENSO events develop. Warm phase PDO and El Niño sea surface temperature anomalies are roughly additive. Under these conditions, the global atmospheric teleconnection patterns set up by elevated tropical Pacific sea surface temperatures can be amplified.

In addition to naturally occurring phenomena such as the PDO, global warming may also affect the ENSO cycle (Trenberth and Hoar, 1996). The warmest years on record were 1998 and 1997, in that order. Occurrence of 1997–1998 El Niño contributed in part to these extremes, because global temperatures rise a few tenths of a degree Celsius following the peak El Niño warming in the tropical Pacific. However, aside from the record warmth in 1997–1998, there has been an underlying trend toward increased globally averaged air temperatures of about 0.6 °C over the past century. Moreover, tree ring and ice core data indicate that the 20th century has been the warmest century and the 1990s has been the warmest decade over the past millennium. The consensus of the scientific community at present is that the recent increase in global temperatures is human-induced through fossil fuel combustion and deforestation (Houghton *et al.*, 1996).

It is reasonable to assume that anthropogenic greenhouse gas warming will affect ENSO because both phenomena are involved in regulating the Earth s heat balance. In addition, an altered ENSO cycle may leave its imprint on the global carbon balance (see Box 3) and on patterns of regional climate change. If global warming were to lead to intensified, more frequent, or prolonged El Niños, those regions affected by El Niño-related drought or flood in the present climate might well be more prone to such natural disasters in the future. How global warming may affect ENSO and other natural modes of climate variability is not known at present though. Computer models used for developing scenarios of how the Earth s climate will change in response to elevated levels of carbon dioxide (CO_2) and other greenhouse gases in the atmosphere differ on how the tropical Pacific Ocean will be affected (Meehl *et al.*, 2000). Many coupled ocean-atmosphere models predict a permanent El Niño-like warming of the tropical Pacific due to increased forcing from greenhouse gases. Some models also exhibit more energetic and higher frequency year-to-year ENSO-like fluctuations superimposed on this permanent warming. However, realistic greenhouse gas forcing in other models can lead to quite different scenarios. The differences among model simulations arise in part because results are very sensitive to the representation of poorly understood but critical processes such as the formation of clouds and their radiative feedbacks on the global energy balance, and the transport of heat by ocean currents and turbulent mixing. Thus, uncertainties in the simulated effects of global warming on ENSO and ENSO-like variability are large, and further model improvements are required to gain confidence in the details of future climate projections based on such simulations.

Instrumental records have also been studied extensively for clues about the relation between ENSO and global warming. Unfortunately, these records are limited to the past 100–150 years, and are too short to describe the full range of natural climatic variability on inter-annual and decadal time scales. Thus, from instrumental data alone it is not possible to unambiguously answer the question of whether the unusual character of ENSO during the past 25 years is within the range expected for natural variations, or whether it is anthropogenically forced. On the other hand, paleoclimatic reconstruction based on proxy data allow for investigation of ENSO variability from periods predating the instrumental record. For example, year-to-year fluctuations in the Earth s climate are evident in New England lake sediments dating from near the end of the last ice age (15 000 years before present) when the Earth was cooler (Rittenour *et al.*, 2000), and

Box 3 El Niño and the Global Carbon Cycle (*see* **Carbon Cycle**, Volume 2)

Each year, seven billion tons of carbon in the form of CO_2 are released into the atmosphere from anthropogenic sources. About half this amount remains in the atmosphere, while the other half is taken up approximately equally by the ocean and the terrestrial biosphere. Ocean uptake occurs at high latitudes where the deep waters of the world's oceans form. Uptake also occurs in the subtropics where surface waters are carried down into the thermocline.

The tropical oceans are a major source of CO_2 to the atmosphere, with the Pacific Ocean dominant because of its great size. Equatorial upwelling outgases about one billion tons of carbon in the form of CO_2 per year into the atmosphere, as water rich in inorganic carbon is brought up from the thermocline to the surface. The amount of carbon released to the atmosphere in the equatorial Pacific would be even higher were it not for photosynthesis, which converts one billion tons of upwelled inorganic carbon each year into living organisms.

Year-to-year variability in global atmospheric carbon concentrations is dominated by the ENSO cycle (Rayner *et al.*, 1999). During El Niño, equatorial upwelling is suppressed in the eastern and central Pacific, significantly reducing the supply of CO_2 to the atmosphere oceanic (Feely *et al.*, 2000). As a result, the global rise in CO_2 noticeably slows down during the early stages of an El Niño event. However, during the later stages of El Niño, global CO_2 concentrations rise sharply, possibly reflecting the delayed response of the terrestrial biosphere to El Niño-induced changes in weather patterns. Widespread droughts and elevated temperatures in the tropics during El Niño contribute to an increase in the number of forest fires, modifying the balance between respiration and photosynthetic uptake of CO_2 in land plants. These processes could result in an anomalous increase in the supply of CO_2 to the atmosphere sufficient to override the reduction in CO_2 from decreased equatorial upwelling.

In addition to year-to-year variations, lower frequency changes in the ENSO cycle can affect the global atmospheric carbon balance. In particular, the 1990s was an unusual decade in that it witnessed both a prolonged El Niño in 1991–1995 and an extraordinarily strong El Niño in 1997–1998. These El Niño events resulted in an overall decrease of oceanic input to the atmosphere of about two to three billion tons of carbon during the 1990s relative to the 1980s (Feely *et al.*, 2000).

in fossil Pacific coral records from the last interglacial period (124 000 years before present) when the Earth was slightly warmer (Hughen *et al.*, 1999). These and other proxy records exhibit decadal modulations in the amplitude of ENSO time scale variations similar to those observed today. Moreover, compared to some coral climate reconstructions, the increased frequency and strength of El Niño events since 1975 could be considered unusual relative to earlier epochs.

However, using paleocliamtic data as a benchmark for evaluating global warming effects in the modern ENSO record is complicated by the fact that background climatic conditions on which ENSO developed during earlier periods of the earth s history have frequently been very different from those which exist today (Tudhope *et al.*, 2001). A further complication is that there are relatively few reliable proxy records capable of defining year-to-year variations in the distant past, and those records are sparsely distributed in both space and time. Finally, the information in proxy records is subject to contamination by non-climatic chemical, biological and physical changes related to micro-environmental factors. Therefore, conclusions based on comparisons with proxy data about the effects of global warming on the ENSO cycle are subject to considerable uncertainty at this time.

CONCLUSION

The dramatic 1997–1998 El Niño highlighted progress made in ENSO research and forecasting since the pioneering work of Bjerknes nearly four decades ago. New observational techniques now allow us to take the pulse of the tropical Pacific day-by-day, and computer forecast models can predict the broad outlines of ENSO-related climatic perturbations up to one year in advance. The accuracy of these models is sufficient in some cases to allow for practical applications of forecast information for planning and mitigation purposes.

These scientific advances, though impressive, are just the beginning. Theories and observations have illuminated many basic features of the ENSO cycle, but fundamental questions such as why the trade winds initially weaken at the onset of El Niño still appear to have no simple answer. How ENSO interacts with the PDO and how it may be affected by global warming are not at present well understood. Though satellites can monitor the globe from space, comprehensive ocean-based observational networks as required for climate research and prediction are limited primarily to the tropical Pacific. This limitation hinders attempts to examine interactions between the ocean and the atmosphere in regions outside the tropical Pacific where important physical processes may affect, or be affected by, ENSO variations.

ENSO forecast systems are in their infancy, in some ways analogous to the early stages of numerical weather forecasting 40 years ago. As might be expected, despite the many seasonal forecasting successes during 1997–1998, there were notable failures. None of the forecast models predicted the ultimate intensity of the El Niño before its onset, and one previously successful model failed completely.

Similarly, predictions of severe drought in Australia and Zimbabwe, and reduced summer monsoon rainfall over India, proved to be erroneous. The reasons for these failures have yet to be fully determined.

The oscillation between warm, neutral, and cold states in the tropical Pacific associated with the ENSO cycle involves massive redistributions of upper ocean heat content. For instance, the accumulation of excess heat in the eastern Pacific due to the eastward movement of warm water and to the depression of the thermocline during a strong El Niño is approximately equivalent to the output of a million 1000 megawatt power plants operating continuously for a year. The magnitude of these natural variations clearly indicates that society cannot hope to consciously control or modify the ENSO cycle. Rather, we must learn to better predict it, and to adapt to its consequences.

The challenge for physical scientists then is to improve ENSO forecast models, to improve our understanding of underlying physical processes at work in the climate system, and to improve the observational data base in support of these objectives. Capitalizing on advances in the physical sciences for practical purposes is a challenge for social scientists, economists, politicians, business leaders, and the citizenry of those countries affected by ENSO variations. The promise of the future is that continued research on ENSO and related problems will be rewarded with scientific breakthroughs that translate into a broad range of applications for the benefit of society.

El Niño/Southern Oscillation (ENSO)

Collectively, El Niño, La Niña, and the *Southern Oscillation* are referred to as El Niño/Southern Oscillation, or ENSO for short. These phenomena are intimately related and arise from coupled interactions between the atmosphere and the ocean in the tropical Pacific. El Niño is sometimes referred to as the warm phase of ENSO and La Niña the cold phase of ENSO. The ENSO cycle is irregular, having a period of roughly 3–5 years, with individual El Niño and La Niña events lasting typically 12–18 months (*see* El Niño and La Niña: Causes and Global Consequences, Volume 1). Shifts in tropical rainfall patterns associated with ENSO result in anomalous tropospheric heating that alters the global atmospheric circulation, producing droughts, floods, unusual storminess, heat waves and other weather extremes in many regions of the globe. The social, economic, and public health consequences of ENSO-related climate variability have motivated coordinated international efforts since the mid-1980s to better understand, monitor, and predict the evolution of the ENSO cycle.

Energy Balance and Climate

Gerald R North
Texas A and M University, College Station, TX, USA

The global average temperature of the Earth changes little from year to year. Until the 20th century, during which the global average temperature warmed by more than 0.60 °C, paleoclimatological evidence from the last 10 000 years suggests that even over hundreds of years the planet's average temperature has not changed by more than about 0.25 °C. One reason for this stability is the powerful constraint imposed by the conservation of energy. The global and annual average temperature is determined by a balance of the rate of solar radiated energy being absorbed by the planet and the rate of infrared radiant energy being emitted from the top of the atmosphere to space. The energy balance of these streams of radiation into and out of the system in part determine the present climate and its sensitivity to system perturbations, such as changes in the solar brightness.

BALANCING THE STREAMS OF SOLAR AND INFRARED RADIATION

The Earth s energy balance is determined by considering the incoming energy from the Sun and the outgoing energy from the Earth. If the planet is in thermal equilibrium with these flows of energy (which typically occurs when the climate is stable), the planet s annual average rates of absorption and emission will be the same.

The amount of solar radiation reaching the Earth at its average distance from the Sun (averaged through the year) is approximately $1365\,\mathrm{W\,m^{-2}\,s^{-1}}$. Satellite measurements indicate that about 70% of this radiation is absorbed by the surface-atmosphere system, the rest being reflected directly back to space, giving the Earth system an albedo of about 30%. Bright areas such as deserts, white cloud tops and ice fields are highly reflective, whereas darker areas such as forests are absorbing. In addition, some solar radiation is absorbed as it passes through the atmosphere itself by such constituents as water vapor and (black) soot particles. Most of the solar radiation that is absorbed, however, is absorbed at the ground or ocean surface. When the radiation is absorbed at the surface, it warms the immediate surroundings, including the surface material (e.g., soils, ocean waters), the overlying air, etc. This local warming can set off many different responses, including raising the local temperature, causing evaporation of wet surfaces, initiating convection, and causing the emission of thermal infrared radiation.

All material bodies radiate and absorb electromagnetic energy due to collisions and other accelerations experienced in the randomized translational, vibrational and rotational motions of the molecules comprising the body. The radiation emitted from a material surface surrounding such a mass is called *thermal radiation*. An important feature of thermal radiation is its distribution of power as a function of wavelength. The amount of thermal radiation that is released depends on the nature of the material surface (or composition of the emitting gas). An *ideal black body* (sometimes called a perfect black body) is a material substance whose surface behaves in such a way that any electromagnetic radiation impinging on it is totally absorbed. The Stefan–Boltzmann Law of thermal radiation states that the rate of radiation energy per unit surface area from a black body is proportional to the fourth power of the absolute temperature (in Kelvins, or K; 0 K is −273•2 °C). As a result, warm bodies emit far more radiation than cool ones.

The power distribution or spectrum for black bodies was first explained by the German physicist Max Planck at the end of the 19th century; Planck s discovery marked the birth of the quantum theory. According to this distribution, radiation from hot bodies tends to be concentrated in shorter wavelengths and that from cooler bodies in longer wavelengths. An example of this is the radiation from a body as hot as the Sun. The effective radiating temperature of the Sun is about 5000 K, although at longer wavelengths the effective radiating temperature is closer to 6000 K. These temperatures lead to radiation across the visible part of the spectrum. Overall, the solar radiation distribution is somewhat bell shaped and peaked at a wavelength of about 0.5 μm. This kind of electromagnetic radiation or light is visible to the eye and its perceived color is white (with a slight emphasis toward yellow in that it is peaked near the center of the visible spectrum). Somewhat cooler bodies such as glowing embers and burning flames (with temperatures of 1500–2000 K) have their peaks in the red part of the visible spectrum, whereas warmer bodies such as very bright stars have their peaks in the blue part of the visible spectrum. For a much cooler body such as the Earth, which has a surface temperature of about 288 K (about 15 °C), the peak of the radiation distribution is about 10 μm, which is in the wavelength region called the *infrared*. The infrared portion of the electromagnetic spectrum is not visible to the naked eye, but can easily be detected by such common devices as infrared cameras, etc. Figure 1 shows two distributions, one from a 5000 K black surface the other from a 300 K black surface.

Kirchhoff s Law states that a black body is both a maximal absorber and maximal emitter of electromagnetic radiation for a given temperature; that is, good emitters are good absorbers and good absorbers are good emitters. However, not all bodies are perfect black bodies. A non-black body will absorb and emit only a fraction of impinging radiation. The fraction of the black body radiation that is emitted is termed the surface s *emissivity*. Because of a

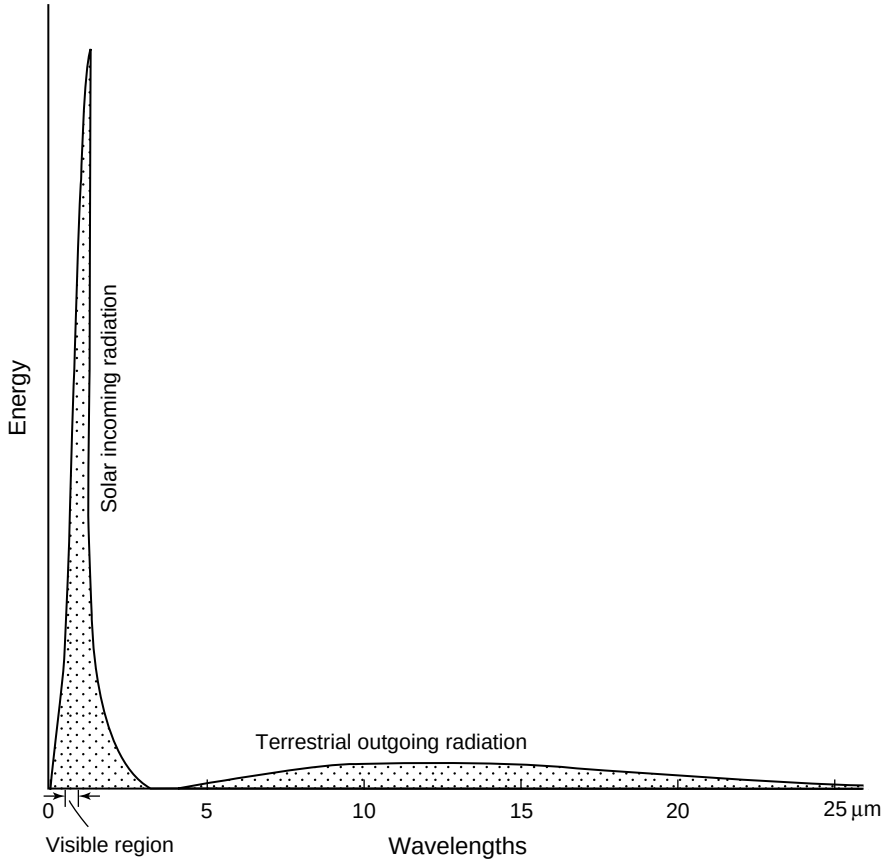

Figure 1 Two distributions, one from a 5000 K black surface the other from a 300 K black surface

material s characteristics, these relationships can be a function of the wavelength of the radiation. That is, because of the properties of a material, a body or layer of gas might have a low absorptivity in the visible part of the spectrum and a high value in the infrared or *vice versa*. For the atmosphere–surface system, there is a complex mixture of situations.

THERMAL RADIATION FROM THE EARTH

The infrared radiation originating in the surface–atmosphere system and eventually released to space has a number of sources and typically goes through a number of absorption and re-emission cycles (*see* Infrared Radiation, Volume 1). Consider first the emission from the ground. By cooling of the surface, this emission causes the transfer of radiation upwards in the atmosphere. Some of the upwelling infrared radiation is absorbed by various greenhouse gases in the atmosphere (a greenhouse gas is one which is largely non-absorbing of radiation with wavelengths in the visible, but generally strongly absorbing of radiation with wavelengths in the infrared). The most important of these greenhouse gases is water vapor, which is confined mainly to the lowest few kilometers of the atmosphere because at higher levels the air is so cold that condensation of water vapor leads to its precipitation out of the atmosphere as rain or snow. Another important absorber of infrared radiation is carbon dioxide, which is present uniformly throughout the atmosphere in concentrations of about 370 parts per million by volume. Other trace gases, including ozone, methane, nitrous oxide, and the halocarbons are also gases that absorb and emit infrared radiation. In addition, clouds are very important, both because they scatter solar radiation and because they act like black bodies in the infrared portion of the electromagnetic spectrum, both absorbing and emitting infrared radiation.

It is important at this point to note that the temperature of the atmosphere decreases with altitude in the troposphere at a rate of about $6\,\mathrm{K\,km^{-1}}$ (this rate is called the *atmospheric lapse rate*; *see* Lapse Rate, Volume 1). Because of the atmospheric absorption and reemission of infrared radiation by greenhouse gases and clouds, the emission to space from the surface–atmosphere system appears, because of its variation in wavelength, to have the appearance of being emitted by a body at a temperature that is cooler than the surface. Averaged over wavelength, this effective radiating altitude is roughly 5 km. Thus, while most of the emission

begins at the surface, some of it is absorbed and re-emitted, often several times, as it makes its way out of the system. As a result, the effective emission temperature to space is that of the air about 5 km above the surface where it is typically about 30 K cooler than at the surface. Hence, the effective emission temperature is considerably less than the surface temperature.

ESTIMATION OF PLANETARY TEMPERATURE

Based on this reasoning, a very simple model of the planetary temperature can be constructed. The rate at which solar radiation absorbed by the surface–atmosphere system is 1365 $W m^{-2} s^{-1}$ times 0.70 (this latter factor, the fraction absorbed is called the planetary co-albedo) gives a net absorption of solar radiation of 956 $W m^{-2} s^{-1}$. The cross-section of the planet as seen by the Sun is a disk, but the total energy absorbed is spread over the entire surface of the sphere. Thus, the actual amount of energy absorbed per square meter averaged over the Earth is one quarter of the absorbed amount of a surface directly facing the Sun; that is, average absorption is about 238 $W m^{-2} s^{-1}$. The Stefan–Boltzmann Law can then be used to determine the temperature of a black body that would emit this much energy per square meter per second. Insertion of this radiation rate into the Stefan–Boltzmann formula leads to a radiating temperature of about 255 K. Using the effective altitude of emission of 5 km, we can then apply the standard lapse rate of the atmosphere to obtain a surface temperature of about 285 K (about 13 °C), which is in very good agreement with the Earth s observed global average surface temperature (which is close to 15 °C). Readers should appreciate that this is not a rigorous theory of the planetary average temperature, but rather a check on the consistency of such assumptions as the 5 km effective emission altitude, as well as the other assumptions such as uniform lapse rate.

LATITUDINAL DISTRIBUTION OF THE ENERGY BUDGET

Figure 2 shows a schematic graph of absorbed incoming and emitted outgoing radiation energy ($W m^{-2}$). The information is averaged around the Earth s latitude circles (zonal averages). The curves indicate that the outgoing and incoming radiation rates do not balance latitude by latitude. The outgoing radiation rate at the poles exceeds the incoming rate of radiation absorbed while the reverse is true in the tropical latitudes. For this to be sustained over time, there must be a net transport of heat from the equatorial latitudes towards the poles by the ocean–atmosphere system.

One can proceed to make a model of the zonal average temperatures. Consider, for example, finite width strips around the planet parallel to the latitude circles in the Northern Hemisphere. The energy budget for the strip consists of four terms: (1) the absorbed solar radiation in the strip; (2) the outgoing radiation to space leaving the area in the strip; (3) the incoming stream of heat entering the strip from the south; and (4) the outgoing stream of heat leaving the strip to the north. Terms (1) and (2) depend upon the absorption and emission characteristics of the surface–atmosphere system in the strip, which involve the amount and types of cloud, snow cover, lapse rate, etc. Terms (3) and (4) depend upon heat conduction via the motions of the atmosphere and the ocean, which on the average carry warm parcels of air and water poleward and cool parcels equatorward. To actually compute these transport terms the detailed motions of the atmosphere and ocean have to be included. This can be done in a number of ways. For example, the transport terms can be estimated by constructing a mathematical system based on highly simplified assumptions such as making the average north–south heat transport by the atmosphere–ocean system proportional to the north–south temperature gradient (i.e., proportional to the difference between average temperatures in neighboring strips divided by their latitudinal width). This means the flow northwards across the southern edge of the strip is proportional to the local slope of the (zonal average) surface temperature, and likewise for the flow of heat out of the strip to the north. Such a simplifying assumption allows the entire problem to be cast in terms of the surface temperature as a function of latitude. The proportionality factor to convert temperature gradient into heat flow can, for example, be an empirically or phenomenologically determined macro-scale thermal conductivity that is derived based on fitting available observations of temperature and energy flows. Using such a model, one can then solve the model for the zonally averaged surface temperature, and for changes that might occur given a range of variations in factors affecting the energy flows. Models of this type are called *energy balance climate models* (EBCMs) and have been used extensively over the last 25 years as guides in the problem of climate change (*see* Energy Balance Climate Models, Volume 1).

However, EBCMs are not dynamical models and they cannot handle such subtleties as changes in atmospheric circulation, cloud cover and cloud type. Theoretically, these are important omissions because clouds, water vapor concentrations and other factors change as climate changes. The only way to include such changes is through invocation of additional conservation laws beyond just the conservation of energy. A minimal set of principles to include involves:

1. the conservation of momentum (Newton s Second Law for the atmosphere–ocean fluid parcels; i.e., each parcel is accelerated by the vector sum of forces acting on it);

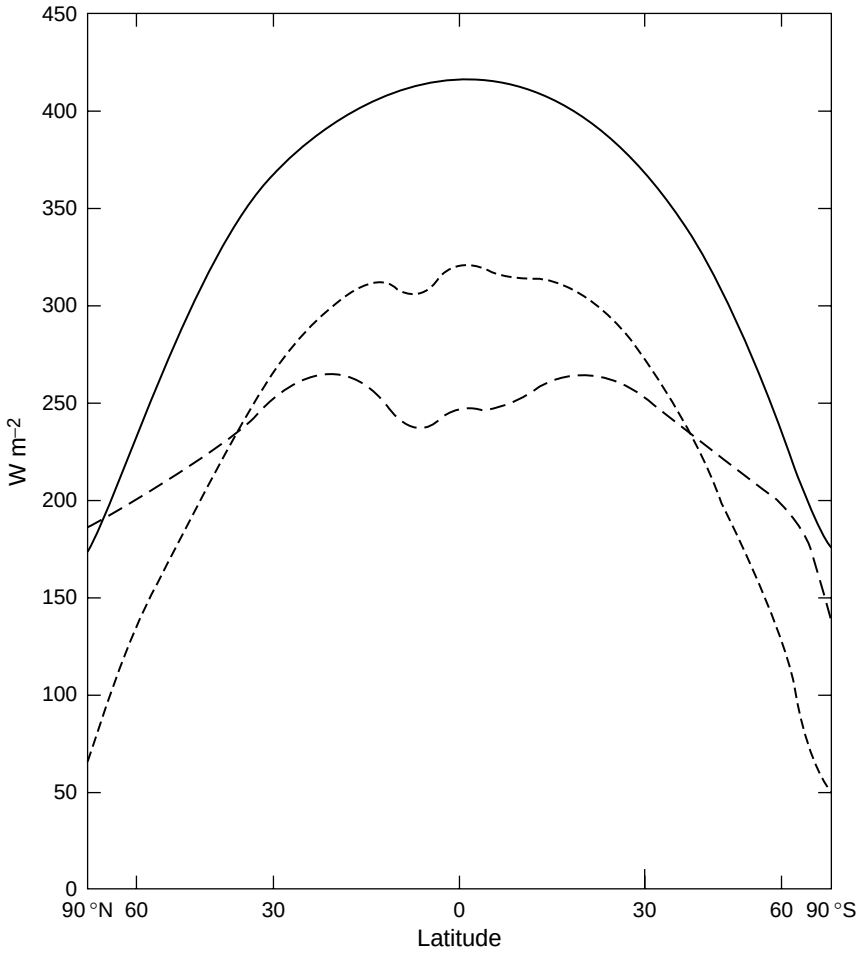

Figure 2 Zonal and annual mean radiation budget for the atmosphere. The solid curve is the net amount of radiation reaching the top of the atmosphere. The short-dashed line indicates the amount of radiation that is absorbed by the land, atmosphere, and ocean. The long-dashed line is the net longwave emission back to space. (These data are from the Earth Radiation Budget Experiment for the period February 1985 through January 1986)

2. compliance with the First and Second Laws of Thermodynamics (the sum of all forms of energy is conserved for a closed system and the entropy of a system and its surroundings always increases or stays the same in a transition);
3. the conservation of water substance in its several forms; vapor, liquid and solid surface water and cloud particles;
4. conservation of the mass of air and other materials, which acts as a constraining equation.

A model that includes these features is called a *general circulation model* (GCM). The GCM might include the motions and thermodynamics of the ocean as well as the atmosphere and ice components.

In order to implement a GCM, one needs to partition the atmosphere (and/or ocean) into small boxes fixed in space, each being a small accounting center wherein the budgets of all the relevant quantities (atmospheric or oceanic pressure, temperature, ocean salinity, wind or current speed and direction, etc.) are tracked. In modern simulations with GCMs, millions of quantities are computed for each time step in the calculation. Obviously, the simulation of a climate with given external conditions (solar constant, greenhouse gas composition, etc.) requires very fast computers with large storage capacity. The detail of such a simulation is generally limited by the availability of computing resources.

Climate simulations with GCMs require two steps. First, one must establish a control climate; i.e., a simulation of the climate under given fixed conditions. As the simulation proceeds, one finds that there is considerable natural variability, as evidenced by the quasi-random fluctuations that are common in nonlinear dynamical systems. Because of this natural variability, simulations (called control runs) to establish equilibrium conditions must typically span hundreds to thousands of years to establish baseline statistics for the control climate. The next step is to perturb the climate with a scenario of future change or, in a pure

sensitivity experiment, to change one control parameter and wait for the new equilibrium climate to establish itself. In these cases, it is often necessary to perform either a very long control run at the new parameter values or, in the case of a time dependent scenario, to perform many realizations of the experiment in order to get a statistically rigorous estimate of the rate of change. The realizations (often called an ensemble) can be averaged to obtain a probable scenario of the response of the model to the external perturbation. If the control runs are sufficiently long and/or the number of realizations are sufficiently many, the change of climate under various perturbations can be estimated.

CLIMATE SENSITIVITY

To get a sense of the sensitivity of the climate to changes in various parameters, it is useful to consider certain hypothetical standard experiments one might perform on the Earth system if one could isolate it in a laboratory (*see* Climate Sensitivity, Volume 1). One such hypothetical experiment is to consider the effect on global average temperature of an increase in the solar constant of 1%. In the case of a black body with no atmosphere, the change can be calculated from simple energy balance equations, and the result if a warming of about 0.6 K. As the actual conditions of the surface–atmosphere system are added to the calculation of sensitivity, complexities arise deriving from the subtle mechanisms operating in the atmospheric column. For example, the presence of greenhouse gases, such as naturally occurring water vapor in the column of air, lead to an increase in the estimated sensitivity. The way this increase manifests itself depends on many details of atmospheric physics. For example, because the emission to space effectively comes from an altitude of about 5 km, the behavior of the lapse rate and other mechanisms controlling the surface temperature are critical. While the change at 5 km might be about 0.6 K, the behavior at the surface might, for example, be very different. The connection between the temperature at 5 km and the surface is mediated by a number of processes, including downwelling as well as upwelling infrared radiation from one layer to another; warming and cooling at the surface; convection of sensible heat by vertical motions of buoyant air (which tends to cool the surface and warm the air above); evaporation of water from the surface and recondensation above in clouds (which also cools the surface and warms the air above); advection (horizontal displacement of air) of air from other locations that changes the vertical temperature structure of the atmosphere; and change in turn of the lapse rate. Other subtle changes such as changes of cloud cover aloft or of the condition of ice and snow at the surface can also be factors in the change of surface temperature for a 1% change of solar constant. This multitude of factors that can intervene to alter the sensitivity from that of a black body are called *feedback mechanisms* (*see* Feedbacks, Chemistry - Climate Interactions, Volume 1).

Because more water vapor will be evaporated, it is generally thought that the concentration of water vapor in the lowest few kilometers will increase if the surface temperature is increased, with the relative humidity remaining roughly constant. This is generally observed to be the case in seasonal changes of the climate and is verified by most GCM simulations that include water vapor as an interactive constituent. With more water vapor in the atmosphere, the absorption of outgoing infrared radiation is increased, leading to increased downward radiation to the surface, causing a warming. Simulations with GCMs as well as simpler models suggest that this positive (because it is amplifying) water vapor feedback mechanism, may be responsible for doubling the sensitivity of global average surface temperature, to such external influences as changes in the solar constant or doubling the concentration of the carbon dioxide concentration.

Another rather simple feedback mechanism is that of snow and ice. One part of this feedback involves the strong effect of snow and ice cover on planetary albedo. This feedback can be illustrated by considering a simple model of the planet with ice caps at the poles. If the surface temperature drops because of, for example, the presence of a dust veil overhead, the area of the ice caps would grow, leading to an increased albedo. Through this mechanism, the initial cooling of the surface leads to a more reflective planet and then further cooling. This particular positive feedback mechanism is somewhat less strong than that due to water vapor primarily because the present ice caps are so small (for colder conditions when the ice caps are more extensive, this feedback can become relatively larger). Nevertheless, it illustrates how rather simple physical processes at the global level can enhance the climate sensitivity.

There are many other feedback mechanisms, the most troublesome of which is the cloudiness (*see* Cloud - Radiation Interactions, Volume 1). Clouds cover on the average about 50% of the planet in the present climate. Clouds affect the incoming solar radiation by being highly reflective; hence, more clouds mean a cooler climate. But clouds also act as an absorber and re-emitter of infrared radiation, leading to a warming influence at the surface. The two effects nearly cancel over much of the Earth, the altitude of the cloud top often determining the local winter. All this means that if the cloudiness properties (percent coverage, height of tops, size of droplets, etc.) change in the course of a forced climate change, the feedbacks could be very subtle indeed. The challenge of determining the net effects of these competing influences is that the mechanisms which might cause these properties of cloud to change are governed by

processes that operate on scales that are finer than can be resolved by the grid structure used in GCMs. This leads to some extremely difficult problems for climate researchers, and even the sign of cloud feedback is not certain.

Based on a wide range of GCM experiments and from analogues derived from past climatic behavior, the sensitivity of the climate to a doubling of carbon dioxide (roughly equivalent to a 2% increase in the solar constant) has been estimated since the late 1970s to be in the range of 1.5–4.5 K, indicating an uncertainty of about 50% (i.e., $3 \pm 1{\bullet}5$ K). Because of the difficulties in incorporating the feedback mechanisms, refining this estimate will be the subject of continued research for many years to come.

