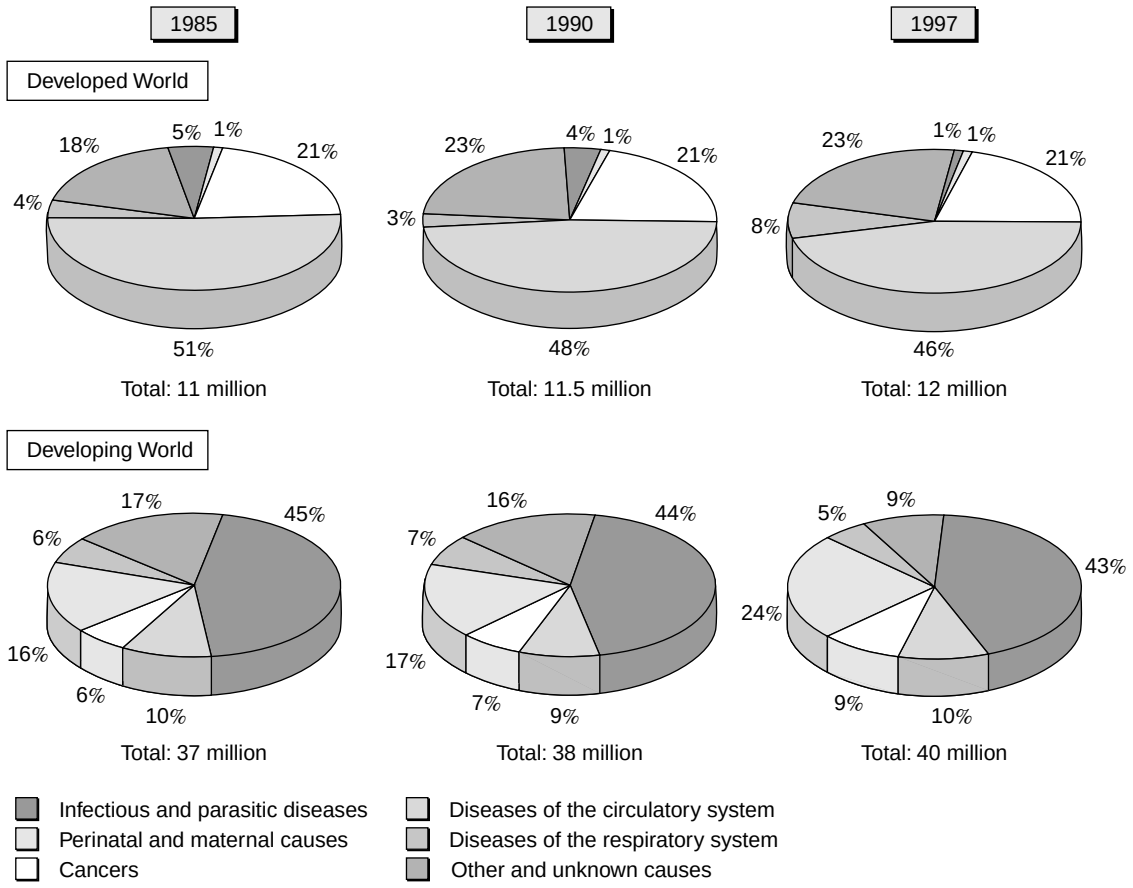
Many examples can be cited on the harmful effects of the preoccupation with making a quick profit at the expense of health and sustainability of the environment, characterizing the lifestyles of modern societies. It is sufficient to look at the epidemiological transition and the estimated trends in mortality for major causes of death, to appreciate the effect on human health. In the industrialized world, control of communicable diseases as a major cause of death has been replaced by non-communicable diseases such as cardiovascular, cancers, injuries and accidents and rising incidence of mental health problems. In the developing countries, the major cause of disease still remain infectious diseases with an increasing rise in non-communicable diseases, illustrating the double burden of disease facing the third world. An alarming phenomenon coming into the picture is the quality of inequity that affects health status differentials between as well as within countries. As we arrive into the 21st century, mental health conditions, cardiovascular diseases, cancers, allergies, chronic respiratory diseases, occupational hazards, and finally violence, are becoming a major scourge. All these constitute significant public health problems, whose root causes emanate from the socioeconomic, political and environmental context in which people live. There is no doubt that the more that action is undertaken as an integral part of the environment, the more the benefits will accrue to health (see Figure 7).

Clearly, sustainable development policies should emphasize longer-term broad-spectrum interventions touching upon the driving forces operating in human societies. In many developing countries, this would mean tackling inequity, poverty, and population issues, thereby contributing to the control of land degradation and deforestation, biodiversity loss, soil erosion, and food insecurity. In developed countries, inequity also needs tackling as evidenced by the fact that sizable population groups live in squalor and relative poverty. Emphasis should be placed on reducing unsustainable consumption, curbing the use of non-renewable fuels, and reducing the generation of solid wastes to minimize transboundary pollution, toxic waste problems, and global environmental change. To implement such proactive preventive approaches successfully, development policies and planning need a long-term horizon with health and environment concerns forming an integral part of the associated planning. A supportive environment for health is free from major health hazards, satisfies the basic needs of healthy living, and facilitates equitable social interaction. Supportive environments, on the other hand, encompass where people live, their local community, their home, where they work, where they learn, and where they play. By looking at the physical, the social, the spiritual, the economic, the political, and above all, the involvement of the people themselves and all civil society, there is hope that protecting our health and our environment can become a legacy to the future generations (WHO, 1997).

CONCLUDING REMARKS

Today, in pursuit of development, societies are constantly confronted with tradeoffs; between health and economic development, between the increased generation of income and the protection of the people, and between sound



Source: The World Health Report 1998.

Figure 7 Causes of death: distribution of deaths by main causes, by level of development, 1985, 1990, 1997

environmental practices and making business profitable. The global value system has been strongly biased in favor of economic gain, quick profit, or cutting down on essential expenditures at the cost of other invaluable attributes such as health and a sound environment. The global value system advocating caring for societies in a caring world is fading (WHO, 1997).

The dominant issue facing policy makers is the respective roles of the market and the State. Taking health as an example, policy makers must be made aware of the inherent limitations and imperfections of a health care system that is controlled by market forces. Although imperfections are inherent in any market, the value of health is such that the potentially grave and dramatic human consequences that could occur in an inappropriately managed health market cannot be allowed (WHO, 1997).

Improved public health is an indispensable pre-condition for the enjoyment of other goods and services. The goods and services needed to protect health and cure disease are essential to individuals in a way in which other goods are not. Consequently, health and the goods and services needed to achieve it are not tradable in the same way as other commodities. This attribute makes health unique and not a commodity like others that can be bought and sold (WHO, 1997).

Technological advances must be anchored firmly to a foundation of human values and to individual rights to life and health. If not, they will imperil the basic social institutions, which order society. Abuses are likely to occur in any system, whether private or public. This anchoring will not be done by the market nor will it be done by the state acting alone. It must be achieved through societal choices made collectively by the state, the market and civil society (WHO, 1997).

It is becoming increasingly clear that the environmental factors that most affect health are linked to underlying pressures on the environment. These pressures are mainly due to factors such as population growth, inequitable resource distribution, consumption patterns, technological development and components of economic development. Since these factors and the health hazards they create emanate from activities of various sectors, effective action to protect health will require coordination and collaboration between various sectors.

There will always be a part of the public domain in health which must remain a public responsibility; e.g., the protection of people from communicable diseases, the control and elimination of disease vectors, and the control and regulations of known health risks. This is because the benefits of these activities accrue to people in an indivisible form. They create, by their very nature, an environment where benefits are collectively enjoyed, and are not available to their delivery through market mechanisms to individual beneficiaries (WHO, 1997).

The health sector must assume its share of responsibility by being the guide and a partner in these actions, so that health concerns are represented appropriately at all stages of implementation. It has an essential advocacy role to play in highlighting the links between health, the environment and sustainable development, when future policies are developed and actions planned. A much stronger partnership between the health sector and other sectors, and an alliance with the environment activities is vital for the successful reduction of health threats arising from poor environmental conditions.

Industrial Responses to Stratospheric Ozone Depletion and Lessons for Global Climate Change

STEPHEN O ANDERSEN

US Environmental Protection Agency, Washington, DC, USA

When the Montreal Protocol on Stratospheric Ozone Protection was signed in 1987, few alternatives to ozone-depleting substances (ODSs) were available or even imagined. Industry predicted that technical progress would be slow, that costs would be exorbitant, that valuable equipment would be abandoned, and that safety might be compromised. As it turned out, these predictions were never realized. In fact, new technologies are more energy ef cient, maintenance cost is reduced, and systems are more reliable than those based on chloro uorocarbons (CFCs) and other ODSs.

The rst decade of technical progress under the Montreal Protocol occurred during a period of growing concern for the global environment and increasing corporate environmental leadership. During this same period, other international environmental treaties were developed including the Basel Convention on the Control of Transboundary Movements of Hazardous Wastes and their Disposal, the Convention on Biological Diversity, the Convention to Combat Deserti cation, and the Framework Convention on Climate Change and its Kyoto Protocol. The 1992 United Nations Conference on Environment and Development (the Rio Earth Summit) intensi ed global awareness of the importance of environmental protection to economic development and began integrating governmental and non-governmental activities.

This contribution documents and illustrates some of the extraordinary individual, association, and corporate contributions to the remarkable success of stratospheric ozone protection and draws important lessons for climate protection. After the Montreal Protocol was signed in 1987, industry in both developed and developing countries responded to the threat of stratospheric ozone depletion by rolling up their sleeves to get the job done.

THE IMPORTANCE OF INDUSTRY LEADERSHIP TO THE MONTREAL PROTOCOL

The Montreal Protocol is a remarkable success in a variety of ways. Foremost, it is environmentally successful because the controls placed on production of ODSs are working, atmospheric concentrations of chlorine and bromine are coming down and ozone depletion will soon end. It is diplomatically successful because it is proving that the global commons can be wisely managed with stringent obligations, adequate financing, global cooperation, and exible procedures. It is economically successful because it was affordable to business and virtually unnoticed in consumer prices. It is technically successful because engineers used the necessity of change to thoroughly redesign systems, resulting in better efficiency, better reliability, and better overall value for consumers.

One reason for this success is that industry and government learned to cooperate to accomplish common objectives. Looking back, it is possible to trace many unanticipated ways that organizations with little previous experience working together ultimately helped each other to overcome technical challenges.

UNITED NATIONS ENVIRONMENT PROGRAM WELCOMED INDUSTRY LEADERSHIP

Until the Montreal Protocol, it was a tradition of United Nations organizations to only seek advice from government and academic experts who were recommended through national diplomatic channels. United Nations Environment Program (UNEP) Executive Director Mostafa Tolba

Box 1 Technology and economic assessment panel

- 1999: 225 members from 46 countries (Argentina, Australia, Belgium, Brazil, Canada, Chile, China, Colombia, Denmark, Egypt, Finland, France, Germany, Hungary, India, Indonesia, Israel, Italy, Japan, Jordan, Kenya, Korea, Malaysia, Mauritius, Mexico, Morocco, Netherlands, New Zealand, Norway, Pakistan, Philippines, Poland, Russia, Singapore, South Africa, Spain, Sweden, Switzerland, Tanzania, Thailand, Tunisia, Uganda, UK, USA, Venezuela, and Vietnam)
- Since 1989, over 700 members from 50 countries

broke with this tradition when he formed the Technology Review Panel (later renamed the Technology and Economic Assessment Panel (TEAP)) to advise the Parties to the Montreal Protocol on how fast the controls could be strengthened. Dr Tolba allowed the TEAP organizing chairs to recruit technically respected and globally in uential industry experts from outside the diplomatic chain of command, instructed members to act independently from their sponsoring organizations, and empowered TEAP to report directly to the Parties to the Montreal Protocol. Contrast this with the Kyoto Protocol where experts are predominantly from government, universities, and institutes and where reports are reviewed and edited prior to presentation to Parties. The daring action was premised on Dr Tolba's belief that the world's best technical experts would know the most about emerging technology and therefore would be far more technically knowledgeable than government and academic experts with access only to published research. Another anticipated advantage was that these experts would be able to craft detailed strategies to remove barriers to new technology and to create business opportunities where alternatives to ODSs would ourish. The Technology Review Panel (TEAP) was formed in 1989 with 116 experts. Over 80% of its members were from industry and less than 10% were from government (Box 1).

CORPORATE LEADERSHIP PRECEDED NATIONAL AND INTERNATIONAL REGULATORY ACTION

Corporate environmental leadership on ozone layer protection began in 1975 when the S.C. Johnson Company announced plans to phase out the use of CFC as an aerosol product propellant. Publicity from the announcement increased public concern for the ozone layer and encouraged product boycotts. Rapid introduction of hydrocarbon propellants gave consumers an environmental choice and persuaded regulators that the impact of a CFC aerosol ban would be minimal. Within 3 years, sales of aerosol products had plummeted as S.C. Johnson took over market share. The United States banned aerosol products in 1978 followed by Sweden, Canada, and Norway.

The US Environmental Protection Agency (EPA) and the Japan Ministry of International Trade and Industry (MITI) promoted corporate leadership worldwide.

Until the Montreal Protocol was signed in 1987, there was very little cooperation between industry and governments. Industry was mostly represented by associations or special interest organizations chartered to defend CFCs by any means. Companies that were members of these organizations were warned to not express any concern for ozone depletion or any technical optimism that could aid or encourage CFC controls. Within companies, research engineers were discouraged from investigating CFC alternatives: The ozone layer is healthy, CFCs do not destroy ozone, technical optimism could encourage regulation, regulation will harm the company; harm to the company hurts stockholders, employees, and customers.

Industry began to support stratospheric ozone protection after the Montreal Protocol was signed. This corporate environmental leadership resulted from at least eight separate motivations:

1. Public interest organizations including Friends of the Earth, Greenpeace, and the Natural Resources Defense Council were creating public demand for CFC-free products. School children were starting letter writing campaigns and boycotts against products such as foam food packaging.
2. The EPA stratospheric ozone office – managed by Eileen Claussen, John Hoffman, and Stephen Seidel – was young and open to innovation. They reasoned that cooperation with business could speed regulatory results and they gave their staff experts extraordinary authority to experiment with innovative programs. In Japan, MITI and industry associations quickly organized to encourage rapid action to protect the ozone layer.
3. Environmental leadership companies with strong environmental ethics began to organize to halt their own CFC use. These companies included AT&T, Digital Equipment Corporation, Motorola, Nissan, Nortel, and Seiko Epson. These corporate leaders believed that technical cooperation could speed technical development of alternatives and substitutes.
4. Developing country governments and companies were advocates of ozone layer protection. Developed countries have historically been in the vanguard of environmental protection because they were the first to experience the negative environmental effects of industrialization and because they were financially able to respond. Developing country populations are often most affected by environmental despoilment and least able to respond to its destructive effects. The lost productivity and increased public spending for health

Box 2 Extraordinary Mexican leadership

- Aerosol product phase-out before protocol adopted
- Invented open-air HC Filling Technology
- Diplomatic advocate
- First country to sign Montreal Protocol
- First country to ratify Montreal Protocol
- First semi-aqueous electronics facility
- Second no-clean electronics facility
- First ODS Country Program
- First article 5(1) to accelerate phase-out

Box 3 Technology from East European and developing countries

- Brazil Low Solids Flux w/o Solvent

- China and India Eco-Frig
- East Germany Hydrocarbon Refrigerator
- India Neem Methyl Bromide Replacement
- Korea New HFC-134a Pathway
- Mexico Open Air HC Aerosol Filling
- Poland Military Halon Bank Management

programs resulting from environmental degradation slows economic development. Environmentally concerned children in uenced their families. Consumers mounted protests against CFC products. Businesses strived to shift from obsolete ODS technology to modern CFC-free technology that was often more profitable. Box 2 illustrates the leadership of developing countries by listing actions taken by Mexico that had a global in uence.

5. The United States Military determined that weapons systems were dependent on CFCs and halons for production, operation, and maintenance and sought to eliminate the supply vulnerability that would come from regulatory controls. The US military leadership inspired other military organizations to cooperate on global environmental protection. Cooperation hastened acceptance of new technology and reduced transition costs. Military leadership inspired suppliers to develop solutions, stimulating work by some of the best inventors in the world. Global military leadership moved the North Atlantic Treaty Organization (NATO) to take the unprecedented step of writing directly to UNEP Executive Director Mostafa Tolba in support of the proposed accelerated phase-out of ODSs. NATO also endorsed technology cooperation and modification of standards to allow production and maintenance of military equipment without the use of chemicals that deplete the ozone layer.
6. Companies dependent on CFCs had over-trusted CFC manufacturers' claims that the ozone layer was healthy and that CFCs were not a culprit. It was a sobering wake-up call for customers when DuPont admitted ozone depletion and supported an international treaty. Companies using CFCs and other ODSs were angry, fearful, and motivated to seek alternatives.
7. Suppliers of alternatives to ODS technology and inventors viewed the Montreal Protocol as a business opportunity. Controls under the Montreal Protocol caused ODS prices to increase and several countries accelerated that price in ation with taxes. For the first time in a decade, ozone protection became a marketing issue. It was significant that CFC suppliers were admitting that ozone depletion was real and that prices would be increasing. The Treaty was a regulatory mandate; governments were working to eliminate barriers to new products and to encourage substitution. Some of the most important technology to replace ODSs was developed and implemented first in developing countries (see Box 3).
8. Environmental awards from EPA, UNEP, and other organizations motivated, inspired and rewarded global citizenship. EPA presented its first annual Stratospheric Protection awards in 1990 and by 2000 had recognized almost 420 individuals, corporations, and organizations from 32 countries (Australia, Belgium, Brazil, Canada, Chile, Dominican Republic, France, Germany, Hungary, India, Indonesia, Ireland, Italy, Japan, Kenya, Malaysia, Malta, Mexico, Netherlands, Norway, Philippines, Poland, Singapore, Spain, Sweden, Switzerland, Taiwan, Thailand, United Kingdom, United States, Uruguay, and Venezuela). UNEP presented 19 awards in 1985, 23 awards in 1987, and one award in 1998 to individuals, corporations and organizations from 19 countries (Australia, Brazil, Canada, Denmark, Egypt, Finland, Germany, Greece, Japan, Malaysia, Mauritius, Mexico, Netherlands, New Zealand, Poland, Sweden, Switzerland, United Kingdom, and the United States). On the 10th Anniversary Celebration of the Montreal Protocol EPA presented Best-of-the-Best Stratospheric Ozone Protection Awards to 71 previous award winners making the most exceptional contributions in the first decade. The winners were from 12 countries: Australia, Brazil, Canada, Germany, Japan, Malaysia, Mexico, Netherlands, Switzerland, United Kingdom, United States, and Venezuela.

CASE STUDY: GLOBAL TECHNOLOGY COOPERATION – MEXICO CFC SOLVENT PHASE-OUT PARTNERSHIP

Material for this case study was provided by Jorge Corona, Head, Foreign Affairs Section, Mexican Environmental Commission of the National Chamber of Industries of Mexico (CANACINTRA). Mr Corona organized the Program for Technology Transfer in the Electronics Industry with US

EPA, UNEP and Nortel, CANACINTRA and the Mexican Electronics Manufacturers Association.

With the support of environmental non-government organizations (NGOs), the Instituto Mexicano del Aerosol A.C. organized the first voluntary sectoral phase-out of CFCs by any developing country. The association and its members achieved the phase-out of CFCs in cosmetic and pesticide products at least 5 years faster than most developed countries and used new technology that was more profitable than the CFC technology it replaced. This favorable experience caused Mexican industry to propose a rapid CFC phase-out in other sectors to take full advantage of superior new technology.

Industry representatives decided to leapfrog CFC solvents as they expanded and modernized factories. The Mexican Solvent Partnership was organized by the Government of Mexico, Camara Nacional de la Industria de la Transformacion, the Canadian telecommunication company Nortel, the International Cooperative for Ozone Layer Protection (ICOLP) (ICOLP member corporations included AT&T, The Boeing Company, British Aerospace, Compaq, Digital Equipment Corporation (DEC), Ford, Hitachi, Honeywell, Hughes Aircraft Company, IBM, Lockheed-Martin, Matsushita Electric, Mitsubishi Electric, Motorola, Nortel/Northern Telecom, Ontario Hydro, Texas Instruments, and Toshiba), and the US EPA. This may have been the first time governments allowed a private company (Nortel) to be an organizing and managing partner in global environmental protection. The Partnership showcased CFC-free technology at Mexican factories of multinational companies and involved Mexican factory managers and solvent cleaning experts through workshops, technology study tours, and training. Nortel assigned a full-time coordinator to identify barriers and to work with the Mexican government and industry authorities to speed technology change.

The Mexican leadership motivated multinational companies to concentrate on modernizing their Mexican production facilities. Within 3 years, AT&T built their first CFC-free factory in Mexico using aqueous cleaning and Nortel built a new factory using no-clean soldering that eliminates the need to clean with CFCs. Mexico was the location of the newest, most environmentally acceptable technology – later duplicated throughout the world.

With the help of multinational companies and associations and the Multilateral Fund, Mexico virtually phased out CFC solvents by 1996.

CASE STUDY: GLOBAL TECHNOLOGY COOPERATION – PHASE-OUT OF CHLOROFLUOROCARBONS IN THAILAND

Yuichi Fujimoto provided material for this case study. Mr Fujimoto was Thailand project director for the Japan Electrical Manufacturers' Association (JEMA).

At a 1990 seminar conducted for the Association of South-East Asian Nations (ASEAN), it was reported that electronics and refrigerator enterprises from Japan, the United States and Europe were primarily responsible for dramatic rates of increase in CFC consumption in Thailand. Responding to this situation, the government of Thailand and multinational companies decided to motivate a rapid phase-out through voluntary pledges.

At the March 1992 Japan–US–Thailand Technical Seminar on Ozone Layer Protection, 35 Japanese and 11 American companies pledged specific schedules for phasing out CFCs and 1,1,1-trichloroethane from Thai operations and joint ventures (AT&T, Dai-Ichi Densikogyo, Digital Equipment Corporation, DuPont, Ford, Fujikura Cable, Fujitsu, Hitachi, Honda, Honeywell, IBM, INOAC, Matsushita, Minebea, Mitsubishi Electric, Motorola, NEC, NHK Spring, Nippondenso, Nissan Motor Company, Nissin Electric, Nitsuko, Nortel, Philips Semiconductor, Signetics, Sanyo, Seiko Epson, Sharp, Sundstrand, Texas Instruments, 3M, Toshiba, Toyota, Yamaha, and ZEXEL).

The original plan was that each multinational company would separately solve its own technical problems. This plan worked well in the electronics manufacturing sector but was unsuccessful for refrigerator manufacturing. Seven Japanese companies and their joint ventures produced household refrigerators in Thailand. Three of these companies imported all the critical parts necessary to complete the phase-out but the other four companies used compressors supplied by a single Thai company. It was therefore crucial that the Thai compressor manufacturer redesign components to achieve high energy efficiency and reliability using refrigerant HFC-134a. The Thai compressors had to be competitive in price and quality with foreign suppliers.

The government of Thailand announced the end of 1996 as its target date for eliminating CFCs used as refrigerants and as blowing agents for insulating foam in domestic refrigerators. This challenging target date was only one year later than the phase-out date for developed countries and was the world's first phase-out for the refrigerator sector in any developing country.

The local compressor manufacturing company was scheduled to supply the new HFC-134a compressors in time for the new refrigerators to be produced by the end of 1996. Unfortunately, prototype compressors tested by the Japanese companies were unacceptable due to manufacturing residue contamination that clogged refrigerant tubes and poor lubrication that caused rapid wear. Despite significant effort to resolve the problems, the local company found itself unable to produce reliable compressors in time for the phase-out.

No other local compressor suppliers could be found with the capability to supply enough compressors to meet the deadline established by the Thai government. The Japanese

companies considered compressors from manufacturers other than the local company but rejected this option because they had pledged to help Thailand build local manufacturing capability. Another option was to postpone the phase-out and wait for a supply of reliable compressors from the local company but this option was rejected because the Thai government was eager to keep the phase-out on schedule.

The only remaining option required additional technology cooperation with the local compressor company. The refrigerator parent companies that were buying compressors in Thailand – Hitachi, Matsushita, Mitsubishi Electric and Toshiba – and the JEMA launched a Tiger Team (Tiger Teams are motivated experts who work as a team to solve problems – confident, decisive, and successful) to assist the local company to improve reliability and to help with its implementation. The US EPA attended follow-up meetings in Thailand and worked with the Thai compressor manufacturers' parent company in the United States to promote its participation in the technical support project.

The ambitious phase-out goals were ultimately achieved through corporate leadership and unprecedented technical cooperation. The seven Japanese refrigerator companies and their joint ventures completed the CFC phase-out by the end of 1996. The Thai Government complemented this technical achievement by prohibiting the manufacture or import of foreign CFC refrigerators after 1996.

CASE STUDY: SUPPLIERS AND CUSTOMERS WORKED TOGETHER TO CHOOSE CHEMICAL SUBSTITUTES

Fluorocarbon manufacturers pooled their resources to quickly and thoroughly test the environmental, health, and safety effects of promising new refrigerants. Individual chemical companies took unusual risks by investing millions of dollars to build facilities to manufacture the new chemicals, even before toxicity and performance studies were completed. In addition, they developed the thermodynamic tables for the new refrigerants in record time, enabling new equipment to be quickly designed and built. Manufacturers of cooling and refrigeration equipment worked closely with the chemical companies to design and build new systems based on the new refrigerants, and to test and optimize their performance.

CASE STUDY: SECTORS THAT RARELY COMMUNICATED JOINED FORCES TO ADVOCATE REFRIGERANT RECYCLING

In 1987, automobile air conditioners were the largest single source of controllable CFC emissions in the US. Normal CFC leakage through rubber hoses, connectors, and seals was very high, and typical repair procedures intentionally released large amounts of CFCs into the atmosphere. CFCs were inexpensive, and no acceptable machines were available to capture and reclaim the CFCs. When confronted with a poorly functioning air conditioner, a service technician typically diagnosed the problem by recharging the system, and then locating the leak by observing the CFC discharging to the atmosphere. The technician would then vent the remaining refrigerant into the atmosphere, repair, recharge, and leak test the system again. Do-it-yourself car owners saved money by merely recharging leaking systems – often recharging several times a year, without fixing the leak. CFCs also entered the atmosphere when an air conditioning component had to be removed to gain access to other automobile systems.

In January 1988, EPA organized its first meeting of the Ad-Hoc Automobile Recycling Working Group. The proposed standard was based on the assumption that some level of CFC contamination would be acceptable, that it was the obligation of recycling equipment manufacturers to design equipment capable of cleaning to a standard acceptable to automobile manufacturers, and that equipment would have to be tested by an independent laboratory to prove its cleaning performance.

By 1989 the Mobile Air Conditioning Society (MACS), the Society of Automobile Engineers (SAE) and EPA developed a CFC recycling standard that was endorsed by international vehicle manufacturers for repair under new-car warranty. Many automobile manufacturers required franchised dealers to employ the new recycling technology. Underwriters Laboratory, also represented on the working group, simultaneously developed the equipment certification program that was available by the time vehicle manufacturers accepted recycling.

Companies that were fiercely competitive in product markets allowed their engineers to jointly develop ozone-safe technology.

In 1989 UNEP formed the TEAP to conduct the first global assessment of alternatives and substitutes to ODSs. A majority of TEAP members were from industry and research institutes, with a minority from governments and universities. TEAP experts were surprised to learn that some technically sophisticated companies had inadvertently avoided typical dependence on ODSs and these experts quickly realized that TEAP could become a catalyst for technical evolution.

The role of the TEAP Solvent Technical Options Committee (TOC) in commercializing no-clean soldering to replace the use of CFC-113 solvents illustrates this cooperation. When the German company SEHO demonstrated controlled atmosphere soldering, electronics manufacturing experts on the solvents, TOC recognized the theoretical potential but were unimpressed by the soldering results. It was obvious to the TOC experts that the component parts were too oxidized, that the ux was mismatched, and

that the soldering wave was poorly formed. However, the promise of the technology was so compelling that experts at AT&T, Ford, Motorola, and Nortel persuaded their companies to experiment with the technology and decided to work as a team.

Some experts concentrated on the ux composition, while others believed that the ux was chemically suitable and worked out ways to apply it to the board more precisely. Still others concentrated on the mixture of gases in the soldering chamber. Several months into development, one company discovered that gas monitoring and control calibrations were critical. Better calibrations dramatically improved the soldering quality. The team consulted with ux suppliers who grasped the opportunity for developing and commercializing new products and intensified development in cooperation with the electronics manufacturers. EPA encouraged the work by documenting and publishing the global environmental advantages that such a technology could provide. TEAP reports reported the progress and alerted potential customers to the possibility of a technical breakthrough.

Meanwhile, engineers at AT&T Bell Laboratories were developing state-of-the-art spray uxing machines to apply precisely the optimal amount of ux to the locations in the printed circuit boards where necessary. Nortel was developing equipment to verify ux concentrations on production boards, and Motorola was experimenting with soldering ultraminiaturized circuits with hybrid components including optical devices and exible connectors. One by one, companies satisfied internal quality controls and moved from laboratory scale to pilot studies and finally to full implementation. During implementation, experts from the intercompany team continued to cooperate to debug operations and optimize performance.

It is impossible to say just when the engineering team realized that their no-clean technology would revolutionize electronics assembly. Engineers who had cautiously reported performance as good as with CFC solvents began to report improved performance. Line managers cautiously increased the speed of soldering to rates never achieved with conventional soldering and found that in some cases defect rates actually *decreased*.