See also: Chaos and Predictability, Volume 1.

SUMMARY

Considering the Earth s energy flows and energy balance is a very powerful way of understanding the climate. Averaged through the year, the surface–atmosphere system adjusts in ways that tend toward a balance of the energy absorbed from solar radiation with the energy emitted to space in the infrared part of the spectrum. In coming to this balance, the atmosphere–ocean system transports heat from tropical latitudes towards the poles. Some of the first models of the climate system were based on this kind of constraint, and reasonably simulated the surface temperature distribution even with only very simplified schemes for horizontal heat transport. The principle of energy balance also provides insights about the sensitivity of the climate to natural or human induced perturbations such as changes in the solar constant or the doubling of carbon dioxide concentration. The sensitivity is controlled by a multitude of subtle feedback mechanisms that can amplify or diminish the response to an external stimulus to climate change. The difficulty with using solely an energy balance approach to such analyses is in the transformation of the estimate of the change at 5 km of altitude where the radiation to space is effectively emitted to an estimate of the change at the surface where people live. Even with its limitations, however, consideration of the energy balance is a key constraint on the system that must be satisfied in all techniques used to estimate changes in the global climate.

Energy Balance Climate Models

L D Danny Harvey
University of Toronto, Toronto, Canada

In order to simulate climate effectively with a numerical model, it is necessary to take into account all of the processes and interactions that in uence the temperature, winds, precipitation, soil moisture, and other variables. These processes must be represented by mathematical equations, but the complexity of the equations and the number of calculations required are such that the number of calculations far exceeds what can be done without a computer. The mathematical formulation of the climate processes is therefore implemented in a computer program, which is referred to as a climate model. There are many types of climate models, varying in the number of dimensions, the number of components (i.e., atmosphere, oceans, biosphere, glaciers) that are included, the variables that are explicitly represented, and the mathematical relationships used to represent climate-related processes. Energy balance climate models (EBCMs) are one of the simpler, but very useful, types of climate models.

EBCMs WITHIN THE CLIMATE MODELING HIERARCHY

In a climate model, physical quantities that vary continuously in three dimensions are represented by a finite number of points laid out on a grid. The most complex models use a three-dimensional (3D) grid to represent the global environment (*see* General Circulation Models (GCMs), Volume 1). In other models, averaging has been performed over one, two, or all three dimensions. The important processes for climate range in size from continental-scale wind patterns, to microphysical processes in clouds at a scale of millimeters or microns, to molecular-scale scattering, absorption, and emission of radiation. The most detailed global models have a horizontal resolution of about 200 km (i.e., calculations are performed on a 200×200 km grid covering the globe). Because not all important processes can be explicitly represented on these scales, *all* climate models, require that special steps be taken to simulate subgrid-scale processes that cannot be directly represented by the model. To accomplish this, subgrid processes have to be represented by simplified, parametric relationships called *parameterizations* (*see* Parameterization, Volume 1). Parameterizations use observed correlations between the variables that are included in the model and the unresolved processes to represent the effect of the

unresolved processes on the resolved variables. The fewer the dimensions retained in a model, the fewer the number of processes that can be explicitly represented in the model, and the greater the reliance on parameterization. In order to understand how EBCMs fit into the climate modeling hierarchy and the contributions they can make, it is necessary to identify the major categories of climate processes and then indicate how these processes are represented.

The major climate processes involve (i) dynamics, (ii) radiation, and (iii) thermodynamics (*see* Earth System Processes, Volume 1). Dynamics refers to forces and motions, and is involved in the computation of atmospheric winds and ocean currents. Two kinds of radiation are relevant to climate: solar radiation (wavelengths of 0.1–4.0 μm) and infrared radiation (wavelengths of 4.0–50.0 μm). Solar radiation is subject to scattering and absorption by the atmosphere, and absorption or reflection by the surface. The Earth s surface emits infrared radiation, some of which is transmitted to space and some of which is absorbed by the atmosphere. The atmosphere also emits infrared radiation, both to space and back to the surface (*see* Infrared Radiation, Volume 1). Thermodynamics refers to heat and changes in temperature.

Climate models can be distinguished in terms of complexity and in terms of comprehensiveness (*see* Models of the Earth System, Volume 1). Complexity refers to the number of processes included in a model and the detail with which they are included. The most complex climate models are coupled, 3D atmosphere–ocean models which are referred to as atmospheric general circulation models (AGCMs) and oceanic general circulation models (OGCMs). These models are capable of representing dynamic processes, so they explicitly compute winds and ocean currents. Because the atmosphere is divided into 10–20 layers in these models, they can perform relatively detailed calculations for the vertical transfer of solar and infrared radiation. Comprehensiveness refers to the number of components of the climate system that are included in a model. The longer the time scale under consideration, the more components that are relevant (at short time scales, some components can be regarded as unchanging). The most comprehensive climate models include the atmosphere, oceans, terrestrial biosphere, seasonal snow and sea ice, glaciers, and the Earth s mantle, at least as far as its response to loading by ice sheets or sea water is concerned. An important principle in modeling the climate system is that the components that are coupled together should be of comparable complexity and resolution, because, otherwise, the errors arising from the most simplified component would likely govern the overall response of the system. It is thus viewed as relatively ineffective to couple a highly detailed representation of one component to a highly simplified representation of another component.

STRUCTURE OF EBCMs

In EBCMs, dynamic processes are not directly represented, and averaging is performed over one or usually two spatial dimensions. In the original EBCMs (Budyko, 1969; Sellers, 1969), the only dimension that was included was latitude. Each point in the model grid represented an east–west and vertical average at that point, without distinguishing between the atmosphere and surface. The Earth, in effect, was represented by a series of east–west strips.

In this type of EBCM, which is still widely used, it is assumed that the transport of heat between latitude strips can be represented by a diffusion process – i.e., the amount of heat transferred is assumed to depend on a diffusion coefficient (designed to represent both the mean transport and eddy-mixing) times the rate of variation of temperature with latitude. This is an example of a parameterization. These models often also represent the net emission of radiation to space as a linear function of the combined surface–atmosphere temperature – another parameterization. The absorption of solar radiation by the latitude strip is represented in terms of the incoming solar radiation, the surface reflectivity or *albedo*, and the transmissivity and reflectivity of the atmosphere. The surface albedo is made a function of a fixed snow-free albedo, with an adjustment for the presence of snow or ice. The latter in turn depends on temperature, which provides the basis for a third parameterization – the relationship between temperature and surface albedo. The temperature of each latitude strip is governed by the balance between absorbed solar radiation, emitted infrared radiation, and the difference between heat diffusing in or out across the two boundaries of the given strip. In mathematical terms, the governing equation is

$$R\frac{\mathrm{d}T}{\mathrm{d}t} = (\text{absorbed solar}) - (\text{emitted IR}) - \text{div}(\text{horizontal heat flux}) \quad \bullet 1 \bullet$$

where $\mathrm{d}T/\mathrm{d}t$ is the rate of change of temperature with time (t), R is the thermal inertia of the latitude strip, and the last term is the divergence of the north–south heat transport. The thermal inertia accounts for the fact that the temperature of the atmosphere–land–ocean system cannot change instantly when heat is added or removed. The divergence of the heat flux is the heat flowing out of the strip across one boundary, minus the heat inflow across the other boundary, divided by the area of the strip. If there is a net inflow of total energy, the strip warms up, while the opposite occurs if there is a net outflow.

The basic one-dimensional (1D) EBCM can be extended to include (a) land–sea resolution, and (b) surface–air resolution (e.g., Harvey, 1988). When land–sea resolution

is introduced, a simple parameterization of east–west heat exchange (e.g., based on the east–west temperature difference) must be added. When surface–air resolution is introduced in the vertical, separate energy balance equations must be solved for the atmosphere and surface, and terms representing vertical heat exchanges due to sensible and latent heat must be added. Heat transport by the atmosphere and the oceans must then be separately parameterized, usually using an approximation based on diffusion. Rather than directly parameterizing the surface albedo, the presence or absence of snow and sea ice can be explicitly computed. This can be done by, for example, (a) specifying the present day pattern of precipitation but using the model-computed air temperature to determine if the precipitation falls as snow or rain, or (b) using the model-computed surface temperature to determine if and how much of the snow should melt on a given time step. Freezing and melting rates of sea ice can be computed based on the energy balance for the ocean surface layer. Figure 1 illustrates an EBCM with surface–air and land–sea resolution and with explicit sea ice and snow processes.

Two-dimensional (2D) EBCMs have also been developed. In one case, the two dimensions are latitude and height (e.g., Peng *et al.*, 1982), and a height-dependent diffusion coefficient for north–south heat exchange is used. In the other case, the atmosphere and surface are collapsed into a single layer, but latitude and longitude are resolved (e.g., North *et al.*, 1983). Even though atmospheric winds and heat exchange are stronger in the east–west than in the north–south direction, an isotropic (same in all directions) heat diffusion coefficient has been used in these models.

In the vast majority of EBCMs, the only variable that is explicitly computed is temperature, although in some cases involving latitudinal or latitude–height EBCMs, precipitation rates have also been computed (e.g., Gallimore, 1983; Fanning and Weaver, 1996). Representing precipitation requires separately parameterizing the north–south transport of sensible heat and of water vapor. In the simplest case, the precipitation rate in a given latitude zone is given by the convergence of the north–south moisture flux plus the rate of evaporation within the zone. That is, all the water that enters the atmospheric box in a zone is assumed to either fall out as precipitation or to be transferred to the next zone, and atmospheric water vapor content is not explicitly computed.

Not all EBCMs parameterize horizontal heat and moisture transports as a diffusion process. In a few cases (e.g., Sellers, 1973), the effects of advective transports at low latitudes, associated with the Hadley cells, have been separately parameterized. In other models, transport patterns drawn from observations or from higher dimensional models are used.

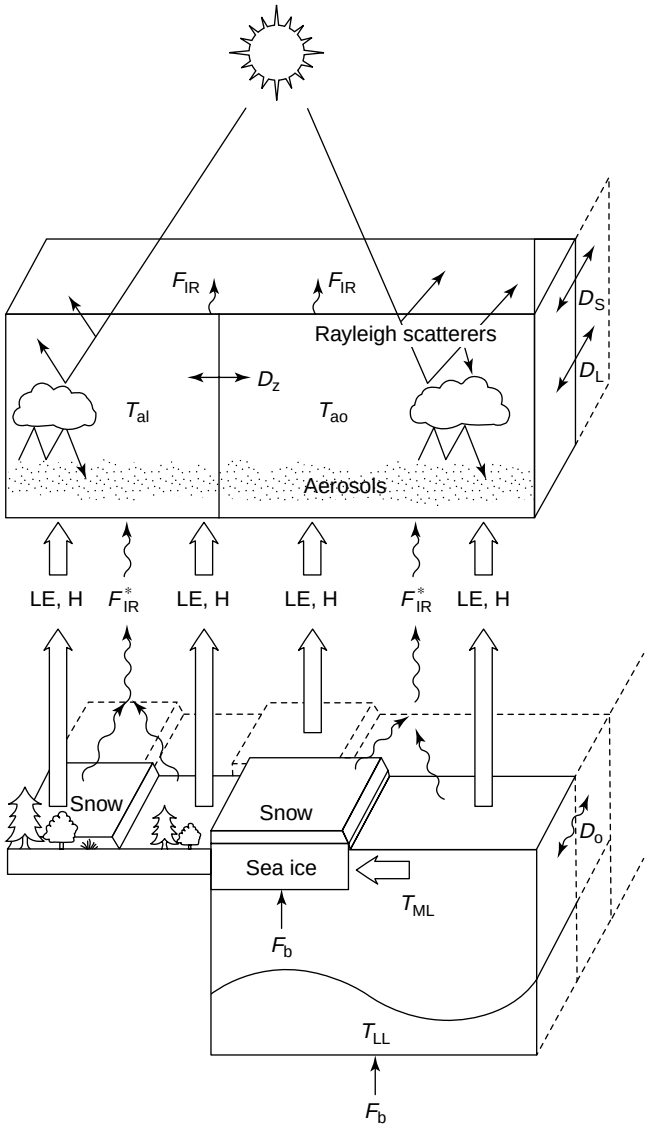

Figure 1 Illustration of a single latitude zone in the EBCM of Harvey (1988). In each latitude zone, a distinction is made between land and ocean and the surface and atmosphere. Partial snow cover on land and on sea ice in the ocean box can also occur. Vertical heat transfer occurs as sensible (H) and latent heat (LE), infrared radiation F_{IR}, and multiple scattering of solar radiation, while horizontal heat transfer is represented by diffusion (D)

The direct parameterization of the infrared emission to space as a function of temperature typically accounts for all the variables that change with temperature and that affect infrared emission. Foremost among these is the atmospheric water vapor content, which is not explicitly modeled in most EBCMs. There are several models in which the atmospheric water vapor content has been explicitly modeled (e.g., Gallimore, 1983; Fanning and Weaver, 1996); this requires a budget equation for atmospheric moisture content and internally calculated precipitation rates. Precipitation

in this case no longer exactly balances the convergence of the horizontal moisture flux plus evaporation. Rather, the small imbalance between these terms leads to changes in the atmospheric water vapor content. The explicit representation of atmospheric water vapor content is useful only if combined with a scheme for computing infrared emission to space that uses this information, rather than being based on temperature alone.

EBCMs with latitudinal, land–sea, and or surface–air resolution (as depicted in Figure 1) can be readily coupled to a 2D (latitude–depth) ocean model (e.g., Stocker *et al.*, 1992; Harvey, 1992). Such models do very well in simulating the large-scale, east–west averaged overturning circulation in the oceans (the so-called thermohaline overturning). Such a formulation allows a more realistic representation of horizontal heat transport by the oceans. In such models, there are two components to the oceanic heat transport: the transport by horizontal gyres and eddies within the surface layer (which is represented by a diffusive process); and the heat transport associated with the explicitly modeled overturning. The thermohaline overturning is driven by horizontal variations in the density of ocean water, which in turn depend on horizontal variations in both temperature and salinity (*see* Thermohaline Circulation, Volume 1). To simulate the distribution of oceanic salinity requires including the effects of precipitation, evaporation, runoff from continents, and the freezing and melting of sea ice, all of which can be computed within the EBCM structure shown in Figure 1.

Finally, EBCMs can be averaged in both horizontal dimensions, and coupled to a vertically resolved (but also globally averaged) ocean model (e.g., Hoffert *et al.*, 1980). In effect, the global atmosphere and ocean surface layer are represented by single boxes, which are underlain by the deep ocean. The two vertical mixing processes in this model are (i) the large-scale thermohaline overturning, and (ii) mean transport and eddy mixing, represented by diffusion. Such a model is referred to as an upwelling-diffusion model. In nature, deep water forms in the polar regions, sinks to the ocean bottom, spreads laterally, and upwells. This is represented in the upwelling-diffusion model by specifying a rate and temperature at which water leaves the mixed layer box, and injecting this water into the lowest model layer. This model structure is shown in Figure 2.

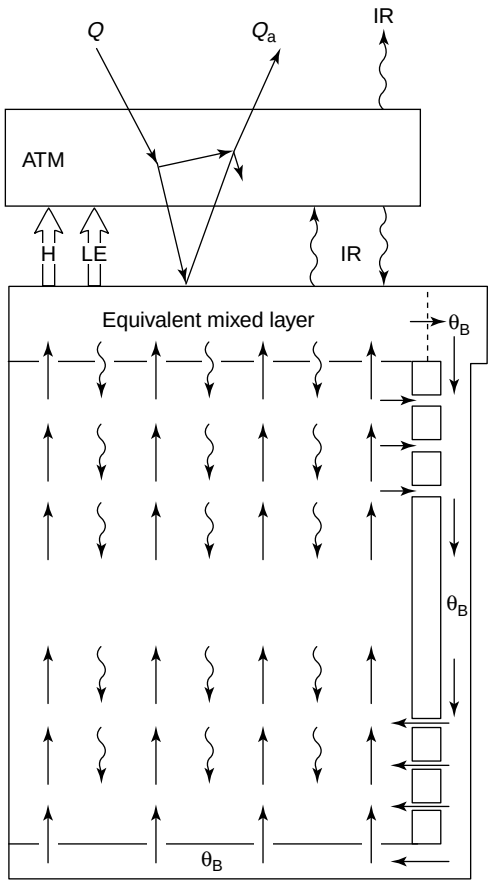

Figure 2 Illustration of a 1D upwelling diffusion model. The model consists of boxes representing the global atmosphere and ocean mixed layer, underlain by a deep ocean. Bottom water forms at temperature θ_B, sinks to the bottom of the ocean, and upwells with an upwelling velocity w. The temperature profile in the deep ocean is governed by the balance between the upwelling of cold water and downward diffusion of heat from the mixed layer. Latent (LE) and sensible (H) heat, and infrared radiation (IR) are transferred between the atmosphere and the surface. Q represents solar radiation

GENERAL APPLICATIONS OF EBCMs

Most researchers would probably agree that the primary purposes for constructing climate models are (i) to understand the factors responsible for the present climate, (ii) to understand the causes of past climatic changes, and (iii) to project future climatic changes for given scenarios due to human activities (emissions of greenhouse gases, aerosols, and their precursors; changes in the land surface). One of the most crucial factors in explaining past climatic change or projecting future climatic change is the *climate sensitivity* – the ratio of global mean temperature response to global mean radiative forcing (*see* Climate Sensitivity, Volume 1). In 3D AGCMs, the climate sensitivity is computed based on the detailed interaction of as many processes as can be incorporated. In EBCMs, only the most basic processes (infrared emission to space; reflection, scattering, and absorption of solar radiation; horizontal heat transport) are included, and these are included in a highly simplified manner. Other variables (such as cloudiness and cloud properties) are implicitly held constant as the climate changes. Although more of the relevant

physics is directly computed in AGCMs, the resulting climate sensitivity is still highly dependent on the ways in which subgrid scale processes (largely involving clouds) are parameterized. The primary advantage of EBCMs is that they can be easily used to study the interactions between those processes that are included, interactions that also occur in AGCMs but are difficult to decipher in AGCMs. Because EBCMs represent only the most critical processes, they are relatively easy to understand and inexpensive to run, so that multiple diagnostic tests can be executed.

Another primary advantage of EBCMs is that they can be readily coupled to other components of the climate system that one would wish to represent in a simplified manner (such as the deep oceans, continental-scale ice sheets, and the Earth's mantle), and the coupled system can be used for very long (up to millions of years) simulations (*see* Climate Model Simulations of the Geological Past, Volume 1). The subcomponents of such models can be constrained to replicate the overall behavior of the more complex models of each of the subcomponents in the coupled system. Because the coupled system is comprehensive but simple, a wide range of interactions can be investigated and important qualitative (and sometimes quantitative) insights can be gained.

An EBCM can also serve as the core of a climate modeling system that includes only those components and processes relevant to the build up of atmospheric carbon dioxide, climate change, and sea level rise during the next century or two. The coupled model can then be used to investigate the consequences of a wide range of different scenarios concerning emissions of greenhouse gases and aerosol precursors, along with different assumptions concerning climate sensitivity, the response of the terrestrial biosphere and oceanic circulation to changes in climate, and other system parameters. The Intergovernmental Panel on Climate Change, for example, has used EBCMs in this manner to compare the climatic response to different emissions scenarios (Cubasch and Meehl, 2001).

SPECIFIC EXAMPLES OF THE USE OF EBCMs

As examples of the types of uses of EBCMs, we provide a brief listing of some of the ways in which EBCMs, for example, has been used to improve our understanding of climate and climatic change. The 1D, latitudinally resolved EBCM, for example, has been used in the following ways, alone or in conjunction with other climate system model components:

- To determine the conditions under which the simulated climate is stable and under which more than one climate state is possible (Cahalan and North, 1979; North, 1984; Matteucci, 1993).
- To investigate the effect of different formulations of horizontal heat transport on climate sensitivity through the interaction between heat transport and high latitude albedo feedback (Held and Suarez, 1974; Lindzen and Farrel, 1977; Held *et al.*, 1981).
- To determine the potential effect on climate sensitivity of changes in surface albedo resulting from climate-induced changes in vegetation (Cess, 1978; Otterman *et al.*, 1984).
- To investigate the basic mechanisms by which changes in the seasonal and latitudinal distribution of incoming solar energy due to changes in the Earth's orbit lead to ice age-scale changes in climate (Schneider and Thompson, 1979; Birchfield and Weertman, 1983; Watts and Hayder, 1984; Lin *et al.*, 1992).
- To simulate glacial–interglacial climatic changes with coupled EBCM-ice sheet-mantle models (Pollard *et al.*, 1980; Deblonde and Peltier, 1991).
- To assess alternative hypotheses concerning the cause of the Younger Dryas cold episode (around 10 000–10 800 years ago) (Harvey, 1989).
- To assess the role of changes in ocean circulation on glacial climates (Bintanja and Oerlemans, 1996).

The 2D (latitude–longitude) EBCM has been used for:

- Elucidation of the relationship between orbital-induced changes in solar radiation and the driving force (land–ocean temperature contrast) for the monsoons (Short and Mengel, 1986).

The 1D (globally averaged) upwelling-diffusion model has been used in a variety of ways, including:

- Investigation of the role of the oceans in delaying the climatic response to increasing greenhouse gas concentrations and the role of ocean mixing-climate feedback in modifying the transient response (e.g., Hoffert *et al.*, 1980; Harvey and Schneider, 1985; Morantine and Watts, 1990).
- Exploring the importance of natural variability in observed global mean temperature variations during the past century (Wigley and Raper, 1990; Schlesinger and Ramankutty, 1994).
- Setting constraints on the magnitude of the global mean aerosol cooling effect (Wigley, 1989).
- Assessing the relative roles of greenhouse gases, aerosols, and solar variability in explaining global mean temperature variations during the past century (Kelly and Wigley, 1992; Schlesinger and Ramankutty, 1992).

Thus, EBCMs, although only one among several types of model being used (*see* Models of the Earth System,

Volume 1), has proven extremely useful for improving understanding of many types of problems.

EOS (Earth Observing System)

EOS is a global observation, data acquisition and analysis program undertaken by the US National Aeronautics and Space Administration (NASA). EOS is meant to provide, for a minimum of 15 years, sustained measurements of the key physical, chemical and biological parameters that define the state of the global Earth environment. The EOS program is a pioneering effort of NASA and the centerpiece of the US Global Change Research Program, a major contribution to the international effort to understand and predict the evolution of climate and Earth environment as a single interactive system.

EOS is unique in that the program combines a major technology push to develop more sensitive, more accurate, and better calibrated instruments for observing the Earth from space, and advanced data processing systems to match, with unprecedented involvement of a broad community of Earth system scientists in the design of improved instruments, data analysis methods and algorithms. EOS is also unique in its interdisciplinary breadth, which encompasses atmospheric physics and chemistry, oceanic circulation and biological productivity, and land vegetation and hydrology.

The first series of EOS missions includes three large polar-orbiting, observatory-type satellites, each carrying several sensors for simultaneous measurement of multiple Earth system parameters, and several smaller missions dedicated to a single measurement. The observatories will be launched during the period 1999 to 2003: Terra on a morning equator-crossing orbit for ocean and land observation, Aqua on an afternoon orbit for atmospheric climate observation, and Aura for measurement of atmospheric composition and chemical reactions. The next series of EOS missions is being planned to facilitate the transfer of advances in science, instrument technology and algorithms achieved in the first series to the next generation of operational observing systems, such as the US National Polar-orbiting Environmental Satellite System, that can continue the same measurements in the long term.

Equilibrium Response

The term *equilibrium response* is used to indicate the steady-state response (e.g., including magnitude and pattern) that a system eventually exhibits when exposed to a sustained change (or perturbation) in forcing or boundary conditions. In studies of the global environment, systems can range from limited domains (e.g., a chemical reaction chamber and the response to adding a new compound) to quite large domains (e.g., the full Earth System and the response to changing the atmospheric composition). Perturbations can range from changes in one parameter (e.g., how a change in the carbon dioxide concentration affects plant growth) to changes in a set of conditions (e.g., how a change in climate affects the distribution of ecosystems). In all cases, the equilibrium response represents the change that would occur as a result of altered forcing or boundary conditions that are assumed to exist indefinitely (e.g., the temperature change in a cold room that ultimately would result from turning on an electric heater). The time for a new equilibrium to be established can be quite long, because the response of the system is normally much slower than the time to impose the perturbing influence.

Investigations of the equilibrium response are made using a wide variety of techniques, broadly described in Models of the Earth System, Volume 1. Small-scale systems can be studied in the laboratory by actually imposing the perturbation; large-scale systems are most often studied using numerical models, although historical and geological records can also be used to study the response to natural perturbations that occurred in the past. An important part of such studies is to investigate not only the immediate, direct response, but also the effects of various positive and negative feedbacks (*see* Climate Feedbacks, Volume 1). Such feedbacks can often take extensive time to develop and create a new equilibrium. For example, it is likely to take thousands of years for the deep ocean to warm and for ice sheets to adjust in response to the atmospheric warming that will be caused by the ongoing increase in greenhouse gas concentrations. Therefore, great care must be taken to allow time in the experiments for all feedbacks to interact and adjust.

For comparison across perturbations of various magnitudes and types, the equilibrium response is often normalized (e.g., by dividing a measure of the response by the forcing) to determine the sensitivity of a system to a unit change in the perturbing force. For example, wide ranges of approaches are used to investigate the response of the climate to various perturbing factors (e.g., changes in solar radiation, volcanic aerosol loading, atmospheric composition). To estimate the climate sensitivity (*see* Climate Sensitivity, Volume 1), these different forcings are normalized by dividing the global average temperature response

by the global average of the change in radiative forcing across the tropopause (*see* Radiative Forcing, Volume 1). The units of climate sensitivity are then $^{\circ}C\ (W\,m^{-2})^{-1}$; i.e., the temperature change for a perturbing influence of $1\,W\,m^{-2}$.

While useful for many purposes, studies of the equilibrium response are highly idealized experiments. For example, perturbations in the real world do not persist indefinitely and multiple factors are changing at the same time. Because of the many interacting processes, calculations for many types of systems would take decades to centuries or longer for the response to come to a new steady state, by which time other factors and forcings may have changed. Developing estimates of the equilibrium response is thus only a first step in understanding how and why systems from as small as a plant to as large as the global environment are changing and may change in the future. The more challenging studies involve examining the time-varying response to individual perturbations and then to the full coupled set of interacting forces and perturbations because it is the time-dependent changes that will actually be experienced (*see* Transient Response, Volume 1).

F

Feedbacks, Chemistry – Climate Interactions

Joyce E Penner
University of Michigan, Ann Arbor, MI, USA

Several important greenhouse gases and aerosols have atmospheric abundances that generally depend on atmospheric chemistry. These gases include methane (CH_4), nitrous oxide (N_2O), hydro uorocarbons, per uorocarbons, sulfur hexa uoride - as well as the chloro uorocarbons, the hydrochloro uorocarbons, and the halons. In addition, the abundance of tropospheric ozone (O_3) and stratospheric water vapor (H_2O) is also determined by chemistry. Tropospheric H_2O generally depends on climatic conditions and the hydrological cycle (including changes in cloud microphysics), and changes in tropospheric H_2O will greatly impact chemistry. A number of gases, termed indirect greenhouse gases, do not directly affect climate, but they control the abundances of direct greenhouse gases through atmospheric chemistry. These gases include the reactive gases carbon monoxide (CO), volatile organic compounds (VOCs), and nitrogen oxides ($NO_x = NO + NO_2$).

Projections of future atmospheric composition depend not only on changes in the projections of population, social structures, economics, and technology and their attendant changes in emissions, but also on the possible effects of climate change on the so-called natural emissions of gases and aerosols. These will change as a result of the biosphere s response to global change and will impact future atmospheric composition. The anticipated changes in climate (e.g., temperature, precipitation) and in chemistry will alter ecosystems and, thus, the natural, background emissions of trace gases. The biospheric response, however, is difficult to project because we have only a poor understanding of how biological communities may change as a result of climate change. For example, it is still not known whether the marine phytoplankton that produce dimethylsulfide (DMS) would increase or decrease as a result of increases in global temperatures (*see also* Dimethylsul de (DMS), Volume 1). However, several biogenic emissions depend directly on physical factors whose changes might be reasonably described if it is assumed that the biosphere itself remains unchanged. This article summarizes the factors that should be considered in determining how changes in climate might affect future atmospheric emissions and composition. A robust calculation of future climate change should, of course, include these changes in composition in order to self consistently determine the future climate.

In addition to climate-driven changes to the terrestrial and marine biosphere, there are also complex interactions that result from increases in nitrogen (N) and other nutrient deposition. Furthermore, elevated surface ozone (O_3) abundances may have an opposite influence on plant carbon dioxide (CO_2) uptake to that of nutrient deposition. Also, increased nitrogen availability from atmospheric deposition and direct fertilization accelerates the emission of nitrogen-containing trace gases (nitric oxide (NO), nitrous oxide (N_2O) and ammonia (NH_3) as well as methane (CH_4)). These complex interactions represent chemistry–biosphere feedbacks that may alter the direct warming influence of greenhouse gases.

The physical factors that determine emissions of important gases and aerosols include changes in wind speed, light levels, ocean circulation, precipitation, lightning frequency and temperature. The compositional changes associated with these changes in physical factors have not been systematically studied. This article provides only a rough outline of possible changes. Table 1 lists the long-lived, radiatively active trace species and provides an estimate of total present-day emissions and the percent of total emissions that are associated with natural processes.

WATER VAPOR (H_2O)

According to the Clausius–Clapeyron relation, as temperature increases, the atmosphere will be able to hold more water vapor. As the evaporation and precipitation cycle moves toward a new equilibrium, the total amount of water

Table 1 Total emissions of trace species important for determining climate, and the percent of emissions associated with natural emissions that may change as a result of climate change

Species	Total emissions	Percentage of total associated with natural emissions
CH_4	550 Tg CH_4 $year^{-1}$	30–45
N_2O	16.4 Tg N $year^{-1}$	60
VOCs	590 Tg C $year^{-1}$	70
NO_x	52 Tg N $year^{-1}$	20
CO	2800 Tg CO $year^{-1}$	40
Sulfate aerosol precursors	88 Tg S $year^{-1}$	30
Organic aerosols and precursors	160 Tg $year^{-1}$	50
Black carbon aerosols	13 Tg C $year^{-1}$	3
Dust	2200 Tg $year^{-1}$	50
Sea salt	3300 Tg $year^{-1}$	100

vapor present within the atmosphere will increase. Changes to cloud microphysics driven by changes in aerosols may also lead to changes in water vapor, although this process has not been systematically studied. Through its reaction with the excited oxygen atom, $O(^1D)$, H_2O is the main source of atmospheric hydroxyl radical, OH (*see* OH- Radical: is the Cleansing Capacity of the Atmosphere Changing?, Volume 2):

$$H_2O + O(^1D) \longrightarrow 2OH \quad (1)$$

Because OH is the main chemical sink for a large number of gaseous compounds, increases in atmospheric H_2O will cause a multitude of chemical changes. The atmospheric lifetime of CH_4 will decrease, as will the lifetimes of the VOCs and carbon monoxide (CO). In addition, atmospheric sulfur dioxide (SO_2) and DMS will be more rapidly converted to sulfate, while organic aerosol precursors will be more rapidly oxidized.

The most important feedbacks caused by increases in H_2O are the climate feedbacks. Because H_2O is a greenhouse gas, increased amounts in the troposphere will cause further increases to tropospheric temperature. Increases in stratospheric H_2O will cause increases in the radical HO_x pool, as well as acting to locally cool the stratosphere with attendant changes in chemistry through changes to stratospheric reaction rate coefficients.

STRATOSPHERIC WATER VAPOR (H_2O)

Water vapor in the lower stratosphere is a very effective greenhouse gas. Natural levels of stratospheric H_2O are controlled primarily by the temperature of the tropical tropopause, which is expected to vary with changes in climate. However, the oxidation of CH_4 is a second important source of mid-stratospheric H_2O and is the reason why there is an increase in stratospheric H_2O abundance from about 3 parts per million by volume (ppmv) at the tropopause to about 6 ppmv in the upper stratosphere. H_2O is also injected directly into the lower atmosphere by aircraft, and future high-flying aircraft may cause even larger increases in stratospheric H_2O than has the present subsonic fleet (*see* Aircraft Emissions, Volume 3). Increases in stratospheric H_2O have been observed, but the vertical profile and amplitude of these changes do not correspond quantitatively with those expected from the recognized anthropogenic sources (CH_4 oxidation and subsonic aircraft).

TROPOSPHERIC HYDROYL (OH)

Tropospheric OH abundances depend on abundances of nitrogen oxides (NO_x), CH_4, CO, VOC, O_3, as well as H_2O. In addition, the amount of solar ultraviolet (UV) (>300 nm) that reaches the troposphere determines the rate of photolysis of O_3 and the production rate of $O(^1D)$. Stratospheric circulation and the distribution of stratospheric O_3 control the penetration of solar UV into the lower atmosphere. As a consequence, OH varies widely with geographical location, time of day, and season. Likewise, the local loss rate of CH_4 also varies. Due to its dependence on CH_4 and other pollutants, tropospheric OH is very likely to have changed since the pre-industrial era and is expected to change again as a result of future emissions (*see* OH- Radical: is the Cleansing Capacity of the Atmosphere Changing?, Volume 2).

METHANE (CH_4)

The abundance of atmospheric CH_4 depends on the balance between emissions and its reaction with OH:

$$CH_4 + OH \longrightarrow CH_3 + H_2O \quad (2)$$

This removal reaction occurs mainly in the troposphere. Climate changes will, as noted above, tend to increase H_2O, which will tend to increase OH. However, as noted above, the concentrations of OH depend as well on a number of other complex, coupled interactions.

Substantial pre-industrial abundances of CH_4 are found in the bubbles of ancient air trapped in ice cores. CH_4 is the natural by-product of anaerobic fermentation, and its large natural emission rates have varied as the past climate has changed. Thus, in addition to the chemical interactions indicated above, a change in climate may well bring about changes in the natural sources of CH_4. Methane emissions from wetlands are sensitive to temperature, as are the rates of carbon and nitrogen cycling. Because there is an optimum temperature for production of CH_4, changing emissions may increase or decrease depending on the response of the microbes that produce CH_4 to the changing conditions. In addition, if wetland extent either increases or decreases in response to changes in the hydrological cycle, the natural sources of CH_4 from these regions will also be affected (*see* Methane, Volume 1).

NITROUS OXIDE (N_2O)

The abundance of N_2O is determined by its removal in the stratosphere through reaction with $O(^1D)$ and photolysis at short wavelengths (<240 nm):

$$N_2O + h\nu \longrightarrow N_2 + O \quad (3)$$

$$N_2O + O(^1D) \longrightarrow 2NO \quad (4)$$

$$N_2O + O(^1D) \longrightarrow N_2 + O_2 \quad (5)$$

As a result of the time required to transport N_2O to the region of chemical loss, its atmospheric lifetime is long, i.e., about 120 years. For this reason, its concentration will respond only slowly to changes in emissions (*see* Nitrous Oxide, Volume 1).

Climate change, including the radiative cooling of the stratosphere caused by increased levels of CO_2, is expected to alter stratospheric circulation and stratospheric O_3 concentrations. As a result, the global mean loss rates of the long-lived gases that are removed in the stratosphere, of which N_2O is arguably the most important for climate change, will change. In these ways, stratospheric circulation, and the distribution of O_3, control the transport of the long-lived greenhouse gases to regions of photochemical loss. At the same time, N_2O supplies ozone-depleting radicals (e.g., NO) to the stratosphere, thereby providing a feedback between the gas and its loss rate.

Soil N_2O emissions are sensitive to temperature and soil moisture as well as to the rates of carbon and nitrogen cycling. The abundance of N_2O deduced from ice cores is consistent with there being large, natural emissions, the rates of which have varied significantly as climate has changed. The atmospheric abundance of N_2O over the next 100 years will likely be driven by changes in both anthropogenic and natural sources, as well as the chemical interactions noted above. This is another example of a biogeochemical coupling with climate change.

OZONE (O_3)

Tropospheric O_3 is both generated and destroyed by photochemistry within the atmosphere (*see* Troposphere, Ozone Chemistry, Volume 1). Its *in situ* sources, such as the sequence shown below, have grown with the increasing industrial emissions of the ozone precursors: CH_4, NO_x, CO, and VOC:

$$CO + OH \longrightarrow H + CO_2 \quad (6)$$

$$H + O_2 + M \longrightarrow HO_2 + M \quad (7)$$

$$HO_2 + NO \longrightarrow OH + NO_2 \quad (8)$$

$$NO_2 + h\nu \longrightarrow NO + O \quad (9)$$

$$O + O_2 + M \longrightarrow O_3 + M \quad (10)$$

$$\text{Net: } CO + 2O_2 \longrightarrow O_3 + CO_2 \quad (11)$$

where M denotes an inert atom or molecule that absorbs excess energy but does not react.

In addition, there is substantial transport of ozone from the stratosphere to the troposphere.

The chemistry of tropospheric O_3 is closely tied to that of OH, and its abundance also varies with changing precursor emissions. The chemistry of the troposphere is also directly influenced by the stratospheric burden of O_3, climatic changes in temperature (T) and humidity (H_2O), as well as by interactions between tropospheric aerosols and trace gases. Such couplings provide a feedback between the climate change induced by increasing greenhouse gases and the concentration of these gases. Another feedback, internal to chemistry, is the impact of changes in CH_4 on OH and hence on O_3. These feedbacks are expected to be important for both tropospheric O_3 and OH.

Natural emissions of the pollutants NO_x, CO, and VOC play an important role in production of tropospheric O_3 and the abundance of OH. These emissions are also subject to changes induced by changes to the physical climate, the biosphere, and chemical systems. Terrestrial and aquatic ecosystems, in turn, respond to near-surface pollution (O_3, NO_2, acidic gases and aerosols) and to inadvertent fertilization through deposition of reactive nitrogen (often emitted from the biosphere as NO or NH_3). This response can take the form of die-back, reduced growth, or changed species composition that may alter trace-gas surface exchange and ecosystem health and function. As with other biosphere feedbacks, the magnitude of the coupling of this feedback system between build-up of greenhouse gases, human-induced climate change, ecosystem responses, and trace-gas exchange at the surface is difficult to assess.

OTHER CHEMISTRY PROCESSES AND COUPLING WITH CLIMATE

Stratospheric O_3 chemistry is determined by reactions on the surfaces of aerosols. Similar reactions have been identified in the troposphere. In particular, the conversion of NO_x to nitrates on aerosol surfaces is now routinely included in chemistry models. A wide variety of other processes may also be important including: removal of HO_x, altering the UV flux and hence photodissociation rates, and catalyzing more exotic reactions leading to the release of NO_x or halogen radicals. These processes are highly sensitive to the properties of the aerosol and the local chemical environment; their importance on a global scale is not yet established. However, if climate change leads to a change in relative humidity, aerosol surface area may change. This would lead to an overall change in the rates of such reactions over and above any change associated with direct changes in emissions of aerosols or aerosol precursors.

Stratospheric O_3 depletion has led to increases in tropospheric UV levels that, as noted above, tend to increase OH abundances. The ozone depletion itself, however, may have reduced the influx of O_3 from the stratosphere, thereby counteracting the tendency to increase OH. Since future changes in stratospheric O_3 may be driven by increases in CO_2 (which reduces stratospheric temperature) as well as possible increases in CH_4 and N_2O, adding radical compounds that may deplete ozone, such processes may play a role in future climate.

IMPACTS OF PHYSICAL CLIMATE CHANGE ON ATMOSPHERIC CHEMISTRY

The most direct changes to atmospheric chemistry that may be anticipated as a result of climate change are associated with the anticipated rise in temperature and water vapor. The first factor will change chemical reaction rates while the second will lead to enhanced photochemical destruction of tropospheric O_3. Recent studies estimate that tropospheric O_3 might decrease by about 5–10% in response to a warmer, more humid climate projected for the middle of the 21st century, as compared to an atmosphere with current temperature and H_2O.

Thunderstorms, and their associated lightning, are a component of the physical climate system that provide a direct source of a key chemical species, NO_x. The magnitude and distribution of this lightning NO_x source provide a background upon which anthropogenic perturbations are determined. The uncertainty in the source strength of lightning NO_x, together with uncertainty in the prediction of the frequency of thunderstorms, precludes an easy determination of how important this feedback might be (*see also* Lightning, Volume 1).

Convection is another climate process whose magnitude may well change as climate changes. Because convection is an important process for delivery of a variety of surface-level pollutants to the upper troposphere, a change in the effectiveness of this process could affect the chemistry of this greenhouse-gas important region. Convection is a parameterized process in climate models, and its treatment tends to be quite different from one model to the next. Hence, evaluation of the significance of any change in this process for chemistry-climate coupling awaits determination.

AEROSOLS

Aerosols have both direct sources that depend on the physical climate system as well as photochemical sources that depend on OH and gas-phase aerosol precursors (*see* Aerosols, Troposphere, Volume 1). Changes in aerosol loading and type are evident in ice core records, so consideration must be given to the possible changes in natural sources in association with future changes in climate. For example, levels of insoluble species, such as dust, recorded in Greenland ice cores were more than 10 times higher during the last glacial maximum compared to present levels. Additionally, sea salt concentrations were much higher during the last two glacial periods than now. It has been suggested that these changes resulted from either higher wind speeds during the glacial maximum or more efficient meridional (north–south) transport in the Northern Hemisphere. In Antarctica, similar increases in dust loading during the last glacial maximum have been interpreted as being associated with an expansion of arid areas and exposure of the continental shelves. Another aerosol species that has been found to have been enhanced in Antarctica was sulfate. Because a similar enhancement of methane sulfonic acid (which is associated with marine biological sources of sulfate) was also recorded, it is thought that the Antarctic increase was due to enhanced biological activity during the glacial maximum. No evidence of an increase in biological activity is evident in the ice cores from Greenland, however.

The increases in sea-salt and sulfate aerosols would have led to additional cooling during ice ages, but the increased dust, because of its ability to absorb solar and thermal radiation, could actually have led to regional warming events. This absorption might help to explain the abrupt warming events that took place as the glacial era was terminating.

In addition to possible changes in sea salt, sulfates and dust associated with changes in wind speeds, precipitation, and biological activity, future climate change may lead to changes in emissions of terpenes. Terpenes are emitted from vegetation and their source rates depend on temperature, precipitation and light levels. They undergo photochemical

oxidation (initiated by reaction with OH, O_3, and NO_3) and produce condensable compounds.

One recent study estimated an increase of about 20% in the emissions of terpenes associated with climate changes projected for 2100, while dust emissions would increase by 10%. A major feedback is associated with sea salt emissions, because the production rate of sea salt is a very strong function of wind speeds. The study estimated that these emissions might increase by 75%. Such a change would result in a significant negative feedback that would tend to moderate climate change; this factor has not yet been included in climate models.

CONCLUSION

A variety of feedbacks to atmospheric chemistry will arise as a result of climate change. Most of these have not been sufficiently studied to allow estimates of their importance at the present time. However, some feedbacks, such as the estimated change in sea salt emissions, are clearly important on the time scale of the next 100 years and should be further studied. Other feedbacks, such as possible changes to the stratosphere and troposphere that result from changes in the exchange of air between these reservoirs, or changes to the troposphere that result from changes in convective processes, will be difficult to assess until much higher resolution climate models become available. Changes in the biosphere itself will lead to changes in emissions rates that may be substantial, given current estimates of the role of the biosphere and other natural emissions in current budgets of the trace species. However, a much better understanding of the processes controlling species abundance and emissions are needed to determine the magnitude of the feedbacks that result from climate changes to the biosphere.

Fingerprinting

Fingerprinting is a term used in the Earth System sciences to describe an approach for distinguishing among the different factors that are likely to be contributing to changing the climate. Although problems can sometimes be introduced because of the limited length of records (especially for the period prior to human influence on the climate), relatively straightforward statistical techniques can be used to detect if any of a number of climate variables is changing (e.g., the temperature record can be analyzed to determine if the world is warming, *see* The Global Temperature Record, Volume 1). However, because the climate system varies naturally (and is thus said to be noisy) and because the potential changes to the climate are varied and the factors contributing to them may generate signals that are comparable in size, fingerprinting techniques have been developed to use in attributing particular amounts of the change to each of the many possible causal factors. This two-step process of detection and attribution is analogous to a doctor first determining that a patient has a temperature, and then using diagnostic techniques to determine the cause of the illness – both steps are essential, and each has its special set of approaches best suited to the goal.

Fingerprinting techniques, sometimes called *optimal weighting*, *optimal filtering*, or *pattern analysis*, were first conceived about 20 years ago when the initial warming due to human-induced activities was suspected (Hasselmann, 1979; MacCracken and Moses, 1983; Bell, 1986; Santer *et al.*, 1994; North *et al.*, 1995). Considering each of the possible factors that might contribute to climate change, it was realized that the particular radiative forcing (*see*

Box 1 Factors that might contribute to climate change

Agent forcing climate change	Effect on surface and tropospheric temperature	Effect on stratospheric temperature
Increase (decrease) in solar radiation	Warms (cools)	Warms (cools)
Increase (decrease) in the incidence of major volcanic eruptions	Cools (warms)	Warms (cools)
Increase in greenhouse gas concentrations	Warms	Cools the stratosphere as a whole
Increase (decrease) in sulfate aerosol loading	Cools (warms), mostly in Northern Hemisphere	Little effect
Depletion of stratospheric ozone	Slight cooling	Cooling, mostly of lower stratosphere

Radiative Forcing, Volume 1) of each potential causal factor would induce a different pattern of change (see Box 1). With each causal factor having its particular character, the challenge is to figure out which factors are contributing to the observed, time-varying patterns of change, requiring in each case that the response of each factor be proportional to its forcing at a given time (i.e., without very good reason, a small change in one factor cannot be assumed to lead to a large response while a large change in another factor leads to only a small response).

The application of the fingerprinting approach to the latitude-vertical pattern of temperature change (Santer *et al.*, 1996a,b) led the Intergovernmental Panel on Climate Change (IPCC) to its pioneering and widely quoted conclusion that the balance of evidence suggests that there is a discernible human influence on global climate (IPCC, 1996). Basically, with the stratosphere cooling strongly and the troposphere warming, particularly in the Southern Hemisphere, it became quite apparent that the temperature changes over the latter part of the 20th century were due primarily to increases in greenhouse gas concentrations (cooling the stratosphere and warming the lower atmosphere), increased sulfate aerosol loading (cooling the Northern Hemisphere more than the Southern Hemisphere) and stratospheric ozone depletion (causing the sharp cooling of the lower stratosphere). Studies since the IPCC s Second Assessment Report have carried the analysis back through the 20th century, finding that an increase in solar radiation may have contributed to some of the warming in the first half of that century, but that the warming in the second half of the 20th century is primarily due to human activities (IPCC, 2001); for a discussion of these developments (*see* Climate Change, Detection and Attribution, Volume 1).

Franklin, Benjamin

(1706- 1790)

Benjamin Franklin was a colonial and US printer, publisher, prolific author, scientist, inventor, philanthropist, and statesman. He brought attention to a central concern of modern environmentalists with a major essay, *Observations Concerning the Increase of Mankind*, published in 1755. Noting that the population of British descent in North America was then one million, but that only 80 000 had immigrated, Franklin calculated that the population would double every 20–25 years. It did for the next century, until immigration surged. In this essay, Franklin also explicitly anticipated the limitations stressed by Thomas Malthus in his famous tract of 1798.

Franklin did much else pertinent to environmental science. He gave a classic explanation of a seemingly paradoxical observation: why storms coming from the northeast actually move in the opposite direction (e.g., hitting Philadelphia hours before Boston). He noted that on lighting a fire in a chimney, the heated air rises, so nearby cooler air flows in to replace it, and other air to replace that. The air near the distant door is last to move, even though the flow is toward the chimney. Accordingly, he suggested that air heated over Florida and the Gulf of Mexico is replaced by cooler air flowing in from the north, generating storms that begin in the south and move to the northeast, directed by the coastline and the Appalachian mountain range.

Other meteorological imaginations and conjectures offered by Franklin include his analysis of the formation of hailstones and his proposal that major climatic changes may result from the vast quantity of smoke, long continuing to issue from volcanic eruptions. He also devoted much effort to measuring ocean temperature profiles from which he mapped the Gulf Stream.

In a cautionary letter written when he was 80 years old, Franklin compiled observations and episodes he had noted over six decades which convinced him of the danger of lead poisoning. For instance, he attributed a sudden attack of dry bellyach that had beset a family to drinking rainwater collected from a leaded roof. He noted that trees planted around the house years before had grown tall enough to shed leaves on the roof, thereby creating acid that corroded the lead and furnished the water ... with baneful particles . He lamented how long a useful truth may be known before it is generally received and practiced on.

Born in Boston, Franklin was the 15th child among 17 (perhaps presaging his concern about population). He attended school only two years, but was an avid, life-long student of literature, philosophy and science. Resentful of ill treatment as a printer s apprentice, at 17 he ran off to Philadelphia. His industry and skill enabled him to acquire a newspaper, *The Pennsylvania Gazette*, which became by the 1730s the most widely read paper in the colonies. His *Poor Richard's Almanack* (1732–1759) also was extremely popular and fostered his reputation for wit and wisdom. He promoted many civic projects, including paving and lighting streets, a circulating library, a fire company, a police force, a hospital, and an academy that later became the University of Pennsylvania. In 1748 Franklin retired from business and thereafter devoted himself chiefly to scientific research and public service. As a diplomat, he lived for 25 years in England and France.

Franklin was greatly esteemed as a scientist as well as a sage. In the early 18th century, electricity was a greater mystery than gravity had been a century earlier. Contemporary scientists hailed Franklin as the Newton of electricity. His book, *Experiments and Observations on Electricity, made at Philadelphia in America*, consisting of letters he had sent to a colleague in England, was a sensation in Europe: it went through some 10 editions (1751–1774), including translations into French and German. Like all of his writings, the book was accessible to a wide public. Franklin s invention of the lightning rod in 1750 had great impact, cultural as well as practical. Before him, lightning was considered a supernatural phenomenon. It was customary to ring church bells, to break the thunder, and store munitions in churches. The presumption of divine protection had long persisted, although many bell ringers were killed and churches damaged by lightning. In 1767 a stroke detonated tons of powder in a Venice church, killing 3000 people. Despite ample demonstrations of the efficacy of his lightning rods, Franklin had to weather thunderous attacks from clergy for his audacity in intruding on a prerogative of the Almighty. He remained unruffled, writing in 1753: Surely the thunder of heaven is no more supernatural than the rain, hail or sunshine of heaven, against the inconveniences of which we guard by roofs & shades without scruple.

Fronts

Fronts are the boundaries between differing air masses. Typically, the term is used for the long (order of hundreds of kilometers) and narrow (order of tens of kilometers) zone of transition between large air masses of different air densities; that is, warmer and/or moister in one air mass and cooler and/or drier in the other. Fronts are further identified by their motion: cold fronts move such that colder (denser) air replaces warmer (less dense) air; warm fronts move such that warmer air overtakes cooler air; and stationary fronts, as the name implies, show little movement. The frontal zone separating the air masses typically slopes with height over the cold (dense) air with slopes on the order of 1 km in the vertical for every 100 km in the horizontal. The circulation associated with fronts is such that, regardless of the frontal movement, the air on the warmer, moister side of the front tends to ascend the sloping frontal surface, leading to the formation of one or more bands of clouds and precipitation parallel to the front. Cold fronts, as they undercut warm and moist air ahead of them, may trigger convection leading to narrower, more intense bands of precipitation. Fronts are typically associated with mid-latitude cyclones and are often easily identifiable on satellite imagery. The term *front* is also used for the leading edge of smaller air masses, such as the gust front at the leading edge of the cool thunderstorm outflow or the sea-breeze front at the leading edge of the cool sea breeze.

GAIM (Global Analysis, Interpretation and Modeling) Program

The Global Analysis, Interpretation, and Modeling Program (GAIM) is one of the framework activities of the International Geosphere Biosphere Programme (IGBP). Its goal is to advance the study of the coupled dynamics of the Earth System using both data and models as tools. GAIM emphasizes activities designed to expand upon the development, testing, and analysis of integrative data sets and models of those aspects of the Earth System where IGBP has the scientific lead, and it commits to collaborate on aspects of the Earth System where the World Climate Research Programme (WCRP) has the lead.

In order to achieve its goal, the GAIM Task Force has established specific objectives dealing with development, evaluation, and application of comprehensive prognostic models of the global biogeochemical subsystem; experiments with existing models; clarifying key scientific issues facing the development of global biogeochemical models and the coupling of these models to general circulation models; contributing to international assessment exercises, particularly the Intergovernmental Panel on Climate Change (IPCC) process; advising the IGBP Scientific Committee, and maintaining scientific liaison with the WCRP Steering Group on Global Climate Modeling.

GAIM coordinates a diverse set of research projects dealing with modeling of the carbon cycle, trace gas processes, and climate–vegetation interactions on a number of time scales and periods ranging from beyond 20 000 years ago through the near- and long-term future. Numerous publications in international journals have resulted from GAIM coordinated research, and a number of international workshops have been convened. For further information, contact GAIM Task Force Office, Institute for the Study of Earth, Oceans, and Space, Morse Hall, University of New Hampshire, Durham, NH 03824-3525, Tel.: +1-603-862-0322/Fax: +1-603-862-1915.

GARP (Global Atmospheric Research Program)

GARP was a massive international research effort to advance understanding of weather and climate, with a view to improving weather forecasting and projection of both natural and human-induced climate changes.

The program was motivated by the development of meteorological satellites in the early 1960s, the development of computer-based numerical weather prediction, and research indicating possibilities for markedly improved forecasts. In 1961, US President John F Kennedy called upon the United Nations (UN) to mount international collaborative efforts in weather prediction. The UN requested the World Meteorological Organization (WMO) and the International Council for Science (ICSU) to plan and organize such a program, which was developed through a series of international scientific conferences beginning in 1967.

The focus of GARP was on improving understanding of the processes determining short-term changes in the atmosphere, which we call the weather; and the factors determining its long-term statistical characteristics, which we call the climate. The central activity was a global observing experiment, designed and implemented over a decade of international work. By augmenting operational observing systems, enhancing and coordinating satellites, and launching special *in situ* observing systems, the atmosphere and oceans of the planet would be observed in unprecedented detail for a full year. The resulting data would permit development of greatly improved models of weather and climate. In parallel with the global experiment, a number of regional observing and research programs were designed.

The Global Weather Experiment, as it came to be called, was very successfully carried out in 1979 with contributions by virtually every nation on Earth. The unique high-quality research data sets obtained have been employed ever since in the development of ever-improving numerical forecast models, and have led directly to the extended-range predictions that are provided today by the world s weather services. These same improvements in numerical models

have advanced our understanding of natural climate variability and human influences on climate.

JOHN S PERRY *USA*

GAW (Global Atmosphere Watch)

Many urgent environmental problems are connected with human-induced changes in the composition of the atmosphere. Long-term data on the chemical composition and physical parameters of the atmosphere are therefore needed. The GAW of the World Meteorological Organization (WMO) was established in 1989 to coordinate international collection of such data.

The GAW provides information on the chemical composition and related physical characteristics of the atmosphere and their trends. The data are particularly essential to understanding the relationship between changing atmospheric composition and changes of global and regional climate, long-range atmospheric transport and deposition of potentially harmful substances, natural cycling of chemical elements in the global atmosphere–ocean–biosphere system, and anthropogenic impacts on these systems.

The GAW monitoring network, consisting of global and regional monitoring stations, relies largely on activities of WMO member countries. Central facilities handle standardization, calibration, data processing, central archiving, publication, training, and analysis. Global stations carry out a complete range of measurements including ozone, other greenhouse gases (carbon dioxide, chlorofluorocarbons, methane, nitrous oxide, water vapor), solar radiation, ultraviolet (UV)-B, atmospheric turbidity, total aerosol load, reactive gas species (SO_2, NO_x, carbon monoxide), chemical composition of rain and atmospheric particles, radionuclides and meteorological parameters. Regional stations assess regional environmental problems such as acid rain, increased surface ozone, deterioration of ecosystems, air pollution in rural areas, airborne pollution of the seas, etc.

Six World Data centers have been established: ozone and UV-B (Toronto, Canada), greenhouse gases (Tokyo, Japan), precipitation chemistry (Albany, USA), solar radiation (St Petersburg, Russia) surface ozone (Oslo, Norway) and aerosols (Ispra, Italy). Quality Assurance Science Activity Centres to oversee the data quality have been established in Germany, USA and Japan.

Results from the GAW serve as the scientific basis for a number of international conventions and declarations aimed at protecting the atmosphere and the environment as a whole.

GCDIS (Global Change Data and Information System)

The Global Change Data and Information System (GCDIS) was originally conceived in the late 1980s as a mechanism for making available data and information produced by the US Global Change Research Program. This concept came from a recognition, by key senior managers in the agencies conducting global change research, that data and information had considerable value beyond their initial use, and that a coordinated effort across the federal agencies would be required. As GCDIS evolved, it was recognized that the interconnected nature of global change research required more than the observations made by the program, extending to virtually all of the environmental data and information and much of the socioeconomic data held by the US Federal Government. It also needed to extend to include process science, in addition to measurements and model outputs. Moreover, not only scientists, but legislators, educators, and the general public have a need in gaining access to these data and information. Thus, the GCDIS became the largest effort in the world to provide environmental data and information to anyone who needs it.

GCDIS, as it currently is structured, uses a World Wide Web based gateway (http://www.gcdis.usgcrp.gov) to direct users to appropriate federal data centers where data and information reside. Data sets are described in searchable catalogs, such as the National Aeronautics and Space Administration (NASA) Global Change Master Directory, which refer users to data and information in over 70 participating data centers (and centers of data) throughout the US Federal Government. These catalogs are maintained by the individual agencies responsible for their data holdings and are supported by linked web sites in a distributed system environment. Users who need additional help may submit electronic questions to Dr Global Change and receive answers directing them to data and information available on the web relating to their global change question. Additional user services are provided by the Global Change Research Information Office and by each participating agency data center. Participating centers adhere to the principle of full and open non-discriminatory data sharing, except for those

data which are restricted by copyright, trade secret, or by law. GCDIS also reaches out to the international community through a series of linked catalogs to include holdings worldwide.

GCMs (General Circulation Models)

see General Circulation Models (GCMs) (**Volume 1**)

GCOS (Global Climate Observing System)

GCOS was established in 1992 to ensure that the observations and information needed to address climate-related issues were obtained and made available to all potential users. It is co-sponsored by the World Meteorological Organization (WMO), the Intergovernmental Oceanographic Commission of the United Nations Educational, Scientific and Cultural Organization (UNESCO), the United Nations Environment Programme (UNEP) and the International Council for Science (ICSU).

GCOS is intended to be a long-term, user-driven operational system capable of providing the comprehensive observations required for monitoring the climate system, for detecting and attributing climate change, for assessing the impacts of climate variability and change, and for supporting research toward improved understanding, modeling and prediction of the climate system. It addresses the total climate system including physical, chemical and biological properties, and atmospheric, oceanic, hydrologic, cryospheric and terrestrial processes.

GCOS does not itself directly make observations nor generate data products. It stimulates, encourages, coordinates, and otherwise facilitates the taking of the needed observations by national or international organizations in support of their own requirements as well as common goals. It provides an operational framework for integrating, and enhancing, as needed, observational systems of participating countries and organizations into a comprehensive system focussed on the requirements for climate issues. GCOS builds upon, and works in partnership with other existing and developing observing systems such as the Global Ocean Observing System, the Global Terrestrial Observing System, and the Global Observing System and Global Atmosphere Watch of the WMO.

GCOS is directed by a Steering Committee that provides guidance, coordination and oversight to the program. Four panels, reporting to the Steering Committee, have been established to prepare specific program elements (atmosphere, ocean, land and space-based observations) and to make recommendations for implementation.

HANS TEUNISSEN *Switzerland*

General Circulation Models (GCMs)

Michael C MacCracken
Lawrence Livermore National Laboratory, Livermore, CA, USA

General Circulation Models (GCMs) are numerical models developed to simulate the 3-dimensional, time dependent dynamics and thermodynamics of the global atmosphere or ocean. Atmospheric GCMs normally treat, for example, the movement of the air horizontally and vertically, temperature and relative humidity, surface pressure and surface- atmosphere interactions, precipitation and storms, and much more. In simulating the geographical distribution of the climate, GCMs provide quantitative frameworks for assembling objective, quantitative representations of the full range of physical, chemical, and biological processes that determine the behavior of the atmosphere and oceans.

The first attempt to construct a comprehensive numerical model of the atmosphere was made by Lewis Fry Richardson (*see* Richardson, Lewis Fry, Volume 1) during the latter part of World War I. He constructed a series of boxes covering much of Europe and the adjacent Atlantic Ocean that represented the state of the atmosphere over this region. Then, starting from a baseline set of observations, he used the equations of motion, which had been developed by Norwegian scientist Vilhelm Bjerknes to explain the movement of weather systems, to calculate the evolution of the weather over the next eight hours. Although his hand calculations took over 100 times longer to complete than for the weather to actually evolve, and although the calculations gave results different than for the real atmosphere,

Richardson was not discouraged. The conclusion of his book (Richardson, 1922) envisioned the creation of a forecast factory staffed by a very large number of teams distributed around the various balconies of an opera house. He proposed that each team would receive information about observations, make calculations with a fast mechanical calculator, and flash their results to neighboring teams needing such information and to a central conductor who would keep the teams synchronous in time and would assemble the results for distribution to the public. This is much the way, in practice, that weather forecasts are made today, except they are done using modern parallel processing computers rather than human calculators.

Studies following Richardson s pioneering effort found a number of shortcomings that had to be overcome to actually construct a functioning model of the general circulation of first the atmosphere, then the oceans, and finally the coupled atmosphere–ocean system. A global grid (actually, at first only hemispheric) had to be used because what happens at remote locations affects the positions and movement of the major circulation features (e.g., the El Niño in the Pacific Ocean has effects far from where it warms ocean temperatures). A more comprehensive and timely set of observations was needed, emphasizing the need for a globally connected network of observation stations spread across the world. The set of observations had to be carefully processed to overcome the problems of unrepresentative data and the need for the data to be dynamically and thermodynamically self-consistent when making the calculations. More advanced numerical techniques were needed to solve the sets of equations that represented the dynamics of the atmospheric motion. These techniques had to be designed to filter out sound waves that traveled so fast that model time steps would have had to be very short. The techniques also had to be designed to conserve key quantities such as atmospheric mass and energy. The set of equations had to include treatment of atmospheric thermodynamics (which controls the air temperature) and of atmospheric water vapor (which determines where clouds form and how latent heat is added to or removed from the system). For longer calculations, changes in surface conditions had to be included in that these can cause changes in where energy is added to and removed from the atmosphere. Finally, faster computers were needed if the rate of calculations for the numerical atmosphere was going to keep up with and then exceed the evolution of the real atmosphere (a necessity if the calculations were going to produce useful predictions).

Following the development of electronic computers during World War II, the Princeton mathematician John von Neumann assembled a team to attempt to actually simulate the evolution of the atmosphere for a few days. With the impressive, but still quite limited, computers available at the time, von Neumann s team constructed a model using a somewhat simplified set of equations that treated mainly atmospheric dynamics. They completed their first trial forecast in 1950, treating a region covering North America using a time step of 3 h and a grid of 270 points about 700 km apart (Charney *et al.*, 1950). While achieving only limited success, this first effort led, as computers advanced, to several additional efforts around the world to start making real time forecasts, led in Sweden by Carl Gustav Rossby and in the US by Jule Charney (*see* Charney, Jule Gregory, Volume 1; Rossby, Carl-Gustaf, Volume 1).

As the speed of computers increased, the next step was to turn weather modules into climate models. The first to do this was Norman Phillips, who constructed a two-layer quasi-geostrophic atmospheric model (i.e., it was based on conservation of vorticity) and carried out a 1 month simulation at the Institute for Advanced Studies in Princeton (Phillips, 1956). This initial effort to simulate the atmosphere s general circulation was extended to a more complete representation of the equations of motion of the atmosphere in the early 1960s. Joseph Smagorinsky led a team within the General Circulation Research Section of the US Weather Bureau in Washington, DC, to construct a hemispheric GCM (Smagorinsky, 1963). Beginning shortly thereafter, Cecil Leith led a team at what is now the Lawrence Livermore National Laboratory to construct a full global GCM (Leith, 1965).