EPA and its contractors tracked and documented the technical development and operating parameters and, in cooperation with the ICOLP published the first no-clean handbook in order to make the know-how and technology available worldwide.

CASE STUDY: JOINT AND INDEPENDENT TECHNOLOGY EVOLUTION PROVIDED GLOBAL CONFIDENCE

In many ways, the implementation of recycling in the stationary sector paralleled that in the automotive sector.

Another issue that will become important to the industry as we face the challenge to protect climate is the *global warming potential* of HFC-134a (*see* Global Warming Potential (GWP), Volume 1). Controls are considered for HFC-134a mindful of its environmental impact, the quantity of use and emissions throughout the world, the importance of its applications, and the availability of technically feasible alternatives. Industry has spent a great deal of time and money commercializing HFC-134a for important air conditioning and refrigeration applications. Is industry capable of exercising self-control, and avoiding unnecessary and conspicuous uses of HFC-134a? Can chemical suppliers resist the temptation to market HFC-134a into cosmetic aerosol applications or for the proposed self-chilling beverage that exhausts several ounces of HFC-134a to cool each can of drink? Can all countries implement best containment practices and recycling for vehicle HFC-134a air conditioners?

Potentially excessive emissive uses of HFC chemicals make them easy targets of regulation. However, it is within the power of industry to recognize these vulnerabilities, to look beyond this quarter's sales figures, and to take the important actions necessary to protect investments and markets over the longer term.

LESSONS FOR CLIMATE PROTECTION

When the Kyoto Protocol on Climate Protection was signed in 1997, a vocal majority of global industry predicted dire consequences from possible regulations to reduce the emissions of greenhouse gases – an end to economic growth, drastic changes in life-style, mass starvation, and political chaos.

Although climate protection is more daunting than ozone layer protection, corporate and military leadership is already showing the world that technology can reduce greenhouse gas emissions. Climate protection pledges by multinational companies (Box 4) and new pro-environment business organizations (Box 5) are consolidating business support and advocating prompt action.

The 1998–2000 EPA Climate Protection Awards winners illustrate this leadership. British Petroleum is reinvesting in sustainable energy and advertises BP: Beyond Petroleum . Trigen Energy supplies heating, cooling, and electricity with half the fossil fuel pollution of conventional generation and Enron Corporation is drastically reducing the emissions from natural gas pipeline compressor stations. Compaq Computer Corporation is integrating environmental considerations into its products, facilities, and operations, while Intel is making semiconductors that automatically save energy. IBM Corporation is the first multinational electronics company to announce phospho uorocarbon (PFC) emissions reduction goals; and Royal Philips Electronics is showing its customers how to reduce energy use by

Box 4 Corporate climate leadership pledges

2% Energy reduction per year	Dow
40% PFC reduction by 2003	IBM
50% PFC reduction by 2010	Motorola
65% Emission Reduction by 2010	Dupont
25% Reduction by 2007–2010	Mitsubishi Electric, Ontario Hydro, Philips, Sanyo, and United Technology
10% Energy reduction by 2008	British Petroleum
10% Energy reduction by 2002	Shell
20–30% Less energy intensity	Japanese & German Steel
10% Renewable Energy by 2010	Dupont

PFC, perfluorocarbon

Box 5 Industry associations advocating climate protection

- Alliance for Responsible Atmospheric Policy
- Business Council for Sustainable Energy
- International Climate Change Partnership
- International Cooperative for Environmental Leadership
- Pew Center on Global Climate Change
- World Semiconductor Council

one-third or more. Trane air conditioning chillers supply extraordinary energy efficiency and near zero refrigerant emissions and Whirlpool invented the super-efficient refrigerator that surpasses energy standards by 30–40%. Honda and Toyota have commercialized the world's first hybrid passenger vehicles and Nissan is lowering emissions and fuel use with new direct injection technology. The US Naval Surface Warfare Center stern ap reduces the power required to propel a ship by 6–14%. McDonald's Corporation's Earth Effort makes climate protection a high priority and the Walt Disney Company Environmentality encourages Disney cast members and employees to undertake positive environmental practices at home and on the job (Box 5).

CONCLUSIONS AND HOPE FOR THE FUTURE

Technology cooperation under the Montreal Protocol mobilized experts from fiercely competing companies to share information and to speed technology development and application. Military organizations broke with precedents and made ozone layer protection a priority for environmental security. Leadership companies announced ambitious goals that stimulated suppliers to do it better without ODSs. Public gratitude and confidence rewarded innovation.

The history of stratospheric ozone protection is repeating itself in climate protection. Multinational companies are declaring climate protection goals. Industry associations are supporting the Kyoto Protocol. National governments are choosing emission reduction strategies. Perhaps most remarkably, industry is working with government to pursue voluntary measures, complemented with regulatory incentives to protect the climate.

Emerging Environmental Issues

R E MUNN AND PETER TIMMERMAN

University of Toronto, Toronto, Canada

*Emerging environmental issues are often thought of as shocking and surprising events, like the discovery of the ozone hole in the Antarctic or the oil spill of the Exxon Valdez. However, most of the issues that are expected to emerge in the 21st century are actually intensi cations or complications arising from already existing trends or problems. One of the important developments of the modern world has been the increasing attempt to predict or forecast the future, as a basis for planning: this has become even more of an imperative as the potential impacts of human decisions and activities stretch further out in time. H.G. Wells once remarked that the 20th century would be a race between education and catastrophe - the arrival of the 21st century has not invalidated the remark, merely moved the nish line. Futures studies, scenario building, forecasting and computer modelling of issues like climate change are all current attempts to foresee possible emerging environmental issues (*see *Futures Research, Volume 5; Scenarios, Volume 5).*

EMERGING ENVIRONMENTAL ISSUES: DEFINITION

It is important to be clear at the outset that an emerging issue is not necessarily an issue that no one has ever heard of, or that comes as a shocking surprise. In a questionnaire survey conducted by United Nations Environmental Programme (UNEP)/Scientific Committee on Problems of the Environment (SCOPE) by the authors and Anne Whyte in 1999, the following working definition of emerging issues was set out:

Emerging environmental issues are defined as those issues (both positive and negative) which are not generally recognized but which will have significant impact on human and/or ecosystem health in the 21st century. They can have impact globally or regionally and can include local issues that occur in many parts of the globe. Emerging environmental issues are associated with one or more of the following situations:

1. One or more of political, social, economic, financial, institutional or technological developments that are likely to cause changes in current trends of human activity which in turn lead to significant environmental changes.
2. New evidence or theory which suggests potentially large environmental changes, but which are currently either not widely accepted or are considered unproven. This would include new recognition of synergisms in human activity, which produce significant environmental change.
3. Lack of adequate policy, action or leadership on an existing issue, which will become more significant, or more urgent in the future.

Examples of past emerging environmental issues cited in that questionnaire included: the effects of pesticides on birds (1950s); the long range transportation of atmospheric air pollutants (1960s); the death of the Aral Sea through uncontrolled water abstraction (1970s); the elimination of guinea worm through water management (1980s); the collapse of North Atlantic fish stocks (1990s).

From this definition it can be seen that numerous kinds of environmental issues can come under the rubric of *emerging*. What this suggests is that a wider exploration of the context out of which these issues emerge, their characteristics, and their implications for environmental policy would be worthwhile. The rest of this article attempts to do this, first, by a discussion of what can be called the arrival of the future; second, by an analysis of some of the recent results of probes into possible emerging issues; and third by some conclusions concerning how to manage emerging issues.

THE ARRIVAL OF THE FUTURE

The 20th century has seen human activities grow to the point where they are capable of affecting and in uencing many of the physical systems of the planet. The increase in our physical capacities ought to be matched by an increase in our ability to understand and predict the consequences

of our decisions – in some sense, to learn how to manage ourselves. There has in fact, been a slow and painful growth of a new set of institutions, ethics, and techniques to begin to cope with our changing status. Central to this growth has been an increasing concern with the future.

At the beginning of the 18th century, the idea of the future barely existed, except as the predictable end of time in the last judgment. With the rise of the idea of progress and development, the future began to be more interesting; and ironically, this happened at the same time as the past began to stretch out further and further backwards. By the beginning of the 20th century, especially in the works of writers like Wells and Verne, predictions of the future became part of popular culture. More directly, through the rise of bureaucracies and planning as part of social management, nation states began to project and implement policies and structures for 10, 20, 30, and more years into the future, particularly since the 1950s. Modeling, and more recently, computer modeling, has made everyone familiar with projections and forecasts as a basis for decision-making.

Now, at the beginning of the 21st century, the future is a subject of widespread debate, controversy, and premature colonization (for example, as one of many, see Kennedy (1993)). Forecasting and expert projections lead decision-making in many arenas, in spite of the ability of events and short-term responses to crises to derail the best laid plans. The credibility of these forecasts, and the weight placed upon them, are central features of contemporary life. For example, decisions are made according to economic forecasts whose predictive ability is not apparently better than other kinds of forecasting. The great current debates over the ozone hole, climate change, and others are in part debates over whether we can have faith in computer models.

The future is casting a longer and longer shadow back over the present, and of course, *vice versa*. Our decisions today are ramifying further and further into the distant future. Similarly, our lack of decision making, given lag times, means that we are using the future as a storehouse for the buildup of risks that we are unable to respond to adequately now. The more that environmental issues deal with cumulative effects and long-term impacts, the more important socially and politically the notion of the future becomes, and the more troublesome.

Who are we to believe? What trust do we have in prediction? Is the present any guide to the future, or is it totally misleading in an era of rapid change and transformation? How are we to probe ahead?

As already mentioned, individual and collaborative quantitative and quantitative/qualitative future modeling for environmental issues has been developing steadily, at least since *Limits To Growth* (Meadows *et al.*, 1972). More qualitative future searching includes:

- popular or mass surveys of citizen opinions about the future or future concerns sometimes, leading to self-fulfilling prophesies;
- key actor interviews; in depth interviews with experts on possible futures in their area of expertise;
- modified Delphi techniques (A *Delphi technique* is an iterative process of expert consultation, gradually focussing on mutually acceptable outcomes, for example, the continuing Millennium Project of the United Nations University).
- scenario creation, for example, the various activities of the Global Business Network, including *The Futures of Women* (McCorduck and Ramsey, 1996).
- general efforts at envisaging futures through future studies (*see* Scenarios, Volume 5).

There is a burgeoning literature on this subject ranging from books to articles (e.g., Southern Africa Beyond the Millennium: Environmental Trends and Scenarios to 2015, *Environmental Planning Issues*). So extensive has this kind of literature become that there is a volume of 450 abstracts of essential books, reports, and articles just on environmental issues and sustainability (*Environmental Issues and Sustainable Futures*, ed Michael Marien, from the World Futures Society and IUCN, 1997).

A particularly interesting trend is the spread of creative approaches to considering the future from, for instance, science fiction, to a wider professional and occasionally public constituency. One version of this, under the general label of backcasting, involves the generation of different alternative futures for a given place or problem, and then using expert techniques to map how one would approach a preferred outcome. This is a looser form of long-range planning. Similarly, the availability of inexpensive computing power has spawned the rise of a number of expert consultative workshops where possible alternatives are assessed and winnowed in some detail. These approaches have their drawbacks, but their most significant advantage is that they can provide something of a feel for the complexities of future issues as they emerge.

CHARACTERISTICS AND TAXONOMIES OF EMERGING ISSUES

This whole discussion presupposes that issues emerge out of the background of a stable system, which then proceeds to manage them, and then new issues emerge, and so on. To think this way naturally promotes the identification of surprising issues that threaten the *status quo*, single issues that can be picked out of the surrounding noise, or issues whose emergence is not so much emergence into the world as their emergence on the agenda of powerful nations or media.

Reference to reports such as *GEO-2 Outlook* (for which the UNEP/SCOPE Questionnaire already cited was preparatory) suggests that for the expert international scientific community, the main emerging issues are rooted in long-term systemic change, the intensification and ramification of existing issues, and the spread of existing issues from one part of the world to another. Surprises, while not discounted, are not of great concern: rather, one might say it would be surprising if some of the stresses on major ecosystems did not result in some unexpected expressions or specifically unpredictable breakdowns.

More theoretically, Kalhok and Gomes (2000) in a working paper for the UNEP/SCOPE Project suggested the following taxonomy of emerging issues, based on historical examples:

Unforeseen Issues

New issues rarely appear without warning; however, their lack of frequency does not undermine their importance.

Chlorofluorocarbons (CFCs) Induced Ozone Depletion

This was virtually unheard of outside the scientific community at the time of Stockholm. Ozone depletion gained some attention by the public following a 1974 front page story in the *New York Times*, but it suddenly became an alarming issue worldwide for scientists, policy makers and the general public, following the discovery of a large ozone hole over Antarctica in 1985. CFCs, which were reported in 1973 to be chemically inert and harmless to the environment, were later determined to be the primary cause of ozone depletion.

Unlikely Events

Certain events may be known to be possible, but their severity, timing and location is unanticipated. With the expansion of human communities and industrial activity, such events have the potential for increased frequency and impact.

Oil Spills

For example, the Torrey Canyon (1967); the Amoco Cadiz (1978); the Exxon-Valdez (1989); Persian Gulf (1991).

Accidental Poisonings and Toxic Chemical Events

For example, methylmercury poisoning, Minimata, Japan (1959); PCB poisoning (Itai-Itai), Kyushu, Japan (1960s); dioxin leak, Seveso, Italy (1976); methyl isocyanate leakage, Bhopal, India (1984); chemical warehouse fire, Basel, Switzerland (1986).

Severe Smog and Air Pollution Events

For example, London (1952), Indonesia forest fires (1997).

Nuclear Accidents

Urals (1958); Three Mile Island (1979); Chernobyl (1986).

Biological Invasions

Zebra mussels, Great Lakes (1980s); Mesquite trees, intentional introduction with unexpected agricultural effects, Sudan (• 1950).

Emergence of New Perspectives

Existing issues may be brought into new light by new developments or findings or by media involvement.

Pollution

For example, *Silent Spring*, the 1962 publication about effects of pesticides and herbicides; discovery of toxic substances in the Love Canal, NY; discovery of contaminants in the Arctic, far from areas of use.

Acid Rain

The Swedish Case Study (1972) presented at Stockholm stimulated international concern and action.

Climate Change

The media sensationalized the unseasonably hot summer of 1988 as evidence of global warming which stimulated scientific research and increased public awareness.

Tropical Deforestation

Satellite images of tropical deforestation in the 1980s vividly demonstrated the extent of the loss of biodiversity.

Consequences of Resource Management

For example, ecological, social, economic and health impacts of the Aswan Dam and the shrinking of the Aral sea from water diversion for irrigation.

Changing Trends

Discontinuities in an expected course of events can be ecologically and economically devastating.

Climate Change

For example, increased occurrence of severe weather events and El Nino.

Resource Depletion

For example, Oil crisis (1970s); Atlantic cod fishery (1990s).

Shifts in Environmental Perception

The way in which scientists, policymakers and the general public view environmental issues changes, often with remarkable rapidity.

1. Earthrise photo from Apollo II (1969) instilled a perception of Earth as a fragile, unified ecosystem;
2. Focus of issues moved from local to national to international due to increased awareness of the transboundary nature, or spatial extent of many issues, e.g., marine and air pollution, habitat loss;
3. Focus on interdisciplinary and interconnectedness of issues: e.g., population, pollution and resource depletion, which were once viewed as independent issues are now also seen in the context of broader issues such as sustainable development, climate change and biodiversity loss, which themselves are interconnected.

A related taxonomy would refer to the internal structure of emerging issues.

Intensification

An existing issue becomes radically more difficult, with a new intensity of impacts.

Extensification

An existing issue spreads, affecting a new range or space.

Boundary Crossing

An existing issue moves over its existing boundary or category, complicating institutional responses.

New Emergent Properties

An existing issue is transformed by synergy or complex internal properties into a completely new problem.

Emergencies/Surprises

A new problem emerges out of nowhere.

Cascades

Higher level problems that set off new responses at lower levels.

Flip-flops

Systems under stress that flip from one state of the system to a quite different state very quickly.

New Problems from Old Solutions

A solution turns into the next big problem.

Other kinds of taxonomy are available, e.g., based on different kinds of risk assessment, or as functions of a scenario-based approach.

THE EMERGING ENVIRONMENT: OVERVIEW

The results of the SCOPE/UNEP Questionnaire (2000) and further consultations suggest that while there are specific priority emerging environmental issues, it is the overall systemic changes underway that are of greatest concern. These changes are very difficult to manage, because they are insidious, cumulative, and widespread, crossing boundaries and jurisdictions. They include ecosystem degradation, loss of biodiversity, major reductions in available freshwater, and so on.

These issues are emerging out of a situation wherein human beings are affecting and restructuring for their own purposes an increasing fraction of the physical and biological systems of the earth. In spite of a number of efforts, it is not known how many people the earth can support, and how the burden of a substantially increasing population with increasing expectations is to be sustained. Some commentators believe that technological innovation will ease this burden substantially in the coming decades; others believe that at least locally, many ecological systems have reached or are already near the breaking point.

As part of the growth of human influence over the Earth, we are also witnessing the spread of a social and economic development pattern originating in the West, which has been amazingly successful to date. The globalization of this pattern, which includes commitments to resource exploitation, increasing free trade, and the promotion of consumer demand as an engine of growth, is of profound environmental significance. For example, one of the basic assumptions of free trade is the cheapness of international transportation, which allows product components to be made in one part of the world and shipped to other parts for assembly. However, the cheapness of transportation is due in large part to the lack of internalizing of the environmental costs of fossil fuel emissions, a major cause of the expected global climate change.

It is also worth noting that (at least in developed countries) there is a trend away from the point source pollutants which figured so largely in the early days of environmental politics, that is, the belching smokestack and the pipe disgorging chemicals directly into a river. This kind of pollution has not disappeared by any means, but it is being replaced by non-point-source pollutants that come from a myriad of small users, or from the overall lifestyle choices of more affluent peoples.

Overall, we can see that the preferred solution to environmental problems is increasingly considered to be economic growth as a spur to improvement, and yet economic growth, while increasing efficiency of production, seems to promote excessive consumption. We are presumably in a transition period between the environmental problems associated with the former, towards environmental problems associated with the latter.

THE EMERGING ENVIRONMENT: THE ROLE OF SCIENCE

At the same time, thanks to the efforts of the scientific community in the past half century, we are beginning

to understand the complexity of global ecological cycles, and the need to promote biodiversity and the preservation of ecological integrity as basic goals for a sustainable society. The examples of dichlorodiphenyltrichloroethane (DDT) and the results of the atmospheric testing of nuclear weapons in the 1960s, which ironically led to great increases in our understanding of the pathways through which chemicals and ionizing radiation move, remind us that emerging issues are often surprises and challenges to our understanding of basic processes, and prod us towards seeking better methodologies of detection and assessment.

The last 50 years have seen enormous advances in ecosystem science and in the development of policies that may allow us to slow down or cope with environmental change in a sustainable manner. The progression of knowledge started with integration among and between the various physical and life sciences, and has led more recently to dialogue with the health and social sciences and engineering.

The role of science is of course central to the identification of many emerging issues. Most obviously, the increasing use of applied science in technology is a major force in human development; but the increasing ability of science to detect and monitor changes in the physical world, either through better understanding or through technical aids such as satellites, is also important. The past 50 years have seen revolutions in understanding how environmental systems function, how complex their interconnections are, and how difficult it often is to determine the impacts over extended distances of space and periods of time of environmental changes.

One of the most important single changes has been the ways in which science and the scientific community have emerged as significant factors in the identification and shaping of emerging issues on national and international political agendas. The international accords on the protection of the ozone layer, biodiversity, climate change, and others, were not only framed and sustained by scientific input; but in some cases (such as the Climate Change Convention) were initiated by members of the scientific community. Because of this shift in their role, the scientific community has begun to develop new mechanisms for consultation and reasoned sifting of evidence, of which the most prominent is probably the Intergovernmental Panel on Climate Change (IPCC).

While some may see these developments as the politicization of science, others suggest that we are entering an era of post-normal science (*see* Post-normal Science, Volume 5) where the management of complex systems under conditions of future uncertainty for human benefit requires a more open acknowledgment of the biases and agendas of scientists and scientific bodies. This is particularly important if one agrees that the definition of an emerging issue is in part dependent on past histories, present priorities and future hopes and fears.

The way the issues are defined obviously affects the way in which the solutions are defined, including the mandates for responding, the resources and institutions brought to bear, and so on. It is, for instance, possible to ask why certain emerging environmental issues have been defined and categorized in certain ways. It took until the 1990s for women's education to be widely acknowledged as a central component of environment and development. Climate change is rarely seen as partly the result of a need to subsidize cheap transportation by fossil fuel use as the basis for increased global trade.

For science and policy purposes, certain sets of distinctions may be useful. We can distinguish between:

- new issues that emerge because of scientific evidence or theory, and which are currently unknown or unproven;
- issues that are well known and proven, but which are not yet on the policy agenda. That is, they are taken seriously by scientists, but not by policy makers.

There may be many reasons for the existence of the second group, ranging from the inability of the scientific community to articulate clearly the characteristics or consequences of the issue. Inherent uncertainty in the projections (making it easy for policy people to adopt a wait-and-see attitude) and outright refusal of the political community to respond in spite of repeated warnings.

We can also distinguish between:

- issues that are connected to one or more point sources, and are therefore relatively easy to pinpoint and manage;
- issues that are rooted in overall social trends or derive from non-point sources, and are therefore much harder to eliminate.

An example of this distinction is between the debate over the elimination of CFCs from the atmosphere versus the much more intractable issue of decreasing fossil fuel use to slow the onset of climate warming.

A third distinction is between:

- issues that are global in scope, but with regional and local consequences;
- issues that are emerging primarily at the regional and local level.

This is not a hard and fast distinction. Purely regional issues can be driven by global trends. Nevertheless, there are issues whose expression or characteristics are firmly regionally based.

Other scientific characteristics of certain emerging issues can be described. They tend to be complex, with multiple

linkages between causes and effects. They are often synergistic, with widespread consequences, and with multiple causes. These issues are often controversial, and characterized by uncertainty. This is sometimes because the scientific uncertainty is too great, due to lack of evidence, the available statistical data are unreliable, or the response of complex systems is unpredictable. On the other hand, scientific uncertainty can be used as an excuse for delaying appropriate political responses. This in turn may be the reason for an issue to progress from being a twinkle in a scientist's eye to being a fully edged problem that is still increasing because it is not yet being addressed by policy makers.

For some issues, local and regional dynamics are currently better understood than global ones; in others, the local scale is less well understood, while the overall nature of the problem is fairly clear. For example, the introduction of new environmental technologies to developing countries is widely seen as a preferred solution to many problems; but it is already clear that the process of introduction can be disruptive and oppressive. The notion that developing countries might have solutions to export to developed countries for their environmental problems is almost never considered.

As in the case of environmental technology, a widespread problem with emerging issues in general is that the socio-economic variables involved in predicting the sequence from issue identification through to impacts are just too complex. Human responses are difficult to predict and/or are understudied in relation to the problem, or often just assumed. This inability to demonstrate consequences weakens the case for immediate action, and policy makers then tend to adopt a wait-and-see attitude.

Many emerging issues are the expression of unsustainable and unintegrated management, where among other things, the relationships among and between issues are being ignored. Further complicating the situation is the fact that the social and political will to respond to the issue is often not there, due to other priorities, short-term economic goals, and a lack of champions or constituencies for the issue, and/or a lack of readily available knowledge.

More and more, though much work is rooted in studies carried out within a single discipline (e.g., meteorology), the dimensions of each issue (e.g., climate change) are increasingly expanding into more and more fields (ecology, chemistry, engineering, the health sciences, economics, sociology, policy analysis, etc.). As an example, the provision of clean drinking water has traditionally been a problem to be solved by hydrologists and engineers. However, when drinking water quality began to deteriorate in New York City in the early 1990s, an environmental assessment of policy options included an economic analysis. In this case, the economically preferred alternative was found to be also the ecologically preferred one. The cost of a new filtration plant would have amounted to between six and eight billion dollars, plus operating costs of 300 million dollars annually. On the other hand, the cost of protecting the watershed (in the Catskill mountains) by eliminating the sources of pollution (sewage, fertilizers and pesticides) in that area was only about 1–1.5 billion dollars (Chichilnisky and Heal, 1998).

These considerations make the identification and management of emerging issues incredibly complex, and as stated often already, subject to interpretation and myriad obstacles, conceptual as well as physical or economic.

THE MANAGEMENT OF EMERGING ISSUES

While there has been a plethora of futures studies, Delphi methods, and scenario constructions in the past few years, almost none of these approaches have dealt with how best to manage the issues that emerge from these studies. They have contented themselves with identifying the issues, often in a scatter gun approach. A more useful approach would relate the characteristics of emerging issues to the characteristics of the management systems that are required to cope with them.

For instance, in Western democratic systems, the social and political systems, while increasingly dependent on forms of forecasting, continue to be focussed on the very near-term demands of the electoral cycle. There are only marginal resources for coping with future issues: the early warning systems in place (the antennae) are assumed to be part of the mandate of the academic and scientific communities scanning the horizon; and the technological and economic communities seeking out new opportunities. However, even these marginal resources can be significant.

Nevertheless, a central problem for the policy makers is that emerging issues are on contested terrain. Because of the uncertainties involved, the hopes and fears they carry with them projected into the future, and the complex relations they have with existing issues, emerging issues can be very controversial, and therefore hard for policy makers to respond to adequately. They are often ash points, institution redefiners, triggers for a cascade of further issues. They are often seen as best avoided: with all the current problems, why take on new ones?

On the other hand, the appropriate management of emerging issues can:

- help shape internal priorities, and build on immediate-term successes;
- provide for some resilience and safety nets in the face of inevitable surprises;

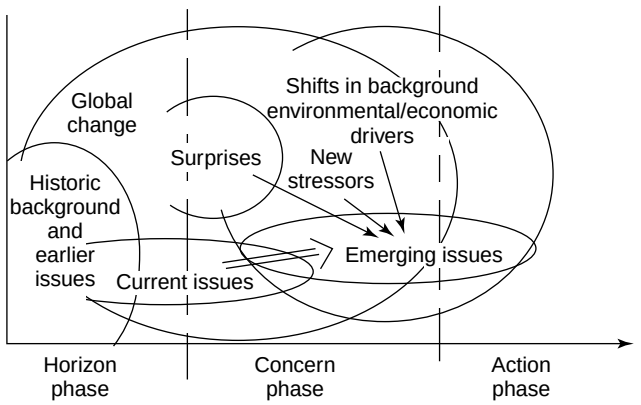

Figure 1 Phases of emerging issues

- open a useful window for wider public input into the policy-making process by connecting emerging issues to larger concerns and hopes.

One useful approach, differing from the earlier taxonomy (by characteristics of emerging issues), is to consider how issues emerge into the public domain (or the scientific domain), always keeping in mind the caveats mentioned earlier about reinforcing the *status quo*. In this approach, the continuity of emerging issues with already existing issues is emphasized: they have a life cycle, which moves them from below the horizon, into the domain of concern, when forces and resources begin to be mobilized to respond, and then into action. This can be followed by reaction, recurrence, or transformation into the next set of emerging issues.

This is sketched out in Figure 1. For policy makers, what is important are the phase shifts of concern, and the triggers that alter the response. There may be different management responses appropriate for each phase.

Horizon Phase/Horizon Issues

Horizon issues are issues that have simply been identified, but have not yet crystallized to the point where their implications and potential impacts can be determined. They may have been identified: their characteristics are still unclear.

In dealing with horizon issues, management needs to take into account:

1. there is a great deal of noise and early debate surrounding horizon issues;
2. these issues are still very uid and in many cases not subject to clear definition;
3. there is a need to gather information from a wide range of sources, and not to lock in on the issue too early;
4. the role of science in this period is to ensure that basic rules of scientific evidence and experiment are being followed in the literature, and if research is being carried on internally. Because of the embryonic status of the issue, in-house science is likely to be most in uential in assessing the credibility of the issue, suggesting appropriate analogies from other related or hitherto unrelated cases, and so on.

Concern Phase/Issues of Concern

In this phase, levels of concern depend upon different criteria, for instance:

1. scientific consensus forming;
2. substantial public concern and input;
3. potential for serious risk;
4. appearing in multiple jurisdictions;
5. availability of appropriate responses;
6. new stressors, real or imaginary, identified;
7. predicted impacts are beginning to appear, etc.

In most bureaucratic systems, this phase is characterized by the initial formulation of policy, creation of task forces, mobilization of research towards policy conclusions, etc.; still falling short of accountable activity.

Action Phase

The Action phase takes place when the issue has entered the full formal policy formulation stage and has become a current issue subject to the usual procedures.

For policy purposes, this kind of sequence of management phases is normal practice, but it is hardly ever articulated very well. For instance, issues that are still inchoate and uncertain don't tend to be immediately enshrined in legislation. The response is rather to wait and see; to scan for the best information; to determine if this issue is worth spending time and resources on; to find out what the leading persons in the field think, and so on. As the article on Social Learning discusses (*see* Social Learning in the Management of Global Atmospheric Risks, Volume 5), study of the ways society learns about new environmental issues is still in its infancy. The movement from the concern phase to the action phase is subject to all kinds of forces, including champions of the issue, strong nongovernmental organizations (NGOs), appropriate available information, media coverage, etc. Only a small part of this whole emerging response to emerging issues can be captured simply by looking at official government action.

Sometimes this system works reasonably well: sometimes, the strategy fails. Wolf is cried, and the wolf in fact appears at the door. The discounted radical scientist turns out to be right; society refuses to acknowledge the problem for social, economic, and even religious reasons; resources are misapplied; monitoring systems are inadequate; obstacles are overcome too late.