These early models represented the vertical structure of the atmosphere in several layers and had a horizontal resolution of about 5–10 degrees in latitude and longitude (roughly 500–1000 km at the equator, with finer resolution near the poles). The interchange of mass, momentum, and energy among grid cells was governed by use of a set of fundamental conservation equations (*see description in* Projection of Future Changes in Climate, Volume 1) and representations of particular processes (*see* Earth System Processes, Volume 1). Descriptions of the structure and characteristics of GCMs can be found in the References and Further Reading sections.

Because of limits in computer resources and data availability, the initial calculations with this type of model typically would simulate a perpetual January condition by assuming fixed sea surface and land temperatures and then letting the model simulation run until the influence of initial atmospheric conditions disappeared. As the global observation network grew and satellites started to provide data over the oceans, these atmospheric models developed further over the next decade and were soon serving as the basis for numerical weather prediction at several centers around the world.

As a complement to the atmospheric models, Kirk Bryan and Syukuro Manabe, working with Smagorinsky, led the effort to develop the first global ocean model. A key limitation in developing and testing ocean models was the lack of knowledge about the oceans, there being reasonable

measurements for only the upper ocean. Whereas the atmospheric models could readily be tested against observations, the ocean model simulations generated currents and ocean flows that had never been seen. Such observations helped to prompt field programs that would go to search for evidence of deep ocean behavior (e.g., the GEOSECs program begun in the 1970s started a systematic effort to sample the world ocean from the surface to the bottom).

The first simulations of extended periods of atmospheric behavior and of the seasonal evolution of the global climate took place in the 1970s, carried out initially by Syukuro Manabe (*see* Manabe, Syukuro, Volume 1) and colleagues working at the Geophysical Fluid Dynamics Laboratory under Joseph Smagorinsky, which had been relocated to Princeton, NJ. The initial simulations typically had a schematic distribution of the continents, cloud fractions prescribed at observed values, and ocean temperatures specified based on observations. Improvements came rapidly, however, and soon the continents were properly shaped, clouds varied based on relative humidity and atmospheric stability, and oceans were represented as a well mixed layer of water about 100 meters deep.

By the mid 1970s, even though the treatment of model physics remained relatively limited, the model simulations were deemed sufficiently interactive and representative to start using the models as experimental tools. Using the numerical models in the same way using an experiment a physical model could be conducted by running the numerical models with multiple sets of conditions. For example, a perturbation study could be run by using one set of conditions (normally representing the present) as a *control case* (or control simulation). Then rerunning the simulation after arbitrarily changing one or more parameters (such as atmospheric composition), and using this result as a *perturbed case* (or perturbed simulation). One of the first such experiments was to calculate the effects on the climate of a hypothetical doubling of the atmospheric carbon dioxide concentration (Manabe and Wetherald, 1975). These early simulations suggested that a warming of about 2.5–3 °C would result, which was not much different than the initial estimates from mathematical analysis made by Arrhenius in 1897 (*see* Arrhenius, Svante, Volume 1). Additional studies using a model developed at the Goddard Institute of Space Studies by James Hansen and colleagues provided the basis for an initial estimate of the climate sensitivity by the US National Research Council (1979) (*see* Climate Sensitivity, Volume 1).

During the 1980s and 1990s, the development of GCMs was relatively rapid, with models being designed to include more detailed representations of the various physical processes, with more accurate and numerically efficient numerical techniques introduced, with finer spatial resolution in the vertical and horizontal, and with fully interactive coupling of the atmospheric and oceanic components of the climate system. In addition, with the widespread availability of supercomputers, GCMs have been developed and are being used at many centers around the world for a wide range of simulations and investigations. Gates *et al.* (1999) and Lambert and Boer (2001) report on efforts to evaluate model performance of atmospheric and coupled atmosphere–ocean models (*see* Model Simulations of Present and Historical Climates, Volume 1). The Intergovernmental Panel on Climate Change (IPCC, 2001) reports on the use of models to study the potential impacts of the increasing concentration of greenhouse gases on the atmosphere (*see* Projection of Future Changes in Climate, Volume 1).

Geological Cycling

Robert Raiswell
Leeds University, Leeds, UK

Understanding the role of time lies at the heart of many geological controversies. In the Bible, the Book of Genesis asserts that the Earth was formed in stages over six days. This view has an identi able starting point, from which time is directly coupled to progress (and by implication global change). There is, however, a less well-known alternative in the Book of Ecclesiastes where Koheleth the Sage states that all streams run into the sea, yet the sea never over ows: back to the place from which the streams ran they return to run again. In this view, the world is maintained in an unchanging state by the operation of processes that are counter-balanced to produce no overall change. Here, time and progress are decoupled. There is no identi able starting point and no overall progress, only a cyclical passage through continuously repeating states. This latter view is the basis of geological cycling.

The debate between a linear (catastrophic) and a cyclic (uniformitarian) origin for the Earth occupied much of the 18th and 19th centuries (Gregor, 1988), and was particularly sharply focused in the dispute over the origin of the oceans. It was comparatively easy to comprehend that river ow could only be maintained by the continued precipitation of water derived from evaporating the oceans because the processes involved are readily observable and occur on a timescale that is short relative to the human lifespan. Thus, the idea of a water cycle was established. However, it was much more dif cult to comprehend the fate of the salts carried by river water into the sea. Many geologists simply regarded the ocean as an accumulation of salts, and becoming progressively saltier with time. Refuting this view proved dif cult and it gave way only gradually in the face of growing evidence that marine sediments hundreds of millions years old were essentially similar to those of the present day. This was impossible to reconcile with an ocean that must have changed in composition as it became saltier.

The uniformitarian nature of geological processes is conceptualized in the rock cycle (Figure 1), even the earliest representations of which show nearly all of the familiar geological processes (the only significant absences relate to plate tectonic processes). Magma is erupted and crystallizes into *igneous rocks*, releasing volatiles and water. These *igneous rocks* are then weathered chemically (by reaction with air and water) and physically (by abrasion through the action of wind, tides and running water). Soluble components are dissolved from the rocks and carried by rivers into the oceans. The solid residues may remain behind for considerable periods of time, where they constitute a soil, but ultimately these too are transported via rivers into the oceans. Here, additional solids are contributed by biogenic materials derived from organisms, and the mixture of weathering products and biogenic material settles to the bottom of the sea to form sediment. Burial occurs with the continued addition of sediment and is accompanied by chemical alteration, which together convert sediments into *sedimentary rocks*. Continued burial is accompanied by heating (the Earth has an average geothermal gradient of $28\,^{\circ}\mathrm{C\,km^{-1}}$), and new rock minerals are formed which are stable at these higher temperatures and pressures, converting *sedimentary rocks* into *metamorphic rocks*. Still deeper burial may ultimately result in melting, which reproduces new *igneous rocks*; the type of material at the starting point of the cycle.

However, this rock cycle is not a simple circle, from which it differs in several important ways. Firstly, the cycle can be short-circuited. For example, sediments need not necessarily become buried and transformed into metamorphic rocks, but may instead be uplifted to the surface of the Earth where they are eroded and weathered into new sediments. Secondly, the cycle is not completely closed. Melting existing rocks may produce magma, but there is also a small amount of new magma introduced to the cycle from the interior of the Earth. Equally, there is a small amount of meteoritic material that enters the cycle from outer space. Strictly speaking, these additions constitute a change such that passage around the cycle may not allow a return to precisely the same starting point. Progression

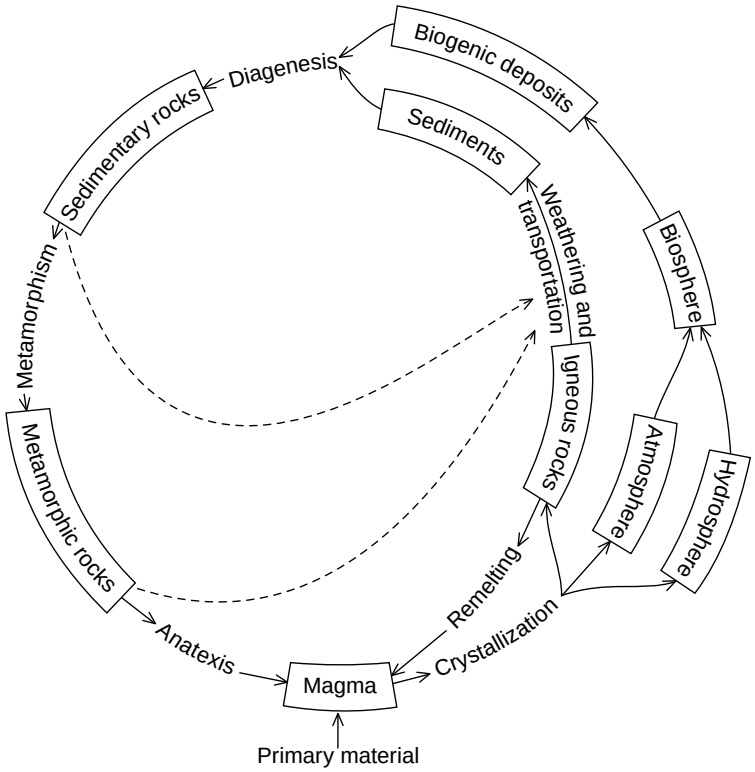

Figure 1 A conceptualization of the geological or rock cycle

in this manner can be envisaged by representing the rock cycle in three dimensions as a coil made up of loops of exactly the same diameter. Viewed end on, effectively in two dimensions, progression down the length of the coil would not be apparent and only a circular movement would be seen. Nevertheless, progress around the cycle does not result in a return to precisely the original state, and thus there is a linear progression (or global change component) to cyclicity, which could be considered analogous to aging.

The rock cycle in Figure 1 is constructed by drawing boxes (or reservoirs) that are connected by arrows (or fluxes). A flux occurs where a geological process (e.g., river transport) transfers material from one reservoir to another, and is expressed in units of mass per unit time. A reservoir represents a mass of material that possesses characteristic physical, chemical or biological properties, and is normally considered to be well mixed and thus homogeneous. This is a reasonable approximation for some reservoirs (e.g., the atmosphere) but is clearly a very poor approximation for the sedimentary rock reservoir (see below). Heterogeneity is an obvious feature of the sedimentary rock reservoir, where the common rocks (limestones, shales, sandstones) are all very different in composition while additionally numerous, less common, rocks exist with still other compositions.

A cycle approach, although an over-simplification, does possess the advantage of giving a good over-view of the relationships between different reservoirs and their connecting fluxes. This can sometimes be useful in identifying those parts of the cycle that are poorly understood. However there are disadvantages in that this approach provides no information on the processes that occur within reservoirs, or on the exact nature of the fluxes between them. Furthermore, on a large scale, it is clearly necessary to use average values, which may have to account for considerable spatial variability (as in the sedimentary rock reservoir). Such averages are difficult to obtain accurately, and may, therefore, be a poorly recognized source of uncertainty.

Nevertheless, cycles do possess the overwhelming advantage of encouraging a quantitative view of geological processes. Figure 2 shows a simplified rock cycle (Gregor, 1988) with the reservoirs and fluxes quantified, and which provides a greatly improved insight into the timescales over which the cycle operates.

(i) A *residence time* (R) can be calculated as:

$$R = \frac{\text{Mass in reservoir}(M)}{\text{Flux or fluxes}(F)} \qquad (1)$$

The residence time represents the time it would take to empty the reservoir (if all the input fluxes ceased) or the time it would take to double in mass (if all the output fluxes ceased). The residence time of

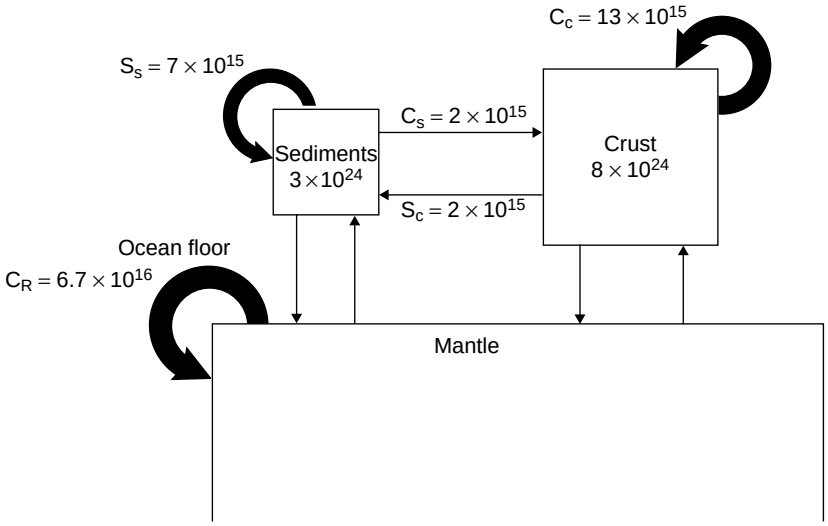

Figure 2 The rock cycle, modified from Gregor (1988). S, sediments; C, crystalline continental crust; S_s, erosion of sediments; C_s, metamorphism; S_c, erosion of crystalline rocks; C_c, recycling of crystalline rocks in tectogenesis. The ocean floor loop (C_r) represents the production and subduction of basaltic rocks (data from Veizer and Jansen, 1985). Reservoirs in grams, fluxes in grams year^{-1}

the sediment reservoir in Figure 2 is about 300×10^6 years, which represents the average time spent by sediments and sedimentary rocks in their reservoir, calculated with respect to the sum of the known input or output fluxes.

(ii) Many geological cycles are considered to represent a steady state, in which the fluxes in and out of a particular reservoir are exactly balanced. Any reservoir that is not so balanced must change in mass with time. Thus, the crust reservoir in Figure 2 is balanced because the flux of material brought in by sedimentation matches that removed to form metamorphic rocks. Geological cycles are usually assumed to be in a steady state because the rock record has remained uniform for a comparatively long time (probably $1-2 \times 10^9$ years) compared to the residence times of typical rock reservoirs (e.g., the sediment reservoir). This indicates that sufficient time has elapsed for non-steady state conditions to produce observable changes. The existence of a steady state allows a balance sheet to be drawn up comparing the sum of all the input fluxes to the output fluxes. The absence of a balance may indicate the existence of an unknown flux, whose operation is required to produce a steady state. Such budgets are thus extremely valuable, although it must be remembered that there can be considerable error in estimating an unknown flux, which is the difference between two comparatively large figures that represent the sums of the input and output fluxes.

(iii) These cycles operate by first order kinetics, i.e., the flux out of a reservoir (F) is assumed to be proportional to the reservoir mass (M). Thus,

$$F = kM \tag{2}$$

where k is a first-order rate constant. Writing $1/k = M/F$ shows from Equation (1) that residence time is the reciprocal of the first order rate constant. Now the rate of change of any reservoir ($\mathrm{d}M/\mathrm{d}T$) is given by:

$$\mathrm{d}M/\mathrm{d}T = S - F$$

where S is the sum of the input fluxes. At a steady state $\mathrm{d}M/\mathrm{d}T = 0$ and so $S = F$, as defined above. However, for a reservoir which is not in a steady state:

$$\mathrm{d}M/\mathrm{d}T = S - F = S - kM$$

This differential equation can be solved with the initial conditions that $M = M_0$ at $T = 0$, $M = M_1$ at $T = t$, which on integrating gives:

$$M_t = M_1 - (M_1 - M_0)\mathrm{e}^{-kt} \tag{3}$$

The term e^{-kt} becomes very small ($\sim$0.05) when $t = 3/k$ or $3R$ and Equation (3) then shows that M_t closely approaches the new value M_1 after the passage of three residence times. This represents the time taken by a reservoir to respond to change by reaching a new steady state.

The rock cycles in Figures 1 and 2 require that matter flows between the reservoirs; thus energy must also be transferred. Many different forms of energy are used in the rock cycle, either within, or between, reservoirs:

solar radiation, kinetic and potential energy, and chemical energy. Solar radiation is the only external source, and without this input, the second law of thermodynamics predicts that a closed system (like an Earth without an external input) would ultimately run down and become disordered.

Operation of the rock cycle is only sustained by solar radiation. The solar radiation absorbed by the crust of the Earth is unevenly distributed across the Earth s surface such that the equatorial regions gain more energy than the poles. This imbalance of energy represents an unstable situation, which winds and currents attempt to eliminate by moving heat from hot to cold regions. Overall, the energy absorbed by the crust is converted to kinetic energy, which appears as winds, currents, glaciers and rivers. These geological processes in turn cause the erosion of rocks.

The utilization of energy in, and the more dynamic aspects of, the rock cycle are more evident in Figure 3, which depicts the land–air–water system of our planet as a giant factory (Garrels and Mackenzie, 1971; Siever, 1974). This representation bears little resemblance to Figure 1, but instead likens the chemical and physical processes occurring on the Earth to the successive steps in an industrial process. There is, however, one major difference between the land–air–water factory and an industrial plant; the former neither requires any raw materials nor creates any finished product. However, the analogy is valid in that the different parts of the land–air–water factory do receive, process and transfer materials through successive operations, just as in an industrial plant.

There are two separate but linked cycles in Figure 3. One involves gas–liquid interactions in the atmosphere, and the other solid–liquid interactions between the crust and the hydrosphere. The gas–liquid system utilizes solar radiation to produce organic matter and oxygen via photosynthesis, with the reverse of this reaction returning carbon dioxide (CO_2) to the atmosphere by respiration and decay:

$$6CO_2 + 6H_2O(\text{water}) + \text{nutrients} \longrightarrow 6O_2(\text{oxygen}) + C_6H_{12}O_6(\text{carbohydrate})$$

Sunlight also drives the distillation plant to evaporate water from the hydrosphere, which is condensed as rain and enters the liquid extractor. Once in the liquid extractor, the second solid–liquid cycle operates on the crushed rock materials delivered by the pulverizer, which crushes rocks through erosion by wind, water and ice. The soluble rock components are leached out from the crushed rocks by water that contains dissolved CO_2 and water. Rivers quickly return the leachates to the oceans and, more slowly, also the residual solids.

The solids delivered to the oceanic reactor slowly deposit out to the bottom of the vessel, and are in turn covered by the following layers of sedimenting material. This vessel also acts as an evaporator, because salts can be formed by the evaporation of seawater in certain parts of the marine environment. Continued burial consolidates the accumulating sediments, first into sedimentary rocks and later into metamorphic rocks (see previous). These changes are produced by a radioactively heated pressure furnace, which can reach high enough temperatures to melt rocks and form magma.

A further benefit of Figure 3 is that it also gives some indication of the spatial variability of rock reservoirs. For example, the oceanic reactor vessel contains four different types of sediment that are spatially separated from each other. The surface of the Earth actually shows considerably more spatial variability in sediment composition than this, but Figure 3 does at least illustrate two important points. Firstly, different types of sediments can be produced in different parts of the ocean as a result of physical separation (by grain size principally) and chemical reaction (often precipitation by organism activity but also hydrothermal addition, evaporation and reaction with seawater). Secondly, it is difficult to reverse this spatial variability. There are no widespread geological processes that are particularly effective at mixing solids, although the rock flour produced by glaciers does provide a reasonable estimate of the average composition of the bedrocks from within the drainage basin. In the absence of effective mixing processes it is hardly surprising that sediments show considerable variation in age and composition across the surface of the Earth.

These observations on sediment composition and mixing can be developed in a general way to apply to all reservoirs in the rock cycle, whether gas, liquid or solid. Quite simply, a reservoir is only homogeneous when the rates at which fluxes add or remove material are slower than the rates of mixing. Because different chemical components can be added and removed at different rates, it follows that a reservoir can be homogeneous with respect to some components and heterogeneous with respect to others. The ocean provides some clear examples of this. Life processes are sufficiently rapid to deplete nutrients (nitrate, phosphate) from the surface layers of the ocean but, beyond the depth of light penetration, photosynthesis becomes impossible and nutrient concentrations are significantly higher at depth. This nutrient/depth gradient persists throughout many areas of the ocean, because the surface and deep layers of the ocean (which lie beyond the stirring effects of wind and wave action) are mixed together only slowly on a timescale of tens of thousands of years. By contrast, nutrients are being consumed and released on an annual basis by plankton. Nutrient mixing is very clearly much slower than rates of removal, and heterogeneity is established. However, the main components of seawater (e.g., sodium, chloride) are removed only slowly into sediments (on a timescale of hundreds of millions of years), and the mixing is here effective at maintaining similar proportions of sodium and chloride at surface and at depth.

The issues of mixing and homogeneity are also of importance in environmental problems, where anthropogenic activity has locally enhanced pollutant levels. In some cases, dispersion of a pollutant throughout a reservoir might greatly mitigate any potential hazard; in other cases dispersion may be undesirable because a more sensitive reservoir may be affected. The ideas developed on the geological cycle can also be applied to environmental pollutants, whether these are natural components whose concentrations have been increased by anthropogenic activity (e.g., CO_2) or are new compounds (e.g., dichlorodiphenyltrichloroethane, polychlorinated biphenyls). The cycle approach can be used to estimate the extent to which a reservoir has been perturbed, the time it will take to reach a new steady state, and the impact of the redistribution of the pollutant to other reservoirs. These questions, which lie at the very heart of global change, require the integration of cyclic processes with linear change (whether by natural aging or by anthropogenic activity).

Geomorphology

The origin of the term *geomorphology* probably lies with two officers of the US Geological Survey in the 1880s, J W Powell and W J McGee. In 1891, McGee wrote The phenomena of degradation form the subject of geomorphology, the novel branch of geology (McGee, 1891). He plainly regarded geomorphology as a practice that would enable geological history to be reconstructed, not by fossils and sediments, as was the norm, but by reconstructing past erosional history. Many scientists had studied the development of erosional landforms before the term was thus defined, and since that time its meaning has become broader. It is true that until the early 1960s the reconstruction of landscape history by studying the nature of surfaces planed off by erosive processes was a dominant approach. Since that time there has been a tendency for geomorphologists to become more deeply involved with understanding not just erosional history (denudation chronology), but also the processes of erosion. In addition, geomorphologists are concerned with weathering, transport and depositional processes, with measuring the rates at which processes operate, and with quantitative analysis of the forms of the ground surface (morphometry) and of the materials of which they are composed. There are many sub-branches of geomorphology. *Climatic geomorphology* attempts to interpret landforms in terms of the climatic conditions under which they developed while *applied geomorphology* seeks to use geomorphology to deal with real world issues of resource location and hazard reduction and increasingly, *anthropogeomorphology*, where the role of humans in modifying the land surface is considered. Geomorphology has much to contribute to the study of the impacts of future global change, because global warming is likely to have a profound effect on ice cap and glacial melting, permafrost degradation, dune reactivation, sea level change, and soil erosion.

Geothermal Heat

The interior of the Earth comprises a large reservoir of heat. This thermal energy is transported to the surface by conductive and advective mechanisms where it is transferred to the oceans or atmosphere and eventually radiated to space. The sources of the internal heat have two time scales: *primordial heat* associated with the very early history of the Earth, and *radiogenic heat* delivered slowly over the lifetime of the Earth. The primordial energy is derived from three sources. First, from gravitational energy liberated (converted to heat) as the Earth was accreted from in-falling rock and dust debris distributed through the early solar system. Subsequently, heat was derived from major impacts such as that which ejected the moon from the Earth and finally gravitational energy liberated by the segregation and sinking of the Earth s metallic core from its silicate mantle and crust, and heat from the radioactive decay of the short-lived isotopes aluminium 26 (^{26}Al), chlorine 36 (^{36}Cl) and iron 56 (^{56}Fe). All of this energy was delivered to or generated within the Earth in the first few hundred million years after the planet s birth. Subsequently, heat continued to be generated within the Earth by radioactive decay of long-lived isotopes: uranium 238 (^{238}U), uranium 235 (^{235}U), thorium 232 (^{232}Th) and potassium 40 (^{40}K), with half-lives of 4.5, 0.7, 14.1 and 1.25 billion years, respectively. Such half-lives are on the order of the 4.6 billion-year age of the Earth, and thus the heat liberated by these isotopes has been added to the internal reservoir slowly over the lifetime of the Earth. At the Earth s surface the internal heat is manifest through phenomena such as geysers, hot springs, steam vents, fumaroles, and volcanic eruptions. At shallow depths below the surface the heat is apparent in the elevated temperatures encountered in mines, and in the steady increase of temperature with depth as found in deep boreholes.

GEWEX (Global Energy and Water Cycle Experiment)

GEWEX was initiated by the World Climate Research Program to observe, understand and model the hydrological cycle and energy fluxes in the atmosphere, at the land surface and in the upper oceans. GEWEX is an integrated program of research, observations, and science activities involving hundreds of scientists throughout the world (Figure 1).

The goal of GEWEX is to reproduce and predict, by means of suitable models, the variations of the global hydrological regime, its impact on atmospheric and surface dynamics, and variations in regional hydrological processes and water resources and their response to changes in the

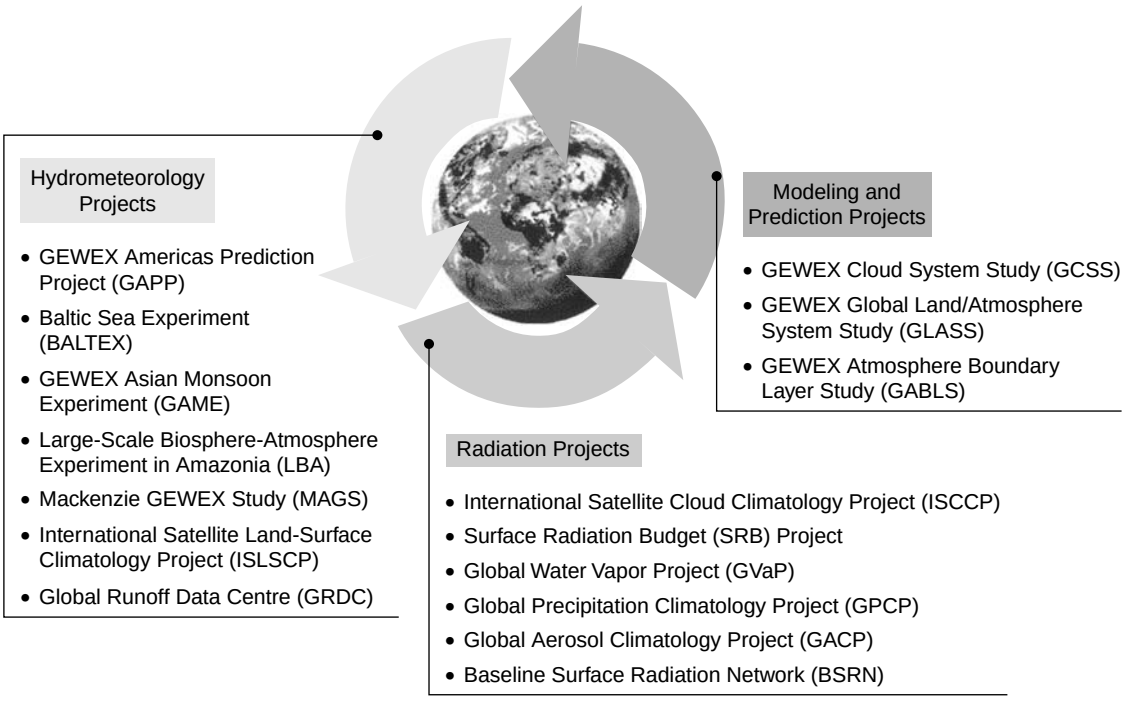

Figure 1 GEWEX projects

environment. GEWEX will provide an order of magnitude improvement in the ability to model global precipitation and evaporation, as well as an accurate assessment of the sensitivity of atmospheric radiation and clouds to climate change.

The objectives of GEWEX are to:

- determine the hydrological cycle and energy fluxes by means of global measurements of atmospheric and surface properties;
- model the global hydrological cycle and its impact on the atmosphere, oceans and land surfaces;
- develop the ability to predict the variations of global and regional hydrological processes and water resources, and their response to environmental change; and
- advance the development of observing techniques, data management, and assimilation systems for operational application to long-range weather forecasts, hydrology, and climate predictions.

GEWEX Research Foci:

- *Radiation*: determine atmospheric and surface radiation fluxes and heating with the precision needed to predict transient climate variations and decadal-to-centennial climate trends;
- *Hydrometeorology*: demonstrate skill in predicting changes in water resources and soil moisture on time scales up to seasonal and annual as an integral part of the climate system;
- *Modeling and Prediction*: develop accurate global model formulation of the energy and water budget and demonstrate predictability of their variability and response to climate forcing.

GEWEX projects are organized by their relationship to the GEWEX research focus areas.

The GEWEX Program Strategy is to build on existing programs and data; produce global data sets of clouds, radiation, water vapor, precipitation, and land surface characteristics; conduct modeling programs to model all aspects of the hydrologic and energy cycles with evolving fully coupled atmosphere–land–ocean components; and conduct pilot studies with international participation encompassing the full range of experimental scales (regional, continental, and global scales) (Figure 2).

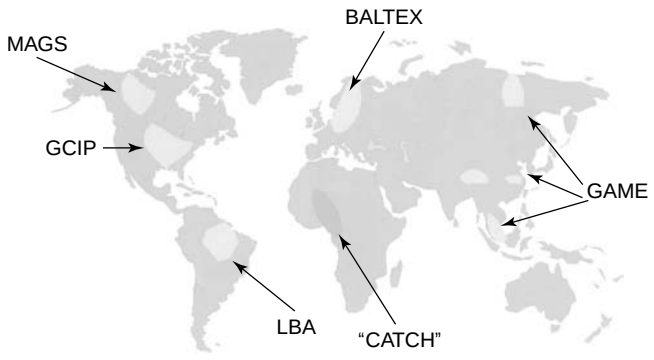

Figure 2 Regional data

A central activity of GEWEX addresses the influence of continental hydroclimatic processes on the predictability of global atmospheric circulation patterns and changes in water resources, with a particular focus on heat source and sink regions, using data sets collected from the GEWEX Continental Scale Experiments and related components of GEWEX, as well as other global hydrology initiatives (website: www.gewex.com⟨http://www.gewex.com/⟩).

PAUL TRY *USA*

Glaciers

Mark F Meier
University of Colorado at Boulder, Boulder, CO, USA

People have long been fascinated with glaciers. This is because of their obvious changes from year to year in response to a fluctuating climate, as well as their striking appearance and the apparent enigma of a brittle, crystalline substance visibly flowing down valleys. Now glaciers are subject to renewed scientific inquiry due to their usefulness as indicators of environmental change through the study of their internal layering and entrapped samples of ancient atmospheres. In addition, their role in causing rising sea levels and other effects on the environment is a cause for concern.

We discuss here all perennial ice masses lying on the Earth s land surface, except for the ice sheets of Greenland and Antarctica (*see* Antarctica, Volume 1; Greenland Ice Sheet, Volume 1). Thus we include mountain glaciers, ice fields, ice caps, and all other masses of glacier ice of less than continental dimension. Several hundred thousand of these glaciers exist on Earth. The combined area of this ice is about 680 000 km^2 with an estimated volume of 180 000 km^3. Were this ice to melt, sea level would rise about 0.5 m. Glaciers occur at almost all latitudes, including on or near the equator in South America, Africa, and Southeast Asia, to around the margins of the Greenland and Antarctic ice sheets (Table 1).

CLIMATE VARIATIONS AND GLACIER FLUCTUATIONS

Most glaciers advance and retreat in response to changes in climate; few are large enough to influence climate directly. The glacier–climate interaction can be pictured as a chain of processes, progressing from climate, through the glacier mass balance, to the resulting change in a glacier. The atmospheric environment (weather, climate) leads to processes of heat and mass exchange at a glacier surface. Mass gains (accumulation) are primarily due to snowfall, and mass losses (ablation) are usually due to melting followed by runoff. The difference between these gains and losses is called the net mass balance. Accumulation, ablation, and balance can be measured at a point or integrated over a total glacier area. Not all meltwater runs off and causes loss of mass to the glacier; some may refreeze in cold snow (internal accumulation). Glaciers reaching the ocean may also lose mass due to the discharge of icebergs.

Glaciers flow from an accumulation area where accumulation usually exceeds ablation and where the mass balance is defined as positive, to an ablation area where ablation usually exceeds accumulation and the mass balance is negative. The boundary between these two areas is the equilibrium line, and its position is a sensitive measure of a glacier s state of health (growth or shrinkage) at any given time. Glacier flow carries the excess mass of the accumulation area to where it is lost in the ablation area.

If the climate changes so that the rates of accumulation or ablation change, this changes the amount of mass added or lost from the glacier and thus its thickness. The rate of glacier flow depends critically on thickness, so the flow changes as the thickness changes. This produces change in the glacier s length (advance or retreat of the terminus), width, thickness, and volume. This change can be observed directly, or inferred from geological evidence of past positions (moraines, trimlines, etc.). Feedbacks occur in this process; for instance, the changed area affects the mass balance because it is now integrated over a different area. These fluctuations tend to bring the glacier to a new equilibrium state (Paterson, 1994).

The discussion above refers to normal glaciers. Two unusual classes of glaciers have inherent instability mechanisms that cause them to fluctuate independently of climate change. Surging glaciers oscillate between short intervals of rapid flow during which they can move up to several hundred meters per day (typical flow speeds of normal glaciers are of the order of 0.1–1.0 m day^{-1}) and periods of slow recovery from an extended position. These oscillations can be repeated at regular intervals from decades to centuries. Tidewater glaciers, which discharge icebergs into the sea and rest on bedrock (not floating), tend to advance slowly when the terminus is in relatively shallow water. But if the terminus backs off into deep water (which might be caused by a minor retreat off a moraine bank), the glacier may retreat irreversibly and rapidly until the terminus is again in shallow water. Such a situation can produce an oscillation of slow advance and rapid retreat; the period of this oscillation for tidewater glaciers in Alaska is of the order of 1000 years. Neither of these oscillations is directly

Table 1 Total areas of glacier ice in major regions, and the dimensions of some well known glaciers[a]

Region	Glacier type	Area (km^2)	Length (km)
Arctic Islands		245 000

related to climate fluctuations, but they could be affected by climate changes.

GLACIER MASS BALANCES

One approach to modeling glacier variations is to use knowledge of climate history, working forward through the mass balance and dynamic response steps. A second approach is to work backward from the size variations through the dynamic response physics to infer the changes in the mass balance. However, it is impossible then to infer the causal climatic changes without additional information, because the net mass balance is the difference between two quantities (input minus output). Thus, understanding the mass balance occupies a central position in investigations of climate/glacier interactions.

Although one cannot infer climatic variables directly from glacier net mass balances, it is often possible to make estimates of snow accumulation and melting based on seasonal data. During winter, accumulation normally predominates over ablation, so a change in balance from the beginning to the end of the winter accumulation season (winter balance) provides an approximate measure of winter precipitation. The summer balance of the rest of the year is related largely to summer melting, which may be estimated using summer temperature. This approximation does not hold true for glaciers in monsoonal or tropical climates, but is useful in most glacier covered areas.

The change in net mass balance caused by a 1 $^\circ$C change in air temperature (mass balance sensitivity) is often used in glacier–climate modeling (e.g., Wigley and Raper, 1995). Oerlemans and Fortuin (1992) show that this sensitivity is also a function of precipitation. This concept has been extended to sensitivities of winter and summer balances to temperature. Numerical models of the changes in glacier mass balances due to variations in annual or winter precipitation and annual or summer temperature have been used extensively, and some of these incorporate glacier dynamics

to simulate glacier advances or retreats. However, these models must be calibrated against a period of observational mass balance data in order to extend the results back in time or into the future.

The World Glacier Monitoring Service in Zurich is charged with archiving and distributing mass balance observations collected around the world (website: http://www.geo.unizh.ch/wgms/). Cogley *et al.* (1998) and Dyurgerov and Meier (1997) have used these data together with additional observations and careful data quality analyses to produce enhanced data sets on the time series of mass balances. A major problem is the fact that before the late 1950s less than 10 glaciers were regularly measured, and since 1960 only 30–85 glaciers have been measured for mass balance. The paucity of the data is exacerbated because most of the measured glaciers are concentrated in Europe, parts of central Asia, and western North America, leaving large gaps in coverage in the Southern Hemisphere and in the polar regions.

These compilations show generally negative mass balances since the 1960s, with increasingly negative values since 1990, and much year-to-year variability (Figure 1). These trends show a crude relation to trends in mean annual Northern Hemisphere air temperature.

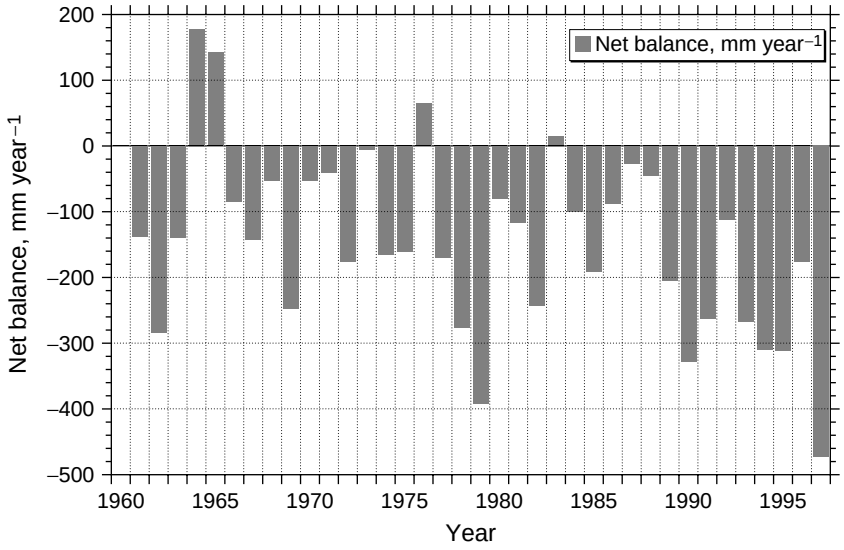

Figure 1 Annual average values of glacier net balances, in mm year^{-1} of water equivalent. The observed values have been weighted by the areas of major glacier covered regions and combined to form a global average. (Data compiled by Dyurgerov, 1999)

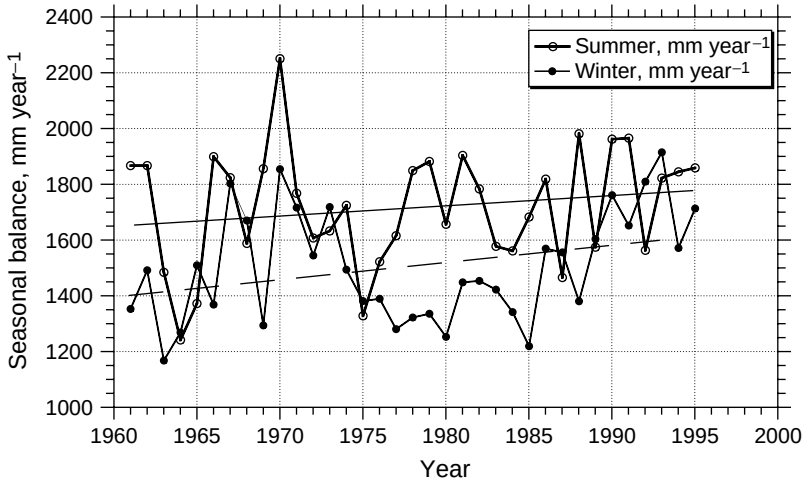

Figure 2 Winter (dots, thin line) and summer (circles, heavy line) balances of the observed glaciers of the world. The observed values have been weighted by the areas of major glacier covered regions to form a global average. Long straight lines indicate trends in the data. (Data compiled by Dyurgerov, 1999)

The trend in seasonal mass balances shows the relation between glacier changes and climate more directly (Figure 2). The trends in both winter accumulation and summer ablation since 1960 have been intensifying, but the annual fluctuations in these balances are often of different sign. During this period the altitude of the equilibrium lines has been rising, leading to diminishing accumulation area and increasing ablation area. Glacier mass balances also show teleconnections related to large-scale climatic patterns (Hodge *et al.*, 1998; McCabe *et al.*, 2000).

ICE CORES

An enormous amount of climatic information is deposited within the layered snowpack at the surface of a glacier. However, most glaciers now experience some summer (or all-year) melting, and this tends to wash out or otherwise degrade much of the interesting climatic information. Very high altitude glaciers (above 5000 m in altitude) at temperate or tropical latitudes, along with polar ice caps and ice sheets, may experience relatively little melting and thus preserve useful climatic information. These records may provide a rich history of paleoclimatic and paleoenvironmental information: accumulation, fallout, chemistry, and stable isotopes (Thompson *et al.*, 1993). These can be used to provide information on both spatial and temporal changes. Such cores have been obtained from high mountains at many latitudes, even close to the equator. The tropical glacier records, especially, show striking evidence of recent warming that is also, unfortunately, degrading these unique environmental and climatic records (Thompson *et al.*, 1993).

THE GLACIER DYNAMICS PROBLEM

Changes in mass balance cause changes in length, width, thickness, and volume of a glacier, but the pattern and rate of the geometric changes involves a dynamic (ice flow) response. Glaciers move by internal deformation caused simply by gravity acting on the weight of the ice, and, in the case of glaciers, which are at the melting point at their base, by sliding over the bed. These processes are very non-linear (Paterson, 1994). They are also sensitive to temperature: temperate glaciers (those at the melting point of ice) flow and react fairly rapidly, whereas cold or polar glaciers (those with internal temperatures below freezing) react much more slowly. Thus glaciers with similar sizes and shapes may react differently, depending on location, to a climate change.

Changes in the glacier s dimensions are not instantaneous so even with a step change in climate from one constant regime to another, the glacier will be out of equilibrium for some time. This response time (defined as the time it takes to reach 63% of the final value for a step change in climate) is typically of the order of 10 to perhaps 1000 years. Jóhannesson *et al.* (1989) have shown that the response time can be estimated as mean glacier thickness divided by mass balance at the terminus. Recent work has shown that response time depends on other factors also, and it is possible for large glaciers to have somewhat shorter response times than small glaciers, contrary to intuition.

In order to model the time series of changes in volume of a glacier, a simple decay (exponential) function may be used with response time controlling the rate of change (e.g., Wigley and Raper, 1995). The mass balance over time can be estimated from observed or projected temperature values using an observed mass balance sensitivity. Compilations of global or regional totals are difficult because each glacier has individual values of each of these parameters, and most glaciers have not been measured. The theory of stochastic scaling (Bahr, 1997) offers an opportunity to circumvent at least some aspects of this problem. It is relatively easy to determine glacier area, from a limited number of glacier inventories or by using aerial photography or satellite imagery. Scaling may, for instance, use the equations of glacier continuum mechanics to relate glacier size to other parameters that are difficult to measure, such as glacier volume and response time. These results can then be used to obtain distributions of the parameter values, which are needed for global or regional synthesis. This technique holds promise.

CHANGES IN GLACIER SIZE

Measurements of fluctuations of glacier length have been collected since at least the 14th century, and in 1894 the International Commission on Glaciers (now the International Commission on Snow and Ice) was formed to encourage and coordinate such efforts. These observations have been extended back in time by other indicators such as old paintings, moraine dating, lichen ages, tree rings, and radiocarbon dating. Although marked differences exist from region to region, these long-term records generally show minimum lengths of glaciers during the Medieval Warm Period, advances in many areas during the Little Ice Age from the 15th through the 19th centuries, and retreats since then (*see* Little Ice Age, Volume 1; Medieval Climatic Optimum, Volume 1). An example is South Cascade Glacier in Washington State (Figures 3 and 4).

An estimate of the time of an early advance of this glacier (5000 years ago) was obtained from radiocarbon dating of tree stumps that had been overridden by the advancing glacier and perfectly preserved until exposed at the terminus by glacier recession in 1958. Other information on terminus positions was obtained from tree ring counts or actual measurements. These data show that the fluctuations

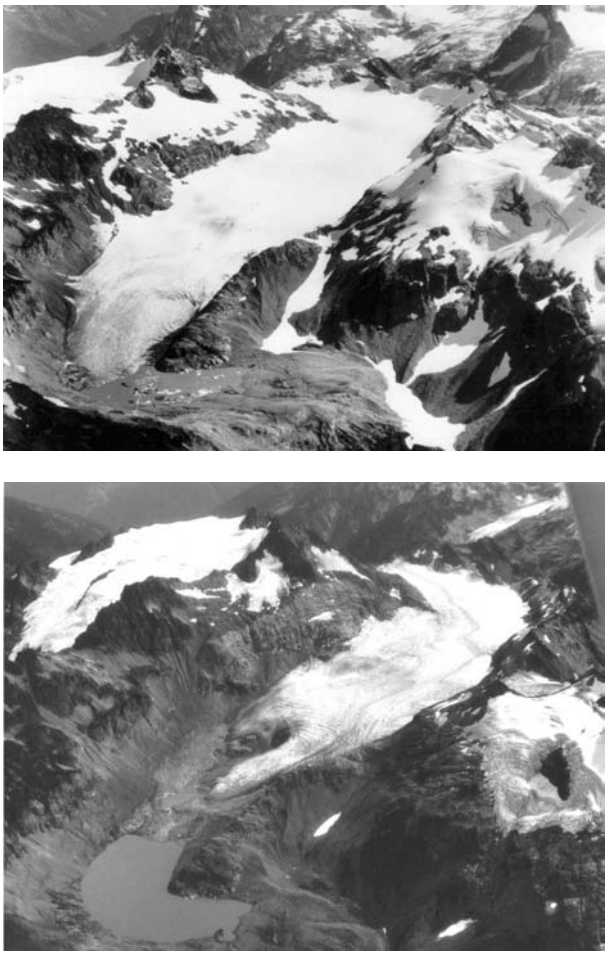

Figure 3 Photographs of South Cascade Glacier, in the North Cascades of Washington State, in 1958 (a) and in 1993 (b). Note the striking recession. (a) photograph by Austin Post, University of Washington; (b) photograph by Robert Krimmel, US Geological Survey

in length varied only between 3.6 and 4.6 km throughout the Medieval Warm Period, the Little Ice Age, and other climatic oscillations over the past 5000 years, whereas in the 20th century the glacier diminished to 2.9 km in length. This recent recession exceeds the 5000 year range of normal climate variability.

Fluctuations in glacier volume or mass balance can be measured. Many glaciers have been mapped repeatedly and some have also had measurements of thickness. For those without thickness data, it is often possible to estimate volume using scaling. A major loss of glacier ice from the late 19th to the late 20th century has occurred (Table 2). As much as half of the ice has disappeared in this century in many temperate and tropical latitudes. The recent loss of ice in Southeast Asia (Irian Jaya) and Africa has been striking, but these tiny glaciers are in a marginal climatic environment for the preservation of ice. Glaciers in the high Arctic have been shrinking very little. These high latitude

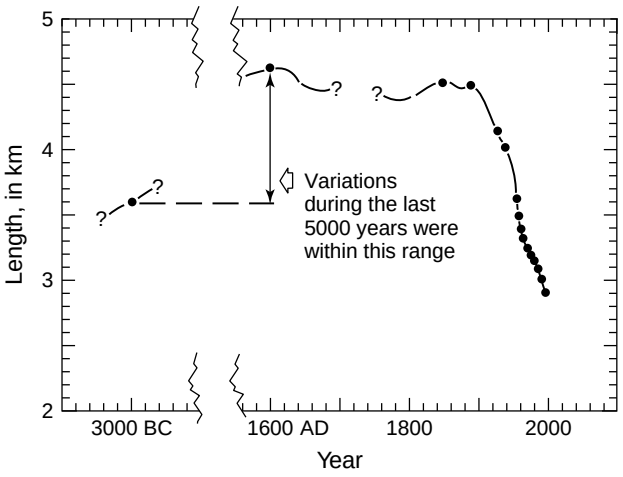

Figure 4 The history of advance and retreat (changes in length) of South Cascade Glacier. The position of the glacier between 3500 BC and 1600 AD is unknown but it had to have been between the limiting positions of these two dates because no evidence of advances beyond the 1600 AD position exists, and the dated tree stump would have rotted had it been exposed before 1958

glaciers are well below freezing in temperature throughout most of their mass, thus global warming may have produced more surface melting, but refreezing of this water below the surface has only warmed the glaciers, producing very little loss of mass.

ENVIRONMENTAL EFFECTS OF GLACIER CHANGES

Runoff, Outburst Floods, and Riparian Ecosystems

Glaciers have a self-regulating effect on streamflow: at a time of climatic warming, increased ablation increases runoff, while runoff may decrease in non-glacier streams. The additional increment of water from glacier wastage is thus especially valuable in semiarid agricultural regions such as along the Andes and in central Asia. But as the glaciers lose mass and area, this extra increment of water disappears, leaving, in a global warming scenario, a significant loss of water supply. Such an effect is expected in 10–100 years.

Glacier outburst floods, the abrupt release of water stored under a glacier in volcanic areas or due to the damming of a tributary river, can have a devastating effect on transportation corridors, other works of humankind, and riparian ecosystems (Bjornssonn *et al.*, 1998). Glacier thinning and retreat may cause a temporary increase in outburst floods but is also likely to prevent others from forming. The net effect is not known but will be very specific to the local environment.

Glacier fed runoff usually has a strong seasonal component (maximum flow in midsummer), and an equally strong

Table 2 Long-term changes in area and volume of glaciers in certain glacier covered regions[a]

Area	Time period	Loss of area (%)	Loss of volume (%)
Changes in mid-latitude glaciers			
Switzerland	1850–1973	27	31

diurnal component (maximum flow in late afternoon). Glaciers also provide finely ground rock particles (flour) to the stream. As a result, glacier rivers are always out of equilibrium and full of sediment due both to the rock flour and the constant adjustment of channel geometries. This produces distinctive types of river flood plains, geomorphic forms, and ecosystems. Removal of the glacier will change these characteristics in ways that are not easy to predict.

Icebergs

Iceberg discharge, called calving, is important in some areas such as Alaska, the Arctic, the Antarctic Peninsula, and high latitudes in South America. The discharge of ice from small glaciers may have major local effects on transportation and marine ecosystems in fjords. Calving may increase due to global change because of the warming of high latitude glaciers and the resulting increases in flow rate, but the effect has not yet been quantified.

Sea Level Rise

Many studies have been made to estimate the contribution of glacier runoff to present day sea level changes, and to project the future contribution to sea level rise for various temperature and precipitation scenarios. The 1995 Intergovernmental Panel on Climate Change (IPCC) (Houghton *et al.*, 1996) estimated that this contribution was between 2 and 5 cm over the last 100 years, out of a total measured sea level rise of 10–25 cm. More recent studies generally fall within this range, but some suggest more and some much less than the IPCC values. The IPCC used simple models to project this component of sea level rise into the future using agreed on scenarios of the growth of greenhouse gases and sulfate aerosols, and thus future regional climates. The central estimates project a sea level rise due to glacier wastage by the year 2100 of about 16 cm, but with a wide spread of possible values. Thus, about a third of the small glacier ice on Earth is likely to disappear during the 21st century (Church, 2001).

Existing estimates range widely due to differing methods of analysis and techniques for averaging or combining data from known glacier observations. Long-term records of mass balance exist for only a tiny fraction (<0.01%) of the world s glaciers, and rather drastic assumptions are needed to develop regional or global averages. Climatological data are more complete, but are seriously inaccurate in high mountain areas, and the problem of calibrating models using mass balance sensitivity still exists because of the paucity of data. The problem is compounded by insufficient knowledge of glacier response times, a very difficult parameter to measure. Modern mathematical techniques, such as scaling, may prove to be useful in developing distribution functions of glacier parameters, which then can be used to make analyses of present change and projections into the next century with much greater confidence. This is a fertile field for research.

Global Plate Tectonics

Global plate tectonics provides the theoretical framework of modern Earth sciences. The theory holds that the Earth s surface layer, the *lithosphere*, is broken into 12 major rigid pieces or plates that move relative to each other. Plate motions are possible because the lithosphere rests upon a partially molten layer, the *asthenosphere* (*see* Plate Tectonics, Volume 1).

The major tectonic features of the globe are caused by plate interactions along three types of boundaries: convergent, divergent, and transform. At *convergent boundaries*, plates collide to generate mountain belts and volcanoes. At *divergent boundaries*, plates separate to form the mid-ocean

ridges and continental rifts. At *transform boundaries*, plates slide past one another to form transcurrent faults, such as the San Andreas, which marks the boundary between the North American and Pacific plates. Most earthquakes and volcanoes occur along plate boundaries, and the world s major physiographic features are records of past or present interactions.

Global plate tectonics is crucial to our understanding of the Earth s dynamic nature. Because the plates are in motion, the configuration of continents and oceans is constantly shifting. This explains continental drift, with its impact on evolution and speciation. Plate tectonics also plays a role in climate change. Throughout geological history, plate motions have directly affected regional climates, as continents moved passively though climate zones, and as the uplift of mountains transformed local climate patterns. Globally, the reconfiguration of continents and oceans alters oceanic circulation, which in turn affects global climate patterns. Furthermore, changes in weathering rates and volcanic activity caused by plate interactions can affect the long-term concentration of atmospheric carbon dioxide (CO_2), which may account for a significant fraction of the long-term cooling from the Cretaceous to the Pleistocene. Tectonics is thus an essential part of understanding both physical and biological global change.

Global Warming Potential (GWP)

Global warming potentials (GWPs) provide a means of quantifying the relative potential integrated forcing on climate from emissions of various greenhouse gases (*see* Radiative Forcing, Volume 1). In the international assessments by the Intergovernmental Panel on Climate Change, GWPs have been defined as the time-integrated radiative forcing from the instantaneous release of a unit mass of a gas, expressed relative to that of the same mass of the reference gas, generally taken as carbon dioxide, the gas of most current concern to climate change. Thus, the concept of GWPs is an index to estimate the relative impact of emission of a fixed amount of one greenhouse gas compared to another, for the globally averaged radiative forcing over a specified time scale. GWPs provide a better measure of the relative greenhouse impacts than radiative forcing alone, as they help differentiate between gases that would reside in the atmosphere for vastly different amounts of time, from days to, in some case, many centuries. The GWP concept is based on the science of greenhouse gas effects, but does not include climatic or biospheric feedbacks nor consider resulting impacts on the environment. GWPs are normally only applied to gases that are well mixed in the atmosphere.

Table 1 gives the GWPs for many compounds of interest, either because of their direct potential importance to climate or because they are being considered as replacements for chlorofluorocarbons (CFCs) such as the hydrochlorofluorocarbons (HCFCs) and hydrofluorocarbons (HFCs). The GWPs are shown for integrated time horizons of 20, 100 and 500 years. No single choice matches all of the applications of this concept. Policymakers often use the 100-year time horizon. In addition to the direct radiative effects of these gases on climate, many of these gases also have indirect effects on climate due to their chemical effects on other radiatively important gases like ozone. For example, the GWP values for methane in the table include its indirect effects on tropospheric and stratospheric ozone and on stratospheric water vapor.

[a] *Source:* World Meteorological Organization (1999).

there may be many predictable components of fluctuations on these time scales. It will extend our understanding, analytical, modeling and predictive capabilities of natural climate variability on seasonal to interannual time scales, building on the knowledge and experience gained in the Tropical Oceans Global Atmosphere (TOGA) program (*see* TOGA (Tropical Ocean Global Atmosphere), Volume 1). Because GOALS has an emphasis on prediction, it will also take an interest in slow components of the climate system that give it a memory. Therefore, how the atmosphere interacts with the oceans, the land surface, and sea and land ice fields are key aspects of GOALS. The potential is to greatly improve seasonal predictions of climate variations and bring that knowledge to applications that would greatly benefit society.

CLIVAR/GOALS will examine the variability and predictability of the climate system on seasonal to interannual time scales by:

1. developing observational capabilities to describe seasonal and interannual climate variability;
2. further developing models and predictive skills for sea surface temperature and other climate variables on seasonal to interannual time scales around the entire global tropics;
3. building understanding and predictive capabilities of the interaction of monsoons with the oceans, El Niño/Southern Oscillation (ENSO) and land surface processes;
4. extending predictions from the tropics to higher latitudes, by improving understanding of CLIVAR arising

from the teleconnection linkages from lower latitudes, and interactions between the tropics and extratropics;

5. exploring the predictability and building predictive models of extratropical seasonal to interannual climate variability induced by the intrinsic low-frequency components from high latitudes such as extratropical sea surface temperatures (SSTs), soil moisture and other land surface processes, sea ice, snow cover, along with other forcings such as from volcanic eruptions. Key aspects will include improved representation in models of critical feedbacks, oceanic water mass formation, the hydrological cycle and sea-air coupling.

Initial foci of GOALS include projects dealing with global aspects of ENSO, the Variability of the American Monsoon System, the Asian–Australian Monsoon system, and African Climate Variability. More information on GOALS may be obtained from the worldwide web at http://www.clivar.org.

Greenhouse Effect

The term *greenhouse effect* refers to the reduction in outgoing infrared radiation to space due to the presence of the atmosphere. It can be and has been directly measured, based on the surface emission (which depends only on temperature) and the emission at the top of the atmosphere as observed by satellites. The greenhouse effect arises because the atmosphere is colder than the surface of the earth, so that the amount of radiation that the atmosphere emits to space is less than what it absorbs from the surface, giving a net reduction in emission to space. The largest contributor to the natural greenhouse effect is water vapor, followed by carbon dioxide and ozone. The natural greenhouse effect causes the global average surface temperature to be about 33 °C greater than it would be otherwise.

The physical mechanisms by which the presence of the atmosphere warms the climate and the primary mechanism that causes a glass greenhouse to be warm are different. A greenhouse heats up by day as the air within it is heated by the Sun. Outside the greenhouse, near-surface air that is heated through absorption of solar radiation by the ground surface is free to rise and be replaced with colder air from above. This cannot happen in a greenhouse because the heated air is physically prevented from being replaced with colder air. The so-called atmospheric greenhouse effect involves the net trapping of infrared radiation, which occurs independently of the movement of individual air parcels or the lack thereof. The term *greenhouse effect* is therefore a misnomer; it would be more appropriate to call it the atmospheric effect. There is, nevertheless, a weak similarity between the effect and what happens in a greenhouse. The glass enclosure will absorb some (close to 100%) of the radiation emitted from within the greenhouse, but will re-emit a smaller amount of radiation to the sky if the outer surface of the glass is colder than the interior of the greenhouse, in the same way that the emission of radiation to space is reduced if the atmosphere is colder than the surface of the earth.

Humans have already started to strengthen the natural greenhouse effect, primarily through the buildup of atmospheric carbon dioxide and, to a lesser extent, methane. As the climate warms in response to the buildup of these and other greenhouse gases emitted by humans, the amount of water vapor in the atmosphere will increase, thereby strengthening the greenhouse effect further (*see* Climate Feedbacks, Volume 1; Energy Balance and Climate, Volume 1; Infrared Radiation, Volume 1).

Greenland

Anna Mia Stampe
Danish Space Research Institute, Copenhagen, Denmark

Greenland, the largest island in the world, is the site of much research contributing to our understanding of the climate and climate changes. Results from Greenland may be seen as a few pieces in that enormous bio-geo-chemical puzzle of the global environment. Climate research involves phenomena over a tremendous range, from oscillations in local weather on decadal scales to the global-scale glacial cycles a hundred thousand years in length.

This article provides:

- *a short description of the geography of Greenland;*
- *a short description of Greenland's contemporary climate;*

- *a discussion of why Greenland is so important in climate research, and finally;*
- *a brief overview of essential results from various scientific fields carried out in Greenland.*

FACTS ABOUT GREENLAND

Geography

Greenland is part of the Kingdom of Denmark, but is not a member of the European Economic Union and it has had home rule since 1979.

Greenland is the largest island in the world. It belongs to the North American continent and is situated within the area 59.5 to 83.4° North and −11.2 to −73.1° East. The ice-free area covers roughly 410 000 km^2, which counts for only 15% of Greenland's total area of 2 166 086 km^2. Figure 1 shows the island with the most important geographical locations indicated. The ice-sheet, or Inland Ice extends 2500 km north–south and up to 1000 km east–west (*see* Greenland Ice Sheet, Volume 1). At the center, the ice is more than 3000 m thick and represents 10% of the world's total fresh water reserves. The highest point is 3700 m high at Gunnbjørns Field on the east coast between Tasiilaq and Illoqqortoormiut. Today the northeastern part – approximately one-third of the whole country – is protected as the world's largest national park (Greenland Statistical Yearbook, 1998).

Greenland is the site of the oldest sedimentary rocks ever dated: 3700 million years. In comparison the Earth is about 4600 million years old (Minik, 1999). The ice-free coastlands are characterized by mountainous terrain. The highest peaks are situated on the east coast where peaks reach almost 4000 m above sea level. Greenland's topology was shaped by the glaciers of previous ice ages, but in several locations traces of geological processes have been found, such as earthquakes, formation of mountain ranges, volcanic activity, etc.

Contemporary Climate

The climate of Greenland is arctic and primarily controlled by the relatively warm surface of the North Atlantic Ocean and cold surface of the ice cap, which rises to altitudes of more than 3000 m. However, the presence of sea ice, cooling of the North American continent in the winter and the steep coasts of Greenland have a significant impact on the local climate, especially to the south. The annual mean temperature is below zero and summer temperatures rarely exceed 10 °C. Only inside deep fjords in the south are temperatures above this level found in summer. The lowest temperature ever recorded in the country was −70 °C at the northernmost tip of the ice cap. The coldest month is February and the warmest month August (in the coastal area: July). To the north the pattern is of continental or high arctic type (cool summers and very cold winters). The range between the coldest and warmest months is as much as 30 °C. To the south the pattern is oceanic (cool summers and relatively mild winters) with temperature ranges less than 10 °C.

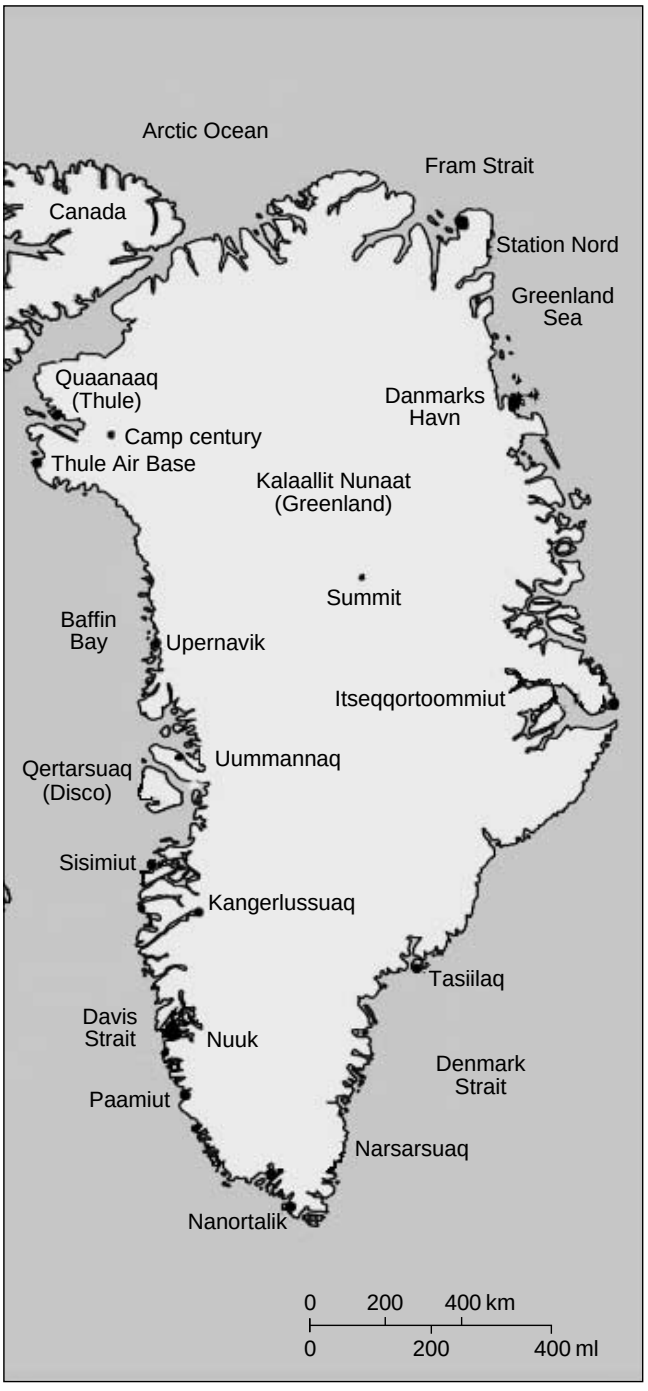

Figure 1 A simple map of Greenland showing the most important geographical locations and deep drilling sites

Precipitation varies considerably, from 800–1400 mm at the coastal stations in South Greenland to only 200 mm in the northernmost areas, which must be considered an arctic desert (Greenland Statistical Yearbook, 1998).