EARLY WARNING INDICATORS

An essential element of any strategy for managing emerging issues is to design monitoring systems that can provide early warning of impending change. There are fundamental difficulties in designing such systems, including:

- Current environmental and socio-economic monitoring systems were originally designed for other purposes, often yesterday's emerging issues and not tomorrow's. They underpin and reinforce current institutions and approaches to dealing with issues. These monitoring systems may generate new kinds of warnings only if there is bleeding or indirect in uence from some quite different stress that affects an existing monitored stress.
- Changing existing monitoring systems to handle new issues may affect the continuity of valuable time series, and should be done with care. The ability to interpret or reinterpret (to mine) existing data sets is often a critical alternative.
- Monitoring systems often are not designed within a larger design framework, so that (for example) socio-economic variables and environmental variables operate on quite different temporal and spatial scales. Linking socio economic with environmental variables is fraught with a myriad of technical difficulties.
- Multiple stresses affect ecological systems, and it is often difficult to connect cause and effect. For example, if forest dieback occurs, is it due to air pollution, drought, bark beetles, nitrogen overfertilization, a particularly sever winter or hot summer, or all of the above?
- Similarly, there may be long lag times between stress and response, such as happens in poorly buffered lakes that are subjected to long regimes of acid rain, and only when the buffering capacity is used up, will there be precipitous changes in lake ecosystems. Recent work on the possibility of non-linear ip- ops of ecosystems from one state to another highlight another aspect of potential sudden change in strongly stressed environments that may not be caught beforehand by conventional monitoring.

Historical experience with emerging environmental issues shows that it was not until the fundamental processes involved were reasonably well understood that future trends and scenarios could be predicted with reasonable chances of being correct. In the meantime, early warning systems must be adaptive: more in the nature of probes than a new generation of monitoring systems for today's problems that will become obsolete or rigid (*see* Monitoring in Support of Policy: an Adaptive Ecosystem Approach, Volume 4).

This supports the idea of using Biosphere Reserves and other model ecosystems as early warning systems in their own right, indicating through changes in their resilience and vulnerability the interactive effects of multiple stresses and larger global shifts in environmental dynamics.

Along the same lines, given the difficulties involved, a basic management strategy for emerging environmental issues must involve the precautionary principle (providing for enough working space for margins of error in natural and human processes) so that no emerging issue becomes large enough to endanger the capacity of the entire system to respond creatively to unexpected change (*see* Precautionary Principle, Volume 4).

Adaptation Strategies

IAN BURTON

Meteorological Service of Canada, Downsview, Canada

The concept of adaptation has come into prominence recently as a result of its importance in human response to climate change. In this connection, adaptation refers to " the adjustments in ecological, social or economic systems in response to actual or expected climatic stimuli, their effects or impacts. It refers to changes in processes, practices, and structures to moderate potential damages or to bene t from opportunities associated with climate change."

The concept of adaptation has a long intellectual history and this is brie y sketched below as a background to its present use in global climate and environmental change. A summary of some ideas about the anatomy of adaptation is provided as well as some ideas about the emergence of a science of adaptation.

Three kinds or levels of adaptation are described and their potential role in sustainable development is discussed.

CONTEXT, DEFINITIONS, HISTORY

The word *adaptation* has been propelled into prominence in the context of global environmental change as a result of its use in the United Nations Framework Convention on Climate Change (UNFCCC), signed at the Earth Summit in 1992. The convention makes a distinction between mitigation and adaptation as responses to climate change. *Mitigation* refers to those actions that might be taken or promoted to prevent or slow climate change, by controlling the level of concentrations of greenhouse gases in the atmosphere. This includes reduction of emissions, such as the reduction of carbon dioxide (CO_2) emissions by increasing energy efficiency, fuel switching, and the use of renewable sources of energy. It also includes various forms of carbon sequestration through which the stock of carbon in forests, and soils, might be increased.

By contrast adaptation refers to the:

> adjustments that are possible in practices, processes, or structures of systems to projected or actual changes of climate. Adaptation can be spontaneous or planned, and can be carried out in response or in anticipation of change in climate conditions.
>
> (Intergovernmental Panel on Climate Change (IPCC), 1996)

Adaptation can be used to moderate potential damages or to benefit from opportunities associated with climate change.

The UNFCCC uses the concept of adaptation to apply to both natural and socio-economic systems. There is, in fact, a long history of the term *adaptation* being used in this way, going back at least to Charles Darwin (1809–1882), and the philosopher and sociologist Herbert Spencer (1820–1903). For Darwin, adaptation was the result of the process of natural selection acting upon natural variability of biological forms and attributes. For Spencer, adaptation is a feature of the fitness of human beings and their prospects for survival. The term *adaptation* in the social sciences thus came, in the 19th century, to be associated with extreme *laissez-faire* policies, and served as a rationalization for racist and other discriminatory beliefs. Although such beliefs are now widely discredited, the old debates about the relative importance of genetic (nature) versus environmental (nurture) in uences have resurfaced in the current ideas of sociobiology (Wilson, 1975, the most authoritative summary of the socio-biological approach to human adaptation). See also Wilson (1998), and its extensions into evolutionary psychology and other social sciences (Wright, 1994), an excellent summary for the general reader of the application of sociobiological approaches into the social sciences and psychology. This intellectual history complicates the use of the word *adaptation* in the current global environmental change context, and it is important therefore to be clear about what sort of adaptation is meant, and what definition is being employed (Dubos, 1965, a classical synthesis of adaptation in human biology and physiology with special reference to human health. See also Dobzhansky, 1962).

The *Oxford English Dictionary* defines adapt' as meaning to fit, to make suitable , or to alter so as to make fit for a new use . Two examples are given of adaptation.

The structure of the outer ear is adapted to collect and concentrate the vibrations , and a comedy adapted from the French . The distinction is important because the processes of biological and social adaptation are so different. It would be less confusing if a specific word were to be employed for each. In fact, the geographer Gilbert White consciously chose to use the phrase *human adjustment* rather than adaptation, when studying the way in which human societies respond to ood hazard (White, 1945, a classic early study that pioneered the approach of human adaptation). The Intergovernmental Panel on Climate Change (IPCC) definition cited above does indeed use adjustment as a synonym for adaptation when referring to socio-economic adaptation.

In addition to the mobility issue, some ecologists are concerned about nitrogen overfertilization and about the harmful effects of global change on species competition, which in both cases might result in biodiversity losses. In the nitrogen overload situation, some species would ourish while others would be seriously stressed, leading to a changed composition of ecosystems (*see* Nitrogen Cycle, Volume 2). In the latter case, some species will adapt more rapidly to global change (particularly to increasing carbon dioxide concentrations and to climate warming) so that species competition will favour some species over others (*see* Plant Competition in an Elevated CO_2 World, Volume 2).

In the early phase of the science and policy debates about climate change (say 1975–1992), interest focused on the adaptation of species and ecosystems to climate change or biological adaptation. Anthropogenic climate change constitutes a threat to natural ecosystems, and there is a risk of mass extinctions (reductions of biodiversity) since the rate of change is projected to be much more rapid than the time required for biological adaptation. Of course plants and animals can, given time enough, migrate (not strictly an adaptation in biological terms) and thus move with the climate. For example, the climatic zone now occupied by the boreal forest that extends in a wide belt across North America and Eurasia is expected to move some 200–300 km farther north. This has led to proposals to create migration corridors, or belts of protected land extending on a south–north axis in order to facilitate migration. This may, in theory, help the more mobile species, such as animals, to survive, but to the extent that they are an integral part of an entire ecosystem and require its support, this form of adaptation depends upon the least mobile elements in the system. More extreme cases of the threat of extinction can occur in small island ecosystems and in mountain regions where there is no possibility of adaptation by migration as the climate changes.

More recently (since 1992), questions of socio-economic adaptation have been added to the concerns about non-human adaptation, and this interest continues to grow as the social and economic implications of climate change become more evident. The scientific consensus is that anthropogenic climate change is now happening, and at the same time it is becoming clear that the stabilization of greenhouse gas concentrations in the atmosphere cannot be easily achieved and will take time. The question is no longer, Is human activity changing the climate?' but What are the risks of the impacts of climate change and how can they best be managed?' (Dotto, 1999, an excellent account for the general reader of the risks of climate change, focusing more on mitigation than adaptation).

WHY ADAPT?

In the context of the climate change science-policy negotiations, there are two main reasons for the assessment of adaptation. First, it is important to know more about the means (including the costs) of reducing the impacts of climate change by adaptation, in order to compare this with the means and costs of mitigation. It is often assumed that there is a trade-off between mitigation and adaptation; that is to say that the more successful the mitigation strategy (as proposed in the Kyoto Protocol, for example), the less the need will be for adaptation, and *vice versa*. While this idea has some theoretical appeal, in practice it will be difficult to get enough of either. The stabilization of greenhouse gas concentrations, and agreement on how this is to be achieved, is an enormously complex task and will require considerable time. Meanwhile the rapid rise in losses from extreme atmospheric events (hazards such as oods, tropical storms and droughts) that has occurred over the past three decades (1970–2000) shows that, in some respects, human societies are often not well adapted to current climate variability. Also, in order for a trade-off to be politically acceptable, there has to be some way whereby the winners (those who benefit from climate change or are least damaged) to compensate the losers. At the international level, no such regime or authority exists and solutions have to be found through negotiations, which are protracted, and in a number of respects still inconclusive.

The second reason for the focus on adaptation has to do with the development of adaptation strategies. It is agreed that adaptation to climate change has the potential to substantially reduce the adverse impacts of climate change, and to enhance the beneficial effects. The new attention to adaptation therefore raises many questions. These include the extent to which socio-economic systems may be expected to adapt autonomously (i.e., by individual, community, or corporate decision-making) and the extent to which planned governmental intervention is required. To the extent that governmental action is required, how are specific adaptations to be identified, assessed and prioritized? And how are adaptations to be paid for? This is also a crucial question at the international level, because the developed country

parties to the UNFCCC have agreed in principle to assist the developing country parties (especially the most vulnerable) in meeting the costs of adaptation (*see* Common but Differentiated Responsibility Principle (Stockholm/Rio), Volume 4).

Despite the fact that the climate (as measured by changes in annual average temperature) is projected to increase more towards the poles (high latitudes) and less in tropical regions (low latitudes), the present judgment is that the people and places most vulnerable to climate change are to be found in the poorer low latitude countries. This is partly because some tropical ecosystems and agricultural systems are often already close to the limits of heat tolerance, but perhaps more importantly because such countries are relatively lacking in adaptive capacity. The capacity to adapt to climate change is a function of wealth (financial resources); availability and access to technology; the level of information and skills or trained human resources; the nature of the existing social infrastructure; the strength or degree of development of social institutions, as well as the distribution of wealth in a society or equity. Thus, the rationale for assistance to the most vulnerable developing countries rests upon the fact that they have least adaptive capacity and that they have historically contributed proportionately less emissions of greenhouse gases that have created the problem in the first place.

In the international political climate of the late 20th and early 21st centuries, a Spencerian *laissez-faire* approach is not acceptable. Therefore, the developed-country parties to the UNFCCC have recognized their own responsibility to provide assistance in meeting the costs of adaptation. In order to facilitate this financial support, the Conference of the Parties (COP) to the Framework Convention have recognized the Global Environment Facility as the financial mechanism for the convention. Parties to the convention are required to make periodic national communications in which they report progress in both mitigation and adaptation. To facilitate these national communications, assistance is available to developing country or non-Annex 1 Parties. For the purposes of addressing adaptation, three stages have been established under the COP. These are in the short term:

- *Stage I*: planning, which includes studies of possible impacts of climate change, to identify particularly vulnerable countries or regions and policy options for adaptation and appropriate capacity-building.

In the medium and long term, the following stages are envisaged for the particularly vulnerable countries or regions identified in Stage I.

- *Stage II*: measures, including further capacity-building, which may be taken to prepare for adaptation, as envisaged by Article 4.1(e) (of the Framework convention).
- *Stage III*: measures to facilitate adequate adaptation, including insurance, and other adaptive measures as envisaged by Article 4.1(b) and 4.4.

At the time of writing (July, 2000) some 25 developing countries have completed their first national communications, and the COP has agreed in principle to move from Stage I to Stage II adaptation.

In some countries and regions, a case can be made for adaptation measures to be taken immediately on the basis of the short-term benefits that would accrue. Six reasons are commonly cited:

- Climate change is already occurring and further changes cannot be prevented, therefore there is no justification for a wait-and-see policy.
- Anticipatory and precautionary adaptation is often more efficient and less costly than forced, last minute, emergency adaptation, or relief, rehabilitation and reconstruction after an extreme climatic event.
- Climate may be more abrupt and more pronounced than current models and estimates suggest. Low probability and unexpected events are possible.
- Immediate benefits can be obtained from better adaptation to current climate variability and extreme atmospheric events, which will also help reduce vulnerability to longer run climate change; the so-called *win-win responses*.
- Immediate benefits can also be obtained by removing or halting current maladaptive policies and practices that may tend to increase present and future vulnerability.
- Climate change brings new opportunities as well as threats. Future benefits can be obtained by adapting now in an anticipatory way.

Recognition of the validity of these arguments has led to an elaboration of the concept of adaptation in the context of climate change. A number of experts have developed ideas about the structure of adaptation, referred to as the anatomy of adaptation. Smit *et al.* (2000) provide a structure of the concept of adaptation to climate change. The rest of that special issue of *Climate Change* contains a further 12 papers on various aspects of societal adaptation to climate change and variability to develop what they refer to as the science of adaptation (Smit *et al.*, 1999). Simultaneously with these developments, scientists in many countries are beginning to carry out research on adaptation with a view to strengthening understanding and to creating adaptation strategies or programs (Bwango *et al.*, 2000).

ADAPTATION TO WHAT?

The first question to be addressed about adaptation is the nature of the stimulus or change that prompts the need to adapt. In the case of climate change, the stimulus is

commonly described as the output of general circulation models (GCMs). Initially, these were equilibrium models based upon a doubling of the CO_2 equivalent concentrations in the atmosphere. More recently transient models have been developed which show changes in climate (mean temperature and other variables) over time, beginning with the present. The output of GCMs is used to study impacts upon human and natural systems, and it is these impacts that are the direct source of stimulation to which an adaptive response may occur.

There are many sources of uncertainty in this process. For example, the level of future concentrations of greenhouse gases in the atmosphere will depend upon the amount of emissions from human activities, and this in turn depends upon the rate of population growth, the mix of types of energy used, the rate of economic growth, and the environmental protection or sustainable development policies adopted and put into practice. There are also uncertainties in the atmospheric models themselves, such as the rate of absorption of CO_2 into the oceans and the land biomass. The scale of the GCMs is such that the outputs are generalized over large regions, and local variations in future climate are not well captured. In addition, the outputs have been largely in terms of mean values and have less information on variability, especially climate extremes. However, it is climate variability and extreme events that have larger significance for impacts than changes in mean values.

The task of identifying and selecting adaptation strategies is greatly complicated by the uncertainties of climate change and climate change impacts. To many policy makers, it seems pointless to worry about what adaptation strategies to adopt in response to the impact, decades into the future, of an uncertain climate upon unknown economic and social conditions.

On the other hand, much can be learned from present adaptation policies and practices. Much attention has therefore been focused on present-day adaptation to climate, as well as trying to learn from past experience with climate variability. Lamb (1982) is a classical reference work on the in uence of climate on society through historical times; adaptation is addressed by implication throughout the text. Adaptation strategies to future climate change can best be seen as a process of incremental improvement in present adaptation.

WHO AND WHAT ADAPTS?

All socio-economic systems and natural systems adapt to climate change, including its variability. It is generally agreed that both human and natural systems are now well adapted to present climatic conditions. Human beings have successfully occupied most of the climatic regions of the planet, and thrive in them to varying degrees. There is virtually no climate projected for the coming decades and centuries that is not now found somewhere on earth and where human society is not successfully adapted. Except on the very long time scales, climate varies more over space than over time.

Individual species adapt over long periods of time by genetic variation and natural selection. Migration of species is also a form of adaptation. Species of plants and animals coexist in complex patterns of ecosystems, but whole ecosystems cannot migrate intact because some species migrate much more rapidly than others. It seems likely, therefore, that the projected climate changes will occur too rapidly for many species to adapt naturally, and that unless human intervention and management can be successfully employed, many species may be lost. Climate change poses a substantial risk to biodiversity. Human beings also adapt to climate on a physiological level, and can become acclimatized to different conditions.

In socio-economic systems, much adaptation takes place at the individual and community levels. Farmers choose crops and the timing and manner of cultivation according to their understanding of climate and climate risks. Houses, roads, bridges, ports, drainage systems, transmission towers and the whole array of human-built infrastructure are designed to withstand the climate extremes of a specific location. Many design features result from centuries of experience and trial and error. For example, local farmers in the Andes have known for centuries the optimum height above sea level to grow maize: at too high an elevation, there is danger of frost while at too low a height, there is danger of drought. How will these people adapt to climate warming? In modern societies, design standards and criteria are carefully worked out by professional experts backed up and implemented by government-approved regulations. So in addition to adaptation at the individual and community level, governments play an important role in facilitating and sometimes requiring adaptation.

Private sector corporations and businesses also adapt to climate, both in the design of their facilities and operations and in responding to variations in market demand prompted by climate variability. In short, climate is such a pervasive factor that everything and everyone adapts. For the development of adaptive strategies to future climate change, there already exists a strong basis of knowledge and experience in adapting to present and past climates.

There are signs however, of less than adequate adaptation in some circumstances. The loss of life and property from extreme climatic events (oods, tropical storms, droughts and the like) has risen rapidly over the past three decades. This increasing vulnerability is not a result of climate change, but arises from population and economic growth and the increasing occupation of hazardous and marginal lands. Present-day climate risks are not adequately taken into consideration in development activities. Burton and Van Aalst (1999), in a World Bank report, describe the

need to take adaptation to climate change and variability into account in Bank lending and other activities; see also Burton *et al.* (1993), which deals mainly with human adjustments to natural hazards, and discusses the value of adjustments in relationship to climate change. For this reason, some specialists refer to *maladaptation* to indicate those practices that result in increased vulnerability to present-day climate, and by inference to projected future climate change. In this connection, Burton (1996) discusses the concept of adaptive capacity.

Decisions and policies directed at adaptation to climate change are not taken in isolation from many other changing circumstances. Thus a farmer is concerned not only with present and future climate but also with changes in market prices for farm products, changing government policies on price supports and crop insurance, new technologies, and many other individual and local factors. Similarly with other sectors in uenced by climate and projected climate change, including forestry and water resources, coastal zones, public health and so forth, decisions about response to climate are made in the context of other rapidly changing circumstances. In this mix of factors, climate is currently often not an important or primary consideration. At all stages of adaptation, therefore, consideration has to be given to the context in which adaptation occurs. At its broadest level this has been interpreted to mean adaptation in the context of sustainable development (Intergovernmental Panel on Climate Change, Third Assessment Report, 2001; see especially Chapter 18, Adaptation to Climate Change in the Context of Sustainable Development and Equity').

CLIMATE CHANGE AND SUSTAINABLE DEVELOPMENT

A broad conceptual approach to climate and sustainable development is shown in Figure 1 (Burton, 1997). The climate cycle is represented by eight ovals, and points of human intervention are represented by seven rectangles. Human impacts on the environment (I), are defined in terms of population (P), level of consumption (or af uence, A) and technology (T) in the well known I • PAT formula (*see* DPSIR (Driving Forces Pressures State Impacts Responses), Volume 4). These factors give rise to greenhouse gas emissions

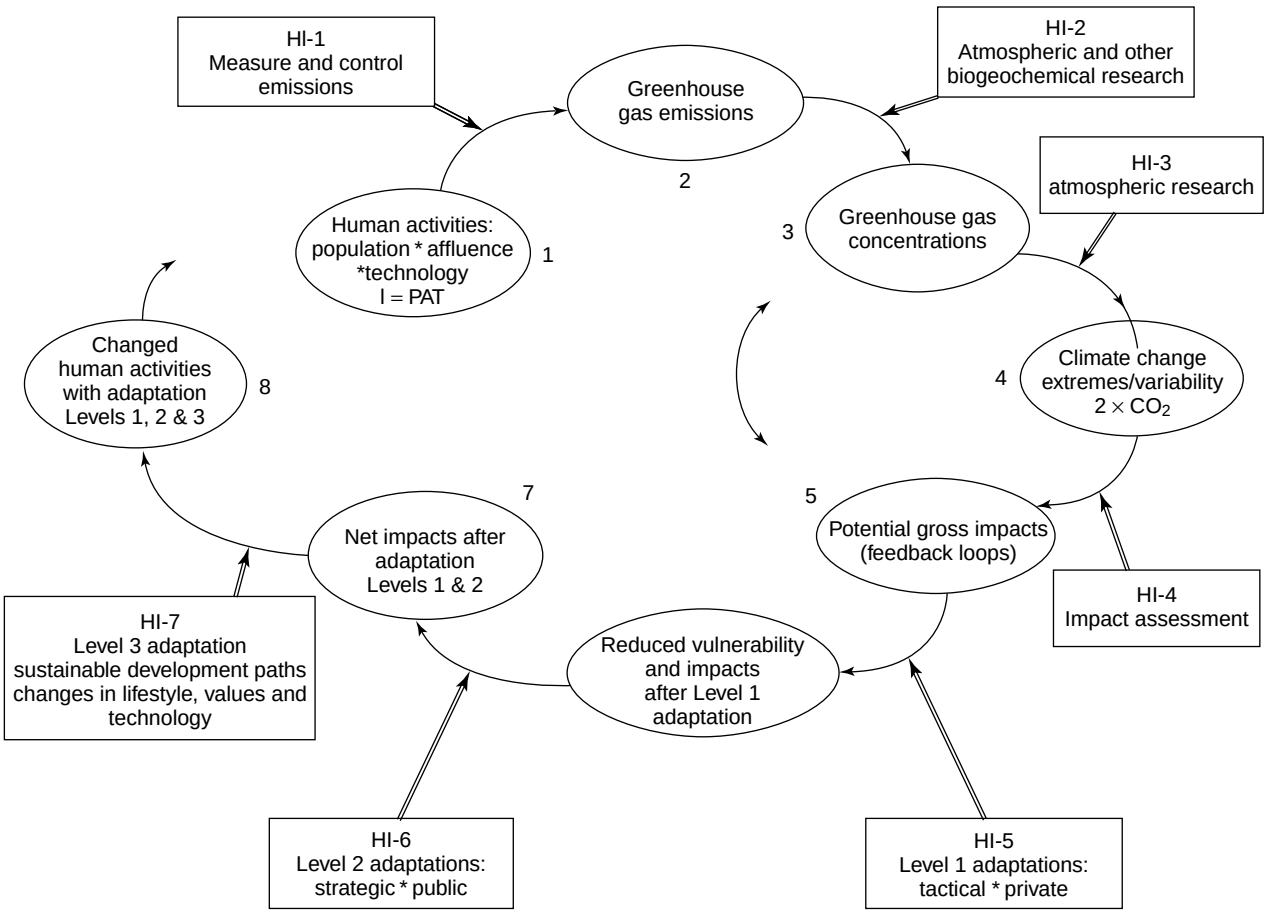

Figure 1 The climate cycle, adaptation and sustainable development; HI, human intervention (reproduced with permission from Burton, 1996)

(oval 2), and in turn to greenhouse gas concentrations (oval 3), and then climate change including variability and extremes (oval 4). Interventions in the cycle include the measurement and control of emissions (box 1), and atmospheric, biochemical, and other research (boxes 2 and 3). Climate changes give rise to impacts (oval 5) and these impacts can have feedback effects, such as the release of methane (a greenhouse gas) in Arctic regions due to permafrost melting. Research on impacts (box 4) is carried out to define the gross or primary consequences of climate change. Three types or levels of adaptation can reduce vulnerability. The first (box 5) is spontaneous or tactical adaptation carried out largely by individuals, communities and the private sector. The second type of adaptation (box 6) refers to those measures and policies that involve specific governmental action, often of a more strategic kind. The collection of such activities can be described as adaptation strategies. Adaptation strategies can fail, or produce contrary or counter-intuitive results if they do not correctly take into account the spontaneous adaptations included in box 5.

Adaptation strategies also contribute to the third type of adaptation, which includes many potential actions and policies directed towards sustainable development such as changes in technology, lifestyle choices, and human values and priorities (box 7). Thus the accumulation of adaptation measures at these three levels changes the basic I • PAT formula giving rise to climate change in the first place. Adaptation to climate change is therefore a potentially important element in the movement towards the sustainability transition (National Academy of Sciences, 2000, an assessment of the present global environmental circumstances of humanity and the steps needed to achieve the sustainability transition).

Sustainable Energy Policies

THOMAS B JOHANSSON

Bureau for Development Policy, United Nations Development Programme, New York, NY, USA

Sustainable development, a goal that the United Nations and its Member States have committed themselves to, implies meeting the needs of people alive today without compromising the ability of future generations to meet their needs. Since energy use is linked to poverty, opportunities for women, security, demographic trends, environmental degradation and economic growth, it can be a lever for improvements in all of these aspects of sustainable development. Access to affordable commercial energy dramatically increases the choices and opportunities available to individuals, which is one way of de ning human development. Indeed, thanks to the ready availability of affordable energy services, many individuals today enjoy a degree of comfort, mobility and capability unprecedented in human history. Energy services refer to the end bene ts of the energy system, such as illumination, mobility and comfortable temperatures and are also required for virtually all, commercial and industrial activities, from agriculture and industry to telecommunications. Meanwhile, two billion people (a third of humanity) nd their time, health and choices diminished by a reliance on traditional fuels for cooking and heating and no access to electricity. Meeting the world's growing demands for energy in conventional ways, however, would be a human and environmental disaster, leading to greater inequity, jeopardizing economic growth and threatening human and ecosystem health. But there are options for using energy in ways that simultaneously address the growing demand for energy services and the necessity of reducing the negative externalities of energy production and use. These options include: improving energy ef ciencies, increasing the use of renewable resources and accelerating the development and deployment of advanced technologies that allow conventional forms of energy to be used in environmentally benign ways.

The magnitude of the challenge is enormous. Energy policy must consider not only the two billion currently without access to commercial fuels and electricity, but also the new demands that will result from population growth; by 2050, another three billion people are likely to need commercial energy. Energy suppliers will need to decarbonize the energy systems radically to stabilize carbon dioxide (CO_2) concentrations in the atmosphere. Governments will need to work with the private sector to reduce local and regional pollution linked to energy use. Fortunately, as demonstrated by various energy scenarios in the literature, the physical and technical resources are available (or in the development stage) to achieve this. Whether they will be effectively used to meet the urgent challenges confronting us depends largely on the policy initiatives that will be taken over the next few decades. Power plants, re neries and other energy investments have long lifetimes. So if we do not make good decisions now, in another 20 years we will be locked in to those choices, and certain opportunities may be lost. Energy scenarios also show that the changes needed to achieve sustainable development are signi cant, and are unlikely to occur in the current policy environment.

The objectives of energy policies for sustainable development are to supply adequate and affordable energy services to support widespread economic growth and social development, and to do so in ways that curb environmental degradation and health-damaging pollutants. Energy used in ways that support human development in all its social, economic and environmental dimensions is what is meant here by *sustainable energy*. Key strategies to achieve this include:

- widen access to affordable and reliable energy supplies;
- make markets work more effectively to support sustainability, through accurate price signals and regulatory approaches;
- mobilize investments in sustainable energy;
- increase energy efficiency in all energy conversions, especially at the point of end use, where considerable cost-effective potential for improvement still exists;

- encourage the use of renewable energy resources (modern forms of biomass, solar photovoltaics, and wind and geothermal energy seem particularly promising);
- accelerate progress of energy technologies (energy efficiency, renewables and conventional fuels) along the energy innovation chain, from research and development (R&D) through deployment and diffusion;
- support capacity building and technological innovation and leadership in the developing countries, where most of the growth in energy demand is likely to occur.

While these strategies can be applied across the board, the specific policy instruments for implementing them may vary with the vastly different situations found among and within different countries. Different social circumstances, economic conditions, resource endowments and cultural factors need to be considered in designing appropriate energy policies.

The approaches discussed here mainly require action at the national level. However, with the growing integration of world markets, harmonization of policies at the international level (for example, energy efficiency standards or environmental taxes) could increase their effectiveness. Globalization, and the growing power of multinational corporations, is one example of the larger trends that policy makers need to consider in designing energy policies. Others include:

- restructuring and liberalization of energy markets, which would bring more competition and private activity to the energy sector, and would change government's role in this arena;
- the emerging information revolution, with its potentially enormous but difficult-to-predict structural consequences;
- greater public participation in decision-making, which is likely to keep equity issues high on the political agenda.

During the last three decades, several global studies have employed scenarios to try to understand the role that energy systems will have in determining our future. Whereas some of the earlier scenarios were prompted by fears of oil shortages and price volatility, concerns have broadened. Now it is clear that ample fossil fuel resources, at reasonable prices, will be available to meet the world's growing demand for energy services, through this century at least. Thus, there will not be a resource-driven change in the world's energy systems for a long time to come.

Two other critical energy-linked challenges are proving to be more problematic: addressing vast inequities in opportunities for different groups of people (especially as these relate to poverty, health and women's lives) and maintaining ecological balance. Both must be addressed in order to achieve sustainable development.

Scenarios (*see* Scenarios, Volume 5), which are dynamic models that analyze the interactions of systems under certain sets of assumptions, suggest that it is possible to simultaneously expand energy services (and redress energy inequities) while limiting environmental degradation associated with energy use. Two scenarios developed in 1998 by the International Institute of Applied Systems Analysis and the World Energy Council (a business-as-usual scenario, and one that is more ecologically driven) compare

Table 1 Characteristics of sustainability in two energy development scenarios in the second half of the 21st century compared with 1990

Indicator of sustainability	1990	Business as usual[a]	Ecologically driven[b]
Eradicating poverty	Low	Medium	Very high
Reducing relative income gaps	Low	Medium	Very high
Providing universal access to energy	Low	High	Very high
Increasing affordability of energy	Low	Medium	Very high
Reducing adverse health impacts	Medium	High	Very high
Reducing air pollution	Medium	High	Very high
Limiting long-lived radionuclides	Medium	Very low	High
Limiting toxic materials[c]	Medium	Low	High
Limiting GHG emissions	Low	Low	Very high
Raising indigenous energy use	Medium	Low	Very high
Improving supply efficiency	Medium	High	Very high
Increasing end use efficiency	Low	Medium	Very high
Accelerating technology diffusion	Low	Medium	Medium

[b] Corresponds to C1 scenario in World Energy Assessment.
[c] For this row only, the qualitative indicators are not based on quantitative features of the scenarios, but were specified by the author on the basis of additional assumptions.

key environmental, economic and energy indicators as they unfold over this century given different assumptions about how energy systems will develop. Both hold population projections constant, and achieve the goal of sustained economic growth. But the other effects, as they play out over time, were substantial. The scenario exercise suggested that continuing in the present direction will result in adverse health impacts, an environmental burden of toxic materials, and increasing greenhouse gas emissions, without fully addressing the current inequities in the distribution of benefits from energy use.

The more ecologically driven scenario achieves a substantial reduction in atmospheric carbon concentrations by the end of the century, as well as considerably less acidification (as re ected by reduced sulfur dioxide (SO_2) emission levels). Achieving these long-term consequences would require ambitious policy measures, including carbon and environmental taxes, to curb environmental damage. This path also demands continued improvements in energy efficiency, a greater reliance on renewable energy sources and a high level of technological innovation, which allows for the use of fossil fuels in non-polluting ways. The ecologically driven scenario, listed in Table 1 assumes a nuclear phase-out by the end of this century. However, nuclear power could be part of the energy supply mix, if the key problems associated with nuclear energy (cost, safety, waste disposal and weapons proliferation) could be adequately resolved. Table 1 compares the implications of the two scenarios from the standpoint of sustainability. The remainder of this article discusses how we can get beyond business-as-usual, and head toward a sound future.

WIDENING ACCESS

A pre-requisite to a sustainable future is greater equity in the distribution of energy services (and therefore, more equality in the opportunities afforded to individuals). Yet despite tremendous efforts to improve energy services to rural populations in the last 20 to 30 years, the population without access to electricity has remained approximately the same in absolute numbers, around two billion people. Approximately the same number rely on traditional fuels (dung, crop residues, and firewood) for cooking and heating. An effective strategy to address the energy needs of the rural populations is to promote the climbing of the energy ladder. This implies moving from the solid biomass fuels to the most convenient and efficient form of energy appropriate to the task at hand, usually liquid or gaseous fuels (coupled with more efficient stoves) for cooking and heating, and electricity for most other uses (including commercial and industrial activities). As new, cleaner technologies become available, it is also possible to introduce new rungs on the energy ladder, and gain even greater efficiencies and environmental acceptability.

Over the long term, using energy in ways that produce near zero harmful emissions will be needed. However, in the near term, small amounts of conventional forms of commercial energy could greatly improve living conditions in rural areas. Meeting the cooking needs of two billion people with conventional energy carriers (such as liquefied petroleum gas), would require an amount equivalent to less than 1% of current commercial energy consumption worldwide, but would constitute a much more efficient use of energy (by about a factor of three) compared to traditional fuels. This means that if the world's poorest people were to move to liquid fuels, their primary energy use (and the resulting health and environmental impacts) would initially decrease, with no corresponding decrease in energy services.

In rural areas, small-scale decentralized approaches may be more appropriate and cost effective than extending energy grids. Successful implementation of such small-scale technologies seems to depend on the active participation and empowerment of the people who use them. Cooperatives, non-governmental organizations and local groups can effectively support delivery of energy services and management of natural resources.

Affordability is critical. However, because the rural poor already pay a high price for the limited energy services they receive, they are often willing and able to pay more than one might expect for energy services if appropriate financing options are offered. The economics of providing basic electricity to rural households should be evaluated according to the costs of supplying comparable energy services through less efficient carriers. Supportive financial and credit arrangements (including micro-credit arrangements of the kind now in existence) will be needed to introduce commercial energy to those excluded from markets, especially in rural areas.

Because commercial energy can be a necessary lever for breaking out of a cycle of poverty, temporary subsidies may be effectively employed, especially within a context of integrated development initiatives. Such subsidies could be looked at as part of a new social contract, in which competitive conditions in the energy sector (a key element of ongoing energy sector reforms) are complemented by the establishment of a public benefits fund to protect various public goods that the market would not. Funds could be generated by small, but non-bypassable wires/pipes charges on electricity and gas providers, and could be used to widen access and support technological innovation.

Such a strategy could be employed while still taking advantage of the forces of competition for efficient allocation of resources. Consider, for example, the rural energy concession, an arrangement in which a substantial market is awarded to a supplier, along with an obligation to serve

all customers within a specified market. If such a concession were awarded competitively, market forces would be brought into play to find the least costly mix of energy technologies. While some subsidization might still be necessary, the competitive process would help ensure that the public funds provided the minimum subsidy required to satisfy the concessionaire's obligation to provide modern energy to all.

Policy approaches to address the challenge of supplying modern energy to rural areas include:

- decentralized rural electrification, using wind turbines, solar photovoltaics or diesel generators, where grid extensions are inefficient;
- public participation in planning rural energy systems;
- innovative credit schemes such as locally managed micro-credit arrangements, are a good example, especially to help consumers meet the hurdle of high initial costs associated with moving up the energy ladder;
- temporary subsidies to help promising energy technologies overcome barriers to commercialization;
- special rates or temporary subsidies to provide enough energy to support basic human needs (possibly supported by a wires charge);
- concessions that offer a significant customer base in return for energy investments in underserved areas;
- bilateral and multi-lateral support for innovative approaches to sustainable energy;
- a social contract, that couples highly competitive markets with an obligation to protect public benefits.

MAKING MARKETS WORK BETTER: PRICING AND REGULATORY APPROACHES

Driven by the force of competition, markets are unsurpassed in their ability to allocate resources efficiently and drive costs down. For that reason, many of the approaches suggested here attempt to harness the power of the marketplace, guiding it toward the achievement of sustainable development goals. Markets never work perfectly however. The effectiveness of energy markets is often hampered by price distortions and lack of competition. Market imperfections also result in inadequate investment levels, low levels of energy efficiency, and lack of support for energy innovation, subjects to be addressed in subsequent sections.

Removing Subsidies

The first obstacle to fair competition in energy markets is the significant subsidies for conventional energy in many countries. These publicly supported cost reductions, which may be granted to producers and consumers (directly, through price reductions, or in less visible forms, through tax breaks, market support, or inadequate metering) often fail to help the most needy and discourage least-cost choices and efficient energy use. In addition to working at cross-purposes to the aims of sustainable development, energy subsidies (exclusive of the transport sector) represent public costs on the order of US$100–200 billion per year. Since these support mainly fossil energy, they create a huge hurdle for new technologies, renewables and energy efficiency improvements to overcome.

Policy approaches to level the playing field include:

- transparent accounting procedures to make subsidies visible;
- phasing out of permanent subsidies and cross-subsidies to conventional energy (fossil fuels, large hydropower and nuclear energy).

An important exception to the general rule of removing subsidies is lifeline rates, that is, the provision of small amounts (perhaps 50 kilowatt hours per household per month) of commercial energy supplies, at little or no cost, to help vulnerable groups meet basic needs or to break out of a cycle of poverty. Where such subsidies are well targeted, and well designed (to encourage use, but not inefficiency), the resulting benefits, including access to the outside world through radio and television, electric light for reading and studying, time savings, health benefits and so on, outweigh the costs.

Internalizing Externalities

A second obstacle to a level playing field is that the market, in the absence of government intervention, fails to account for social and environmental costs of energy production and use, which are called *negative externalities*. Prices that do not re ect these costs tilt the playing field to the advantage of fossil fuels at the expense of societal aims (and make it difficult for more sustainable forms of energy to compete). Finding ways to accurately figure externalities into the pricing equation proves to be difficult, however, partially because there is no consensus on how to measure their costs in monetary terms. These external costs are, however, estimated to be quite substantial – in some cases comparable to, or in excess of, the cost of the primary energy itself.

Nevertheless, a number of interesting policy initiatives are attempting to integrate externalities into prices at the national level, through gasoline taxes and other means. In many European countries, taxes on gasoline are well above the base cost of the fuel itself. Differential fuel taxes can be seen as another way to start to account for externalities. They have been adopted in a number of countries to support ethanol fuel or compressed natural gas use, both of which reduce oil import dependence and improve urban air quality. Generally speaking, targeted taxes that penalize the use of environmentally harmful forms of energy are

more effective than a general energy tax. From a theoretical point of view, carbon taxes are the simplest and most consistent method for internalizing the cost of mitigating climate change. A mix of energy and carbon taxes would address a wider range of environmental impacts associated with energy production and use.

From a national perspective, internalizing environmental costs can undermine the competitive position of domestic industries. That's why, in a world where markets are becoming more integrated, international cooperation to harmonize environmental initiatives could be an important step toward a more sustainable future.

Fine tuning taxes on energy use so as to more accurately re ect the environmental impact and other externalities of use can encourage energy efficiency and the use of cleaner forms of energy. An additional dividend is that the chain of cause and effect between energy production and use and resulting externalities becomes clearer and the polluter-pays principle better established (Jefferson, 2000). Such taxes can be used to offset other taxes or to support many of the measures discussed here, particularly technological innovation and wider access.

Policy options to incorporate external costs into prices include:

- differential fuel taxes;
- environmental taxes;
- environmental regulations (which have associated costs);
- carbon taxes;
- emissions trading.

Regulatory Approaches

Throughout the 20th century, grid-based energy systems were looked at as natural monopolies. But new technical developments, such as the smaller scale of new power plants, the drive for greater efficiency, and the wave of liberalization are creating new system models. Increasingly, various functions of these former monopolies have been unbundled, that is, the production, transmission and distribution functions are no longer vertically integrated. Rather, they are operated by independent entities that compete in the arenas of generation and distribution. This has opened up the gas and electricity sectors to increased competition, including that from independent power producers (IPPs). Although in some circumstances this diminished role for government in supplying and distributing energy could be seen as a threat to public welfare, it also presents an opportunity for a different kind of government participation. Indeed, implementing regulatory measures to protect societal objectives and maintain fair competition may be a more appropriate and effective role for government.

In the process of liberalization, corporations are created that act under the provisions of the legal, economic and regulatory systems of the country. Changes in these framework conditions often demand readjustments, with associated costs and changes in competitiveness, and are therefore often resisted. However, once a new framework is introduced to replace a monopoly situation, the process of change has already begun. This transitional period, while the rules are in ux, often presents a timely opening in which to introduce and negotiate provisions that address social and environmental concerns. Because of ongoing market reforms, many countries are now in a position to take advantage of this window of opportunity.

Regulatory approaches to protect public benefits include:

- measures to widen competition, for example, by guaranteeing IPPs access to power grids and giving energy service companies opportunities to bid on supply contracts;
- creating a public benefits fund (see above) to support sustainable energy developments;
- allowing prices to re ect marginal costs of supply;
- obligations to serve specific regions in return for exclusive markets (concessionaire arrangements);
- obligations to buy (such as Renewable Portfolio Standards, that help bring down the cost of clean new technologies);
- energy efficiency and performance standards;
- reporting requirements to ensure transparency.

MOBILIZING INVESTMENTS IN SUSTAINABLE ENERGY

Since capital investment is a prerequisite for energy development, the lack of capital for energy investments can thwart economic development. A major challenge in raising funds for energy investments is the perceived risk to investors and adequate rates of return. Returns in the energy sector are often lower than those in other infrastructure investment alternatives. And within the energy sector, rates-of-return considerations favor large-scale, conventional projects over smaller-scale, clean, and innovative energy alternatives. Likewise, the scale and dispersed nature of investments in energy end-use efficiency do not attract capital under current models.

Scarce public sector funds, especially in developing countries, are sought by many projects besides energy supplies including rural development, education and health care. Because energy supply, more than any other alternative, is often seen as capable of generating revenues early on, the energy sector is increasingly viewed as suitable for private sector investment. But private capital is not owing into many countries at an adequate rate to support energy sector development.

Foreign direct investment (FDI) in energy projects has been estimated at about 5–15% of the total, which amounted to some $400 billion in 1997. While FDI is an important source of financing for energy projects, it is generally commercially motivated. The sponsor of investments not only expects to recover the initial capital but also counts on competitive returns. Where political systems and markets are unstable, or where the rules are changing, risks are high. The 47 least developed countries receive little or no FDI. To a large extent, foreign investors lack confidence in the ability of developing country energy projects to provide stable (and competitive) returns until the investment has been recovered.

Official development assistance (ODA), in contrast, is publicly supported aid delivered through grants. While the level of ODA increased from US$34 billion in 1984 to US$56 billion in 1997 or 0.25% of the Organization for Economic Cooperation and Development (OECD) gross domestic product (GDP), it is still far below the 0.7% target that has been agreed to by the industrialized countries.

Policy options to encourage investments in sustainable energy include:

- encouraging good governance to create conditions more attractive to investors;
- creating multi-laterally backed insurance to protect energy sector investments;
- added incentives to invest in sustainable energy, such as the *Clean Development Mechanism*, whereby industrialized countries may be able to earn credits for investing in carbon abating projects in the developing world (*see* Clean Development Mechanism, Volume 4);
- increasing ODA to agreed-upon levels and tying some of it to capacity building and investments in sustainable energy.

IMPROVING ENERGY END-USE EFFICIENCIES

If energy resources with zero or near-zero emissions were widely available and affordable, the need for energy efficiency and conservation would not be so urgent. But conventional fossil fuels are likely to dominate world energy use for the next half century. In the absence of clean energy technologies, energy efficiency is crucial to meeting the need for increased energy services while reducing environmental and health burdens. In theory, energy efficiency improvements of an order of magnitude are possible (based on analysis using the second law of thermodynamics). Whereas increasing energy efficiency in generation and distribution tends to be driven by the market, improvements in end-use efficiency are more difficult to realize. This is true in part because such improvements represent decentralized activities that require wide participation. Because the substantial potential benefits of energy efficiency measures are incremental and dispersed, it is not an easy issue to mobilize support for.

From a societal perspective, achieving greater end-use energy efficiency generally requires less investment than new generation (freeing up investment for other purposes), and it means fewer energy-related environmental externalities to deal with. From an individual perspective, it can mean significant savings over the long-term. However, many obstacles prevent energy efficiency from reaching its economic potential, including:

- lack of information, technical knowledge and training;
- uncertainties with regard to the performance of investments in new and energy efficient technologies;
- lack of capital or financing possibilities;
- high initial and perceived costs of more efficient technologies;
- high transaction costs (for searching and assessing information and for training);
- lack of incentives for careful maintenance;
- differential benefits to the user compared to the investor (for example, when monthly energy bills are paid by the renter rather than the property owner);
- consumer patterns and habits.

A number of the policy initiatives to address these barriers are relatively simple and effective. Correct pricing signals, as discussed earlier, can make energy efficiency investments more attractive. Additional policy options to overcome barriers include:

- labeling schemes (tied to testing programs) to better inform consumers;
- procurement policies to maximize economies of scale, buy down costs, and reduce transaction costs;
- voluntary or mandatory efficiency standards for appliances, vehicles and buildings;
- technical training in new energy efficiency technologies and their maintenance;
- credit mechanisms to encourage customers to make energy efficiency investments;
- greater reliance on energy companies to provide energy services, which may also include end-use technologies, rather than simply energy supplies.

This second point can be illustrated by a technology procurement policy that was successfully introduced by the Swedish energy agency (NUTEK) in the late 1980s. NUTEK convened a group of public and private companies who represented a large share of the appliance market, and issued a bid for more energy efficient, freon free refrigerators. The winning model had energy requirements that were one-third less than the most efficient model then on the market.

DEVELOPING AND ENCOURAGING DIFFUSION OF SUSTAINABLE ENERGY TECHNOLOGIES

Current technologies are not adequate to deliver the energy services that will be needed in the long-term and simultaneously protect human health and the environment. Thus, a prerequisite for the achievement of a sound energy future is accelerated progress for new technologies along the energy innovation chain, from R&D, to demonstration, deployment and diffusion (Table 2). This process can take decades and be stalled at any point along the way.

Over the long term, radical changes in energy technology will be needed to support sustainable development aims. During this new century, some combination of the following technologies, which offer high levels of inherent cleanliness and safety, will be needed:

Table 2 The energy innovation value chain

Stage of effort	Laboratory	Pilot to market	Achieving lower costs per unit	Widespread diffusion
Activity	R&D	Demonstration projects	Buy down of cost	Increasing investments in sustainable energy technologies
Key barriers	Government austerity makes allocation of funds for energy R&D problematic	Government austerity makes allocation of funds for energy R&D problematic	Financing incremental cost	Transaction costs
	Difficulty for private sector in capturing benefits	Difficulty for private sector in capturing benefits	Cost uncertainty	Prices for competing
		Risks	Technological and other risks	Technologies exclude externalities
		Large capital costs		Lack of retail finance
				Lack of information
Policy options to address specific barriers	Increased public funding (national and international)	National and international support for demonstration projects	Obligations to buy (such as Renewable Portfolio Standards, which guarantee markets for new technologies)	Obligations to buy
	Tax deductions for private R&D	Low cost or guaranteed loans	Obligations to supply (such as the Non Fossil Fuel Obligation in the UK)	Obligations to supply
	Collaborative research partnerships and funding	Project aggregation to reduce costs	Tax incentives	Green labeling and marketing
		Temporary price guarantees for products of demonstration projects	Large-scale procurement policies	Renewable energy concessions
			Temporary subsidies	Capacity building
				Clean development mechanism

Source: UNDP *et al.*, 2000.

- fuel cells for transport, stationary power and combined heat and power generation;
- fossil fuel derived hydrogen (H_2) with sequestration of the separated carbon dioxide (CO_2);
- modernized biomass technologies for production of liquid and gaseous fuels and electricity;
- photovoltaic and wind power technologies coupled to energy storage to provide dispatchable power;
- wide deployment of much more energy-efficient end-use technologies.

Fortunately, a wide range of promising advanced energy technological options can already (or may soon be able to) address energy needs in sustainable ways if adequate attention is given to energy innovation. Long lead times for new technology dictate that intensive energy innovative activity is needed today, to establish a portfolio of new energy technology options to choose from over the longer term.

Direct government support is more likely to be needed for radically new technologies than for incremental advances, which can generally find support from the private sector. Scarce public resources can be used more effectively to support emergent technologies offering major public benefits not fully valued in market prices, that have steep learning curves and good prospects for market penetration after the incentives or subsidies are phased out. Because of the risks involved, and the fact that clean energy does not necessarily command higher prices than conventional energy, targeted policy approaches are needed, both to encourage supply (push) and stimulate demand (pull) (Geller, 1999).

Research and Development (R&D)

While R&D is the first step in the energy innovation chain, both public and private sector expenditures on energy R&D have generally been falling. Energy R&D expenditures are low in relation to both the direct value of energy expenditures in the overall economy and in relation to the sustainable development challenges posed by conventional energy. Moreover, much of this money has been used to support nuclear energy technologies; in recent years, only about 10% goes toward energy efficiency and another 10% toward renewable energy technologies.

Several OECD economies are now moving away from direct state support of R&D toward a complex mix of incentives based on:

- regulatory requirements on private industry to develop technologies with low carbon emissions;
- tax incentives for the development of low carbon technologies that are neutral between technologies, such that the choice of which technologies to develop can be delegated to private initiative;
- marketable permit systems, such as the proposed (under the Kyoto Protocol) programs of Joint Implementation and the Clean Development Mechanism; and
- special financing facilities, such as the Global Environment Facility, which blend their own concessionaire finance with the hard finance of the Multilateral Banks and industry to achieve a softer financial blend for innovative environmental projects.

These are all clearly more market-oriented initiatives. However, the scale of existing incentives is insufficient in light of the emerging environmental problems: and the continuing competition from fossil fuels.

Moreover, the scope of energy R&D should be extended in order to address the particular energy needs of the developing world, which will account for most of the world's incremental energy requirements. New energy technologies should be tailored to the specific resource endowments, capabilities and cultures of individual countries.

Demonstration through Widespread Diffusion

Even after the viability of energy technologies has been established, decades of demonstration projects and market growth may be required before these new technologies can command major market shares. Demonstration projects, however, are generally costly, risky and difficult to finance. Although public funds may be crucial at this stage, one way of limiting risks is to bring in the private sector as well. Some of the most successful demonstration projects have been those where the government role has been to set performance and cost goals, and to provide some capital, while the private sector takes responsibility for finding ways to meet the goals, and also shoulders some of the financial risk.

Buying down Costs for New Technologies

Some public support or incentives may be needed to bring clean energy technologies to the point where they can compete with conventional energy. Economies of scale in production, learning and experience curves, and cost reductions through competition can all help drive the costs of new technologies down. Typically, manufactured goods show cost declines of about 20% for each cumulative doubling of production, and this pattern can be seen for a number of rapidly growing renewable technologies, including windmills, solar photovoltaics and gas turbines. But the market alone will not typically be able to overcome the higher initial costs of new energy technologies.

Temporary subsidies to promising, emergent technologies that offer major public benefits not captured in prices, can take various forms, including tax incentives, subsidized loans or guaranteed prices, government procurement and competitive market transformation initiatives.

The UK's Renewables Non Fossil Fuel Obligation and California's Renewal Portfolio Standards are examples of initiatives that encourage cost buy downs by stipulating that suppliers include a specified percentage of renewable energy in their portfolios. Green pricing, whereby customers can choose to pay higher prices for environmentally friendly energy, is a market-based mechanism to initially boost production, even at higher costs, and ultimately bring down prices.

FOSTERING TECHNOLOGICAL INNOVATION AND LEADERSHIP IN DEVELOPING COUNTRIES

In many respects, the achievement of sustainable development depends on what happens in the developing world, where energy demands are set to grow substantially in any scenario of economic success. However, thanks to technological developments, the developing world need not retrace the wasteful and polluting path taken by the industrialized world. Indeed, from the standpoint of their natural endowments (the higher incidence of solar insolation, for instance), nascent infrastructure and growing markets, developing countries are well positioned to profit, both socially and economically, from deploying clean energy technologies at an early stage of development.

Developing (and transitional) countries need to further develop their own resources (human, natural and technological) so that they can create energy systems appropriate to their own circumstances. But they also need assistance in terms of technology transfers, financing and capacity building. The declining share of ODA relative to other investment capital suggests that much of this support will need to be led by the private sector, and/or by private/public sector partnerships. International industrial collaboration offers one means by which the private sector could gain markets while fostering the migration of new technologies to developing countries. Public sector agencies, private research institutes and regional institutes that provide training in technological management are additional possibilities to further technology sharing and capacity building.

Capacity and Institution Building

If developing countries are to meet their energy needs, they will require more human capital and stronger institutions. Technological and managerial capabilities are critical for successful technology transfer and innovation. Human capital will be needed to form and staff public sector agencies and research institutes and to create and staff the private companies that will produce, market and install energy efficiency, renewable energy, and clean fossil fuel technologies. Without strong private sector actors and markets as well as sustainable energy programs and agencies, sustainable energy initiatives in developing countries are likely to be *ad hoc*, limited in scope, and insufficient to overcome the full set of barriers inhibiting large-scale implementation.

Strong government/private sector collaboration has been a key characteristic of many successful market development programs. This means involving the private sector in program design as well as implementation. Successful national energy efficiency and renewable energy centers and programs are already operating in Brazil, China, India, and Eastern Europe. These centers and programs work with the private sector, utilities, and other entities to introduce and widely disseminate energy efficiency and renewable energy measures and to:

1. provide education and training;
2. conduct R&D and demonstrations;
3. adopt and implement efficiency standards;
4. perform product testing, labeling, and certification;
5. conduct marketing and promotion;
6. encourage local manufacturing of energy efficiency and renewable energy technologies;
7. help establish and support energy service companies;
8. provide financing and/or financial incentives;
9. develop and analyze policy reforms.

Taking the Lead

Although the principle of technological *leapfrogging* (*see* Leapfrogging Technology, Volume 4) is widely accepted, conventional wisdom cautions against developing countries taking the lead in the deployment of emerging energy technologies, and assuming the risks involved in commercializing technologies and systems not widely in use elsewhere. In fact, the development assistance community has not typically supported innovation in the energy sectors. But there are several reasons to question this view.

First, inherently cleaner energy resources would mean that developing countries could effectively address their growing air quality and other environmental challenges with less regulatory infrastructure than would be required if these goals were pursued by mandating and enforcing the use of increasingly more stringent end-of-pipe control technologies.

Also, rapidly growing markets, with high demand for energy-intensive industries, like those found in many developing countries, offer favorable conditions for energy technology innovation. In developing countries, large, rapidly growing markets, plus lower wage rates at all levels of technical, scientific and engineering professions make both manufacturing and product development attractive options for technology owners. When new technologies are introduced in developing countries, some components could

be produced locally. Local manufacture implies not only local job-creation opportunities but also potentially lower costs than for the same technologies imported from the industrialized world, leading to large domestic markets and opportunities for export growth.

Taking advantage of the current window of opportunity for market leadership will be a challenging task. Three prerequisites for successful outcomes are the establishment of an appropriate legal, regulatory, and policy framework; the rational pricing of energy; and the creation of strong domestic capital markets.

Policy options to encourage technological innovation in developing countries (many of which could benefit from the support of bilateral and multilateral financing and development cooperation agencies) include:

- R&D and demonstration projects emphasizing clean energy supply and energy end-use technology innovation;
- encouraging the introduction of new energy technologies through international joint ventures and other mechanisms;
- adopting and enforcing strong energy efficiency and environmental standards in developing countries so that new infrastructure is state of the art (and so that polluting technologies do not get locked in);
- attractive financing, market development assistance, and government procurement for products made by clean energy technology entrepreneurs whether these companies are locally owned, international, or joint venture.

Because of the long lifetimes of power plants, refineries and other energy investments, even vigorous policy measures will not produce major changes in energy systems and emissions before 2020. But the seeds of the post-2020 world will have been sown by then. Thus, choices about the world's future energy systems are relatively wide open now. This window of opportunity is particularly significant for those developing regions where much of the infrastructure has yet to be installed, offering the possibility of a very rapid introduction of new, environmentally sound technologies. Once infrastructures are in place and rates of economic growth decline, a phase of largely replacement investments will begin. In this phase, changes can be made, but they will take much longer to affect the average system performance. If we do not make good decisions now, by around 2020 we will be locked in to those choices, and certain development opportunities might not be achievable later. Thus, sustainable development dictates a global perspective, a very long time horizon and an early initiation of policy measures (Nakičenovič, 2000).

A key challenge for human society now is to move beyond the tangible pressures experienced today and to manage global resources with future generations in mind. Taking such actions, in the face of competing short-term interests, will essentially require a paradigm shift. For this shift to occur, the sustainability debate will need to move to center stage, and be accompanied by greatly raised levels of public awareness, information and commitment. Continued dialogue and consensus building within the international community, between the public and private sectors, and within society at large is needed to advance sustainable energy policies at the national, regional and global levels.

ACKNOWLEDGMENTS

This paper draws heavily on material prepared by convening lead authors (and their respective teams of experts) of the World Energy Assessment, especially Dennis Anderson, José Goldemberg, Michael Jefferson, Eberhard Jochem, Nebojsa Nakićenović, Amulya K N Reddy, Hans-Holger Rogner, Kirk Smith, Wim C Turkenburg and Robert H Williams. Janet Jensen provided excellent editorial assistance.

Dematerialization and Sustainable Development

MOSTAFA K TOLBA AND JIH C YANG

International Center for Environment and Development, Cairo, Egypt

When the term sustainable development was coined more than 15 years ago, it clearly meant that the patterns of development being pursued were not sustainable. Sooner or later, we had to refocus our attention and have serious plans for achieving sustainable development. Agenda 21, adopted at the 1992 Rio Summit (the United Nations Conference on Environment and Development), charted the general path in this direction, but we need detailed plans. Recognizing that the root cause of our sustainability problems is the persistent imbalance between the growth and the dematerialization rates of our economic activities, it follows that the solution lies in accelerating dematerialization, so that it may catch up with growth and nally put a stop to growth's runaway demands on the Earth's natural resources. Dematerialization denotes acts that reduce the consumption of materials (energy, water, land, forests, minerals, etc.) in each unit of economic output. The issue of dematerialization can be reduced to achieving a balance as given by a simple equation: dematerialization rate = growth rate.

From this simple relationship, we may begin to explore the challenges we face, and comprehend the actions we must take, however dif cult they may be. Extending this simple logic, we may also grasp, quantitatively, the size of one of sustainable development's most complicated issues - the North/South dispute. Simple calculation would show that just one percentage point of extra dematerialization performance by the developed world (the North) would create enough room under the overall sustainability cap for the developing world (the South) to grow essentially unrestrained out of their under-development and unsustainable ways.

Dematerialization is the key to our sustainability struggles, and traditional approaches such as ef ciency improvements and cleaner production can only go so far. Ef ciency (or cleanliness) is neither easy nor, as a resource, limitless. If it has to progress as fast as growth, it will not be able to keep up for long. For dematerialization to have a realistic chance to catch up with growth, growth must itself become a lot less material dependent. The outcome will hinge upon the ways in which society progresses in the information age. Will it make growth ever more material-less? Or will paradigms such as E-commerce accelerate sales and consumption of the world's natural resources? Such are the crucial questions upon which our sustainability fates hang.