Most of Greenland is surrounded by sea ice, except for the southwestern shores, which are normally free of sea ice throughout the year. Several meters thick, sea ice of Arctic Ocean origin drifts southwards in the East Greenland Current and deteriorates near Cape Farewell. Locally formed sea ice (thickness: about 1 m) covers most of the Davis Strait and Baffin Bay from mid-winter until late summer. Permafrost, i.e., layers of permanently frozen soil, prevails over all of northern, and partially southern, Greenland.

In winter an area of high pressure normally exists over the northernmost part of Greenland (and northern Canada and the Arctic Ocean). Cooling of the atmosphere, primarily due to the negative radiation balance over the ice cap or sea ice covered waters far from open water, contributes to formation of this high-pressure region. The high pressure is accompanied by northerly winds (a winter monsoon) prevailing in the west and northeast Greenland waters. At the same time a low-pressure area, extending from Newfoundland via Iceland to the Norwegian Sea, together with an area of similar low pressure along the southwest coast, reflects the main zone of cyclonic activity. It appears that Greenland generally receives its stormy weather from the southwest. About 60–70% of all cyclones approaching South Greenland arrive from directions between west and south-southeast.

In summer, the mean gradient of sea level pressure around Greenland is weak and no prevailing wind direction is discernible. Cyclonic activity may take place anywhere in the Greenland area. During the year the highest pressure normally occurs around April. The lowest pressure occurs in September/October over Canada and in December/January over Greenland.

Due to the large temperature gradients and instability of the atmosphere many Atlantic cyclones develop and pass near the southern tip of Greenland, frequently causing very strong winds off south and southeast Greenland, often intensified by the orography in the fjords or at the coast.

WHY IS GREENLAND INTERESTING FOR CLIMATE RESEARCH?

Greenland is of tremendous interest to climatologists and other geophysicists for the following reasons:

- Greenland s Inland Ice represents a store of water and energy making it an important parameter in climate modeling.
- Almost all living species (flora or fauna, including humans) in an arctic region like Greenland, are on the edge of existence and to a very high degree depend on the mercy of nature.
- Climate research has shown that regions at high latitudes in general tend to be much more sensitive to climate change than are low-latitude regions. This means that if any global changes in climate occur they are more likely to be discovered in the Arctic, where impacts most probably will be more pronounced.
- Greenland is among the cleanest environments in the world, meaning that it is possible to get samples that are not polluted by contemporary waste products.
- Finally, we find in the ice caps a neatly stacked archive of information on the climate. The ice itself contains physical and chemical indications of the past. The world s two biggest ice caps, the Antarctic and the Greenlandic, provide us with time series of climate data reaching several hundred thousands years back in time. These Greenlandic data are important climatic indicators for the North Atlantic region, and in many cases also for global climate conditions as the ocean currents link the Northern and Southern Hemisphere.

When it is said that Greenland (and the Arctic in general) is a clean environment, it should in the same breath be mentioned that it is at the same time extremely sensitive to anthropogenic pollutants. Pollution in the Arctic affects nature as well as the people, of whom the majority depend on wildlife harvesting, which is the basis of their society, culture, and economy.

Sadly and ironically, Arctic people are scarcely themselves responsible for any of the major pollutants threatening the environment. On behalf of eight Arctic countries (Canada, Denmark/Greenland, Finland, Iceland, Norway, Sweden, Russia, and US) comprehensive investigations of the extent and levels of anthropogenic pollutants have been carried out by the Arctic Monitoring and Assessment Programme (AMAP) (1997). AMAP reports show that, in particular, among the harmful substances are a number of persistent organic pollutants (POPs), heavy metal contaminants from industrial sources in Europe and North America, sulfur and nitrogen compounds from sources associated with industries, energy production and transport, and finally radioactive contamination from nuclear plants. The contaminants are spread though the atmosphere and the oceans from which various processes remove them and make them available to plants and animals. This often leads to an accumulation within the food chain, leaving the higher mammals such as seals, polar bears and humans as the final destinations for these substances.

The above mentioned pollution sources are all remote and controlled by foreign political decisions. Thus, keeping the Arctic clean depends to a great extent on the common sense and goodwill of other nations.

TIME SERIES OF ENVIRONMENTAL DATA

The most important things to be aware of when working with climate data, typically a time series of various parameters, are the time scale and the limits of interpretation. Often we see time series of historical data, apparently showing a significant trend. However, if the data were viewed on a longer time scale, they would not have exhibited the same dramatic effect. The problem is that most often we only have data from recent years, a decade or a century, making it impossible to see the longer variations. Continuous and reliable measurements of atmospheric or hydrospheric parameters have only been carried out since the middle of the 19th century. When we are talking about climate variations, we should always bear in mind that the small portion of data we have does not represent the general system. Neither will a model, solely based on these data, be able to describe climatic regimes different from the present one. Therefore, it is tremendously valuable, when sources such as ice and sea-sediment cores can provide us with data series reaching much further back.

Sea-sediment cores are excellent long-scale cross-references to the glacial cores. Because the annual deposition of organic matter on the seabed is much lower than the annual snow deposition on the ice caps, the yearly resolution is much lower than for the ice cores. On the other hand, from sea-sediment cores we can obtain much older information.

CLIMATE RESEARCH IN GREENLAND

Greenland is the setting for a great many research projects, including biological, chemical, geophysical and meteorological ones. All of them contribute to a better understanding of climate and the Earth as a complex system. The following merit special mention:

- Extensive mapping of the distribution of flora and fauna. The Zackenberg Station on the west coast is the base for this work, which contributes to the general picture of Greenland s present bioclimate (Rasch, 1999).
- Meteorological measurements, which (as part of the global meteorological network) contribute to climate research as well as forecasting.
- Ozone measurements are also closely linked to the Global Ozone Monitoring Network. This is an important task because the thinning of the stratospheric ozone layer is worst over the Arctic and Antarctic regions (Goutail *et al.*, 1999).
- Magnetic field measurements: little is known of the extent to which our climate, especially cloud formation, is affected by cosmic particles. Measuring the Earth s magnetic field, which is highly influenced by particles produced by magnetic eruptions on the Sun, may provide further insight.
- Oceanography: the sea and the currents surrounding Greenland are very important parts of the global circulation.
- Sea ice studies: the extent of sea ice and the associated drift patterns are closely watched, partly for safety reasons because sea ice can be extremely dangerous to navigation, and partly because sea ice plays an important role in the complex climate system.
- Glaciology: in Greenland this primarily involves ice core drilling and analysis, mass balance studies and glacial morphology. All three fields contribute to understanding of the past climate.

A few words about the Inland Ice would be appropriate here, because it is the most characteristic feature of Greenlandic geography. The Inland Ice is the world s second largest ice cap. It covers approximately 1.7 million km^2 and 65% of this is situated above 2000 m altitude.

To the early Inuit people, the interior of the Inland Ice was a mythological, dangerous area only occupied by spirits and wickedness. This barren ice desert was no place for humans to go. To the Europeans, who later came to the island, the Inland Ice was primarily an obstacle blocking easy travel from one coast to another. Eventually explorers saw it as a challenge; arm wrestling with Nature. Who would be the first to win? Although many attempts were made, it was the then only 27 year old Norwegian, Fridjof Nansen and his party who first crossed the Greenland Inland Ice on their first polar expedition in 1888. Subsequent explorations included those by the American, Robert Peary and the Dane, Ludwig Mylius-Erichsen. Many different scientific (especially meteorological and geodetic) expeditions followed during the 20th century. Among other scientists, the German, Alfred Wegener, and later the Frenchman, Poul-Emile Victor, completed several important projects. Willi Dansgaard from Denmark initiated the era of climate research through ice core drilling in the late 1960s.

The ice cap is created when moist air from the sea is forced by the wind over the mountains in the coastal areas (orographic lifting). This causes the air to lose its humidity in the form of snow, which does not melt because of the northern location and high altitude. The annual accumulation is, on average, 35 cm. The snow is slowly compressed due to subsequent depositing of snowfall; within approximately 100 years the ice is transformed into glacial ice. Glacial ice is characterized by tiny bubbles of air, which were originally between the loose snowflakes, trapped within the ice matrix. These bubbles provide well preserved samples of atmospheric composition from the time when they were sealed off (in Greenland typically at a depth of 70 m). By extracting this air from ice cores from Greenland, and in addition Antarctica, we have a record of carbon dioxide (CO_2) reaching several hundred thousands years back (compared with approximately 45 years of operational atmospheric measurements). The annual layers of ice are

perfectly preserved down through the ice cap. However, due to gravity, they are stretched more and more in lower layers near the bedrock, because the ice, being a plastic material, slowly flows towards the coastal areas, where, in the form of huge glaciers, the ice either melts or breaks off as icebergs. This is illustrated in Figure 2. A significant part of the ice is also lost through sublimation from the surface. All in all, this leaves the ice cap in dynamic equilibrium, as long as the system is not disturbed by exterior forcing such as changes in temperature (for example due to changing ocean currents), precipitation, or solar irradiation.

The idea behind ice core drillings is that atmospheric impurities remain on the surface once they are deposited there. The impurities may be deposited either though simple fallout or as captured by precipitation. The substances include windblown continental dust and biological material, volcanic compounds, sea salt, cosmic particles and isotopes produced by cosmic radiation. The temperature on top of the Inland Ice is too low for rainfall or melting, processes that could remove the substances. The low temperature also prevents post-depositional chemical reactions. Nothing is added and nothing is removed; therefore, the impurities remain undisturbed in the ice as indicators of chemical and physical conditions of the past climate. The composition of the annual layer is only altered through decay of radioactive impurities and through diffusion processes, the latter being a significant process during the firnification (the transformation by compression of snow to ice). Chronological layering is the reason why, by drilling ice cores from the ice cap, we can obtain continuous time series of physical and chemical parameters of our past climate.

The first ice core drilled to bedrock was in 1966 at Camp Century (77.2 °N, 61.1 °W) 225 km east of Thule. This was a scientific breakthrough and an impressive engineering achievement. Other drilling projects followed and from

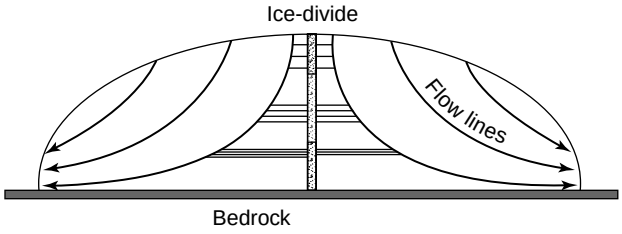

Figure 2 A schematic view of the cross-section of the ice sheet resting upon a horizontal subsurface. Ice particles deposited upon the snow surface will follow lines that travel closer to the base the farther inland the site of deposition. An ice mass formed around the divide (the location where the ice flow has only a vertical component) will be plastically deformed (thinned) with depth as suggested by the thin horizontal lines. The black arrows are flow-lines. They show the assumed profile of the horizontal velocity component

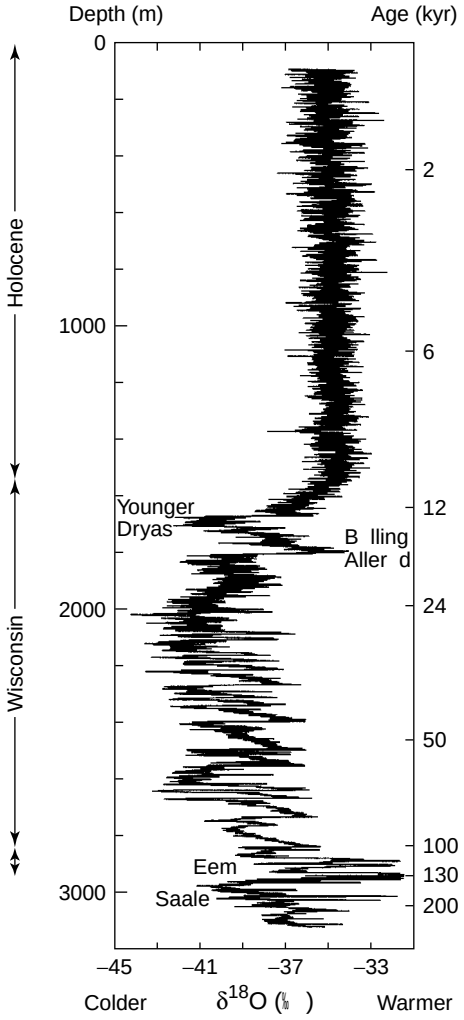

Figure 3 Stable isotope profile of the more than 3000 m long ice-core from the GRIP project drilled at Summit. This curve is produced on the basis of 55 cm mean values. The delta value is a proxy for temperature, the lower the delta value, the colder the air. The *y*-axis to the right indicates the corresponding age. (Reproduced by permission of The Glaciology Group, Department of Geophysics, University of Copenhagen)

the more than 3000 m long ice cores from the Greenland Ice Core Project (GRIP) (72.6 °N, 37.6 °W) and the Greenland Ice Core Project 2 (GISP2) (72.6 °N, 38.5 °W), both close to Summit, we now have a very accurate and detailed temperature profile reaching back about 250 000 years, i.e., back through the last glaciation (the North American Wisconsin Stage corresponding to the European Wurm Glacial Stage), through the previous warm period (the Eemian interglacial period in Europe and Sangamon in North America) and well into the previous ice age (the Saale period in Europe and the Illinoian Glacial Stage of North America) (Dansgaard *et al.*, 1993; Johnsen *et al.*, 1992). Camp Century and Summit are both marked on Figure 1. The

temperatures obtained through ice cores are only proxy values, calculated on the basis of the relation between the stable oxygen isotope ratio (which can be measured very accurately using a mass spectrometer) and the atmospheric temperature at the time of the precipitation. The stable oxygen isotope ratio is measured relative to a sample of standard mean ocean water and given in units per mille. This value is called δ^{18}O. The lower the δ^{18}O value, the colder was the atmosphere. Typical values for Greenland are between -25 per mille (contemporary) and -35 per mille (glacial values). The empirical relationship between the δ^{18}O value and temperature for Greenland is: $\delta^{18}\mathrm{O} = 0.34T - 13.7$. The δ^{18}O–temperature curve obtained from the GRIP core is shown in Figure 3.

Among the major results from the ice cores are the discovery of rapid oscillations of the climate during the Eem period. From marine oxygen isotope records it was known that climatic conditions driving the Eem were at least as warm as today, probably a bit warmer, and apparently also as stable. But the two Greenlandic cores indicate that the Eem was far from being a climatically stable period such as our present Holocene. On the contrary, the rapid regional-to-global climate oscillations that are found during most of the last 110 000 year glacial period, also persisted through the previous warm Eem period. Actually, unstable conditions seem to be more the norm than the exception. This indicates that our recent Holocene period is unique regarding climate. It is not pure guesswork to suggest that this is one of the major reasons for cultural developments in recent millennia in Asia and Europe. Other things being equal, mankind has more energy to develop agriculture and social culture when he doesn t need to fight the elements each day just to survive.

Close to bedrock (where the Eemian ice is to be found), the δ^{18}O profile of the two deep cores, GRIP and GISP2, disagree. To resolve the ambiguities, another big deep-drilling project, NorthGRIP, was initiated in north-central Greenland in 1996. Figure 4 shows the camp as it looked during the first drilling season in 1996. The drilling is expected to terminate during the summer 2001 season. Because the Eemian ice at NorthGRIP is situated higher above bedrock, the layers are less influenced by the bedrock topography; thus, this new core should be able to provide us with the most detailed and reliable data yet of the Eemian period.

From these ice cores we now know that Greenland is roughly 26 °C warmer today than during the recent ice age. This has been confirmed also by direct measurements of the preserved ice age temperature in the ice sheet (Dahl-Jensen *et al.*, 1998). When Eric the Red arrived at Greenland s west coast in 982 AD, the land probably lived up to its name. The climate was milder than today, providing relatively hospitable conditions for settlements to be established and grow. However, during the Little Ice Age (a somewhat ambiguous definition of several colder periods from approximately 1200 AD, to 1850 AD) the Norse cultures in Greenland died out (Dansgaard *et al.*, 1975) (*see* Little Ice Age, Volume 1). The coincidence of events is of course no proof, but it is believable that there is a connection, especially when one degree Celsius means dramatic changes in the ecosystems that are so vital to the population.

The ice cores also show that many of these oscillations, some of which, such as the Younger Dryas and Bølling/Allerød, have been known from sea-sediment cores, were even more rapid than hitherto anticipated. Studies

Figure 4 The NorthGRIP camp as it looked in 1996 where the NGRIP deep drilling project started. (Reproduced by permission of The Glaciology Group, Department of Geophysics, University of Copenhagen)

have shown that the climate can change abruptly within decades, and it has been suggested that the trigger of these fast climatic shifts could be changes in the global ocean circulation, a very important process, which through the Gulf Stream is closely coupled to the Greenland region.

The global circulation system transports enormous water masses which carry energy (or heat) that is critical to the Earth s climatic condition. An important part of this circulation system is the so-called Nordic Sea heat pump (Broecker, 1997; in popular form by Calvin, 1998). Hypersaline water (the result of heavy evaporation due to cold, dry winds from Canada) of the Nordic Seas (the Greenland Sea and the Norwegian Sea) pours like a sub-surface waterfall south into the lower levels of the North Atlantic Ocean with a ferocity of more than thirty times the Amazon River s combined output.

Cold water also sinks in the Labrador Sea between Canada and the southern tip of Greenland. The strength of the process is related to the North Atlantic Oscillation (NAO). The NAO is a major disturbance of the atmospheric circulation and climate of the North Atlantic–European region that is linked to a waxing and waning of the dominant middle-latitude westerly wind flow during winter. Salt sinking on such a grand scale in the Nordic Seas causes warm water to flow much farther north than it might otherwise do. The result is that northern Europe experiences a milder climate than it s latitudinal position otherwise would suggest.

Greenland Ice Sheet

Waleed Abdalati
NASA Goddard Space Flight Center, Greenbelt, MD, USA

The Greenland ice sheet contains roughly 6% of the world's fresh water and 8% of all terrestrial ice, and with a volume of nearly 3 million km^3, it contains enough ice to raise sea level approximately 7 m. Through its exchange of energy, moisture, and mass with the atmosphere and surrounding seas, the ice sheet is an integral part of the regional climate system. Warmer than its austral counterpart, Antarctica, more than half of the Greenland ice sheet experiences some surface melt during the summer. This melt, with its associated reduction in albedo, creates a positive feedback by increasing the amount of absorbed solar energy at the surface, which in turn enhances the melt process. Consequently, this relatively temperate ice sheet is believed to be particularly sensitive to changes in climate. What is not known, however, is how cloud, precipitation, and other feedbacks will affect the overall ice sheet balance as climate changes. A widely accepted notion is that in a warming climate, at least initially, the lower and more temperate edges of the ice sheet will lose mass due to melting, while the upper portions are likely to thicken with increased accumulation. The result is expected to be a net loss of mass, contributing to an increase in sea level.

At a time when record high temperatures are being reported globally, and sea level is rising as much as 2 mm year^{-1}, by some estimates, the current state of balance of the Greenland ice sheet has important implications, yet until very recently, scientists have been unable to say with any certainty whether the ice sheet is growing or shrinking. Assessing and understanding the balance of the ice sheet have been approached by examining individual components of the large-scale mass balance equation (accumulation, melt-runoff, and discharge) and by direct measurement of the combined effects of these components.

Satellite radar altimetry has been used to measure ice sheet surface elevations for over 20 years in southern Greenland and roughly nine years for the ice sheet as a whole. By comparing observed elevations of locations at different points in time, the change in elevation, and by inference mass balance, can be determined. However, because of the physics of the radar interaction with the snow surface, the best results are generally limited to the flat high portions of the ice sheet. As a result, the most dynamic regions are either omitted from such studies, or their findings are widely questioned.

Recently, however, advances in global positioning system (GPS) techniques and airborne laser-ranging have enabled the measurement of ice sheet surface elevation from aircraft to better than 10 cm accuracy over most locations on the ice sheet. Comprehensive repeat elevation surveys with a five-year time separation between re-surveys were completed in the spring of 1999 (Figure 1). By comparing results from the two sets of measurements, the elevation change and subsequent mass balance were estimated at negative 51 km^3 year^{-1} ice (51 billion tons of water). Essentially all of this change was occurring at the lower elevations (below 2000 m), especially in southeast Greenland where thinning on one glacier exceeded 10 m year^{-1}. The upper areas, above 2000 m, which comprise approximately 60% of the ice sheet were essentially in balance over the 5-year period, but with some regional variability associated with topography and climate patterns. High elevation balance was also observed on the 20-year time scale by comparing ice flux through the 2000 m contour line with the accumulation within the region. These flux estimates were based on measured surface velocities, and accumulation rates were derived from an extensive network of ice cores. These higher elevation estimates are in broad agreement with satellite-derived estimates for the same regions.

The spatial variability that is observed at high elevations is consistent with changes in accumulation and precipitation rates over the observation period, suggesting that accumulation is the dominant mechanism controlling high elevation balance. Such a relationship is reasonable since above 2000 m, melt is very limited, except in the south, and flow rates are relatively small and stable. Precipitation estimates for 1985–1999, derived from sophisticated atmospheric models of the whole ice sheet, indicate that areas north of 70 °N have been experiencing a positive trend of just a few mm year^{-1} of water, whereas regions south of 70 °N show a reduction in precipitation on the order of 1–2 cm year^{-1}, increasing to more than 3 cm year^{-1} closer to the southeast and southwest coasts, where precipitation rates are high.

The regions below 2000 m experience seasonal melt, and as such are most sensitive to small temperature perturbations. Satellite measurements of emitted microwave energy have been successfully used to assess the spatial extent of melt, a proxy for surface ablation, by exploiting a distinct melt signature in the microwave emission of snow. Analysis of the spatial extent of summer melt shows a slightly increasing melt trend over the last 21 years on the order of 1% per year. This correlates with summer coastal temperature increases over the same period of nearly one-quarter of a degree. Similar trends are also reflected in the albedo values, which have generally decreased since 1981. This melt trend was more than four times as strong during the 1980s and early 1990s, although the aerosol loading of the stratosphere created by the Pinatubo eruptions in 1991 contributed to cooler temperatures globally and the lowest melt year (1992) in the 21 year record. Regression analysis of the melt/temperature relationship suggests a 1 °C temperature rise will increase the spatial melt extent by nearly 50%.

Coastal weather station temperature observations have been useful in helping scientists understand recent conditions of the ice sheet. However, of more importance are the climate conditions directly over the ice sheet, for which there is a paucity of data. With a growing network of 21 automatic weather stations initiated in 1995, the ice sheet climate record has been and will continue to be dramatically improved. Ice sheet temperature maps developed with data from 18 of these stations show significant increases in temperature on the ice sheet when compared to similar maps for the 1951–1960 time period. At elevations above 2000 m, warming of approximately 2 °C has been observed, reducing to 1 °C farther coastward in the 1000–2000 m elevation area. Such a change is important because warmer snow generally has a lower albedo and also requires less energy to melt.

When viewed as a whole, there are no significant recent accumulation trends on the ice sheet, but temperatures have risen and melt rates have increased. These factors contribute to the ice sheet balance, which at present is negative. Discharge rates are just now beginning to be reliably calculated for a number of outlet glaciers, so assessments of how these vary in time have yet to be made. With the complex nature of the climate system, the non-linear geological controls of the ice sheet, and the uncertainty in the feedback

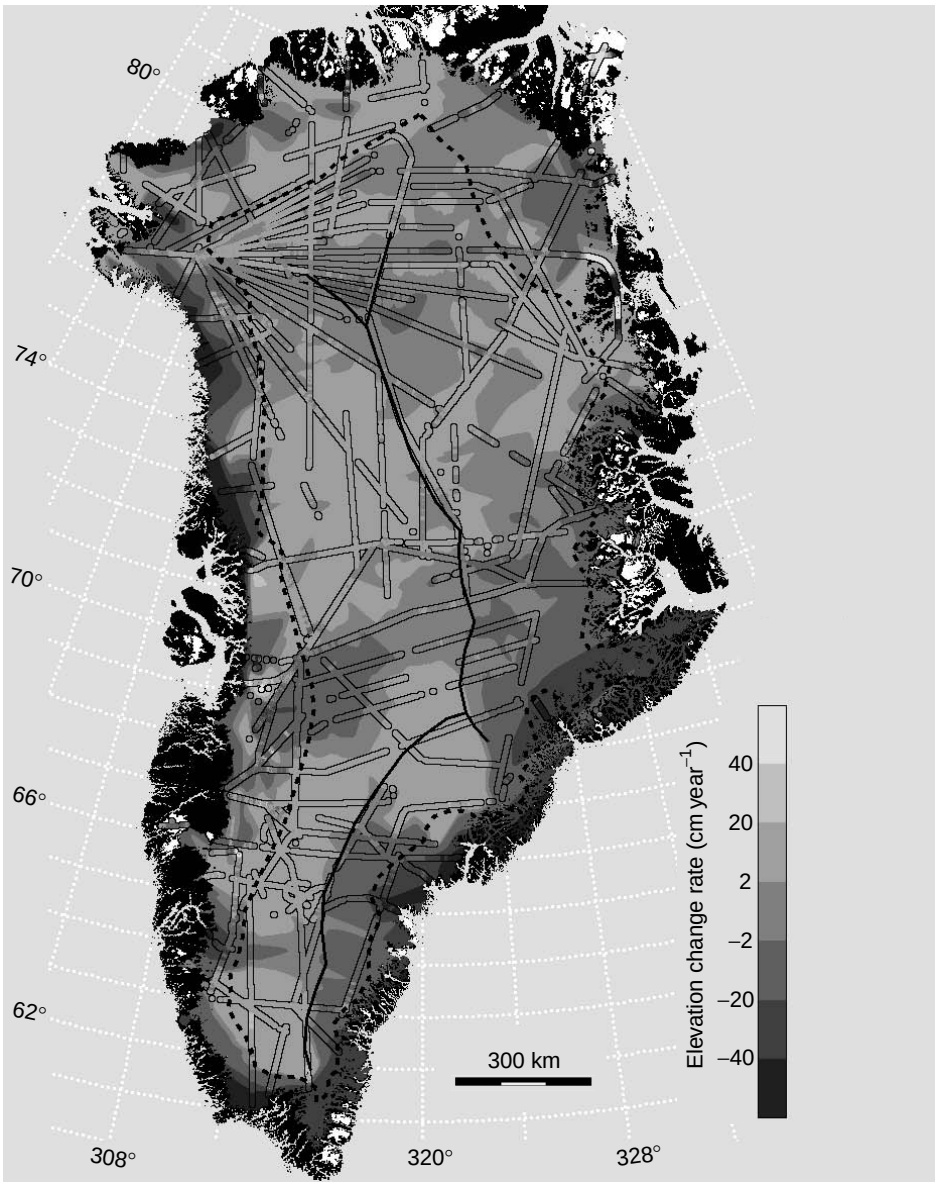

Figure 1 Observed 5-year elevation change of the Greenland ice sheet derived from airborne laser elevation surveys completed in June, 1999. The black line-pairs within the ice margin are the flight lines along which the surveys were made. The dashed line is the 2000 m contour and the solid line is the ice sheet central ridge. The region between ±2 cm represents an area of no change within the measurement uncertainty

mechanisms, it is difficult to assess how the current trends relate to the backdrop of the long-term conditions. Extrapolating these relatively brief observations to the longer time scales is not possible. However, with advances in technology and modeling, we are able to make a comprehensive assessment of the present state in the ice sheet, the factors that contribute to its balance, and how they are changing. Understanding these trends and the responsible mechanisms is an important step toward predicting their future behavior, and significant progress is being made toward that end (*see* Greenland, Volume 1).

Ground Temperature

Henry N Pollack and Shaopeng Huang
University of Michigan, Ann Arbor, MI, USA

Temperatures beneath the surface of the Earth have long been measured and used in various aspects of the geological and agricultural sciences, and now are being exploited in environmental science as indicators of climate change.

The temperature of the ground surface on which we live is the outcome of coupled physical and biological processes in both the atmosphere and the ground (Geiger, 1965; Sellers, 1992) that are quite complex in detail. The most signi cant factor is the balance of incoming radiation, principally solar, and outgoing terrestrial radiation. Other important factors include latent and sensible heat uxes, ground or vegetative surface roughness and albedo, soil chemistry, hydraulic conductivity, thermal diffusivity, and moisture content, wind, chemical uxes to and from the atmosphere and more. Moreover, the relative signi cance of the factors varies with time through the diurnal and seasonal oscillations, as well as through longer term changes associated with changing land use, vegetation and climate. Because the energy ux from the Sun is some 4000 times the energy ux from the Earth's interior, the surface temperature of the planet is dominated by external, rather than internal, forcings.

Given the largely external control of the surface temperature, temperatures in the Earth s near subsurface (the outer few hundred meters) are governed principally by two processes. The first is the outward flow of heat from the deeper interior, comprising heat residual from the accretion of the Earth, and radiogenic heat produced over the lifetime of the Earth (*see* Geothermal Heat, Volume 1). The second is the spatial and temporal variations of temperature at the ground surface as it interacts with the atmosphere. The deeper heat flow reflects long-term deep-seated geological processes, and has a characteristic time scale of change on the order of millions of years. The surface temperature variability derives from topography, vegetation patterns, and climatological processes that have diurnal, seasonal, decadal and millennial characteristic time scales, much shorter than the geological processes that determine the deeper heat flow. The climatological perturbations can be thought of as transient effects superimposed on the quasi-steady-state temperature regime of the deeper heat flow.

Temperatures beneath the surface are determined in a number of ways, but the most common method is simply to lower a thermometer to a given depth in a borehole and observe the temperature at that point. Measurements can be repeated at successively greater depths until a profile of temperature versus depth is obtained (Figure 1). Another measurement scheme utilizes a number of temperature sensors fixed at various positions along a cable, which is then introduced into a borehole quasi-permanently for long-term monitoring of temperatures at the selected depths. For measurements at or very near the surface, thermometers can be buried directly in the soil. Temperatures have also been obtained at various working levels of underground mines, where thermometers are inserted into horizontal borings in the walls of the shafts to reach virgin rock temperatures undisturbed by the opening of the mineshafts and tunnels. In all these settings, various types of thermometers have been used, liquid-in-glass in some earlier surveys and electrical resistance thermometers for most modern logs.

In the absence of any climatic or other surficial perturbations, the subsurface temperature distribution reflects only the deep heat flow, and in a homogeneous medium is characterized by a linear increase of temperature with depth. The rate of increase, known as the geothermal gradient, is directly proportional to the amount of the heat flow from below, and inversely proportional to the thermal conductivity of the rock through which it is being transported. The geothermal gradient averages around $25\,^{\circ}\mathrm{C\,km^{-1}}$, but varies regionally in the range of $10-50\,^{\circ}\mathrm{C\,km^{-1}}$ in most geological settings on the continents. The regional variation arises both from regional differences in the heat flow from the interior and in the rock type at the surface. The geothermal gradient is apparent in the deeper parts of the borehole temperature profiles shown in Figure 1.

Perhaps the earliest interest in subsurface temperatures arose in the operation of underground mines where, because of the geothermal gradient, elevated temperatures at the working levels necessitated ventilation and cooling for work at deeper horizons. In the petroleum industry subsurface temperatures also play a significant role in the kinetics of the organic chemical reactions that produce petroleum and natural gas. Coal grade is also dependent in part on the temperature to which the coal has been subjected in the subsurface.