REFOCUSING SUSTAINABLE DEVELOPMENT

If sustainable development is going to have a meaningful future, our views on how to achieve that desirable state will have to change. When people talk about the subject nowadays, they speak most of the time about what we shouldn't do, sometimes about what we should do, but almost never about how to do it. Even when the subject of actions is raised, suggestions tend to be disparate, anecdotal and lacking the structure and rigor that characterize the action plans of serious enterprises. Sustainable development has been around too long to be still without a coherent plan or even a compelling scenario. Can anything so important be talked about without a blueprint?

Implementation of sustainable development will be, by all measures, one of the toughest actions we will ever take, and so far we are not exactly overloaded with ideas. This however is no reason to avoid the subject. If it is indeed so critical to the future of mankind, then we have no choice but to face it head-on. What follows herein is an attempt to outline the how-to-do-it aspects of sustainable development.

SUSTAINABLE DEVELOPMENT'S OBJECTIVE IS TO CHANGE DEVELOPMENT

Curiously, few people nowadays seem to remember that sustainable development began as a movement to change development. Just look at the definition of sustainable

development given by the World Commission on Environment and Development (WCED) in 1987: sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own needs .

The people who wrote this didn't waste time getting to the point. They didn't mention pollutants, wastes, toxics, energy use and its effects on climate, losses of habitats and biodiversity, fresh water shortages or an assortment of other well-known sustainability issues, which are only symptoms. It's the causes that WCED was worried about, and the causes are much more troublesome. They are the most instinctive and normal things we humans do – the pursuit of development.

Too Much Growth is a Threat to Sustainability

Over the last 100 years, economic activities of mankind have grown 80-fold, and this growth has increased our demand and consumption of natural resources many, many fold. If we keep this up for the next 100 years, our economic activities will expand 80 folds more. Today's environment is under pressure, can we imagine what would happen then. That is only for the next 100 years, but we humans expect to be around for a lot longer than that. It's simple arithmetic. We can't go on the way we are going now.

Too Little Growth is a Threat to Sustainability

If too much growth is the primary reason for our sustainability problems, then too little growth wouldn't be far behind. Today, a full one-third of all humans live on the borderline of abject destitution, and their ways of life are not only humanistically unacceptable but also among the most environmentally damaging. Sustainable development for them is to grow, and to do so in an unrestrained manner for as long as it takes to reach an acceptable level of subsistence. That means the developed world must, in addition to taking care of the sustainability consequences of its own growth, go the extra distance to make room for the developing world to grow out of its underdevelopment miseries as fast as they can.

Even the Transition is a Threat to Sustainability

Not only are too much growth and too little growth the main causes of our sustainability problems, even the transition from developing to developed is problematic. When developing countries develop, they will most likely do so with not only the most labor-intensive but also the most material-intensive kinds of economic activities. High value-added, innovation-driven economic activities, low in energy and material intensities are the forbidden games only the most technically advanced countries can play. Can we blame the developing countries for undertaking material-intensive actions until they finally manage to develop? What are their options than to stay underdeveloped? They do not have other options. To stay underdeveloped is not an option.

CAN GROWTH BE STOPPED?

There are, theoretically, two kinds of things we could do to rein in runaway growth. One is to stop growth, and the other is to change the way we grow so the accumulation of environmental damages will stop. Can growth be stopped? The answer is no. There are several reasons.

1. Growth has been an integral part of human development for a very long time. It is probably a little late to try to persuade humans to give up growth now.
2. Sustainability problems are long-term. They are only painful and jolting enough for the majority of humans to want somebody else to mend their ways, not themselves.
3. There simply must be room for growth for the developing world.

Thus, making development sustainable is our only real option. The WCED statement, for example, called for development to be changed rather than for growth to be stopped. This view, however, has become more and more blurred as sustainable development becomes more and more popularized. There are even rumbles within the environmental community itself that the term sustainable development be replaced by sustainability because the word development is so very offensive to the environment. This would be most unwise. How are we going to change development if we keep avoiding it?

THE DYNAMICS OF SUSTAINABLE DEVELOPMENT

What makes development sustainable or not sustainable? The answer is actually quite simple (only the doing part is tough). What is sustainable development? It is as simple as: a form of development that is sustainable.

If we cannot do away with growth, then the only way to make development sustainable is to have growth with no added environmental impact.

How do we do this? There is actually only one way: to dematerialize as fast as we grow.

Here the word dematerialization denotes acts that reduce the consumption of materials (energy, water, land, forests, minerals, etc.) in each unit of economic output.

Or in equation form: dematerialization rate = growth rate.

Here dematerialization rate is measured as the rate of decrease of material intensity, which in turn is defined as

units of a certain material consumed (like kilo–liter oil equivalent in the case of energy) per unit of economic output (like dollars).

This simple equation tells us the root causes of our sustainability problems and answers many of the questions concerning the implementation of sustainable development. It gives the criteria on how sustainable development would have to be, and spells out the size of our tasks. It even lets us monitor how close or far away we are from our targets. It is the governing equation for the implementation of sustainable development.

Herman Daly, a leading economist who originated steady state economics, has argued that the answer to our sustainability problems lies in distinguishing growth from development, where growth is mere accumulation of wealth while development, on the other hand, is the improvement in quality of life. What kind of quality was he referring to? Simply stated, if it doesn't meet the dematerialization = growth requirement, it is not going to be of sufficient quality to achieve sustainability.

UNDERSTANDING DEMATERIALIZATION

Dematerialization is not a new thing. A part of our evolution has always been to become more efficient, to use less and less energy and materials to produce more and more goods and services. Neither is it new in sustainable development. However, as the basis for the actions we must take to make development sustainable, dematerialization needs to be looked at with considerably more care and rigor than we have in the past.

One of the most common mistakes made in studies on dematerialization is the lack of understanding that dematerialization should always be measured against growth. Dematerialization rate is the rate of change of material intensity (units of material like energy, water, etc. consumed per dollar of economic output, like gross national product (GNP) in the case of a nation) just like growth rate is the rate of change of GNP. So if in 1998, the energy intensity of a certain country is 1 kilo–liter oil equivalent per dollar of GNP, and in 1999 the figure went down to 0.97, the dematerialization rate for that country in 1999 would be 3% year^{-1}. *Dematerialization de cit* (i.e., growth rate minus dematerialization rate) rather than dematerialization itself, is the important parameter here. It is the size of the deficit that measures how close or far away we are from a state of sustainability, not the rate of dematerialization itself. We are better off with a 1% dematerialization rate when the growth rate is 3%, for example, than 2% when the growth rate is 5%. If we fail to appreciate this, we would draw very wrong conclusions.

Our current state of understanding on the subject of dematerialization is full of this kind of error. The following is an example. Figure 1 shows a sample of China's growth and energy dematerialization performances during its robust growth years. Dematerialization is not the problem but dematerialization deficits surely are.

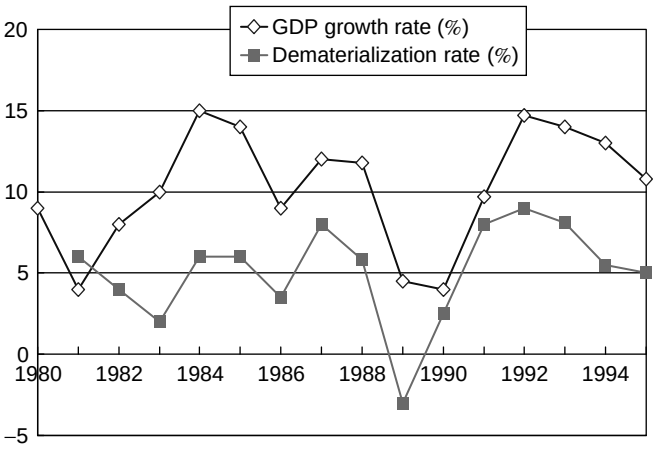

Figure 1 Growth and energy dematerialization rates for China for the years 1980–1995

Technology's Role in Sustainability

Technology almost always dematerializes. Historically, each new generation of technologies has almost always been more efficient and less material intensive. But if technology is so good to the environment, how is it that the results it brought were so bad? This is the typical growth versus dematerialization situation. Technology by itself is not bad. The trouble is that it has always done a lot more for the growth side of the equation than for the dematerialization side. An example is information technologies. They may have very low material intensities, but if, say, E-commerce stimulates growth and increases the demand and consumption of materials more than it displaces the share of heavily material-dependent industries' share in our overall economic activities, E-commerce would be bad for sustainability, not good.

Is a 1% Energy Efficiency Improvement a Positive Sign?

It is almost standard practice now to cite the fact that our energy intensity has been improving by about 1% a year since the 1800s as a sign that we are moving continuously on a positive dematerialization course. This cannot be more incorrect. Not only is this not a sign of improvement, the fact is that efficiency gains have consistently been far outpaced by the growth rates of our economic activities, and therefore the increases in demand and consumption of energy, is the very reason why we have such a major climate change issue now.

Do we have a Surplus of Dematerialization Technologies?

Many people contend that we have plenty of technologies available for our dematerialization purposes. The fact is that these technologies are plentiful only because of the dismal dematerialization performance we have managed to achieve so far. If we begin to dematerialize at a rate close to that of our growth rates, our stock of materials will be depleted in a hurry. Studies by the Electric Power Research Institute of the US have indicated that the existing stock of energy efficiency technologies would be enough to improve energy efficiency by 24–44%. How long will this last if we start to dematerialize energy at the kind of rates dictated by the Kyoto Protocol targets (which are essentially a form of dematerialization = growth requirement)? Less than 10 years.

Two kinds of people on opposite ends of the environmental spectrum – environmental idealists and right-wing contrarians – tend to over-dramatize our past performances and current capabilities in dematerialization. The former want people to believe dematerialization is easy, so everybody should be compelled to do it. The latter want people to believe dematerialization is easy, so nobody would be forced to do it. In reality, dematerialization is not easy at all, but everybody needs to do it.

Are Development and Environment no Longer Antagonistic Under Sustainable Development?

Many people have said that environmental and developmental interests are now no longer antagonistic, but aligned under the banner of sustainable development. This kind of optimism is grossly premature. If our dematerialization deficits are not narrowing, then things are not any more aligned or any less antagonistic than ever before. Antagonism between environment and development did not end when we invented the term sustainable development. It will end only when development finally becomes truly sustainable.

How Much Corporate Environmental Action Would Be Enough?

If a company published in its company environmental report that it has improved its energy or water intensity 5% last year, was that a good result? Yes and no. If the company's sales grew 10%, then 5% efficiency improvement was not sufficient. Now, if that company dematerialized certain natural resources 20% (twice its 10% revenue growth rate), was that a good result? Still yes and no. Very large gains in material intensity are most often the result of certain old technologies being phased out. The aggressive targets usually end when the phasing-out is completed (and the focal point of the next report would be shifted to another topic). Dematerialization has to happen at equivalent or greater than growth rates on a continuous, year-in and year-out basis. It is a forever kind of effort.

Most of what corporate-based environmental actions have achieved has been the reduction of pollutants and wastes. This progress is good, but this is the easiest part of our sustainability struggle. Pollution problems are largely solved in the developed world anyway. What industry needs to do now is to dematerialize the natural resources out of its products and production processes.

Businesses are where our society's capabilities are concentrated. They have the responsibility to show leadership in our toughest sustainability battles. At a minimum, they need to reduce the material intensities of their business activities at least as fast as the growth rates of their revenues; otherwise they would be asking the rest of society to subsidize them in our struggles to reach sustainability.

INDUSTRIAL AGE DEMATERIALIZATION: CLEANER PRODUCTION

When we talk about dematerialization, we usually associate it with things like cleaner production, pollution prevention, efficiency improvements, renewable energy, industrial ecology, design for environment and other such familiar actions. For convenience, let us group them together and call them *cleaner production* (the UN's Environmental Programme definition of cleaner production covers essentially everything of environmental worth).

Cleaner Production: How Far can we Run with It?

Unlike pollution control, which draws upon technologies developed for its specific purposes, cleaner production relies to a large extent on pushing harder the dematerialization attributes of mainstream technologies, such as new processes; to advance the causes of sustainability. But the development of these mainstream technologies is driven mainly by competition and growth purposes. Isn't there a contradiction here? What would we get at the end of the day, more dematerialization or more growth?

This question should be broken down into two parts. The first part is: do we need these mainstream technologies to play a major role in sustainable development? The answer is absolutely yes. Human affairs are driven by these mainstream technologies. They have got to become cleaner and more eco-efficient. All elements of cleaner production must be pushed to their very limits, and all kinds of incentives, including both sticks and carrots, must be brought to bear to make them happen. But will they be pushing dematerialization or growth harder? That's the second part of the question.

We are a long way from being able to control the environmental outcomes of technology. Most, if not all, of

the important technologies come out of the growth side, for growth purposes. They can become cleaner, for sure, but is it reasonable to expect these technologies, created for growth reasons, to do more for dematerialization than for growth? Pushing cleaner production may narrow the gap between growth and dematerialization, but can it bridge it? Let us look at what happened in the 1970s during the energy crisis – a time when the pressure and the incentives for dematerializing energy were greatest.

Probing the Limits of Cleaner Production

Growth and energy dematerialization rates of six developed economies are shown in Figure 2 for the period 1987–1996, which was relatively uneventful and is thus treated as a norm, and in Figure 3 for 1971–1982, which were the energy crisis years.

We note first that even though energy dematerialization (efficiency) rates were generally about one percentage point higher during the crisis years than during the normal period, most of these countries were still a long way from erasing their dematerialization deficits. We note also

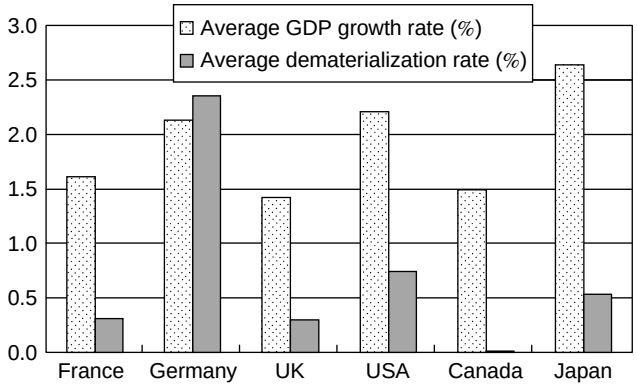

Figure 2 Growth and energy dematerialization during the early Information Age (1987–1996)

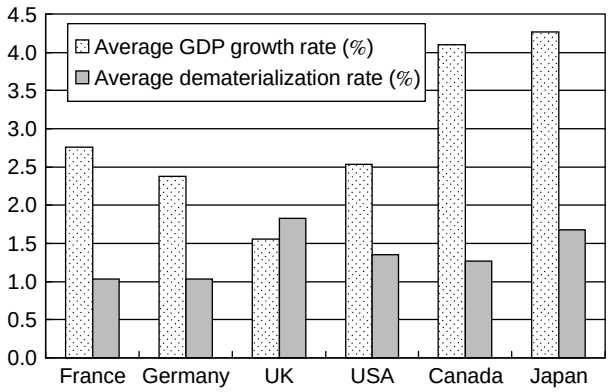

Figure 3 Growth and energy dematerialization during energy crisis years (1971–1982)

that 1987–1996 were the years when we first realized the threat of climate change and the need to reduce energy use to mitigate it. Yet if we have done anything to reduce the threat, we surely cannot find it in the energy dematerialization data shown in Figure 2 (Germany's good showing was mainly the result of reunification).

Businesses are usually vigilant about keeping their energy costs down, for competitive reasons. Businesses that stay in business would have to be efficient. Thus, Figure 2 represents the best that business can do under normal circumstances, with normal investment/return considerations. There is of course room for improvement, but that would take extraordinary actions and inducements.

It is premature to pass judgment on the efficacy of cleaner production, corporate environmentalism, etc. After all, it is less than a decade since Rio, when many of these dematerialization efforts were just getting started. However, sooner or later the effects must register on graphs like Figures 2 and 3. We need to see the effects of environmental actions on dematerialization versus growth charts, or they would show much motion but little movement.

Now back to the question, Would cleaner production bridge the dematerialization versus growth gap? The fact that we didn't bridge the energy gap even during the energy crisis years tells us that the answer is most likely not. To bridge the gap we need something outside the realm of the Industrial Age when cleaner production was spawned. That something is to be found in the Information Age.

INFORMATION AGE DEMATERIALIZATION: BITS-FOR-ATOMS

Bits are the fundamental unit of digitized information, while *atoms* are the fundamental unit of materials. The phrase bits-for-atoms, means the substitution of information for material. It is an obvious fact that our struggle to reach sustainability will take place largely during the Information Age. Given this obvious fact, it is truly bewildering that sustainable development has taken in so many fringe issues scarcely related to its core tasks, and yet has remained so distant and withdrawn from this one thing that is surely going to dominate human development for the foreseeable future. This will have to change.

Shapes of the Information Age

To get a feel for the Information Age, let us first look at its raw power. In the next 15 years, a combination of the expansion in usable bandwidth and advances in digital signal compression will increase the transmission capacity of bits by 5–6 orders of magnitude. When those bits reach us, the electronics at our fingertips will be able to process them about 1000 times faster. That means our power to access and use information will expand by 100 million to a

billion times in the next 15 years, or about 10 times every two years.

That is not all. What will truly transform our lives will actually be the so-called connection power. We have right now about 200 million computers that are connected together through the Internet and other networks at a rapid pace. By 2005 there will be 500 million of them. Mathematicians long ago proved that the intelligence of a network is proportional to the square of the number of its constituent members. That still is not all. Non-computer chips, which are already permeating all kinds of products and equipment, totaling six billion today and growing faster than computer processors, are also being increasingly interconnected through wired or wireless means.

Sustainability Promises of the Information Age

What would the Information Age bring to our dematerialization versus growth race? Could it be the force that finally reverses dematerialization's long-running losing battle with growth? Or could it push growth so much harder that, in spite of all information technology's ample dematerialization attributes, our race towards sustainability would actually get worse at a faster pace?

We will look at the positives first. Indeed, it has been said that the only way to dematerialize is to chip away the material contents of Industrial Age economic activities through cleaner production. Can't growth happen with little or no material dependency? Yes it can, in the Information Age. Information-based economic activities are much less material intensive, and many of their fastest growing elements are virtually material-less. With information power growing the way it is, many things are possible and on time horizons much shorter than we think. Bits-for-atoms is not just the foundation to our emerging network economy, it is also where our brightest hope for a breakthrough to sustainability lies.

To explore the potential of this bits for atoms shift in our growth, let us compare the material intensity of the Industrial Age to that of the Information Age. Table 1 shows the energy consumption share and gross domestic product (GDP) share of Taiwan's heavily material dependent industries. For a total consumption of 34% of Taiwan's energy, these industries contributed less than 7% to its GDP. This should be compared with Taiwan's present information industry. Data from the Hsinchu Science Park, the so-called Silicon Valley of Taiwan, will be used as a case in point. Studies show that its energy intensity was approximately one-eighth of the all-industry average, and its water use intensity was even smaller – in the order of one-fiftieth. Compared to its Industrial Age counterparts, information age growth is essentially material-less.

How important would bits-for-atoms be in our sustainability battles? If the bits-for-atoms transition in growth doesn't happen, then our only weapon would be cleaner production (in the broad UN sense). If future growth is 3% a year, then cleaner production would have to deliver 3% dematerialization a year to make the sustainability balance. That's a 20 times improvement in 100 years, 400 times in 200 years. Can cleaner production keep delivering these kinds of improvements? No. The cleaner you become, the tougher and costlier it is to become even cleaner. Sooner or later, cleaner production plateaus and further improvements would essentially run out. How soon we would come to this kind of dead-end depends on how fast we dematerialize. If we continue on our business-as-usual mode, we would never even know that we have this dead-end problem. Even if we dematerialize at close to the current rate of growth, we will run into this dead-end, perhaps in the next 30–50 years. Bits-for-atoms must build up a head of steam by then because it will be the only solution left.

Sustainability Pitfalls in the Information Age

While full of promise, the Information Age's beneficial effects on moving towards sustainable development are by no means a sure thing. Far from it, as a matter of fact. We are already quite a number of years into the Information Age and the bits-for-atoms shift has not even made a dent on the material content of our growth. If there is one thing that the rapidly advancing Information Age technologies will be sure to bring, it is not dematerialization, but

Table 1 Profiles of heavily material-dependent industries in Taiwan

	Energy consumption		Production	
	Amount (10^6 KLOE)	Share in national energy consumption (%)	Total sales (1991 $\$10^6$)	Share in GDP (%)
1977	0.77	36.9	–	–
1982	1.04	36.2	4618	6.5
1987	1.55	36.4	7885	7.1
1992	2.03	34.6	10 308	6.5
1997	2.72	34.7	14 330	6.7

GDP, gross domestic product.

increases in our productivity, and therefore greater acceleration in growth. Quoting *Wired* (July 1997), the so-called magazine of the networked world:

> Historians will look back on our era as an extraordinary moment. They will chronicle the 40 years from 1980 to 2020 as the key years of a remarkable transformation. In the developed countries of the West, new technologies will lead to big productivity increases that will cause high economic growth. And then the relentless process of globalization, the opening up of national economies and the integration of markets, will drive the growth through much of the rest of the world.

This may be nirvana for business executives but nightmares for implementers of sustainable development. Epochal technological advances are pushing the developed countries of the world onto new S curves, giving them the impetus for faster growth heretofore unrealizable for these mature economies. That is not even the most troublesome part. With explosive communications, technologies driving the globalization of not only knowledge but also ideas, economic democracy and free-market entrepreneurship will ourish in the Third World, unleashing many new Taiwanese and Koreans into the newly industrialized ranks. Two countries on the move are China and India, the first and second most populous states on Earth each with quality technical capabilities, low cost labor supply and large domestic markets, to create and sustain comparative advantages and robust economic performances for years to come. If we think growth is bringing too much pressure to our ecosystems now, we have to think again. All signs are pointing to faster growth, and therefore greater dematerialization challenges.

Indeed, in all likelihood our sustainability aspirations will suffer the bad side of the Information Age, before it will see the good side. Have we seen any signs that growth is less material-dependent or that dematerialization is catching up with growth? Mankind seems to have this very nasty habit – whenever we are given something that is twice as efficient, we want to use it four times as often (some people call this the rebound effect). Esther Dyson talked about this behavior in her book *Release 2.0: a Design for Living in the Digital Age* (Dyson, 1997). For her, advances in communication technologies didn't reduce her travel at all; she is actually traveling a lot more because she can now manage her office from the road!

Would information power be so potent that it will, for the first time, make growth so scarcely material-dependent that it overcomes the rebound effect and begins to promote dematerialization faster than it does growth, until finally it erases our dematerialization deficits? Or would it just push growth so hard that all of our best dematerialization efforts would be futile? That is almost the most crucial question in the sustainable development issue, and the Information Age.

CONSERVATION AND INCENTIVES

Whichever Age we are in, Industrial or Information, conservation will have to be a central and lasting part in our dematerialization struggles. The 1% extra dematerialization rates for energy during the energy crisis years (Figure 3) were largely the result of redoubled conservation efforts. Water conservation in the Los Angeles Basin has held today's consumption at the level of 30 years ago. Many metals are now recycled at very high rates (copper more than 90%, aluminum and lead over 80%, zinc 60%) that have prolonged the use of reserves, kept prices level and netted substantial returns.

Three things are important to understand about conservation.

1. enlightenment and behavior changes only play a small part. Easy options can only do so much. People who want to reduce wastes or improve efficiencies often discover that things are not as easy as they look and there are often substantial costs involved.
2. different conservation options cost different amounts. Large early gains are possible through exploitation of the easy and inexpensive options but the same rates of improvement cannot be kept up. For that to happen, costs typically would have to increase and there needs to be further and continuous technological innovations.
3. economics is what drives conservation. If we don't get enough conservation, the way to get more is not through persuasion and education. It is by changing the economics.

Conservation is Big Money

Conservation is not the esthetic endeavor that most people subconsciously perceive it to be. It involves big money. A 1% increase, for the US, on top of its present energy efficiency improvement rates, for example, would result in savings greater than a trillion dollars over the next 20 years (savings from dematerialization are compounded). This kind of money, however, doesn't grow on trees. Making it happen would entail upfront investment on the order of hundreds of billions of dollars by American corporations and citizens. That money is just for energy, only one percentage point of it. That's the kind of money involved when we talk about dematerialization and sustainable development.

Why are Incentives Needed?

Do people fork over this kind of money for the love of their neighbors? Most certainly not. Somebody would have to make it worth their while.

It is fashionable in sustainable development discussions nowadays to talk about the many technologies we have at our disposal that could not only cut deeply into our

material intensity but also earn us a nice profit doing it. One wishes that things were so simple. The fact is, yes, we will indeed earn a profit with these technologies. However, the majority of energy efficiency technologies actually have lower lifetime costs than their less efficient counterparts, but many of them never make it to the market because, as investment options, they don't measure up. There are two main reasons. One, their rates of return, or payback periods, are not good enough to compete with other investment options. Secondly, besides saving money they don't really do much else, like strengthening their potential investors' competitive positions or enhancing their core competencies.

What would it take to make people invest in efficiency and dematerialization technologies that do not compete favorably with other investment options? Two things. One is *command and control* (*see* International Environmental Law, Volume 5), such as product efficiency standards. The other is *incentives*. The best approaches would be those that combine the best attributes of each.

Incentives: Innovations Versus Brute Force

Command and control looks convenient. We pass a certain regulation or adopt a certain standard and the job is more or less done. In reality though, it takes considerable persuading for industry to accept new more stringent product efficiency standards, for example; and three years later new standards will again have to be negotiated upwards to keep efficiency gains rising. The result is that this kind of program often starts out well but soon runs into its own sustainability problems.

When people think of *incentives*, they typically think about taxes, fees and charges, which are put in place to change people's behavior. Their benefits are two. One, they discourage people from doing certain things because the costs are too high. Secondly, they give additional investment incentives because the materials or energy saved now cost more. Many economists believe that anything can be corrected if we get the prices right.

But, if this is so, why is it that there are still so many inefficiencies uncorrected? The reason is that, more often than not, price fixing is neither the most cost-effective nor the most efficient solution. Furthermore, new taxes, fees or price hikes often have only one-time effects. After a while we will have to raise them further if we want the improvements to continue. That could become very unpopular.

Experience of the demand-side management programs run by the American utilities, the market-based programs of many water utilities, and many cases with permits and trading, has shown that there are many innovative approaches that give considerably better results than straight taxes, fees or charges. They are a lot more popular. The most direct incentives such as rebates, which reimburse cash right into the hands of people who have made efficiency investments, are often far more cost-effective than price fixing. The reason is simple. At any one time there would be only so many people contemplating making efficiency or dematerialization type investments. It is a lot cheaper to provide incentives only to these people rather than raising the prices for everybody. Lawrence Berkeley Laboratory's analysis showed that the differences were as large as seven or eight times.

We should remember that all incentives are not created equal, some are more cost-effective than others, and innovations are always preferred to brute force. Mixtures of command and control and incentives are often the best approach. We could, for example, adopt a standard that stipulates a lower efficiency for a product to be allowed into the market, but sweeten it by giving the best 20% of these products a 30% purchase rebate. Or, the government could offer certain monetary rewards and set minimum efficiency-gain targets to let businesses come up with the best and the most innovative ways to bid for them. The possibilities are endless. In the age of sustainable development, these kinds of programs would have to flourish to the maximum extent possible.

PUTTING A NUMBER ON THE NORTH/SOUTH ISSUE

The North/South issue is one of the most complex and politically charged issues in sustainable development. It boils down to this: how much extra responsibility should the North bear so that the South may be given enough room to grow. We have been for decades mired in international wrangling between North and South bureaucrats, and there is little daylight in sight. The debates have been conducted often without common grounds or even common metrics, which are prerequisites for meaningful negotiations.

Why can't we take a scientific approach to the whole thing? Can we put a number on how much extra should the North do? We can, in fact. We have just never tried. It would be impossible only if we want the answer to be quantitatively precise. But quantitatively meaningful answers are not difficult at all, as demonstrated as follows.

We will divide the world into two blocks – a North block representing economies that have *per capita* incomes above 10 000 US dollars, and a South block below it (Table 2). Both are growing now at approximately 3% a year.

The state of sustainability as defined by the dematerialization = growth requirement can then be expressed with the following equation:

$$\bullet 1 - S_0 \bullet [1 + g_1 - d_1]n + S_0[1 + g_2 - d_2]n = 1 \quad \bullet 1 \bullet$$

Here S stands for the South-block total GDP as a fraction of total global GDP. The North would thus be $(1 - S)$.

Table 2 North and South Characteristics. Data Source: Britannica Book of the Year, 1996

	North	South
Average Per Capita GDP (US$)	23 000	1000
Number of Countries	48	169
Total GDP (US$ billion)	19 326	4983
Population (million)	846	4823

g and d, respectively, stand for the average growth and dematerialization rates over the n year span. Subscript o stands for the base year (year 0). Subscripts 1 and 2 denote the North and the South, respectively. The equation expresses the assumption that world material consumption (expressed as the sum of North and South consumptions) stays constant for the next n years.

Solutions to this equation are shown in Figure 4. It can be seen that if the North were to dematerialize at 1% beyond its minimum requirement (3%), the South would gain approximately 2% of extra growth (or 2% of allowable dematerialization deficit). How much difference would this 2% allowable dematerialization deficit or growth surplus make? A big difference. From Figure 5, it can be seen that the South would be able to expand its 50-year growth

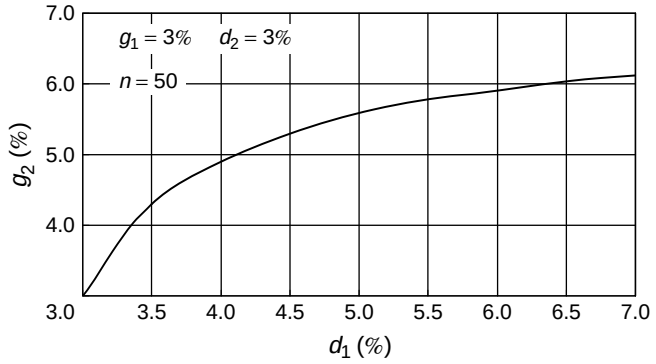

Figure 4 Sustainable South growth rates at various North dematerialization rates

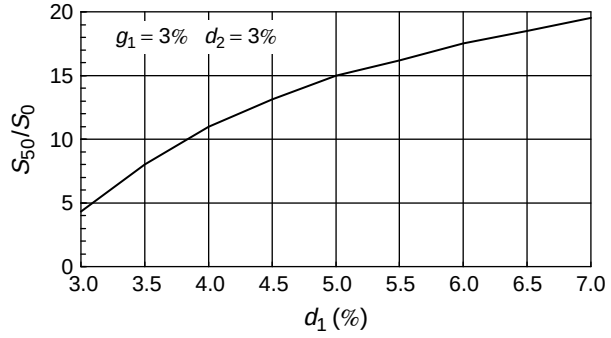

Figure 5 Sustainable 50-years South GDP expansions at various North dematerialization rates

from 4.4 times under the baseline scenario (minimum dematerialization by the North) to 11 times (1% extra dematerialization). This should be pretty close to or even greater than unrestrained growth. At this rate, North/South income disparity at the end of the 50-year period would be reduced from approximately 4 : 1 to 1.5 : 1. Human ills far beyond sustainability problems would be greatly relieved if this would actually occur.

Is it unrealistic for the South to dematerialize as fast as the North? Not necessarily. When the South starts to grow in any substantial way, it will shed its inefficient ways and, if governments do things right, build its growth on the newest and therefore the most dematerializing technologies from the North, while the North must wait out the depreciation of its own older technologies.

The demonstration given above, while simplified, should give us a quantitatively meaningful feel for the size of the North/South issue of sustainable development. Can we put a number on how much the North should give? Yes we can. The answer is 1% extra dematerialization beyond meeting its own minimum requirements.

HOW OUR SUSTAINABILITY BATTLES ARE WON: A SCENARIO

One day we may begin to take the implementation of sustainable development seriously, and start to put forth real efforts to balance growth with dematerialization. We will call it *day one*. Thirty years after day one, dematerialization rates will finally catch up with growth rates, and we will finally reach a sustainability balance. The balance will still be tenuous because neither of the two main driving forces for dematerialization – cleaner production and bits-for-atoms, is at a steady state. Cleaner production began quickly but slowed down, running into increasingly higher costs and diminishing returns. Bits-for-atoms started more slowly but began to accelerate as people's well-being is increasingly derived from virtual things. At the same time, as underdevelopment gradually disappears due to information-age stimulated globalization and development in the developing world, growth rates across the globe will slow down. One hundred years after day one, the contribution by cleaner production will have run out. But we are not worried. Bits-for-atoms has taken over completely. Growth is now slower and no longer material dependent. Dematerialization deficits are automatically erased. Sustainable development has been achieved.

Eco-efficiency

ROBERT U AYRES

Center for the Management of Environmental Resources, Fontainebleau, France

Eco-ef ciency is a business strategy that emerged in the 1990s, in response to general recognition that the end-of-pipe treatment approach, dominant in the 1970s and 1980s, is too limited. In particular, it cannot adequately deal with global threats, such as the accumulation of greenhouse gases in the atmosphere and acidi cation of soils. The eco-ef ciency strategy is, essentially, to radically increase the value-added to material/energy inputs, which is tantamount to reducing the inputs per unit of service provided to customers. Implementation of this strategy at the company level implies a systematic search for win-win opportunities, i.e., opportunities to reduce environmental emissions pro tably.

Undoubtedly there are many such opportunities waiting to be uncovered, and the search for them should be a high priority. However, it is unlikely that the major global environmental threats (such as climate warming and sea level rise) can or will be eliminated by the voluntary adoption of process changes that are pro table in the near term. For instance, the evidence is strong that major new technologies, such as solar power or wind power, could only be competitive with existing established energy technologies after a considerable investment in research and development and capital accumulation to achieve necessary economies of scale and learning. Such investments would not necessarily be pro table in comparison with other more conventional opportunities. The essential role of government, therefore, is to create the necessary incentives for the private sector to make the needed investments.

The article discusses alternative policy approaches, ranging from regulation by government agencies to taxation of emissions or taxes on resource consumption. More innovative approaches are getting attention now. One, which has theoretical economic bene ts, is the creation of tradeable emissions permits (now a part of the Kyoto protocol). Another possibility is the use of tradeable consumption permits. Meanwhile, the eco-ef cient strategy for the private sector can be reformulated as a systematic program aimed at moving away from the sale of products to the sale of services, thereby treating the products themselves as capital assets. This change in perspective has very real consequences in terms of product design, for instance. Some sectors of industry (notably chemicals) have voluntarily moved in the direction of acknowledging downstream responsibility for their products. Government policies encouraging recycling and take-back will encourage this trend. Organizational and engineering implications of these new approaches are discussed.

> Eco-efficiency is reached by the delivery of competitively priced goods and services that satisfy human needs and bring quality to life, while progressively reducing ecological impacts and resource intensity throughout the life cycle, to a level at least in line with the earth's estimated carrying capacity.

> WBCSD (1995)

INTRODUCTION: HISTORICAL BACKGROUND

The deteriorating state of the human environment began to achieve headline status in the late 1960s. *Earthday* in 1970 marked the creation of the Environmental Protection Agency (EPA) in the US and comparable agencies in other western countries. This was followed quickly by the publication of *Spaceship Earth* by René Dubos and Barbara Ward, and the United Nations Stockholm Conference in 1972. This resulted in the institutionalization of environmental concerns at the international level through the creation of an Environmental Directorate at the Organisation for Economic Co-operation and Development (OECD) and a new United Nations agency, the United Nations Environmental Program (UNEP). However, the initial approach to environmental protection at the practical level was largely limited to what has been termed end-of-pipe treatment of sewage, large-scale industrial polluters of air and water and motor vehicles. In the following decade the scope of government programs was expanded in various ways, to include solid wastes and especially toxic and hazardous wastes.

In the 1980s the limitations of this end-of-pipe treatment approach began to become clear, especially with regard to stratospheric ozone depletion, acidification and greenhouse warming. These problems are all attributable to emissions that are either excessively costly or impossible to remove from waste streams. The case of acidification is a partial exception, in that there is a realistic possibility of removing sulfur dioxide from the ue gases of large coal-burning power plants through ue-gas desulfurization (FGD) technology. However, this technology is quite expensive and energy intensive and cannot realistically be applied to small industrial boilers or households (which dominate coal consumption in China, for instance). The potential for treatment of NO_x in combustion products is quite limited, and NO_x emissions continue to increase, despite the introduction of catalytic post-combustion treatment technologies in power plants and some motor vehicles. The notion of removing and sequestering carbon dioxide from power plant ue gases has been given serious consideration (as a hypothetical alternative to other approaches to carbon dioxide reduction). However, the same objections apply; even if this were technically feasible for some large electric power plants, it would not be applicable to smaller combustion sources. The case of chloro uorocarbons (CFCs) is the most straightforward: to the extent that recycling was feasible, it was already being done for the most part. Emissions were mostly leaks, which are inevitable and cannot be recaptured.

In the early 1980s, these facts created widespread concern that economic growth in the developing countries seemed to be in con ict with the imperatives of environmental protection, especially to the extent that the latter might involve increased costs. The response at the international level was the creation by the UN General Assembly of the Commission on Environment and Development, chaired by the then Prime Minister of Norway, Gro Harlem Brundtland. The commission prepared a major report, Our Common Future (1987, *see* WCED (World Commission on Environment and Development), Volume 4), which tried to make the case that environmental protection is an essential element of economic development. In so doing, it offered a definition of sustainable development that was necessarily vague enough to achieve political consensus but which, consequently, provided little operational guidance. One obvious prerequisite of long-term sustainability, however, is the reduction of anthropogenic pressures on the environment. These pressures arise from the competition between human needs and desires for food, housing and living space and the needs of other species. Above all, they arise primarily from extraction and processing of natural resources and using the environment as a sink for the disposal of waste ef uents and garbojunk.

More recently, the notion of *sustainable consumption* has emerged, to re ect the recognition that consumption of physical materials and energy derived from non-renewable fuels cannot exceed some finite limits imposed by the carrying capacity of the Earth. The biosphere can only absorb a limited amount of waste products (including, but not limited to carbon dioxide (CO_2)) associated with the extraction, processing and disposal of materials. There are many indications that the limits are not far away if, indeed, they have not already been exceeded.

It is now becoming clear that economic development in developing countries over the next half century at recent growth rates, combined with population growth that is already unavoidable, would require a five- to tenfold increase in the consumption of natural resources (Friends of the Earth, undated). This magnitude of increase may well be physically impossible, due to resource scarcities and capital constraints. It would certainly impose enormous stresses on the environment.

But even if such rapid gross national product (GNP) growth were feasible from an economic perspective, it would be inconsistent with ecological sustainability. For these reasons, a number of experts have proposed that the total worldwide consumption of materials (especially hydrocarbon fuels) should be stabilized. But allowing for inevitable global population growth, which will certainly increase by more than 60% in the next 50 years, and allowing for economic growth in the non-industrialized countries, especially China and South Asia, stabilization at the global level can only be achieved by sharp *reductions* in the consumption of materials in the industrialized West. Von Weizsacker *et al.* (1994, 1998) suggest a reduction factor of four. Others suggest the need for an even more dramatic tenfold reduction (Factor Ten Club, 1994). Whether the appropriate divisor is four or ten does not matter so much as the fact that any reduction at all means a major U-turn in economic development strategy (Ayres, 1996; Ayres and Weaver, 1998).

Bearing in mind these, and other problems, a new bottom-up way of thinking about emissions reduction also began to emerge in the 1980s. It has been variously called source reduction, waste reduction, clean technology, low-waste (or non-waste) technology, design-for-environment (DFE), dematerialization, industrial ecology and eco-efficiency. There are minor differences among these approaches. For instance, waste reduction emphasizes energy conservation and materials utilization efficiency. Clean technology emphasizes technical change that reduces emissions at the source, such as the classic example of substituting water soluble paints and cleaning agents for coatings and cleaning agents requiring volatile hydrocarbons or chlorocarbons. DFE emphasizes the potential for reducing wastes by making products more repairable, more remanufacturable or more recyclable. Industrial ecology emphasizes the potential for recycling wastes from one industry as feedstocks to another, as biological organisms recycle nutrients. (Oxygen is a waste product of photosynthesis,

while carbon dioxide is a waste product of animal and plant respiration.)

THE ECO-EFFICIENCY STRATEGY

The term eco-efficiency was first used in the book *Changing Course*, an input to the Earth Summit conference of the UN Commission for Environment and Development (UNCED) held in Rio de Janeiro, June 1992 (Schmidheiny, 1992). Some of the early works including the underlying ideas of eco-efficiency are given in Smart (1992) and Fussler and James (1996).

All of the bottom-up approaches summarized above share a common focus on process-change to reduce emissions at the source rather than to remove or treat them later on. Eco-efficiency can be regarded as an umbrella that subsumes all of the others. But it differs from the others in that it is being developed and promoted by a business group – the World Business Council for Sustainable Development (WBCSD) (*see* WBCSD (World Business Council for Sustainable Development), Volume 4) – as a strategy for business. Whereas the other approaches are typically defined by an outcome, eco-efficiency is a concept more firmly based on a business perspective. The basic approach, slightly simplified, is to increase the value-added to customers per unit of materials/energy input.

Eco-efficiency suggests the objective of maximizing value added per unit resource input. This idea is essentially equivalent to maximizing resource productivity at the company level (taking into account scarce environmental resources as well as energy and raw materials), rather than simply minimizing wastes or pollution associated with a given product.

From a management standpoint, there seem to be four key elements. They have been identified as follows (WBCSD, 1995):

1. providing real services based on the customer's needs;
2. assuring economic viability for the company;
3. adopting a systems (life-cycle) viewpoint with respect to both processes and products;
4. recognizing, at the company's policy level, that the environment is finite, that the carrying capacity of the Earth is limited, and that the company bears some responsibility regarding the environment.

The first two elements have always been, and remain, firmly in the domain of corporate management. However, with regard to elements 3 and 4, adopting a life-cycle viewpoint and recognizing that the earth has limited carrying capacity may not be enough to ensure that a company's actions are consistent with the imperatives of global sustainability.

It is possible to estimate the effect if all people worldwide were to buy or use a given product. Consider, for example, that nearly everybody wants to own a car. What are the implications for highway construction, loss of valuable farmland, petroleum consumption, air pollution, etc.? Such calculations, and questions, are essential aspects of the life cycle perspective. But they offer little or no guidance as to how an individual company should behave. This is because the carrying capacity is characteristic of the system (i.e., the Earth and the biosphere) as a whole. In short, it would seem that long-term sustainability for the Earth system is not a manageable criterion for an individual product or a company.

Proponents of eco-efficiency argue that there are many win-win opportunities for value creation that are also environmentally friendly. Some firms have introduced slogans expressing this idea, such as PPP for Pollution Prevention Pays (3-M Corp.) and WRAP for Waste Reduction Always Pays (Dow Chemical Co.). Unfortunately, these slogans cannot be taken too literally. The thrust of eco-efficiency is to actively search for, and create, such opportunities. However, most economists are quite skeptical about claims of win-win possibilities, at least at the level of process change. In the view of many experts, pollution prevention and waste reduction are more likely to be costly than profitable. There is evidence from the experience of end-of-pipe treatment to support this skeptical view.

If the global carrying-capacity criterion is beyond the control of firms operating in a competitive market, what then? One theoretical possibility would be regulation, at the global level, of total materials and energy consumption and waste output. Regulation could be accomplished in either of two ways. The first might be termed command and control, implying an authoritarian central bureaucracy to allocate production, akin to the central planning agency of a communist country. This approach would be the ultimate nightmare for most businessmen. It would certainly be politically unacceptable in today's world.

The second approach would be favored by most economists on theoretical grounds, in any case. It would be to internalize the social and environmental costs of excessive materials production and consumption by imposing taxes or ef uent charges. The notion of internalizing can be understood in the context of economic theory as eliminating externalities, or external costs, which are costs to a third party, not directly involved in a buy-sell transaction. Pollution, noise, congestion, and so on, are all externalities, in that they are costs that have to be borne by people who had no part in (and no gain from) the economic activities and transactions that caused the problem. Generally, such costs should be charged to those who caused them. This idea is sometimes expressed as the *polluter pay principle* (*see* PPP (Polluter Pay Principle), Volume 4). In the case of pollution, it is generally optimal for the cost to be charged to the party that has the greatest potential for eliminating the pollution through process or product redesign,

namely the manufacturer. In principle this could be done by imposing a tax equal to the social cost of pollution, and using the revenues to compensate those who suffer damage (Goulder, 1995). The tax would raise the cost of materials and/or energy consumption, discouraging trivial and low-value uses, and encouraging conservation. Tax revenues would then be used (in principle) to pay for pollution abatement or remediation, or to compensate those who suffer damage. The controversial carbon tax is an example of such a proposal.

Unfortunately, while this neat solution might work in some cases, it has drawbacks. One is that the social and environmental costs in question are impossible to calculate accurately. Some would inevitably be penalized too much and others too little. Moreover, experience suggests that a special-purpose tax collected by government is unlikely to be used as the theory requires (i.e., to abate the pollution or compensate those who are harmed by it). It is far more likely that the tax would be lumped in with general revenues and re-allocated to other purposes favored by law makers and their constituents. Also, the administration and enforcement of such a tax would itself be costly.

Another possible solution involving less governmental (i.e., bureaucratic) intervention is the adoption of *tradable emissions permits* (*see* Tradable Permits for Greenhouse Gases, Volume 4; Tradable Permits for Limiting Stratospheric Ozone Depletion, Volume 4; Tradable Permits for Sulfur Emission Reductions, Volume 4). This avoids the need for centralized global administration, but introduces other problems. In the case of carbon emissions from fossil fuels, at least, this approach is being seriously considered at the international level. But, as the 1997 Kyoto Conference revealed, to obtain a binding and enforceable agreement among a hundred or more sovereign nations, each concerned with protecting or advancing its national interests, is a very difficult challenge.

An alternative to taxes or tradeable emissions permits would be *tradeable consumption quotas*. This follows directly from the notion of sustainable consumption mentioned above. At the international level it would be no more difficult, and possibly easier, to negotiate than tradeable permits. One virtue would be that it would force the public to recognize that consumption – in the case of fossil fuels, at least – is essentially equivalent to pollution. To reduce the latter it is necessary to limit the former. Moreover, since the quotas could be allocated to individuals and traded directly through computerized markets, government intervention would be limited to determination of the quotas, and supervision of the allocation and trading system. The sellers of surplus quotas (underconsumers) would receive the income and spend it as they like. Buyers (including all industrial users) would simply pay the market price (Ayres, 1998). For them the effect would be similar to that of a carbon tax, except that the money would go directly to consumers rather than to a government agency.

A consistent business strategy can achieve the desired result without either excessive regulation or excessive use of fiscal mechanisms. Many businesses could voluntarily adopt the strategy of internalizing the product or, more simply, selling service instead of products. Since material wastes and environmental pollution are directly attributable to the production and consumption of material products, the only way to reduce wastes emissions in the long run is to reduce throughputs.

Hence, regardless of the choice of government policy instruments, whether regulatory or fiscal, the ultimate goal of an eco-efficiency strategy for companies must be to sell only the immaterial service content embodied in durable goods, retaining ownership and responsibility for the goods themselves. The effect, in the long run, would be to eliminate most durable goods, from cars to refrigerators, from the consumer market – along with consumer goods normally required for operation and maintenance, such as fuel, lubricants and antifreeze. It would also ensure a much higher degree of re-use, renovation, remanufacturing and recycling. This combined strategy would result in a gradual, but ultimately radical, *dematerialization* of the economy. Consumer goods, such as food products, cosmetics, pharmaceuticals, household cleaners, and so on do not embody enormous amounts of materials, except as packaging. The problem of reducing excessive use of packaging materials can be dealt with in other ways (*see* Dematerialization and Sustainable Development, Volume 4).

ECONOMIC/ORGANIZATIONAL PERSPECTIVE

Can radical dematerialization be accomplished without sacrificing economic growth and prosperity? This is a contentious but essential question. As already noted, mainstream economists are generally skeptical. A macroeconomic perspective can help to clarify the issues here. Until the late 1960s economists were inclined to conceptualize economic activity as a closed loop between production, consumption and investment, all measured in monetary terms. The connection with real material objects and the physical world from which materials are extracted, processed, made into products and finally disposed of as wastes, was never considered to be an essential aspect of economics until 30 years ago (Ayres and Kneese, 1969). Even now, these links are ignored in the great majority of economics textbooks and research papers.

However, the material aspects are vitally important to any consideration of long-term sustainability: human activity now competes with natural processes in terms of materials fluxes, especially with regard to the most toxic metals and the most environmentally harmful substances. Most

environmental problems are attributable either to land-use changes or materials consumption. It is true that emissions of wastes and pollutants are the most obvious problem. But it is also true that inputs become outputs. Every raw material extracted from the environment is a potential waste, and most become actual wastes within a few months. Only a small fraction is incorporated into durable goods, and very few durables survive more than a few decades.

The problem is mechanisms: economic growth in the past two centuries can be attributed largely to two growth engines. The first and most important was and is the dramatic decline in raw material prices, especially fossil fuel prices, beginning with the first industrial uses of coal and steam power in 18th century Britain. The availability of steam power facilitated the mining and transportation of coal, and eventually the generation of electricity and finally the production of all other goods and services. The process continued with the discovery and exploitation of petroleum and natural gas. The effect has been a long-term decline in the cost of mechanical power (i.e., work) delivered to the point of use. This, in turn, has permitted the substitution of machinery for human and animal labor and an enormous increase in output.

The second of the two growth engines has been *returns to scale*, which makes products cheaper to make as demand increases. In both cases the impetus to economic growth arises from the fact that demand for a product tends to increase as (real) prices fall. This phenomenon is called the *price elasticity of demand*. Falling consumer prices, as noted above, result from increasing use of fossil energy and mechanical power and exploiting economies of scale in manufacturing. The two cycles together are illustrated in Figure 1.

But the problem is that both drivers of growth are inherently materials intensive. The first depends on increasing the overall use of input materials (fuels) to replace labor. The second depends on increasing output of manufactured goods to achieve economies of scale. Thus the only way to reduce the materials intensity of the economic system – it would seem – is to lose the benefits of the two fundamental growth mechanisms or break the link to materials consumption. In the case of the first growth engine – declining energy/power costs – dematerialization requires development of other non-polluting sources of power, especially the sun, without reversing the downward cost trend. Perhaps this is technically feasible (despite many difficulties).

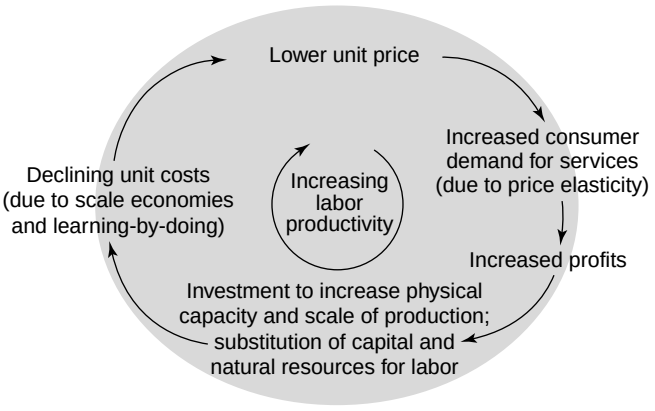

Figure 1 Old growth cycle (Salter cycle)

To enjoy continuing declines in consumer prices without depending on mass production and its associated economies of scale is less straightforward, if only because it is not really a technological problem, although information technology can probably play an important role. As already mentioned, the critical transition requires converting firms from a product orientation to a service orientation. This is fairly easy in some cases; it might simply mean renting or leasing capital goods and taking them back for remanufacturing on a scheduled basis rather than selling them. For consumer durables, however, the problem is much more complex. At bottom, it implies a change in the incentive structure of the competitive free-market system itself.

All durable goods in the service-based economy of the future would ideally be owned and maintained by service providers. In fact, they should be regarded as productive assets, to be used as efficiently as possible and conserved as long as possible. This means a change in the growth mechanism. One of the apparent advantages of an economy based on services is that it is inherently more labor-intensive than the mass-production manufacturing and throw-away economy. Repair, renovation, disassembly and remanufacturing are inherently more labor-intensive than original equipment manufacturing (Stahel and Reday-Mulvey, 1981; Stahel, 1994). These activities are much less able to exploit economies of scale or learning-by-doing precisely because they are less repetitive and standardized. For workers, however, they will be more interesting and will require higher levels of skill.

But what seems at first like an advantage in terms of job creation (especially from a European perspective) is a disadvantage from the perspective of labor productivity. The growth mechanism that depends on economies of scale to reduce prices and increase demand would operate in reverse: more labor per unit output means higher unit costs and that means falling demand. A fundamentally different economic mechanism is needed to reduce service costs as such. The likely mechanism for cost reduction in the service sector is *information technology* (IT). The other, and increasingly important, mechanism for cost-reduction is research and development applied to add value to services. Taken together these can be described as the new growth cycle (Figure 2).

Figure 3 shows schematically the limits of eco-efficiency as applied to the manufacturing economy, *vis-à-vis* the

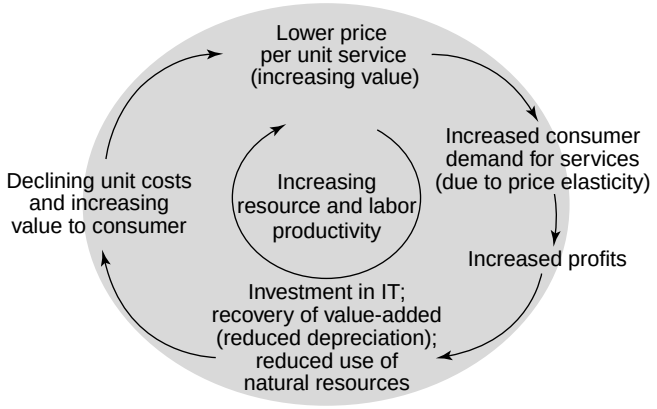

Figure 2 New growth cycle

service economy. It is convenient and evocative to label the latter as the spaceship – or zero-emissions – economy, in as much as it is an economy in which all materials must be recovered, repaired, re-used, remanufactured or as a last resort recycled sooner or later. In the spaceship economy nothing can be wasted without penalty.

ENGINEERING PERSPECTIVE: TO CLOSE THE MATERIALS CYCLE

Having considered the problem from a high-level economics perspective, it is now appropriate to consider the technical possibilities for approaching the goal of zero emissions. From an engineering point of view there are, essentially, three types of technologies to reduce wastes and emissions. These are:

1. energy and materials conservation;
2. product life extension: re-use, repair, renovation, remanufacturing, recycling;
3. waste mining: conversion of wastes into useful products.

All of these strategies are implicitly subsumed under the eco-efficiency umbrella. Note that waste treatment (at the end of the pipe) is not included, for the simple reason that waste treatment does not actually reduce the volume or mass of wastes, except in the rare cases where it creates a potentially useful product. One example is the use of FGD waste, which consists largely of calcium sulfate, as a substitute for primary gypsum in the manufacture of plaster wallboard. This is currently being done in Kalundborg, Denmark, where FGD waste from the ASNAES power plant is used as feedstock for the GYPROC wallboard plant (Ayres and Ayres, 1996). In that case it fits under the third category (waste mining). Otherwise, waste treatment simply shifts the waste from one environmental sink – air or water – to another (e.g., land). In too many cases, waste treatment has removed an emission from the air only to leave it in water, or vice versa. The substitution of aqueous cleaning agents for hydrocarbon or chlorocarbon solvents is an example of the first. The incineration of water treatment or sewage sludges is an example of the second. Incineration converts solid wastes into airborne wastes, usually to save landfill space. This sort of transfer is seldom desirable in the long run.

The first major category of emission reduction technologies generally includes efficiency improvements and process changes (source reduction, clean technology, etc.). Conventional energy-saving technologies, such as

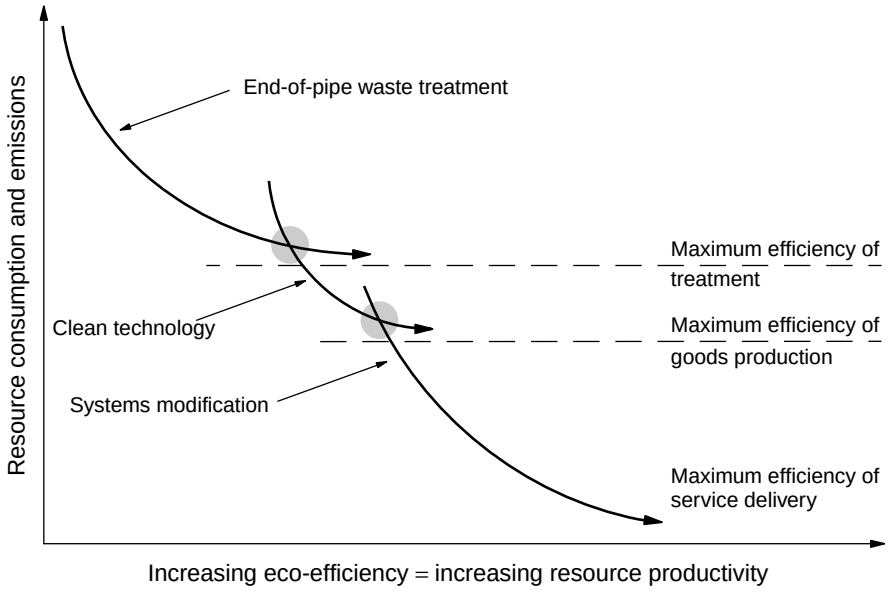

Figure 3 Three stages of eco-efficiency

co-generation, improved insulation, compact fluorescent lights, microwave ovens, smaller lighter vehicles, and so on, fall into this category. The same is true of a variety of industrial process innovations and material substitutions.

The second approach to reducing emissions is to extend product life by some combination of re-use, repair and renovation, remanufacturing and recycling. Re-use is very common among certain categories of consumer goods, such as clothing, shoes, blankets, books and furniture. Much of this is informal (e.g., clothing for refugees collected by churches), but there are fairly well-developed secondary markets for some categories of goods, such as books, bicycles, personal computers and automobiles; these items are frequently sold by departing students to incoming students at universities, for instance. Computerized bulletin boards within major institutions facilitate resale and re-use, and some of these information exchanges are reaching wider audiences through the Internet.

There is a major opportunity for increasing re-use in the area of shipping containers. Transport packaging – mainly consisting of corrugated paperboard boxes and wooden pallets – accounts for 16% of the US municipal waste stream. Re-usable packaging has long been standard for milk producers and soft drink bottlers, as well as some breweries. But in other cases, it is still relatively rare. Reusable packaging is technically feasible in virtually all cases. In fact, it offers a number of quantifiable environmental and economic benefits apart from waste prevention, including resource conservation and lower unit costs (Saphire, 1994).