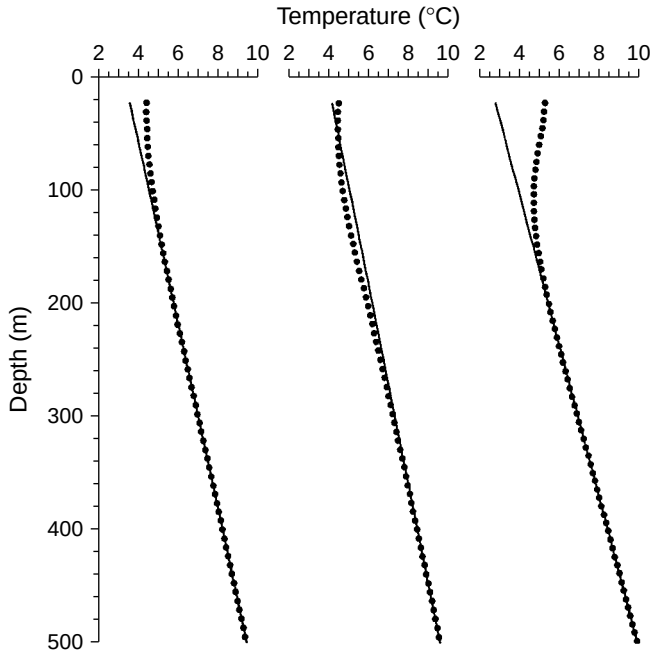

Figure 1 Temperature measurements (shown by dots) at various depths below the ground surface in three boreholes in eastern Canada. The curvature in the upper parts of the profiles is a response to temperature changes at the surface. The linear increase of temperature with depth in the deeper sections of the holes is the undisturbed geothermal gradient. The line is the extrapolation of the geothermal gradient up toward the surface; its intercept at the surface indicates what the mean surface temperature at each site was prior to the temperature changes at the surface

Beginning in the 1960s geologists and geophysicists recognized that present-day heat flow and subsurface temperatures were important parameters in understanding the composition, structure and dynamics of the Earth. Accordingly, a major global effort was made to measure these quantities in as many places as possible. Three decades later, subsurface temperatures had been determined in some 10 000 boreholes distributed unevenly over all the continents (Pollack *et al.*, 1993).

For the purpose of determining the terrestrial heat flow, the measurements of subsurface temperatures are typically made in boreholes a few hundred meters deep. The geothermal gradient, if not apparent in the upper few tens of meters because of near surface perturbations, usually can be recognized at depths below 100 m or so. The near surface observations, noise in terms of determining the geothermal gradient, were recognized as containing useful information about processes and conditions at the surface or in the shallow subsurface environment.

Climate change involving variations in the surface air temperature was identified as one possible cause of the subsurface temperature perturbations. Some of the early interest in climate change was in how it might affect the estimate of the geothermal gradient and thus the determination of heat flow from below. Accordingly, various climate change scenarios, such as the generally increasing temperatures as Earth emerged from the Last Glacial Maximum about 20 000 years ago, were constructed from other geological evidence and climate proxies. The temperature history at the surface reconstructed from such sources was then used as a time-varying boundary condition for a forward model of the perturbed subsurface temperatures and temperature gradients, which in turn could be used to make a climatic correction to the observed heat flow (Birch, 1948). These calculations revealed that climatic events occurring in the early Holocene (i.e., about 10 000 years ago) perturbed temperatures to depths of 1–2 km, and had a small but measurable effect on the estimate of the terrestrial heat flow (Beck, 1977).

There also was some early interest in using the observations of temperatures in deep boreholes and mines as constraints for the reconstruction of Holocene climate history (Lane, 1923; Cermak, 1971). More recent climate changes, such as the warming that has been observed instrumentally since the mid-to late 19th century (Jones *et al.*, 1999), the Little Ice Age of the 17th and 18th centuries, and the Medieval Climate Optimum occurring in the 13th and 14th centuries AD, would leave signatures confined to the upper few hundred meters, a depth range sampled by many of the boreholes used to determine the terrestrial heat flow (*see* Little Ice Age, Volume 1; Medieval Climatic Optimum, Volume 1). Of particular interest has been the warming of the late 19th and 20th centuries (Lachenbruch and Marshall, 1986; Pollack *et al.*, 1998) and the importance of determining the relative strengths of natural and anthropogenic forcings over the same time interval. The latter forcing is thought to arise from the well-documented increases in the concentrations of atmospheric greenhouse gases in the industrial era of human history.

Temperature changes at the Earth s surface propagate into the subsurface by heat conduction through the soil and rock. The process is entirely analogous to the warming of a cold ceramic cup following the pouring of hot tea into it. The interior surface of the cup experiences an increase of temperature, which then propagates through the wall of the cup and can be sensed a short time later on the exterior surface. The pace at which the signal propagates is governed principally by the thermal diffusivity of the conducting medium, a physical property that is directly proportional to the thermal conductivity of the material. The characteristic values of these properties in most Earth materials is such that all temperature changes at the surface during the last millennium would be confined (at present levels of detection ability) to the upper 1 km of the Earth. This slow diffusion places Earth materials in the category

of thermal insulators, as compared with metals, which transport heat more easily.

All fluctuations of temperature at the Earth s surface can be spectrally decomposed into thermal waves of different periods, with variable amplitudes and phase relations. The theory of heat conduction shows that thermal waves diminish in amplitude exponentially with depth, but that the attenuation is frequency dependent. Longer period waves attenuate more slowly with depth than do shorter period waves. Thus the Earth acts as a low-pass frequency filter, allowing a long period wave to propagate to a greater depth than a short period wave before being attenuated below the level of detection. The diurnal and seasonal variations of surface temperature, although relatively large in amplitude compared to long climatological trends, cannot be detected at depths greater than a few meters and few tens of meters, respectively. Thus, at increasing depths below the surface, only progressively longer term temperature trends are imprinted.

Virtually all of the common interpretation schemes that reconstruct ground surface temperature history from subsurface temperature profiles are cast in terms of the one-dimensional theory of heat conduction. In such a representation, the link between a present-day temperature-versus-depth profile and the past surface temperature history that produced that present-day profile is principally through the thermal diffusivity of the medium, the material property that governs space-time relations in a conductive system.

As noted earlier, many thousands of boreholes around the world have been subjected to temperature logging in the course of measuring the terrestrial heat-flow. Thus, there exists an abundance of observations. However, because of the many investigators and different measurement practices and techniques, the data are of a highly heterogeneous character. Temperature logs usually comprise measurements of temperature at discrete depths in the borehole, commonly at intervals of 5, 10 or 20 m. The boreholes penetrate to depths ranging from a few tens of meters to more than 1 km. The thermometers used have different sensitivities, generally in the range of 0.1–0.01 °C. Some borehole logs are accompanied by lithologic information and site characteristics, but most are not. Even with such heterogeneity, however, quality data are sufficiently abundant and the analysis tools sufficiently flexible to allow credible climate reconstructions from these data at many sites around the world.

Caution must be exercised in selecting data for analysis and in interpreting the reconstructions, because in addition to climatological perturbations of the subsurface temperature regime, there are many other non-climatological perturbations to contend with. Because the theoretical framework of all techniques of climate reconstruction is the one-dimensional theory of heat conduction in a laterally homogeneous medium (i.e., only vertical conductive heat transfer), any subsurface temperature variations that arise from conditions that depart from that theoretical model have the potential to be incorrectly interpreted as a climate change signature. Thus, surface topography and vegetative patterns, lateral heterogeneity in the subsurface arising from geological structures juxtaposing different rock types, and advective (non-conductive) heat transfer by groundwater movement all can alter the subsurface temperature regime with perturbations of the same order of magnitude as a climate change signature.

Many of these non-climatological disturbances can be quantitatively modeled and their significance estimated if sufficient information about the setting of a borehole is available. Alternatively, one can average the individual results from a number of boreholes spread across a region. Because it is unlikely that each borehole would have the same surficial topography and vegetative cover, or subsurface geological structure and hydrologic regime as the other boreholes, a common signal seen in the ensemble of reconstructions can more safely be attributed to climate change (Pollack *et al.*, 1996).

Analyses of several hundred temperature profiles (Pollack *et al.*, 1998; Huang *et al.*, 2000) from boreholes on six continents, taken as a global ensemble, indicate a temperature increase over the past five centuries of about 1 °C, half of which has occurred in the 20th century alone (see Figure 2). This estimate of 20th century warming is very similar in trend to the instrumental record of surface warming determined from meteorological stations (Jones *et al.*, 1999). Individually, and not surprisingly, the boreholes show a fair amount of variability, with some recording cooling and others indicating warming. But more than 75% of the borehole sites show a warming of some magnitude over

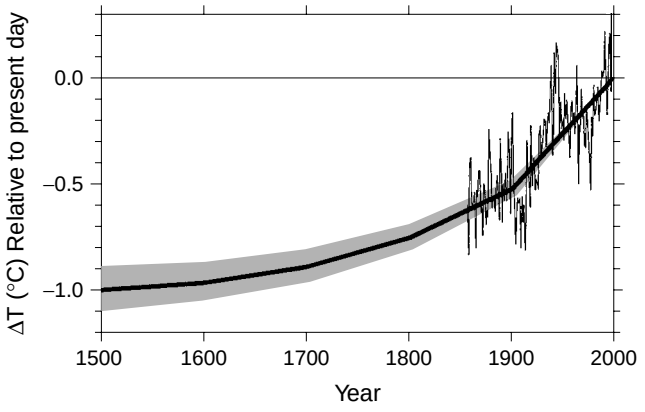

Figure 2 A reconstruction of the global mean ground surface temperature history as inferred from more than 600 borehole temperature profiles from six continents, displayed relative to the present-day temperature. The shading represents the standard error of the estimate. Also shown for comparison is a five-year running mean of the globally averaged instrumental record of surface air temperature since 1860 (modified from Huang *et al.,* 2000)

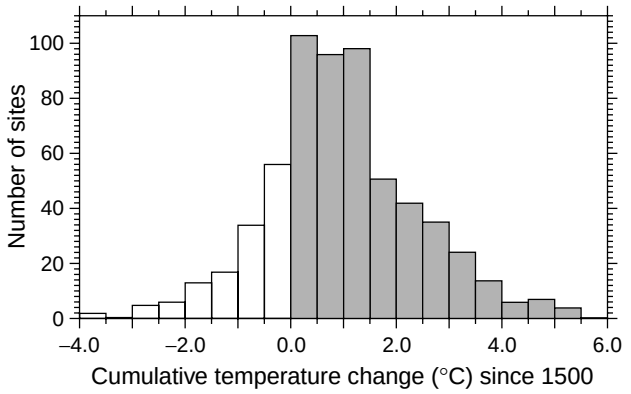

Figure 3 Distribution of temperature change since 1500 at the boreholes used in the reconstruction shown in Figure 2. Columns with shading indicate a net warming over the past five centuries, and columns without shading indicate a net cooling. More than 75% of the sites have experienced warming in this time interval

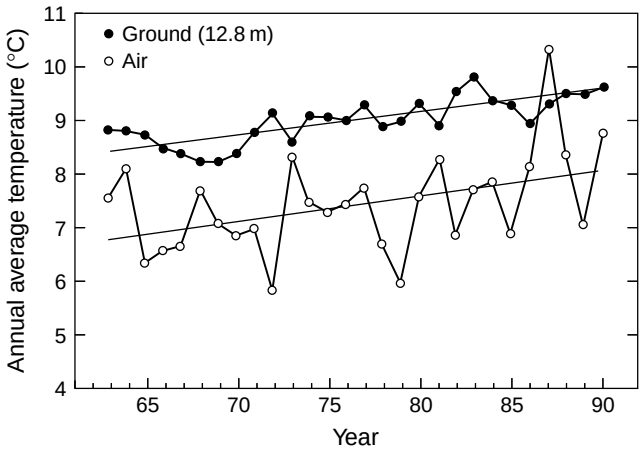

Figure 4 Annual mean soil and air temperatures at a site in north-central USA in the interval 1963–1990. Soil temperature is at a depth of 12.8 m. The lines are temperature trends over the 28-year time interval. (Modified from Baker and Ruschy, 1993)

the past five centuries (see Figure 3), clearly confirming the overall warming of the ground surface in that time interval.

Another large body of shallow subsurface temperature data comes from measurements of soil temperature at meteorological and agricultural research and experimental stations, and in boreholes drilled into permanently frozen ground (see, e.g., Baker and Ruschy, 1993; Osterkamp and Romanovsky, 1994). These measurements typically are made at depths of a few centimeters to a few tens of meters, with permanent installations of the thermometers to enable monitoring temporal changes. They frequently are accompanied by other instruments that determine air temperature and other meteorological variables at or near the surface, and soil moisture and various chemical parameters in the near subsurface. Diurnal temperature changes are observed in the upper two meters of the soil, and annual (seasonal) changes in the upper twenty meters. Annual time series for soil temperatures are rarely a century long, and usually much shorter.

An example of a soil temperature time series is displayed in Figure 4 (modified from Baker and Ruschy, 1993). At the 12.8 m depth of observation, inter-annual variations are still apparent, as well as an upward trend of temperature of $0.04\,^{\circ}\mathrm{C\,year^{-1}}$ over the 28 year time interval of the measurements. Although these shallow measurements can provide information about the surface temperature history only for the time interval represented by the time series, they are useful complements to the longer but less well resolved histories determined from the deeper borehole temperature profiles.

Although the ground temperature and the air temperature near the surface generally show similar trends of temperature change (Figure 4), the air and ground temperatures are rarely the same. Differences of several degrees are not uncommon, with the ground temperature usually warmer than the air temperature. These differences sometimes arise from simple and obvious causes, such as the effect of snow cover on the ground during winter months, which insulates the ground from the much colder diurnal and seasonal air temperature variations. The latent heat effects during the freezing and thawing of soil moisture also hold the soil temperature near $0\,^{\circ}\mathrm{C}$, independent of what the air temperature may be doing. If there are long-term changes in soil moisture that parallel long-term changes in ground surface temperature, then the trends of air and ground temperature may slowly diverge, because the latent heat effects in the soil play a greater (or lesser) role (Majorowicz and Skinner, 1997).

Hadley Circulation

The *Hadley circulation* is one of the simplest and best-known conceptual pictures (models) of the prevailing circulation of the Earth s atmosphere (*see* Atmospheric Motions, Volume 1). George Hadley originally described the conceptual model in 1735, based on a combination of sparse, mostly near-surface, atmospheric observations and 18th century physical understanding. Despite these limitations, the conceptual model is still valid, with some modifications.

In the modern picture, the stronger solar heating at low latitudes relative to high latitudes leads to rising air at or near the equator, and sinking air near the poles. To close the circulation, air flows towards the poles in the upper levels of the atmosphere, and towards the equator near the surface. There are then two equator-to-pole circulation patterns, or Hadley cells, one in each hemisphere. The Hadley cells convert potential plus thermal energy to kinetic energy. As a by-product of this conversion, they transport heat from low to high latitudes, cooling the lower latitudes and warming the higher latitudes.

The Hadley circulation also exerts a profound influence on the prevailing atmospheric winds, producing the eastward jet streams in the mid-latitude upper troposphere, and the low-latitude surface easterlies and mid-latitude surface westerlies. Because the Earth is spinning eastward on its axis, and the distance of the atmosphere from the axis of rotation decreases from equator to pole, the poleward moving air in the upper troposphere acquires eastward velocity relative to the ground, due to the tendency to conserve angular momentum (much like a spinning skater pulling in his or her arms). Similarly, air in the equatorward moving lower branches of the Hadley cells eventually acquires westward velocity, but with weaker magnitude than the upper level winds due to surface friction. As the field of meteorology developed after Hadley, an important modification to Hadley s original picture was to take into account the passage of air through storm systems at middle and high latitudes, which reduces the eastward velocities in the upper levels, and causes apparently poleward prevailing midlatitude surface winds.

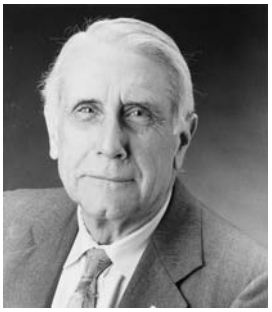
EDWIN K SCHNEIDER *USA*

Halocarbons

Halocarbons are a category of chemicals containing carbon and at least one of the halogens; fluorine, chlorine, bromine and iodine. Compounds in this category are of both natural and anthropogenic origin. Applications for the human-produced halocarbons include pharmaceuticals, crop protection, refrigerants, plastics as well as a wide range of other industrial and consumer products. Halocarbons involved in global environmental change possess three common characteristics: the compounds are persistent in the environment (generally decades to centuries), mobile in the environment, and either unique to the environment or they are emitted in sufficient quantities to provide a significant enhancement to a natural background concentration. Several classes of gaseous halocarbons that contain chlorine or bromine, including chlorofluorocarbons (CFCs) (*see* Chloro uorocarbons (CFCs), Volume 1), hydrochlorofluorocarbons (HCFCs), halons and some chlorocarbons, are involved in the stratospheric ozone-depletion issue. Production and use of these compounds are controlled under an international agreement, the Montreal Protocol on Substances that Deplete the Ozone Layer (*see* Ozone Layer: Vienna Convention and the Montreal Protocol, Volume 4). Those classes of compounds plus other gaseous halocarbons including hydrofluorocarbons (HFCs) and perfluorocarbons (PFCs) are involved in the global climate change issue. HFCs and PFCs are among the compounds listed for control under the Kyoto Protocol to the United Nations Framework Convention on Climate Change. Several of the higher molecular weight chlorocarbons are implicated in a third global environmental change issue, that of persistent organic pollutants (POPs). In addition to the three

characteristics listed above, these POP compounds bioaccumulate through the food web.

MACK MCFARLAND *USA*



Hare, Kenneth

(1919-)

F Kenneth Hare, geographer, climatologist and environmental scientist, was born in Wylye, England, in 1919. He graduated from King s College, University of London, and during World War II served as an operational meteorologist and climatologist with the United Kingdom Air Ministry.

Kenneth Hare came to Canada in late 1945 to teach at McGill University where he became Department of Geography chairman and later Dean of Arts and Science (1962–1964). For his research in arctic climatology and biogeography he was awarded a PhD (University of Montreal, 1950). At McGill he became a leading authority on heat and water balances, on climate change, and on environmental and land-use matters while serving as a senior officer of Canadian and American meteorological societies, the Arctic Institute, the Canadian Association of Geographers, and the American and Royal Geographical Societies. He was named a member of the National Research Council of Canada in 1962–1963.

In 1964, Dr Hare became Master of Birkbeck College (1964–1966) and professor at King s College, University of London, where he chaired/participated in many official enquiries and became president of the Royal Meteorological Society. He was a founding member of the UK Natural Environment Research Council in 1965–1968. He returned to Canada to become president of the University of British Columbia and was elected a fellow of the Royal Society of Canada in 1968. Dr Hare returned to teaching and research at the University of Toronto and was later seconded to Environment Canada as director-general of research coordination. In 1974–1979 he was the director of the Institute for Environmental Studies at the University of Toronto.

As program organizer, Dr Hare played a leading role in the World Meteorological Organization s 1979 World Climate Conference and was the first chairman of the Advisory Group on Greenhouse Gases. In 1988, he was honoured with international meteorology s premier award, the International Meteorological Organization (IMO) Medal. In Canada, Dr Hare served as Provost of Trinity College (1979–1986), Chancellor of Trent University (1988–1995) and chairman of the University of Toronto s Advisory Board of the Institute of International Programs (1990–1994). He has chaired/participated in the Royal Society of Canada s programs and studies on acid precipitation, nuclear winter, Pb in the environment, asbestos and global change. Also, Dr Hare was chairman of the Canadian Climate Planning Board (1979–1990) and of the Technical Advisory Panel on Nuclear Safety of Ontario Hydro (1991–1994). He has been much involved in nuclear waste management in Canada and elsewhere.

Dr Hare s published books include *The Restless Atmosphere* (1953), *On University Freedom* (1967), *Climate Canada* (co-author, 1974 and 1979), and editor of *The Experiment of Life* (1982). He has also published about 250 articles on geography, climatology and the environment in professional and popular scientific journals and yearbooks. Dr Hare has received honorary doctorates from eleven Canadian and Australian Universities and is a fellow of the American Meteorological and Geographical Societies and was president of Sigma Xi in 1986–1987. He was awarded the Patterson Medal in 1973, the Massey Medal in 1978, the Patron s Medal of the Royal Geographical Society in 1977 and the Cullum Medal of the American Geographical Society in 1987.

Made an Officer of the Order of Canada in 1979, Dr Hare was elevated to Companion, Canada s highest honour, in 1987. He is now a University Professor Emeritus at the University of Toronto.

Heinrich (H-) Events

John T Andrews
University of Colorado, Boulder, CO, USA

Heinrich (H)-events were first specifically described in 1988 and named by Broecker and others in 1992. They were defined as sharp peaks in the ratio of {% lithics/(% lithics + % foraminifera)} in sand-sized late Quaternary sediments from Mt Dreizack, a seamount west of Portugal. Because most deep-sea sediments consist mainly of foraminifera (sand-size carbonate tests of marine animals) and clay-size material, the dramatic increase in the numbers of lithics (i.e., grains of quartz, feldspar, and other minerals), required a significant increase in the flux of sediments from land to the oceans. The only reasonable source for this sized material was glacial sediment entrained in icebergs from the large ice sheets, which existed on the landmasses around the North Atlantic, and the massive North American Ice Sheet in particular. Research indicated that the major source of sediment for deep-sea H-events is the Hudson Strait region of Canada, a major trough which controlled the major drainage from the ice sheet toward the North Atlantic.

Evidence from cores in the North Atlantic indicates that the ocean circulation of the past 100 000 years (100 kyr) has undergone dramatic changes (Bond *et al.*, 1992). During some intervals, which are called Heinrich (H)-events, the Gulf Stream, that provides the heat to warm northwest European winters virtually disappeared. These changes appear to be associated with the introduction of freshwater into the North Atlantic basin. An understanding of the mechanism, which led to these abrupt changes, may provide some guidance as to what the future may hold under various global change scenarios.

H-events can be characterized as short-lived phenomena, lasting several hundred years and separated by about 7 kyr on average. These events are associated with plumes of glacially derived sediments being transported to the south and east across the North Atlantic (Figure 1). Studies have used a variety of methods to date the individual H-events and their duration (Bond *et al.*, 1992; Hillaire–Marcel *et al.*, 1994). The most recent 4–5 events can be dated directly by radiocarbon methods, whereas events older than 40 kyr are dated based on assumptions about sediment rate. The youngest widespread event, H-0 is of Younger Dryas age and thus had a duration of 1 kyr and occurred between 10 and 11 kyr. The best estimates for the dates of other events are: H-1 = ±14.5 kyr, H-2 = ±20.5 kyr, H-3 = ±27 kyr, and H-4 = ±36 kyr. All the events are estimated to have a duration of a few hundred years to 1 kyr.

During the 1960s and into the 1980s the prevailing paradigm for Quaternary ice sheet growth and decay was based largely on the notion that these changes were forced by solar insolation in the northern summer months (the Milankovitch theory, Imbrie *et al.*, 1992). Thus, ice sheets developed over a 100 kyr interval with stadial and

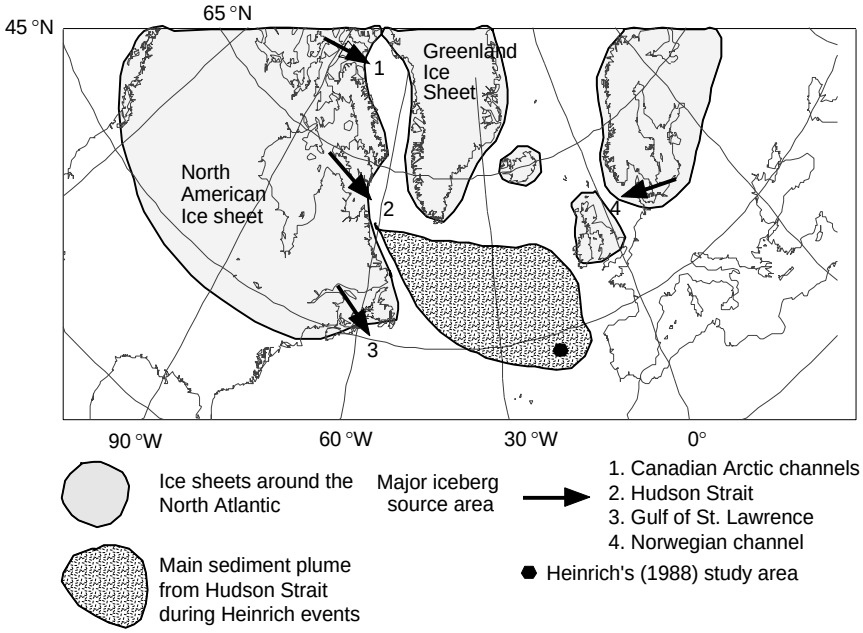

Figure 1 Map showing the North Atlantic and the main area of deposition of IRD during H-events primarily derived from the export of glacial-eroded sediment through the Hudson strait

interstadial events associated with the 21 and 41 kyr periodicities. At the same time, however, glaciologists were advancing the notion that marine-based ice sheets, i.e., ice sheets grounded below sea level, were inherently unstable. Such a designation applies to the present West Antarctic Ice Sheet, and applied to the former North American and Fennoscandian ice sheets. In the late 1970s and the 1980s researchers working on marine sediments off NE Canada had noted distinct changes in sediment color and mineral composition, especially the occurrence of intervals dominated by detrital carbonate. However, a detailed radiocarbon chronology was not available at this time, thus they were unable to assign an age or rate of sediment accumulation to these intervals (Andrews, 1998). However, in the 1980s, the advent of accelerator mass spectrometer (AMS) radiocarbon (^{14}C) dating of small (2–6 mg) samples of foraminifera revolutionized our concepts of ice sheet–ocean interactions.

H-events were first described in detail in a paper by Heinrich (1988) and their paleoclimatic significance developed by Broecker *et al.* (1992). Heinrich examined the sand fraction $>150\,\mu$m and counted the number of foraminifera, and the number of lithic (mineral grains) at closely spaced intervals in cores from Mt Dreizack, a seamount west of Portugal. He noted variations in the number of lithic grains which he ascribed, following Ruddiman (1977), to deposition from far-travelled icebergs (so-called iceberg-rafted debris, IRD). Heinrich expressed his data as a ratio of {% lithics/(% lithics + % foraminifera)}. His work showed a series of 6 discrete intervals (H-events) of high IRD and/or low foraminifera numbers within the last glacial cycle (marine isotope stage (MIS) stages 2–4). However, it was the work of Bond and co-authors (Andrews and Tedesco, 1992; Bond *et al.*, 1992) that demonstrated:

1. the widespread distribution of these events in the North Atlantic;
2. the widespread occurrence within the H-sediments of detrital carbonate;
3. the probable source for the IRD being the area of Hudson Strait (Dowdeswell *et al.*, 1995; Hemming *et al.*, 1998), which served as the major drainage conduit for the Laurentide ice sheet (LIS).

Dansgaard/Oeschger (D/O) events are those with H-intervals occurring during intervals of extreme cold (as seen in the Greenland ice sheet isotope records), but which then rapidly give way to warm conditions. Several authors, e.g., Lowell *et al.* (1995) have suggested correlations between H-events and other proxies for global change in areas removed from the North Atlantic, whereas others have noted that IRD events in Nordic Seas sediments do not have the same pattern as those off northeast Canada and in the IRD belt (Figure 1).

MECHANISMS

The discussion on the mechanism(s) for H-events lies at the heart of their importance to the global environment (Alley and MacAyeal, 1994; Clarke *et al.*, 1999). Two hypotheses have been proposed: in the first case, generally favoured by glaciologists, it is argued that H-events represent mechanical instabilities in the LIS, possibly associated with changes in the basal temperature regime; the second hypothesis argues that the global nature of short-lived events occurring at the same time as H-events indicates that they are caused by global atmospheric forcing. However, a rapid change in the atmospheric temperature cannot be transmitted quickly to the bed of an ice sheet because of the thermal properties of ice. Andrews (1998), however, presented a qualitative argument for the links between the atmosphere, ice sheet bed, and changes in relative sea-level.

OUTSTANDING PROBLEMS

Three outstanding issues related to the study of H-events remain. These are:

1. the specific glaciological mechanism(s) which led to the massive flux of icebergs into the North Atlantic;
2. the distribution of sediment within the ice sheets which allowed such long transport routes of sediment entrained in the icebergs and;
3. the chicken and egg question – are H-events the cause of, or the product of, global environmental change?

Holocene

The *Holocene* epoch is the current interglacial, or post glacial epoch following the Pleistocene. Interglacials are defined by the widespread presence of broad-leafed trees, such as oaks, in Central Europe, whereas glacial periods are defined by the replacement of deciduous forests by grasslands (Imbrie and Imbrie, 1986). The Holocene began about 10 000 years ago, when there were still remnant Laurentide and Fennoscandian ice sheets. However, greater solar insolation in Northern Hemisphere summers than the present led to warmer conditions than present (or pre-industrial) times in many places not under the direct influence of the ice sheets. The more positive orbital insolation forcing 10 000 years ago was the result of differences in the Earth s precession, which determines the date of perihelion (Earth s closest approach to the sun), and obliquity, or tilt (*see* Orbital Variations, Volume 1). Today, perihelion occurs in Northern Hemisphere winter, whereas at the start of the Holocene, perihelion occurred during Northern Hemisphere summer, resulting in warmer summers and colder winters in the Northern Hemisphere. The Earth s tilt was nearly 1° greater 10 000 years ago than the present, resulting in more extreme summers and winters in both hemispheres (Kutzbach *et al.*, 1998). These differences in orbital insolation also resulted in a stronger Southwest Asian monsoon, resulting in higher lake levels throughout Asia and Africa during the early Holocene (Prell and Kutzbach, 1992). The remaining ice sheets were mostly melted by 6000 years ago. However, partly due to changing orbital insolation, the late Holocene during the last 4500 years was cooler and drier than the early Holocene. This most recent time frame is often referred to as the Neoglacial (Crowley and North, 1991).

Houghton, John Theodore

(1931-)

Sir John Theodore Houghton was born in 1931, and became a leading UK satellite and climate scientist and author. For more than 40 years, Sir John Houghton has exerted a strong and beneficial influence on the development of the science of meteorology and its applications to practical problems throughout the world.

Sir John is well known internationally for his research in remote sensing of the atmosphere from space. In cooperation with Professor Desmond Smith, he developed the Selective Chopper Radiometer for the Nimbus 4 and 5 satellites in the early 1970s. Other instruments developed by the group at Oxford University led by Sir John, provided, for the first time, global information of the structure of the stratosphere and mesosphere and played a major part in the implementation of a detailed study of the radiation, dynamics and chemistry of the whole atmosphere. In cooperation with Professor Fred Taylor, then at the Jet Propulsion Laboratory, Sir John developed the Pioneer Venus Orbiter in 1978.

As chief executive (formerly director-general) of the UK Meteorological Office he was responsible for major innovations in the meteorological service and was influential in developing the United Kingdom s strong international reputation in many areas of climate research. Sir John was the driving force in establishing the Hadley Centre for Climate Prediction and Research which, since its inception, has sought to collaborate in, and contribute to, the growing international research effort on climate change.

As permanent representative of the United Kingdom with the World Meteorological Oganization (WMO) for 8 years (and third vice president 1987–1991), his combination of thorough technical knowledge and his appreciation of practical problems enabled him to exert a valuable influence on the development of WMO policy.

Due to his gift for achieving consensus at meetings, he is held in high regard as a chairman. Between 1981 and 1984 Sir John was chairman of the Joint Scientific Committee for the World Climate Research Programme and from 1992 to 1996 was chairman of the Joint Scientific Committee for the Global Climate Observing System. He was invited in 1993 to chair the Intergovernmental Meeting on the World Climate Programme: The Climate Agenda.

In 1988, he was appointed chairman of the Scientific Assessment Working Group of the Intergovernmental Panel on Climate Change (and is currently co-chairman). This working group, IPCC, Working Group I, has produced five major reports under his leadership (see Intergovernmental Panel on Climate Change (IPCC): an Historical Review, Volume 4; IPCC (Intergovernmental Panel on Climate Change), Volume 1). To achieve this has required great sensitivity to the political aspects of climate change, combined with firmness to ensure that the reports remained faithful to the underlying science.