Renovation and remanufacturing are options applicable mainly to capital goods and consumer durables. Truck and aircraft engines have been routinely remanufactured for a long time. The concept is closely related to a more recent concept of design for environment, which is now subsumed in the broader concept of *industrial ecology* (*see* Industrial and Anthroposystem Metabolism, Volume 3). But the fundamental point is that products that are designed with remanufacturing in mind will be designed differently than products designed for once-through consumption and disposal. They will, for instance, be designed for longer life and easier disassembly (Stahel, 1982, 1994; Navinchandra, 1991; Frosch and Gallopoulos, 1989). Firms that have begun to convert themselves from durable goods manufacturers to service companies include Xerox (copiers), Pitney-Bowes (postage meters), IBM, and a variety of others in businesses as diverse as elevators, furnace linings, truck tires and office carpets (Ayres *et al.*, 1997; Ferrer, 1997; Ayres, 1998).

Recycling of materials is also an important part of an integrated system; the technologies and economic factors are well described elsewhere in this encyclopedia.

The third way to reduce waste emissions is to convert them into useful products. This is a core idea of industrial ecology. Consider the famous Danish town of Kalundborg, where the idea was first implemented in practice (Frosch and Gallopoulos, 1989; Ehrenfeld and Gertler, 1997). The town has three primary producers: a petroleum refinery (Statoil), a coal fired electric power plant (ASNAES), and a large pharmaceutical and enzyme manufacturer (Novo Nordisk). By integrating these activities, it has been possible to reduce wastes dramatically while increasing value added. Thus the power plant supplies waste heat to the pharmaceutical plant, as well as serving a fish farm and a greenhouse. It also produces fly ash that is sold to a cement manufacturer and synthetic gypsum (calcium sulfate) from its FGD facility, to a wallboard manufacturer. The refinery supplies waste hydrocarbons as supplementary fuel to the power plant, and sulfur from its desulfurization process to a chemical company that makes sulfuric acid. Finally, the pharmaceutical manufacturer generates organic wastes that are consumed by the fish or used as fertilizer in the greenhouse.

Other potential opportunities to utilize industrial process wastes can be identified (Ayres and Ayres, 1996). For instance, phosphate rock processing (to produce fertilizer) yields a form of synthetic gypsum as well as by-product fluorides that can replace mined fluorspar for manufacturing synthetic cryolite (for the aluminum industry), or fluorides used in toothpaste. Coal burning power plants generate large amounts of fly ash and bottom ash, that can be utilized as an additive to Portland cement or, as a substitute for bauxite as a source of alumina.

Agriculture and agro-industry also offer opportunities for integration and synergy. Agro-industrial operations that utilize organic wastes on a large scale are both technically and economically feasible in some cases. Such wastes are available on an industrial scale in tropical plantations, sugar refineries, oil mills, breweries, pulp/paper mills, meat processing, dairy processing, and so on. In some cases, the integration process began long ago and is already virtually complete. For instance, large-scale meat processing in the US and Europe generates very little true waste – except some water pollution – because economic uses have been found for virtually every part of the animal, including hides, hair, bones, hooves, blood and even glands. The same is largely true of cane sugar, grain and oilseed milling in industrialized countries. Sugarcane waste (bagasse) and sugar beet processing wastes are underutilized.

However, smaller scale food and fiber processing activities, especially in the tropics, still generate a surprising amount of potentially utilizable organic waste. Paddy husk (from rice) can be used in paper-making, as a fuel for mushroom culture. Its potential value is said to be greater than that of the rice itself. R A Wickramasinghe of the Central Environmental Authority of Sri Lanka has compiled an astonishing list of potential uses of different parts of the coconut palm, ranging from the major commercial use as oil (for margarine, soap and candles) to activated

charcoal, wood, roof thatch, rope, brooms, vinegar, sugar, arrack, fodder, vitamin supplements, wound dressings and even teeth cleaners. However, he points out that certain wastes, such as coir dust (from coconut fiber processing) have virtually unlimited life in storage, but no known uses. Four million tons of this material (which is 90% water) have accumulated in Sri Lanka alone. The items mentioned above all came from materials that were distributed at a workshop on the development of non-waste technologies in developing countries.

Several interesting possibilities for utilizing tropical wastes have been identified in the United Nations University Zero Emissions Research Initiative (UNU ZERI) program, making use of mushroom farming, fish farming or other secondary sources of food or feed (Pauli, 1994; UNU, 1995). For instance, a small beer brewery in Namibia is now successfully recycling its water and organic wastes into a series of potentially profitable secondary activities including mushroom growing and fish-farming, while simultaneously saving fresh water.

Wood pulp and paper production probably still constitute the biggest single source of industrial water pollution in the world, despite great improvements in recent years. The fundamental problem is that, for all types of paper except newsprint, roughly half of the organic substance of the wood, namely lignins and ligno-cellulosics, is essentially wasted. In the most efficient modern pulp and paper mills in Scandinavia and North America, these wastes are burned for energy recovery. But, given the high moisture content, relatively little net energy is actually recovered and all of the potential chemical building blocks in the material is lost.

One of the most interesting long-term possibilities, also identified in the UNU ZERI program, is the development of an innovative steam cracking technology for separating the cellulose fibers from pulpwood and simultaneously cracking the high molecular weight lignins and ligno-cellulosic compounds. Lignocellulose, in particular, can be cracked to yield cellulose (about 30%) hemicellulose and lignin. The latter can be utilized mainly as a binder for particle board. However, hemicellulose is a valuable feedstock. It can be hydrogenated to produce xylitol (a sweetener), hydrolyzed to carbohydrates (sugars) which can be converted to ethanol, or dehydrogenated to produce furfural, from which a number of herbicides and rubber chemicals are subsequently derivable. The Tigney process was originally developed in Canada, but much of the further development has been carried out in Estonia.

ORGANIZATIONAL PERSPECTIVE: FROM PRODUCTS TO SERVICES

While some of the above concepts are technologically feasible and potentially economically attractive, they do not seem to self organize themselves spontaneously. The Kalundborg case in Denmark, now approaching 30 years of age, remains unique (Frosch and Gallopoulos, 1989; Ehrenfeld and Gertler, 1997). The economic system, as now structured, does not seem to encourage the emergence of integrated industrial ecosystems except in very special cases. The explanation is open to dispute. Regulatory barriers are one of the problems. However, the most plausible explanation is that it is not possible to optimize at the system level without a long-term central planning and coordination authority at the same level (Ayres, 1996).

This planning and coordinating function might be accomplished most naturally by centralized ownership, i.e., vertical integration and top-down management of the whole system. But one should not rule out *a priori* the possibility of other modes of organization, such as the Japanese keiretsu, that would be effective. A very powerful marketing organization, a city or county, or even a non-profit foundation, might be able to provide this essential planning and coordination function, for example.

An even more interesting possibility might be for the public authorities to create an integrated local utility for each industrial park to provide electric power, process heat, space heat, water and waste disposal services within the complex. In the first place, such an integrated utility would automatically incorporate several internal synergies, such as the potential for co-producing heat and power, and the potential for reducing solid waste disposal costs and electric power generation costs by incineration. In the second place, such an enterprise would have a strong incentive to create a joint venture with a building materials group that could utilize y ash and FGD wastes to cement, concrete products and wallboard, much of which could be used on site. However, in its absence, the decentralized pure market system, such that each activity (firm) interacts with the others only by competitive buying and selling, is unlikely to achieve the desired degree of integration.

In short, the inability of a group of decentralized manufacturing firms to optimize the use of by-products and secondary resources, and thus to minimize overall waste and pollution, constitutes a kind of market failure. In any event, waste reduction through process change is only the tip of the iceberg. It presupposes no change in the mix of goods and services produced and consumed by the economy. However great the potential for waste reduction (and dematerialization) by process change alone, there must be much larger potentials at the system level.

However, it is necessary to begin at the product level. This implies extending the useful lives and increasing the recoverability of value from durable goods. It also implies reducing the dissipative uses of materials (including fuels). A firm that simply sells its products to others and retains no responsibility for subsequent maintenance or disposal has no incentive to facilitate longer life – quite

the contrary – and little incentive to reduce operating cost if that means significantly higher initial cost. In fact, a manufacturing firm has a clear economic incentive to minimize product life so as to encourage early replacement. (The automobile companies, in particular, have been accused in the past of adopting a deliberate policy of planned obsolescence (Galbraith, 1968)).

It follows that major opportunities to reduce waste by extending life, and reducing operating and maintenance costs require one of two things. Either there must be long-term responsibility on the part of the manufacturer itself, or there must be a service provider with enough economic clout to dictate design specifications. In either case, some version of vertical integration, by ownership or by contract, appears to be needed. This can be termed *product internalization*, to suggest the economic effect without using language that has other connotations. The important economic implication is that in a product-as-service regime, products are capital assets and must be treated as such. Dissipative uses will be discouraged naturally. Owners of such product assets will have every reason to preserve them, upgrade them and recover value from them. Thus, conservation of value added by manufacturing is another way of characterizing the new paradigm.

One of the major implications of internalization of durable goods by service providers would inevitably be a sharp increase in re-use, renovation, reconditioning, remanufacturing and recycling. Here again, one can foresee significant opportunities for double dividends, since a durable product that is designed for long life, efficient reconditioning and eventual remanufacturing can offer a much higher value per kilogram of embodied material over its useful life than a product designed for minimum initial cost.

For instance, if automobile engines were truly designed for remanufacturing, the most complicated mechanical parts, such as the crankshaft, camshaft and the engine block itself would be made of very hard and durable materials, but with easily replaceable wearing surfaces such as roller bearings, piston rings and cylinder linings. The remanufacturing process would consist of disassembly, washing, replacement of all wearing parts, including gaskets and valves, and re-assembly. This could be partly mechanized, depending on batch size, although it would definitely be more labor intensive than the original manufacturing process. However, such engines would last indefinitely.

Leasing of durable goods by the manufacturer is the most obvious, and possibly the most common way to achieve effective internalization. Many kinds of capital equipment, including aircraft, are already leased by specialized leasing firms. However, in most cases this is purely a financial arrangement to free up the buyer's working capital. The aircraft, computer or machinery leasing firms are simply financial intermediaries; they take no responsibility for either the operation or the maintenance of the equipment itself. These responsibilities remain with the end-user, not the manufacturer. Here the aircraft case is the best model, since airlines – service providers – handle their own maintenance, or use specialized subcontractors, and have a very strong in uence on airliner design.

The case of rental car firms is very different. Car rental firms do take responsibility for maintenance, but only for relatively new vehicles. Operating costs (fuel) are simply passed on to consumers. Rental cars are invariably sold through the second-hand market while still relatively new, normally after only one or two years. Car rental firms, in practice, are merely marketing arms for the automobile manufacturers (and are mostly owned by them). They have no in uence whatsoever on vehicle design. Insurers potentially have some in uence in this domain, but they rarely choose to exert it. (For example, insurers could do a great deal to in uence manufacturers to make straightforward design changes that would reduce the costs of car theft; up to now they have neglected to do so; instead, costs have simply been passed on to consumers.) Thus, car rental, as currently practiced, cannot be regarded as a significant step towards internalization. It would become so only if service providers were forced to compete to sell services directly (per trip or per passenger km traveled) and if final disposal responsibility remained with the original equipment manufacturer.

The issue of industry structure in a service-oriented society is also important. From the standpoint of maximizing service output (and revenue) per unit of materials and energy input, the optimum organizational structure would seem to be a vertically integrated company whose operations encompass the entire life cycle of the product, from cradle to grave. The structure of AT&T (prior to its forced breakup) was close to this. One subsidiary, Western Electric Co. designed and manufactured telephones and all the various kinds of switching and transmission equipment for all operating divisions of AT&T. The individual Bell companies handled all maintenance for subscribers, and owned all the phones. When any equipment was replaced, it was recycled (or remanufactured) as a matter of course. The breakup of the system opened the way for independent equipment manufacturers, but cut the links between design, manufacturing, maintenance and recycling. Now old phones and other telephone equipment are not recycled, but are mostly junked and sent to landfills.

The same sort of vertical integration once characterized the computer industry. In its heyday, IBM manufactured all the equipment, wrote software, leased the computers to its customers, did the maintenance under contract, and took back the old equipment when the next generation machines were available. It is only to be expected

that, despite the rapidity of technological obsolescence, some re-usable electromechanical parts and components were recovered and re-used in less demanding machines, such as card punchers, sorters, magnetic tape readers, drums and printers. Why not? The customers were paying for service, and the service was guaranteed by IBM. Xerox Corp. had a similar rental with take-back policy in the early days, which also eroded over the years. Now, a smaller proportion of the Xerox machines are leased, which has reduced the number of returned end-of-life machines to just one-half of those retired. These cases illustrate the trade-off between vertical integration and competition.

Monitoring in Support of Policy: an Adaptive Ecosystem Approach

JAMES J KAY[1], MICHELLE BOYLE[1], AND BRUCE POND[2]

[1] *University of Waterloo, Waterloo, Canada*
[2] *Ontario Ministry of Natural Resources, Peterborough, Canada*

*The development of a monitoring program is usually regarded as synonymous with generating indicators. This simplification reflects the belief that there exists a correct set of things to measure. Once these measures are discovered, there remains only the task of collecting the data and making the results available. Such a traditional approach permits monitoring programs to be developed that are disassociated from the context; that is, people and their concerns. Ungrounded initiatives can produce fragmented programs that are not effective and do not use resources efficiently. (For example an inventory of one Biosphere Reserve in which we were involved revealed over 60 separate and uncoordinated monitoring initiatives.) Or, their abstruse utility may cause them to fizzle out before they are even implemented (*see *Biosphere Reserves, Volume 2).*

These shortcomings occur despite the best intentions and conscientious work. The difficulty lies in the fact that normal science and available problem-solving tools are insufficient when dealing with complex systems. Issues of sustainability are persistently untidy and demand an examination of the wider ecological-economic system to resolve. Thus, conventional monitoring methods applied to sustainability tend to fail. New approaches and tools that incorporate complexity into monitoring programs are required.

A reframing of science, propelled by the need to unravel complexity, is emerging under the rubric of post-normal science (Funtowicz and Ravetz, 1993; Kay et al., *1999) (*see *Post-normal Science, Volume 5). In this article, we present a scheme where the activities of monitoring and assessment are treated as an integral component of an adaptive ecosystem approach to sustainability and health.*

In this ecosystem approach, governance, management and monitoring form a triad of activities that are carried out in the context of an issues framework of human concerns and an explicit conceptual model of the ecological-economic system. Taken together, the issues framework and the conceptual model focus the discussion of sustainability: the sustained health and integrity of the ecological-economic system. Governance, management and monitoring activities then inform decisions to resolve the necessary tradeoffs and continually chart a course to sustainability.

In most Western jurisdictions, the issues framework and conceptual model, which animate an ecosystem approach, take the form of policies and/or regulations, which are enacted as part of a legislative process. In this traditional mode, monitoring, as described in this article, is undertaken in support of policy. However, there are forms of virtual governance emerging which have no formal legislative powers and whose governance does not take the form of traditional policy. For example, United Nations Biosphere Reserves are often overseen by an informal and ad hoc assembly of concerned individuals and non-government organizations. Even though these individuals may have no legal power, they do act as stewards of the Reserves and in effect, manage them. Monitoring, as discussed herein, is meant to be in the service of such initiatives as well as the more traditional policy-based approaches to environmental and sustainability issues.

COMPLEX SYSTEMS THINKING, SETTING THE STAGE

A central challenge of successfully resolving the issues of sustainability for ecological-economic systems (see Figure 1) is learning to deal with complexity; that is, understanding situations in which dynamics are dominated by *self-organizing phenomena* (Kay *et al.*, 1999; Kay and Schneider, 1994; Schneider and Kay, 1994b). A theoretical basis for such an understanding is emerging and is referred

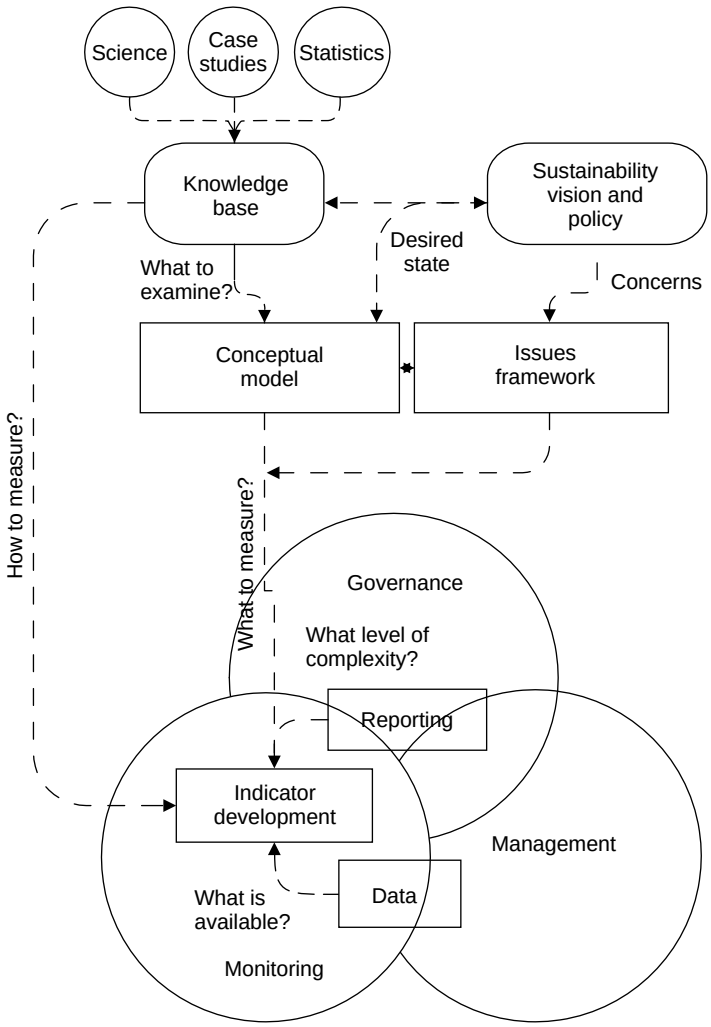

Figure 1 Monitoring in context; the arrows show an influence on indicator development

to as complex systems thinking (see Table 1). Its main elements are hierarchy and self-organization theory.

The hierarchical nature of complex systems requires that they be studied from different types of perspectives and at different scales. There is no one correct perspective. Rather, a diversity of perspectives is required for understanding. By their nature, such systems are self-organizing. This means that their dynamics are largely a function of positive and negative feedback loops. Linear, causal mechanical explanations of their dynamics are precluded. In addition, emergence and surprise are normal phenomena in systems dominated by feedback loops. Inherent uncertainty and limited predictability are inescapable consequences of these system phenomena.

Complex systems organize about *attractors*. Even when the environmental situation changes, the system's feedback loops tend to maintain its current state. However, when system change does occur, it tends to be very rapid and even catastrophic. Precisely when the change will occur, and to what state the system will change, are generally not predictable. In a given situation, there are often several possible system states (attractors) that are equivalent. Which state is currently occupied is a function of its history. There is not a correct state for the system, although there may be a state which is preferred by humans. This new understanding of complexity suggests a different role for science and monitoring in the quest for sustainability.

Hierarchy

There is growing comprehension that sustainability issues must always be examined within their broader context. Every system is a component of another system and is itself, made up of systems. So, a wetland must be understood in the context of the subwatershed it is a part of, and in terms of the processes and species, which make it up. The body of thinking which deals with these issues is called *Hierarchy Theory* (Ahl and Allen, 1996). Its central tenent

Table 1 Properties of *complex systems* to bear in mind when thinking about ecological-economic systems

Non-linear: behave as a whole, *a system*. Cannot be understood by simply decomposing into pieces, which are added or multiplied together
Hierarchical: are *holarchically nested*. The system is nested within a system and is made up of systems. Such nestings cannot be understood by focusing on one hierarchical level (holon) alone. Understanding comes from the multiple perspectives of different *types* and *scale*
Self-organizing (internal causality): are non-Newtonian, not a mechanism, but rather *self-organizing*. Characterized by: goals, positive and negative feedback, autocatalysis (self-reinforcing processes), emergent properties and surprise
Window of vitality: must have enough complexity but not too much. There is a range within which self-organization can occur. Complex systems strive for *optimum*, not minimum or maximum
Dynamically stable?: may not have equilibrium points (that is they may not exist for the system)
Multiple steady states: do not necessarily have a unique preferred system state in a given situation. *Multiple attractors* can be possible in a given situation and the current system state may be as much a function of historical accidents as anything else
Catastrophic behavior: experience sudden unpredictable behavior and state changes
Bifurcations: moments of unpredictable behavior when a system's development may proceed in either of two divergent directions
Flips: sudden discontinuities, rapid change
Holling four-box cycle: the ongoing process of birth, growth, death and renewal, e.g., the shifting steady state mosaic of a wildfire-driven forested landscape (Holling, 1986)
Chaotic behavior: have limited predictability. Our ability to forecast and predict is always bounded regardless of how sophisticated our computers are and how much information we have

is that sustainability issues can only be understood in terms of systems embedded in systems which are also embedded in systems or, in the vernacular of hierarchy theorists, as *nested holons*.

Hierarchy theory requires that a study of complex systems begin by careful consideration of the types of perspectives required and the appropriate scales of investigation. For example, the traditional ecological perspective, which dictates an approach based on studies of population dynamics of individual species, is not helpful in understanding fire dynamics in ecosystems. Rather, understanding of fire phenomena comes from studies of communities and landscapes over local and regional scales.

The researcher must take care to identify the human sustainability issues at hand and the appropriate perspectives and scales of investigation necessary to deal with these issues in an ecological-economic context. This identification process can only occur in the context of human values and requires bringing a diversity of views to bear on the question at hand.

To do otherwise is to court disaster. For example, research on ecosystems and sustainable food production in some areas of the upper Amazon watershed have historically centered on cattle production and its effects. A community-based hierarchical system analysis of the situation revealed the main food source to be fish with cattle playing an incidental role. Thus, community health and development initiatives focusing on beef production were sorely misplaced. Another example comes from an early Canadian environmental impact assessment that examined the effects of development on reproduction of caribou herds. Later, it was noted that the most serious effect of development was on the food source of the caribou, but this was not studied as part of the impact assessment. The study focus was on the reproductive habitat of a single species, and ignored the (much more relevant) broader food chain.

The challenge for science is to abandon the normal approach of searching for the single correct model for dealing with a problem. Instead, the message of hierarchy theory is that we must develop a manner of investigation that uses a diversity of different perspectives and models, which brings different players to the table, and which synthesizes the different perspectives together into understanding.

Self-organization and Attractors

Complex systems have multiple possible operating states or attractors, and may shift or diverge suddenly from any one of them (Holling, 1986; Kay, 1991; Ludwig *et al.*, 1997). For example, a portion of a natural area (A natural area is a section of countryside which has been set aside to be maintained in its natural state e.g., a national park or Biosphere Reserve) in Southern Canada is a closed soft maple swamp in a wetland community. However, the amount and duration of the ows of water can radically alter this operating state. Drying events, such as an extended drought, could change the operating state to an upland forest community or grassland with associated vegetation structure. If extended periods of ooding do occur, high water levels would shift the operating state to a marsh ecosystem. The shift happens because red and silver maple are tolerant to ooded conditions within 30–40% of the growing season. If ooding events are greater than this threshold, the forest trees die and give way to more water-tolerant herbaceous marsh

vegetation. The feedback mechanism, which maintains the swamp state is evapotranspiration (i.e., water pumping) by the trees. Too much water overwhelms the pumping capability of the trees and not enough shuts it down. The point of this example is that the current ecosystem state is a function of its physical environment and the accidents of its history. A single dry or wet season can change, for decades, what is on the landscape.

Each of the ecosystem states, in this example, is as ecologically healthy and appropriate as the others. There is not a right community for this landscape. Each is equally right. Thus, scientists cannot tell decision-makers or policy makers which of these states is ecologically better. Scientists can only provide information about the different tradeoffs each state represents. A decision regarding which of these states to promote is necessarily a value decision. In fact, since water ow is the key in uence which determines the organizational state of this portion of the natural area, decisions about which ecosystem state to promote hinge on what kind of land use and development is allowed on the lands adjacent to the natural area; clearly a political decision.

A similar example comes from the management of the same natural area (Lister and Kay, 2000). Currently, the aquatic ecosystem consists of a fast moving, highly oxygenated cold water stream in which brook trout thrive. However, another state, which is normally incompatible with the survival of brook trout, is emerging: a slow moving, low oxygen, warm water stream interrupted by ponds and small wetlands. In this case, beaver and muskrat are dominant species that shape and maintain the habitat and its constituent communities. The current ecosystem trajectory is tending towards this state due to several factors, including an invading population of beaver and purple loosestrife. The beaver dam the stream, thus providing more habitat for beaver; and the purple loosestrife choke out the other species in the wetland. Both factors slow the water ow, increase water temperature and decrease dissolved oxygen. The emergence of this attractor was a surprise to the local managers of the natural area. However, managers operating at the much larger scale of the drainage basin (of which this natural area is part) were not surprised, as they have followed the beaver migration into the area for years.

The group responsible for the natural area would like to maintain both the trout stream and the beaver and their ponds. However, this may not be feasible since the two ecosystem states are potentially mutually exclusive. A difficult choice may have to be made to favor one over the other. The irony is that ecosystem managers may have to trap beaver (Canada's national animal) and keep them out of the natural area in order to preserve a pristine state which will likely require intensive human management to maintain.

In making this choice, the values of various stakeholders and community members will play an essential role in the decision-making process. The role of the scientists will be to inform decision-makers about the ecological options, the tradeoffs and uncertainties involved, and various strategies for in uencing what happens on this landscape. However, scientists cannot inform us about the correct way to proceed, nor, can they predict with certainty what will happen in the situation. So, the role of science in decision-making for sustainability changes from problem solver (in the sense of providing a solution for the situation) to the role of facilitating understanding about the biophysical realities of the situation. In this manner, both experts and stakeholders contribute to the resolution of the situation.

Narratives

By their nature, ecological-economic system dynamics cannot be captured in a single model. Multiple descriptions are required to deal with complexity, and self-organizing phenomena cannot be explained in terms of a linear mechanistic causal description. Consider the case of shallow lakes, such as Lake Erie in North America. Two different attractors for shallow lakes have been identified (Carpenter and Cottingham, 1997; Kay and Regier, 1999; Regier and Kay, 1996; Scheffer, 1998). In the *benthic* state, the ecosystem is characterized by high water clarity and lake bottom vegetation. As nutrient loading increases the turbidity of the water, the ecosystem crosses a catastrophe threshold and ips into a hypertrophic, turbid, phytoplankton ecosystem, i.e., a *pelagic* state. Lakes exist that regularly ip between the two attractors. At least three quite different descriptions of such a lake will be needed, one for the pelagic state, one for the benthic, and one for the intermediate stage as the system ips between attractors.

The nature of these descriptions is also quite different. The description is in terms of the feedback loops that tend to maintain the ecosystem in its current state. Of particular importance are those feedback loops which buffer the system from changes in external in uences. In the case of Lake Erie, the benthic ecosystem has elaborate feedback schemes, operating at different spatial and temporal scales, to limit the phosphorous in the water column. The pelagic state has elaborate schemes to accomplish just the opposite. Describing the ip from one attractor to the other involves accounting for how environmental in uences (acting at different spatial and temporal scales) disable one feedback system while enabling another. Such a description takes the form of a multi-layer narrative which recounts the ecosystem's operation from different perspectives and scales (Kay and Regier, 1999; Kay *et al.*, 1999). While individual elements may consist of traditional scientific models and descriptions, synthesizing these elements together into a narrative transcends them to invoke a more complete picture of the system. Narratives are a cornerstone of the description of the dynamics of complex systems. They are also the

end product of monitoring programs undertaken as part of an adaptive ecosystem approach to sustainability and health.

Ecological-economic Systems as Self-organizing Holarchic Open (SOHO) Systems

Our premise is that resolving sustainability issues for ecological-economic systems entails understanding these systems as SOHO systems. Such an understanding comes from thinking through the hierarchical nature of these systems by considering issues of type and scale, and the bounding and nesting of the system. This hierarchical systems description of the important processes and structures, and their relationships and context, is essential. In addition, the self-organizing behaviors of the system need to be identified, described, and understood in so far as is possible. This involves identifying the attractors accessible to the system, the feedbacks which maintain the system at the attractors, the external in uences which define the context for a specific attractor, and conditions under which ips between attractors are likely. The overall understanding of system behavior that comes from studying aspects of a SOHO system is summarized in the form of a narrative. (A more detailed discussion of these notions can be found in Kay *et al.*, 1999.)

As mentioned above, a hierarchical system description requires identification of the important aspects of the system. What is deemed important can only be identified by examining the context of human values and human sustainability issues associated with the given situation. Therefore, in order to undertake a SOHO approach, the stakeholders and actors involved in the situation must participate. As well, their roles, issues, concerns and the aspirations that they bring to the situation must be understood. This understanding is summarized as an issues framework for the situation, which includes a vision for the future.

The process of identifying the important ecological and societal aspects of the system proceeds on the basis of the human issues framework and vision. Together, the SOHO system description and the issues framework are the starting point for an adaptive ecosystem approach to sustainability and health (Figure 2).

MONITORING AS PART OF AN ADAPTIVE ECOSYSTEM APPROACH TO A SUSTAINABLE SOCIETY

The complexity of resolving sustainability issues, necessitates a SOHO system approach. SOHO systems have the ability to decouple their behavior from environmental change, to generate novel behavior, and to self-organize in response to change (in a way that we cannot determine). These properties thus limit our capacity to predict how such situations will unfold. In principle, in many situations it will not be possible, or even appropriate, to make accurate quantitative models which forecast the future. It may be more useful to generate qualitative narratives of how the situation might unfold.