Sir John has continued to represent meteorology in the higher echelons of British science. From 1994 to 2000 he was one of the five members of the British Government Panel on Sustainable Development. He became a member of the Royal Commission on Environmental Pollution in 1991 and from 1992 to 1998 was chairman of this distinguished body.

Sir John is a committed Christian and has sought to build intellectual bridges between science and religion. He has authored two books on this subject, in addition to his well known books on the physics of the atmosphere and climate change.

Sir John was elected a fellow of the Royal Society in 1972. In recognition of his outstanding services to science and meteorology, Sir John received the Queen s Honour of Commander, Order of the British Empire in 1983 and, in 1991, the Royal Accolade of Knight Bachelor.

Human-induced Changes in Atmospheric Composition

see Anthropogenic (**Volume 3**)

Humidity

Humidity refers to the water vapor content of the air, and may be expressed in several ways.

The *absolute humidity* is the mass of water per unit volume of air. For example, extremely humid air at normal room temperature contains about 20 g of water vapor in each cubic meter of air. The most common and most useful measure of humidity, however, is the relative humidity, because this governs processes of evaporation, condensation, and precipitation. *Relative humidity* is defined as the ratio between the actual moisture content of the air and the saturation moisture content. The latter is simply the

maximum amount of moisture that can be put into the air by evaporation. In other words, when the air is saturated, surfaces of water gain as many molecules of water from the air as they lose, and no net evaporation takes place.

Low values of relative humidity indicate dry air, and encourage high rates of evaporation. When the relative humidity increases to reach or to briefly exceed saturation levels (as occurs, for example, when air cools by radiation at night under clear skies or in rising air currents), water may condense on tiny particles in the atmosphere to form fog, clouds, or precipitation, or to form dew or frost on cold surfaces.

Another measure of humidity often encountered is the *dew point*. This is the temperature at which moisture will condense on a cold surface. The closer this temperature is to the ambient temperature, the higher the humidity.

The amount of water vapor in the atmosphere generally decreases with altitude, and varies markedly over the globe. However, relative humidity can sometimes increase with altitude, mainly as a result of cooling of air through ascent or loss of heat through radiation. These processes govern the formation of fog, clouds, rain, and snow that in turn determine the habitability of our climate and our planet. In summary, water is both the most variable and the most vital trace component of our atmosphere.

JOHN S PERRY *USA*

Hurricanes, Typhoons and other Tropical Storms – Descriptive Overview

Kendal McGuffie
University of Technology, Sydney, Australia

Tropical cyclones (TCs), known regionally as typhoons, hurricanes and cyclones, are devastating weather events to which the human population is increasingly vulnerable. The physical character, development and effects of these storms are the same in the North Atlantic (hurricanes), in the Southwest Paci c (TCs), North and South Indian Ocean (cyclones) and in the Northwest Paci c (typhoons). The terms hurricane and typhoon can therefore be considered as regionally speci c names for severe tropical cyclonic storms. These storms, no matter what oceanic region they occur in, can be referred to as TCs without loss of correctness. Tropical cyclone is a generic term for a non-frontal synoptic scale low pressure system that originates and develops over tropical or subtropical waters. When the sustained surface wind speed in such a storm is less than 17 m s^{-1}, the term tropical depression is used. Once the winds reach 17 m s^{-1} and until the sustained wind reaches 33 m s^{-1}, the term tropical storm is used. When the sustained wind exceeds 33 m s^{-1}, the storms are called hurricanes in the North Atlantic, Northeast Paci c (east of the international dateline) and in the Southeast Paci c (east of 160°E).

The term *typhoon* applies in the Northwest Pacific and storms in the Southwest Pacific, Southeast Indian ocean are called *severe tropical cyclones*. The term severe cyclonic storm is applied in the North Indian Ocean, and in the southwestern Indian Ocean the term *tropical cyclone* is used. It is a popular myth that TCs are referred to as *willy-willys* in Australia, but this is not the case (the term applies to dust devils). The only term in common use in Australia is tropical cyclone. The spectrum of storms is named differently in all six tropical cyclone basins, and in the North Indian Ocean the names for different storm intensities vary by country.

Despite this diversity in naming conventions, the same processes occur in all these storms and, with the exception of the fact that cyclonic rotation in the Northern Hemisphere is anti-clockwise and is clockwise in the Southern Hemisphere, the following discussion applies to all such storms. The concept of sustained surface wind varies somewhat between agencies. The World Meteorological Organization (WMO) suggests use of a 10-minute average and this is utilized by most countries. However, the Joint Typhoon Warning center in Guam utilizes one minute winds, which results in some discrepancies when comparing statistics between regions (usually referred to as basins).

ORIGIN OF NAME

The origin of the regional names is not a modern imposition. The word *hurricane* derives originally from the Mayan god, Hurakan, who blew his breath across the chaotic water and created the dry land. The word *typhoon* is believed to have come from the Mandarin word t ai fung, meaning great wind. The term *kamikaze* also derives from a 14th century typhoon, which devastated a Mongol fleet that was about to invade Japan. The kamikaze, or divine wind, was therefore a source of great fortune for Japan. The only term in common use in Australia is tropical cyclone. The term super-typhoon is used in the Northwest Pacific to refer to typhoons that have a maximum sustained wind speed of at least 65 m s^{-1}. This is the equivalent of a category four or five hurricane in the North Atlantic or a category five cyclone in the Australian region (Table 1). The term

Table 1 The Saffir/Simpson scale used to categorize North Atlantic hurricanes compared with the Australian scale developed by the Australian Bureau of Meteorology showing approximate correspondence of the categories

Classification and Saffir/Simpson Scale	Effects	Australian category definitions
Tropical depression winds: $<17\,m\,s^{-1}$	Negligible house damage. Damage to some crops, trees and caravans	
Tropical storm winds: $17–32\,m\,s^{-1}$		Category 1: winds $17–25\,m\,s^{-1}$
	Minor house damage, significant damage to signs, trees caravans. Heavy crop damage. Risk of power failure, small craft may break moorings	Category 2: winds $26–34\,m\,s^{-1}$
Category 1: winds $33–42\,m\,s^{-1}$	No real damage to building structures. Damage primarily to unanchored mobile homes, shrubbery, and trees. Some small craft in exposed moorings may be torn free	Category 3: winds $35–45\,m\,s^{-1}$
Category 2: winds $43–49\,m\,s^{-1}$	Some roofing material, door, and window damage. Considerable damage to foliage and some trees blown down. mobile homes, etc. Flooding damages piers and small craft in unprotected moorings may break their moorings	Category 4: winds $46–62.5\,m\,s^{-1}$
Category 3: winds $50–58\,m\,s^{-1}$	Some structural damage to small residences and utility buildings, with a minor amount of curtainwall failures. Foliage removed from trees and large trees blown down. Mobile homes are destroyed. Flooding near the coast destroys smaller structures with larger structures damaged by floating debris. Terrain may be flooded well inland	
Category 4: winds $59–69\,m\,s^{-1}$	More extensive curtain wall failures with some complete roof structure failure on small residences. Complete destruction of mobile homes. Major erosion of beach areas. Terrain may be flooded well inland	Category 5: winds $63+\,m\,s^{-1}$
Category 5: winds $70+\,m\,s^{-1}$	Complete roof failure on many residences and industrial buildings. Some complete building failures with small utility buildings blown over or away. Flooding causes major damage to lower floors of all structures near the shoreline. Massive evacuation of residential areas may be required	

cyclone was itself coined in 1855 by Henry Piddington, a 19th century British meteorologist, from the Greek word describing the coil of a snake, recalling the characteristic pattern of flow towards the center of the storm. Cyclones also occur outside the tropics but these storms are different in character from TCs. TCs are driven by energy from the warm tropical ocean. The energy source for extra-TCs or mid-latitude cyclones comes from the strong latitudinal temperature gradient that exists in these regions.

NAMING OF INDIVIDUAL STORMS

The naming of storms seems to have arisen as a matter of convenience for weather forecasters. The attachment of a single label to a storm means that the storm can be unambiguously tracked throughout its life cycle. The first use of a proper name for a TCs is attributed to Clement Wragge, an Australian meteorologist. An informal naming system operated during World War II in the Pacific and from 1952, storms in the North Atlantic were given names from the phonetic alphabet (alpha, baker, charlie ... etc.). Women s names replaced these in 1953. The current convention is for a pre-arranged list of male and female names, which are created for each basin. Some basins (such as the North Atlantic) start at A each year, whereas others cycle through the list continuously. Where a storm causes significant damage, deaths or distress, the name is retired. Examples of retired names are Camille (1969), Andrew (1992) and Tracy (1974). North Indian ocean cyclones are not named. Despite occasional criticism of the practice, it is well established and understood by both meteorologists and the general public. Table 2 shows the lists of proposed cyclone names for the North Atlantic for 2003 and 2004.

Table 2 Lists of proposed North Atlantic storm names for 2003 and 2004. Naming of storms reduces confusion when multiple storms occur at the same time. Storm names are usually retired when a storm causes significant damage or loss of life (e.g., Andrew, Camille, Tracy)

CONDITIONS FOR TROPICAL CYCLONE DEVELOPMENT

There is a popular conception that warm ocean temperatures are the prime genesis factor for TCs. While these are important, they are only one of a number of conditions that are necessary for the development of a tropical cyclone. The first three parameters can be said to define the dynamic potential for storm occurrence and the last three define the thermodynamic potential. These necessary conditions include:

- a pre-existing weather disturbance, which provides a means for extracting energy from the ocean;
- warm tropical oceans with temperatures of at least 26.5 °C that provide a source of energy for the storm;
- a minimum distance of at least 500 km from the equator to ensure that a rotating storm can develop;
- suitable temperature and moisture distribution within the troposphere; and
- relatively light winds aloft to ensure that the vertical structure of the storm is maintained.

Even the achievement of all these conditions is not sufficient for the development of a tropical cyclone. We know this because these conditions can be satisfied without any cyclone forming. The exact processes that result in the genesis of a tropical cyclone are still a topic of active research.

The areas of the globe in which TCs occur is indicated in Figure 1. Some areas of the tropical ocean virtually never experience storms intense enough to be described as TCs. The distribution also makes it clear that cyclonic storms never cross the equator. TCs are a seasonal occurrence with most basins having a maximum frequency during late summer to early autumn. Frequency of occurrence of TCs by basin is presented in Table 3.

STRUCTURE OF TYPHOONS

The most distinctive feature of a typhoon or tropical cyclone is the eye (visible in Figure 2). The eye is an approximately circular area of light winds found at the center of a severe tropical cyclone. Complete calm exists at the center of rotation of the storm, but significant winds can be found away from the center of the eye. In some circumstances the eye can be cloud free (in which case it is very easy to locate on satellite imagery) and stars or blue sky may be visible to an observer at the surface. In other cases, the eye may be covered by high cirrus clouds. The eye is surrounded by a ring

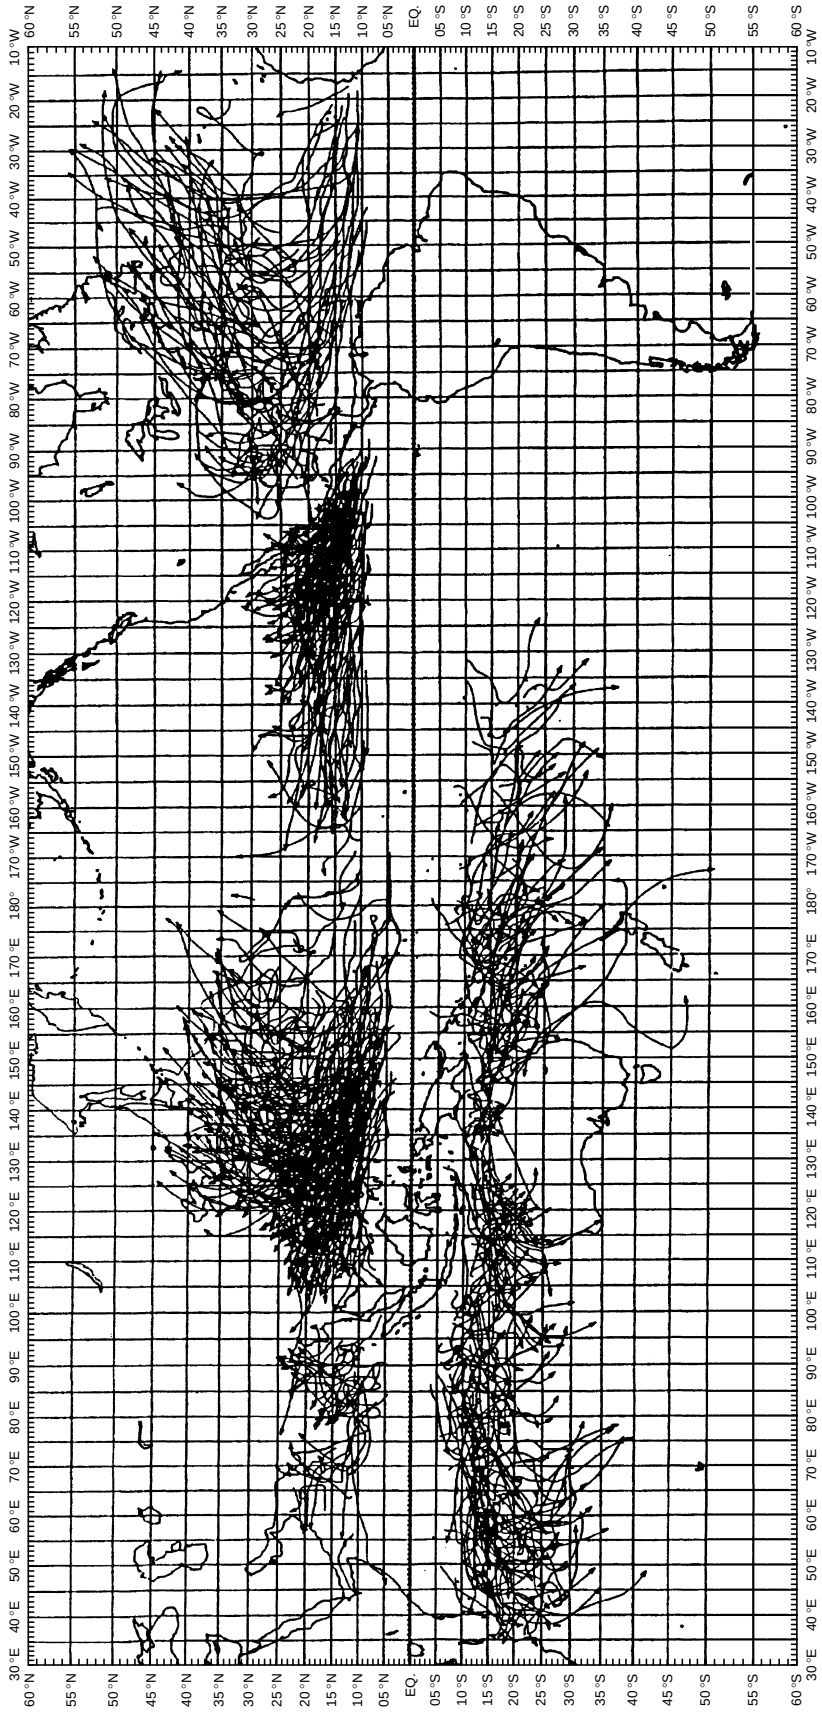

Figure 1 Global map showing regions of tropical cyclone occurrence (World Meteorological Organization, 1993). The map shows tracks of storms with maximum winds $>17.5\,m\,s^{-1}$ for the period 1979–1988

Table 3 Averaged annual total numbers of TC (wind at least 17 ms^{-1}) and intense TC (wind at least 33 ms^{-1}) and their standard deviations for all tropical cyclone basins (number per year)[a]

		North Atlantic Basin	East North Pacific Basin	North Indian Basin	South-west Indian Basin	South-west Pacific Basin	North-west Pacific Basin	Totals
Mean	TC	9.3	17.8	5.2	10.6	16.4	26.8	86.1
	Intense TC	5.0	10.3	2.0	4.8	7.5	16.4	45.9
Standard deviation	TC	2.6	4.7	2.2	3.2	4.6	3.9	7.9
	Intense TC	1.7	3.5	1.9	2.6	2.6	3.4	7.0

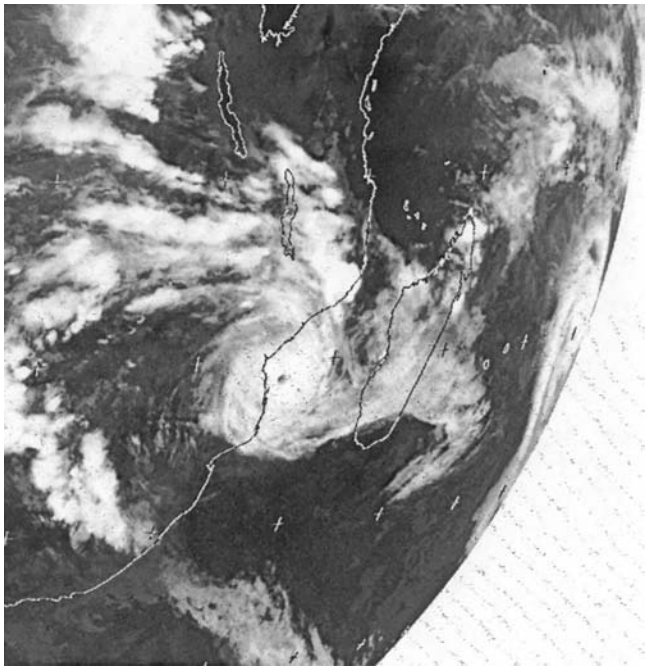

Figure 2 Meteosat image of tropical cyclone Eline as it approaches the coast of Mozambique on 21st February, 2000. Earlier rains had already swollen rivers and displaced 200 000 people. The central clear eye is visible in this image. (Image courtesy of University of Nottingham)

of deep convection known as the eye wall, the region of most destructive winds. Beyond this central core, the storm tends to be organized into spiral rainbands, which are coherent bands of convective storms that extend to the periphery of the storm and well away from the region of maximum winds. These rainbands are important in the maintenance of the central core of the storm as they consist of convective cells that move (spiral) in towards the eye. Typhoon eyes range in size and structure and are not necessarily exactly circular. They are typically 30–60 km across, though they can be as small as 8 km or as large as 200 km. If the cyclone is particularly intense, it may exhibit a double eye wall. The level of observational detail that is required to monitor the changes in the nature of the eye wall is considerable, and, because these storms originate and develop over the ocean, detailed observations are not readily available for all cyclones. As a consequence, the behavior of the eye wall, which is generally the most destructive region of the storm, is still a topic of active research.

DEVELOPMENT AND MOVEMENT OF TROPICAL STORMS

Typically, a tropical cyclone will develop from a tropical depression and progress through more intense stages, although the rate of development can vary quite considerably. In the North Atlantic, TCs typically begin their life in atmospheric wave disturbances (about 60% of all hurricanes and 85% of intense or severe hurricanes). In other regions, cyclones are spawned in monsoon troughs and associated with mesoscale convective clusters that provide the pre-existing weather disturbance for the cyclone to form. The exact course of an individual storm is difficult to predict, as tropical storms move and develop in response to a complex array of forcings. The storm movement follows the overall environmental flow in the troposphere, but interactions with mid-latitude weather systems such as cold fronts and upper level jet streams act to deflect this otherwise smooth motion in a relatively unpredictable manner. The storms rely on a steady supply of energy supplied by the evaporation from the warm tropical ocean surface. As the storms move over cooler water or over land, they rapidly decrease in intensity. As the storms move polewards they carry significant amounts of moisture to higher latitudes, which often results in heavy rain and flooding in these extratropical locations.

MEASURING AND OBSERVING TROPICAL STORM CHARACTERISTICS

Each year, approximately 80–90 TCs occur around the globe. The level of variability in this annual total is around 10%. For individual basins, the variation can be much larger and no obvious correlation exists between individual

basins. Since the advent of effective satellite observation of typhoons, cyclones and hurricanes, our ability to forecast the behavior of storms has increased. As a consequence, the number of deaths that have occurred due to TCs has decreased dramatically, particularly on the high seas. Since 1944, regular aerial reconnaissance of hurricanes has been undertaken in the North Atlantic; aircraft flights into these storms do not occur in any other basins on a regular basis. Such aircraft reconnaissance is extremely expensive (and potentially dangerous), but provides valuable information about the nature and position of the storm that can be fed into numerical models to predict the future track and development. Conventional satellite imagery provides useful information on position and intensity. The Dvorak technique is an empirical technique that uses pattern matching to estimate the intensity of a storm from the patterns of clouds visible on satellite images. Observations using both passive microwave sensors and windfields derived from satellite mounted radar scatterometers provide additional information on the nature and position of the storm. The benefits of enhanced communications such as the World Wide Web now mean that advanced satellite products are available in real time to all forecasting centers with minimal additional investment.

IMPLICATIONS OF CLIMATE CHANGE

The instrumental record of relevance to interannual variability and trends in tropical cyclone, hurricane and typhoon activity is rather short and extensive analysis is therefore difficult. The quality of databases on tropical cyclone activity is highly variable. Even within a single basin, changes in observational networks, techniques and definitions may produce biases and errors in the datasets that have implications for studies of natural variability and trends in cyclone activity.

The balance of evidence collected by the Intergovernmental Panel on Climate Change (IPCC) suggests that the increases in greenhouse gas concentrations in the atmosphere are causing detectable climate change. A number of factors will offer improved understanding of the impacts of global change on tropical cyclone activity.

- Increased realism in three dimensional coupled climate models.
- Improved observations of air–sea interaction and other aspects of storm genesis and evolution.
- Further studies of past changes through palaeo-evidence.

Human vulnerability to typhoons, hurricanes and TCs is increasing as the population of coastal regions increases. At the same time, the costs of tropical cyclone impacts are increasing as infrastructure and insurance costs increase. Concerns about the impacts of global climate change therefore relate to many aspects of the storms: the frequency of occurrence; intensity (mean and maximum); structure and rainfall patterns. We still do not know how to predict the maximum intensity of today s storms, nor do we have a complete predictive model of storm genesis.

Although datasets are limited, some analysis of trends and variability has been undertaken at a regional scale. The number of typhoons in the Northwest Pacific showed a steady increase from 1980–1996; however, this period followed a decrease of almost identical magnitude in the previous 20 years. Difficulties in obtaining consistent wind measurements from the historical database have limited comparative studies of intensity. In the North Atlantic, there is substantial year to year variability, but no significant trend.

SUMMARY

Observational networks and technology have improved substantially over the last 40–50 years with a significant reduction in the loss of life resulting from improved warning to shipping and coastal communities. Changes in global climate in response to increased greenhouse gases have the potential to affect the frequency of occurrence, intensity and distribution of these storms. Because a number of factors influence the genesis of TCs, the exact influence of global change remains unclear. Although sea surface temperatures are predicted to rise, other changes in the structure of the atmosphere are likely to have a mitigating effect on storm formation and intensity and the 26.5 °C threshold is thought likely to rise under greenhouse conditions. Thermodynamic modeling studies of the effects of doubling the carbon dioxide concentration have indicated that there is likely to be a moderate increase in maximum potential intensity of storms; evidence of increased area of occurrence derived from regional scale models, however, is tentative and preliminary. There is no certainty that a storm will reach its thermodynamic maximum potential intensity and there are many uncertainties in other aspects of storm structure and behavior, particularly in the way the storm exchanges energy with the ocean.

Hurricanes, Typhoons and other Tropical Storms – Dynamics and Intensity

Jenni L Evans
The Pennsylvania State University, University Park, PA, USA

Tropical cyclones are the most destructive natural phenomenon on Earth. Winds, rain, river ooding, mud slides, coastal inundation and erosion contribute to loss of life and property due to these storms. In the aftermath of a storm moving inland from the sea (making landfall), disease outbreaks are a constant danger due to contamination of the local fresh water supply (from brackish water contamination) and the prevalence of standing water (creating new breeding areas for disease vectors such as mosquitoes).

An overview of current understanding of tropical cyclone formation (cyclogenesis), seasonal and interannual variability, intensity change, and storm motion is presented. This provides a background from which to infer potential changes in tropical cyclone characteristics in a warmer climate. Such changes in tropical cyclones in a warmer climate are strongly tied to changes in the tropospheric wind, temperature and moisture structure of the global tropics. The more sensational claims of increased tropical cyclone occurrence are not supported and, while the strongest storms may increase in intensity by 5- 10%, evidence is lacking for the effect on average storms. Further, a 5- 10% difference is within the range of interannual variability in the present climate and so will not be readily detected initially. While global storm statistics may be largely unchanged, recent evidence of a tendency for a more El Niño/Southern Oscillation-like structure in warmer climate regimes suggests regional changes in tropical cyclone frequency and possibly in preferred storm tracks.

INTRODUCTION

Tropical cyclones are clearly the most destructive natural phenomenon on Earth, visiting death and destruction across the global tropics each year. As a tropical cyclone passes by, the winds and rain become stronger and stronger until they die off rapidly as the eye of the storm passes over. This brings a time of deceptive calm (often accompanied by blue skies). Then, as quickly as they ceased, the winds and rain return and the storm may rage for hours more. To anyone who has experienced or witnessed the aftermath of one of these storms, they stand out as terrifying examples of the power of weather. Satellite images (e.g., Figure 1) illustrate many aspects of the structure of a tropical cyclone: the central, calm and (usually) cloud free eye region surrounded by an eyewall of deep thunderstorms and bands of cloudiness that spiral outward from the eyewall (although these are sometimes obscured by high clouds). These tropical low pressure systems are typically 12–15 km tall and the strongest winds may extend from a few kilometers to hundreds of kilometers from the center.

While we have only named individual storms since the 1960s, this storm type has different names originating in the folklore of the various regions in which it occurs: *hurricane* in the Atlantic and *typhoon* in the western Pacific. These terms are used to designate the strongest of these storms in each region. A tropical cyclone begins life as a depression. Each depression is tracked, but it is not a named tropical storm until its intensity (area averaged sustained surface winds over its center or minimum pressure) exceeds $17\,\mathrm{m\,s^{-1}}$ (with stronger gusts). Once the sustained winds are above $34\,\mathrm{m\,s^{-1}}$, a tropical storm becomes a tropical cyclone, and at $67\,\mathrm{m\,s^{-1}}$, it becomes a Category one hurricane or typhoon. There are five hurricane (typhoon) categories, with storms in Category three, four or five being known as severe tropical cyclones (intense hurricane in the Atlantic or supertyphoon in the Western North Pacific). Threshold values for these categories vary slightly between the different basins, as does the time over which the sustained winds are recorded (one minute in the Atlantic and eastern Pacific, 10 minutes elsewhere) (*see* Hurricanes, Typhoons and other Tropical Storms - Descriptive Overview, Volume 1).

TROPICAL CYCLONE CLIMATOLOGY

Annual global tropical cyclone activity is remarkably stable. Approximately eighty tropical storms are observed around the globe each year and of these, two thirds reach hurricane (typhoon) intensity (Figure 2). The average annual variation of global occurrence is only $\pm 7\%$, although regional variations are much wider and are largely uncorrelated from one region to another.

Tropical storms exhibit a definite seasonal variation. The season extends from June to November in the Northern

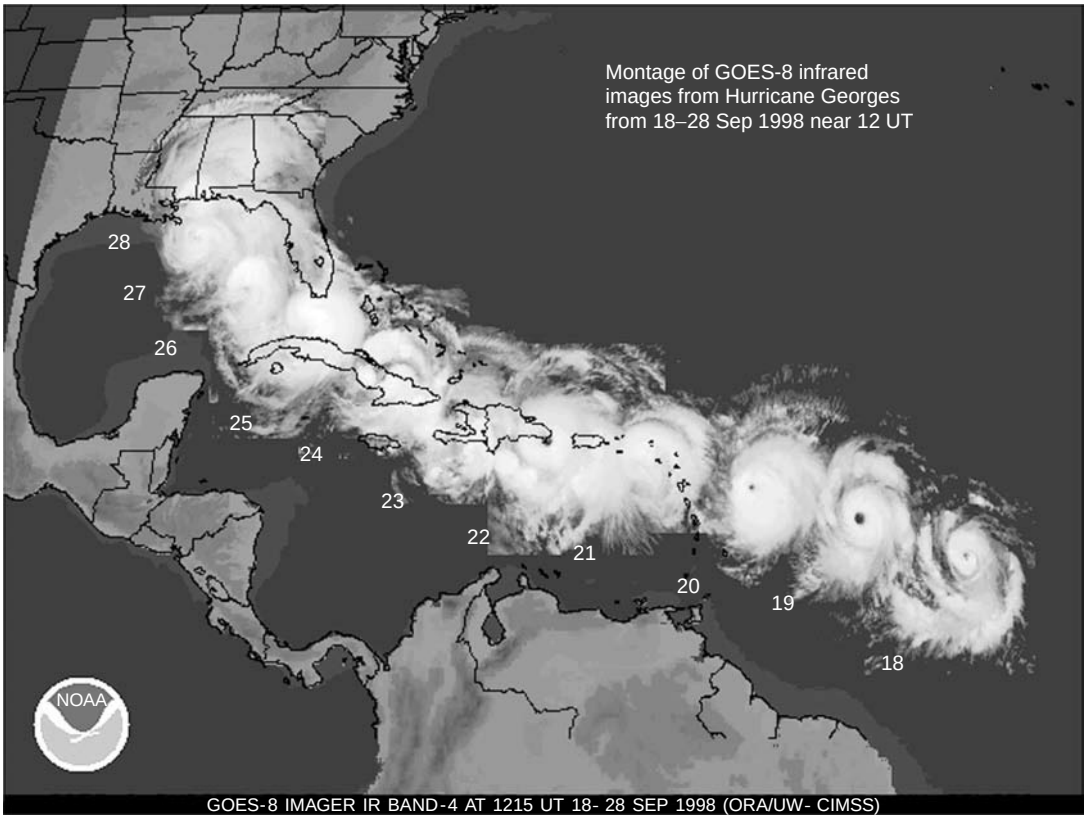

Figure 1 Montage of infrared (IR) satellite images of Hurricane Georges (1998). The data are from the GOES-8 satellite and cover the period 18–28 September 1998. This image was provided by Gary Wade at NOAA/NESDIS/ORA. Between 18 and 28 September 1998, Georges progressed from a minimal hurricane (984 hPa on 18 September) to a peak intensity of 937 hPa (Cat-4 Hurricane; 20 September) and eventually decayed after making landfall about 1130 UTC on 28 September 1998 near Biloxi, MI. After reaching its peak intensity on the 20th, Georges crossed a series of Caribbean islands on the 21st: Antigua (0430 UTC), St Kitts (0800 UTC), Puerto Rico (2200 UTC), and the Dominican Republic early on the following morning (0430 UTC). Hurricane Georges then proceeded towards Cuba, making landfall on the 23 September at 2130 UTC, before crossing Key West as a minimal hurricane (25 September at 1530 UTC). The variations in the storm intensity are generally evident in the variations of the cloud signature

Hemisphere (NH) and December to May in the Southern Hemisphere (SH). The western North Pacific basin is the only region in which tropical cyclones have been observed in all months of the year. Peak tropical cyclone activity occurs in late summer/early autumn in each hemisphere (August–October in the NH and January–March in the SH). This seasonal bias coincides with the maximum in regional sea surface temperatures (SSTs) (exceeding the critical lower limit of 26.5 °C) and favorable large-scale winds.

CONDITIONS OBSERVED TO BE NECESSARY FOR TROPICAL CYCLONE FORMATION

Formation of tropical cyclones (tropical cyclogenesis) occurs over oceans in preferred regions: the poleward side of the monsoon trough in the Pacific and Indian Ocean basins and easterly waves in the North Atlantic and eastern North Pacific basins (Gray, 1968) (Figure 3). Tropical cyclones are not observed in the South Atlantic or eastern South Pacific basins.

A number of temperature and moisture (thermodynamic) and windfield (dynamic) conditions have been observed to be necessary for tropical cyclone formation, however no single condition has been determined to be sufficient. That is, all of the factors described below could be present and yet a tropical cyclone may not form, but a tropical cyclone will not form if any of these factors is missing. This lack of predictability of tropical cyclone formation makes it difficult to study because, by the time we re sure that a storm is forming, it already has!