The premise of the traditional approach to management (anticipatory management) is that it is possible to predict and anticipate the consequences of decisions. Once all the necessary information is gathered to make a scientific forecast, the right decision can be made. This approach is not valid when dealing with complex systems, however. Given the limitations imposed by complexity, the focus of management and decision-making strategies must be on maintaining the capacity to adapt to changing environmental conditions. Adaptive management involves a very different agenda than anticipatory management (Gunderson *et al.*, 1995; Holling, 1978). In adaptive management, differences between how the future actually unfolds and how it was envisioned are seen as opportunities for learning. This is in sharp contrast to anticipatory management, which sees such deviations as errors to be avoided. Much of the agenda of adaptive management is learning through experimentation rather than focusing on error avoidance. Monitoring plays a crucial role in adaptive management. It provides feedback necessary for adaptive learning, information to generate narratives, and advice to determine if alternative courses of action are required.

At the core of an adaptive ecosystem approach is the premise that a sustainable society maintains itself in the context of the larger ecological system of which it is part. The formulation of a sustainable society involves realizing a vision of how the landscape of human and natural ecosystems should co-evolve as a self-organizing entity. Decision-making comes to be understood for what it has always been, finding our way through partially undiscovered country rather than charting a scientifically determined course to a known end point. A framework for this undertaking is presented in Figure 2.

In this post-normal approach to sustainability, science takes on a different function (*see* Post-normal Science, Volume 5). The scientist's role in decision-making shifts from inferring what will happen, that is, making predictions which are the basis of decisions, to providing decision-makers and the community with an appreciation, through narrative descriptions (scenarios), of how the future might unfold. Through these SOHO descriptions, science informs society about known ecological constraints and possibilities (see the top left hand box in Figure 2). People provide an image of how they would like to see the landscape of human and natural ecosystems co-evolve (see the top right hand box in Figure 2). A dialogue must ensue (the diamond box in Figure 2), which explores the desired and the feasible options and reconciles these in a vision of how to proceed. Scientists inform this dialogue by providing future narratives that will evolve as scientists participate, as

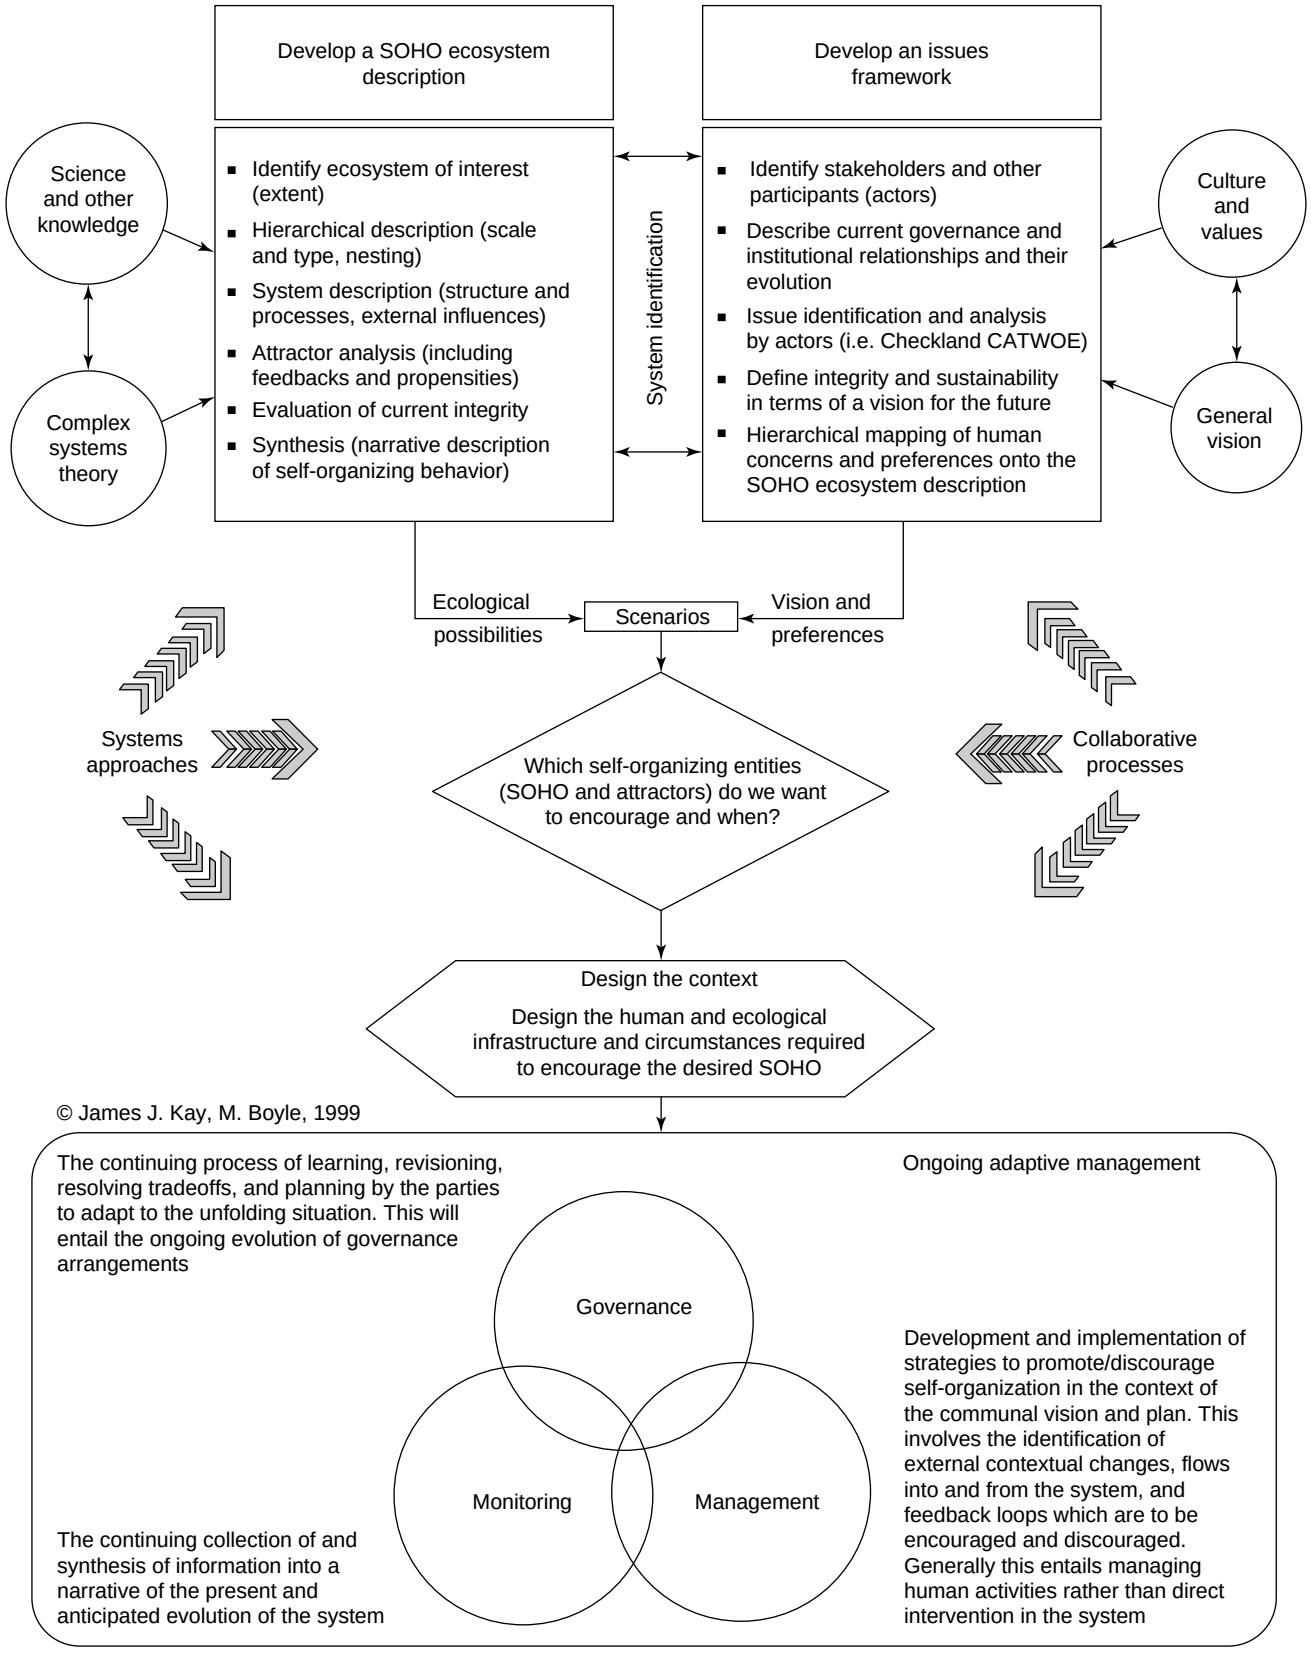

Figure 2 An adaptive ecosystem approach to sustainability and health; SOHO stands for self-organizing holarchic open systems

equals, with others in the process of resolving the vision. Having resolved a community vision for the future, the next phase is to design an adaptive program for the realization of the vision.

This adaptive program consists of a plan and infrastructure for the triad of activities, governance, management and monitoring. *Governance* refers to the continuing process of learning, revisioning, resolving tradeoffs, and planning to adapt to the unfolding situation. The ongoing evolution of governance arrangements and structures is required to accommodate these activities. *Management* is the activity of translating the vision into reality. It involves the development and implementation of strategies to promote or discourage specific forms of self-organization (i.e., trajectories to particular undesirable attractors or system states) in the context of the communal vision and plan. This means maintaining the context for the self-organizing complex SOHO systems, rather than intervening in the system in a mechanical way (Ahl and Allen, 1996). Maintaining the context involves identification of external contextual changes, ows into and from the system, and feedback loops to be encouraged or discouraged. Generally, management concentrates on the relationship between humans and natural ecosystems, and guides the human side of the relationship. Monitoring is the activity of observing the human and natural systems and synthesizing the observations into a narrative of how the situation has actually unfolded and how it might unfold in the future. This narrative is used as the basis for governance and management; that is, for learning, revisioning, and adapting human activities as the human and natural ecosystems co-evolve as a self-organizing entity.

THE ENTERPRISE OF MONITORING

As stated at the beginning of this essay, the traditional view of monitoring tends to focus solely on indicators. By implication, monitoring is restricted to collecting data and reporting. Our position is that it is precisely this narrow interpretation of monitoring that is responsible for its impotence in the service of decision-making and policy. Our thesis is that monitoring, done in isolation from a decision-making process and community needs, is an academic exercise whose utility is left to happenstance. This is why we have gone to some length to set out the context for monitoring. The details of the activity of monitoring follow.

The input to a monitoring program is a statement about: which SOHO ecological-economic system is the focus of attention; what aspects are of importance; how it is hoped that these will change over time (i.e., a narrative of the future); and, probably, a plan or strategy for making these aspirations happen. This statement is an end result of the process depicted in Figure 2 before the box labeled ongoing adaptive management . Such a statement is referred to in this discussion as a *sustainability vision.*

Traditionally, in most Western jurisdictions, the sustainability visions have taken the form of policies and/or regulations, which are enacted as part of a legislative process. In this traditional mode, monitoring, as described herein, is undertaken in the support of policy. However, there are forms of virtual governance emerging which have no formal legislative powers and whose governance does not take the form of traditional policy. For example, United Nations Biosphere Reserves are often overseen by an informal and ad hoc assembly of concerned individuals and non-government organizations. Even though these individuals may have no legal power, they do act as stewards of the Reserves and in effect manage them. While they have no instruments that resemble policy in its traditional sense, they most certainly will have a vision and a plan for the Biosphere Reserve. Similarly, coalitions of concerned citizens can emerge around a sustainability issue (for example, air or water quality issues in a region) and take it upon themselves to make changes in society to alter the current situation. Monitoring, as discussed herein, is meant to be in the service of these initiatives as well as the more traditional policy based approaches to environmental and sustainability issues.

The approach to monitoring that follows is not appropriate for all situations. For example, if one is simply trying to enforce a specific regulation, like water quality standards, then the monitoring exercise is simply one of appropriate surveillance to trigger an enforcement process. Similarly if one is trying to resolve a normal scientific issue, like the effect of a fertilizer on a crop, a different approach to monitoring is appropriate. However by the same token, approaches to monitoring that are appropriate to these situations are not appropriate for dealing with the broader issues of sustainability.

An output of a monitoring program is a narrative of how the organization of the SOHO system has actually changed and how it might unfold in the future. This narrative is compared to the narrative of the sustainability vision. The comparison is used to re ect on all aspects of the sustainability vision and on the appropriateness of the monitoring program itself. This assessment is the basis for learning on the part of those undertaking management and governance. In this way the monitoring program is a re exive activity.

The Monitoring Process

Figure 3 depicts the different activities involved in the process of monitoring. (The activity of developing a monitoring program is discussed below.) It should be expected that as part of an adaptive approach, the monitoring program will need to be revised from time to time. Data

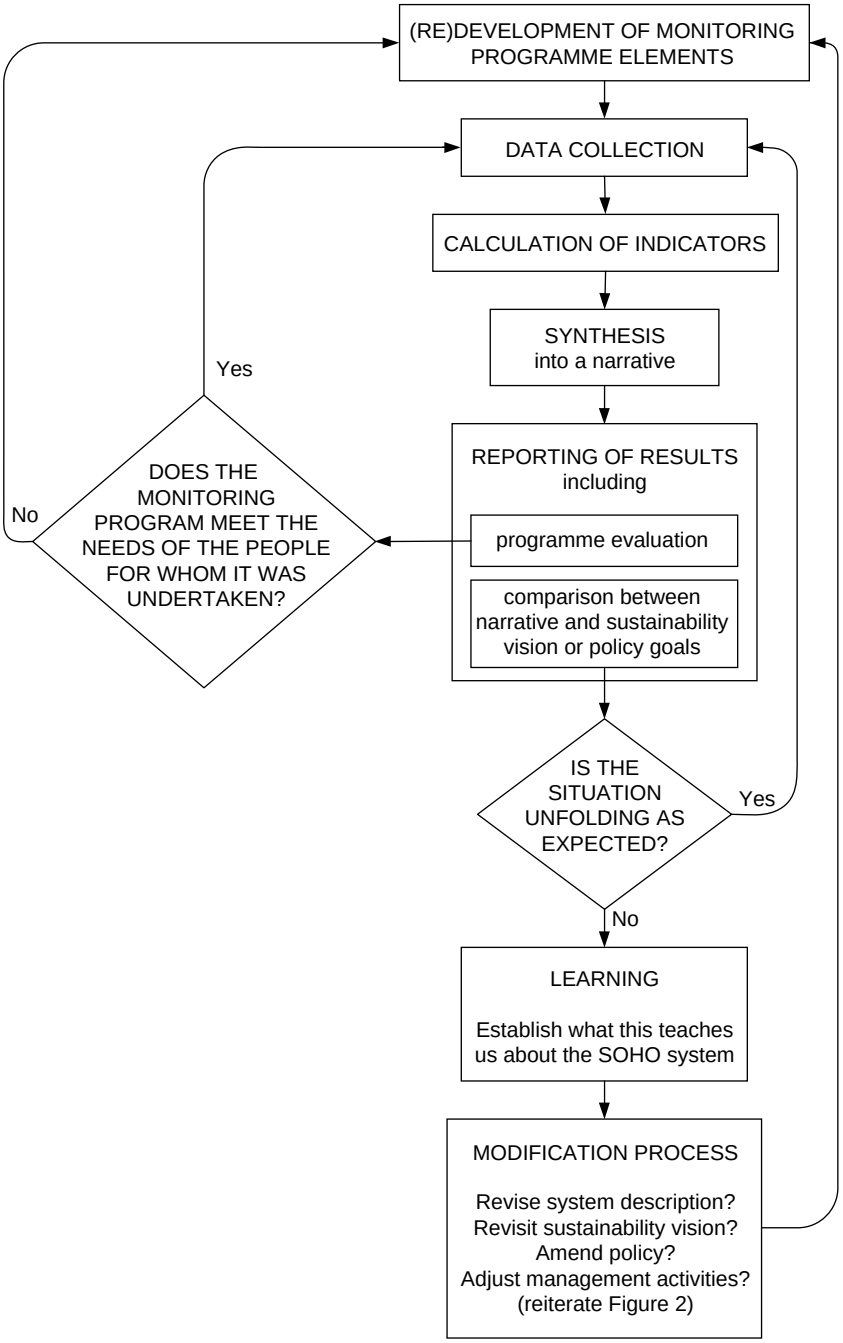

Figure 3 The monitoring process

collection and calculation of indicators are the activities traditionally associated with monitoring and there is an abundant literature on these activities. Synthesis is about generating the narrative about the current and future status of the ecological-economic system and comparing it to the goals and aspirations expressed in the sustainability vision or policy. The next stage is reporting. This is the communication of the findings of the monitoring and assessment to those involved in management and governance. It is a crucial element of the interface between the triad of activities that make up an adaptive approach to sustainability.

The report provides the opportunity to perform two crucial evaluations that are at the heart of the learning process which makes this approach adaptive. One evaluation involves the monitoring program itself: Is it meeting the needs of the people for whom it is undertaken? The other evaluation is an assessment of whether or not the

situation is unfolding as articulated in the sustainability vision or policy.

Given that ecological-economic systems are complex, it is reasonable to expect that the situation is not unfolding in accordance with the sustainability vision or policy. If this is indeed the case, then it should trigger an investigation into what the discrepancies teach us about the behavior of the ecological-economic system as a SOHO system (such discrepancies may herald global environmental change). Discrepancies should also trigger a reevaluation of the policy. Does our description of the system, and what is deemed important, need to be revised? Is the vision still feasible, or is a revisioning exercise in order? Are new management strategies or tactics required? In essence, one should go through another iteration of the process outlined in Figure 2. This reiteration may very likely result in modifications to the monitoring program itself.

Attributes of a Monitoring Program

Based on a review of literature (Boyle, 1998) on monitoring and indicators, and from consideration of the principles of complex systems theory and post-normal science, we have compiled a list of attributes which a comprehensive monitoring program should possess. This list is quite separate from characteristics of the system of interest or from the indicator selection criteria. Our research revealed that there is often confusion between attributes, which apply to a monitoring program or to the set of indicators as a whole, and criteria that serve to evaluate individual potential indicators. (The latter are discussed separately under the section Indicator Development.) The following list of attributes is not only helpful to keep in mind during the design of a monitoring program, but it also becomes an important tool in evaluating whether the program actually provides the required information and meets the needs of the users.

A comprehensive monitoring program should:

- Be relevant and decision supportive. The monitoring program must be relevant to both the issues of concern, and to the users of the information. The information provided to decision makers must be understandable, timely and as forward looking (anticipatory) as possible so that decisions may be made before the system is adversely affected.
- Take into account considerations of scale and type. The monitoring program should provide information at a range of spatial and temporal scales (hierarchically nested) that are appropriate to the vision yet also be sensitive to changes (temporal, spatial and across groups). The program must examine different types or perspectives of the system and consider abiotic, biotic and cultural factors. A separate issue is that data must be collected and reported at appropriate, but not necessarily the same, scales.
- Be based on a conceptual systems model that explicitly recognizes relationships between society and environment. The conceptual model of the SOHO system must be scientifically valid and should re ect the integration between society and the environment in several ways. It must be nested to deal with considerations of scale and type (as above) and be based on ecosystem and institutional boundaries. Human systems must be acknowledged as a subset of the ecological systems that support them and linkages between the economy and the health of ecological systems must be made. It is also important to monitor the feedbacks between society and the environment.
- Allow for an overall integrated evaluation of the system. In order to evaluate the state of the system, the monitoring program should collect a variety of different types of measures. It is important to monitor the sensitivity to magnitude, direction and duration of known stresses, (including socioeconomic and cultural ones) but also to monitor for ecological integrity (which would reveal unanticipated problems). Continuous measurement from stressed to non-stressed conditions tracks the pathways of change between states. An evaluation of the system should be able to assess: its organization (structure and process); states; the quantity and quality of ows of energy and materials; and, whether changes are reversible or controllable. Historical and baseline information can be used to identify natural ranges of variability and trends over time. The monitoring program should thus re ect our knowledge of naturally occurring changes as part of normal system behavior and responses. Cumulative effects should be measured and compared with threshold values for the system. Emergent properties of the system should also be detected and evaluated. Finally, all system assessments should rely on both scientific, objective measures as well as experiential, subjective ones.
- Be adaptive and exible. The program must be adaptive and exible enough to: deal with environmental (including catastrophic) changes; incorporate new information, technology and scientific research; and adjust to changes in the political context or societal values. It is useful to have a monitoring scheme applicable to diverse operational situations at different scales and for different ecological systems, yet the program must also be tailored for specific applications.
- Be practical. A program design is useless if it is not practical and cost effective. Employing existing expertise, data sets and tools (e.g., geographical information systems (GISs) and modeling methodologies) can save time and money and incorporate the work of others.

DESIGN OF THE ELEMENTS OF A MONITORING PROGRAM

Many sources in the literature offer steps or stages to follow in designing a monitoring program. In reality, of course, the process is not linear. Information and knowledge become available piecemeal and many insights are gained along the way. Steps are taken and retaken. We have chosen to separate the design steps and the process of monitoring, which are two quite different activities. A monitoring program, then, is made up of elements (Table 2) that are collectively used in the enterprise of monitoring. Developing the elements of the program should not be confused with the development of the protocol for the activity of monitoring, that is, the monitoring process. The latter is about designing a human activity system as depicted in Figure 3, the former is about designing tools for the analysis of ecological-economic systems.

Table 2 Elements of a monitoring program

An issues framework: the impetus of a monitoring program is always to assess progress towards a set of human goals. Hence, a clear articulation of the goals and users of the information is the foundation of any monitoring program
A conceptual model of the world: the model represents how we look at the world in the context of the goals. It serves to delineate the system that should be monitored. It provides a framework that relates the indicators to each other in the context of the overall system being monitored
A set of indicators: the indicators characterize the system being examined in a meaningful way for the users
A methodology for data collection and storage: carefully laid out procedures to address the practical and technical issues involved in data collection must be established to ensure accuracy, consistency and statistical robustness. Equally important is the storage of the data, so that it is accessible and usable in the future (*see* **Metadata**, Volume 2)
A methodology for calculating indicators: the data collected will have to be manipulated in order to derive values for the indicators. Again, a method to do this accurately, consistently and in a statistically appropriate manner is required
A process for synthesis: synthesizing the information that the indicators provide into an overall narrative of the status of the system is essential to completing the central task of the monitoring program, that is, to assess progress towards the human goals and aspirations which motivated the enterprise
A methodology for reporting: The values of the indicators and the results of the system assessment (the narrative which results from the synthesis) must be reported to the intended audience or users of the information. A methodology for presenting it in a clear, purposeful, and timely manner for decision making is crucial to the utility and success of the monitoring program

The relationship among these elements is shown in Figure 1. Strictly speaking, the issues framework and conceptual model should be developed as part of an overall adaptive ecosystem approach to sustainability and health, rather than as specific elements of a monitoring program. These elements would be produced as part of the analysis of the situation, as described by the right- and left-hand top boxes of Figure 2. They would provide the context for the monitoring program. However, it is usually the case that the development of a monitoring program is not initiated in the context of a larger approach to sustainability. If this occurs, the development of a monitoring program (in particular the development of the first two and last two elements of the program in Table 2) can be used as impetus to stimulate the development of the governance and management activities necessary to complement monitoring.

Issues Framework

The decisions that guide our choices and actions in relation to the environment are inextricably rooted in human concerns that are based upon our worldview and shaped by our culture and values. These considerations determine our general vision of how we want the world to be. In many cases, where a traditional approach is taken, the perspective brought to bear on a problem remains implicit in the problem-solving procedure. The same can be said of decision-making criteria. This fact is often a source of conflict as sustainability is not primarily a technical, scientific, or managerial problem. It is about dealing with people and their diverse cultures, interests, visions, priorities and needs. Pursuing sustainability entails participation of these myriad stakeholders, each having a legitimate perspective, and arriving at a resolution that all can live with. The purpose of the issues framework is to bring the diverse interests, visions, priorities and needs of the stakeholders into focus in an integrated way.

It is difficult to bring stakeholders with diverse beliefs and opinions together to resolve often highly contested and emotional issues. These problems, though significant, are not insurmountable. See, for example, Ramírez (1999) and Burgoyne (1994) for methods in stakeholder analysis and collaboration. Related discussions on public participation in environmental planning may be found in Warriner (1997) and Beckenstein *et al.* (1996). We have found that a variant of the Soft Systems Methodology (SSM) (Bunch, 2000; Checkland, 1981; Checkland and Scholes, 1990; Wilson and Morren, 1990) is a useful way to proceed to develop an issues framework that recognizes and incorporates the perspectives of all stakeholders.

The issues framework is designed to explicitly: (a) identify the actors and stakeholders; (b) describe and define the situation; (c) determine the important issues and concerns; and (d) disclose the values applied in making decisions

and judgments. The issues framework takes the form of a hierarchical mapping of human concerns and preferences onto the SOHO ecosystem description (the conceptual model). Thus, it facilitates comparison of various scenarios that re ect the socioeconomic and ecological possibilities. It defines integrity and sustainability for the situation in terms of a vision for the future. The issues framework lays the foundation for developing a clear statement of vision and articulated preferences in terms of characteristics or features of the desired ecological-economic system. Therefore, the sustainability vision directs the choice of information, which should be collected by the monitoring program.

Conceptual Model

The conceptual model for a specific situation describes how the important considerations (derived from the issues framework) are related in a dynamic system. Such a description requires complex systems thinking. The practical result is a framework for a narrative of the behavior of the ecological-economic system of interest. A comprehensive conceptual model should naturally lead to indicators by effectively telling us where to put meters'.

The explicit development of a conceptual model is crucial for the activities involved in monitoring, management and governance. Our literature review revealed, however, that (a) many monitoring programs do not explicitly define the assumptions underlying the model, and (b) there are many different types of conceptual models in use. (Some examples are outlined below in the subsection entitled Traditional Conceptual Models.) Furthermore, we found that none of the existing conceptual models adequately deals with the complexity of ecological-economic systems. Little attention is paid to the considerations of scale and type, holons, nesting, self-organizing entities, attractors, feedback loops etc. or in short, a systems description to provide the framework for narratives. This means, more often than not, that the monitoring program does not provide sufficient information to generate a system description that will be able to deal with sustainability issues.

Traditional Conceptual Models

A review of traditional conceptual models used in monitoring programs can be found in Boyle (1998). Many current monitoring programs are based on a *stress-response model*. When an ecological system is subjected to a disturbance that it cannot absorb, it will change in some way. The stress-response model (Rapport *et al.*, 1985) attempts to link stresses with responses and therefore provides early warning or predicts how, and when, a system will respond to in uences. There are many examples of indicator frameworks which utilize this model, for example Canada's State of the Environment Reporting Program (Environment Canada, 1995). An improvement in this monitoring approach is the inclusion of *cumulative effects*, that is, compounding effects from more than one source or persistent additions from the same source (Cocklin *et al.*, 1992). Monitoring under the stress-response model is limited, however, to addressing questions regarding known cause and effect relationships in a system. The notions of monitoring for *ecosystem health* and, more recently, *ecosystem integrity* are efforts to monitor and evaluate the status of the system as a whole. *Ecosystem health* monitoring focuses on attributes of the system that give an overall indication of any problems in the system, analogous to taking a person's temperature in the human health model. (See, for example, Breckenridge *et al.*, 1995 for measuring the health of rangelands; and Svanberg, 1996 on ecosystem health indicators for the Baltic Sea.) *See* Ecosystem Health, Volume 4; Ecosystem Integrity, Volume 4.

Evaluations of ecosystem health are based on an assumption of homeostasis (as is human health in a medical context). This assumption is generally not appropriate for ecological systems. A system could completely change from a forest to a wetland because of a river diversion, for example. The system may still be perfectly healthy, only it is now a wetland. To incorporate this range of possible healthy systems, the idea of ecological integrity has emerged to assess the system's crucial characteristic; its ability to reorganize itself (Woodley *et al.*, 1993). Thus, integrity includes responses to a changing environment, or even change from within, as long as its ability to self-organize is maintained (Kay, 1991; Kay and Regier, 2000). Integrity is a concept that has been used most often in monitoring natural and protected area (Noss, 1995; Soulé, 1995; Woodley, 1993).

Straddling the evolution of the ecological conceptual model, the integration of social and economic dimensions has been recognized as important. A shift is also occurring in the human goals that motivate monitoring activities. People are increasingly concerned with living sustainably and wish to assess progress toward this goal. In the last few years, there has been an explosion of sustainability monitoring initiatives (Hodge, 1996; Maclaren, 1995; Nilsson and Bergstrom, 1995; Rees, 1996).

An effort to combine both the social and ecological is the *pressure-state-response model* (Adriaanse, 1993). This model suggests three different, but related and integrated, types of indicators for each sustainability issue. Pressure indicators measure pressures on the environment due to human activities. State indicators measure the quality of the environment, and the quality and quantity of natural resources. Finally, response indicators measure how, and how well, society is doing in response to environmental changes and issues. The advantage of this framework is that it results in a group of indicators for each issue that address the sources of the problem, its current status, and what is being done about it. The Dobriš assessment, used by the

European Environmental Agency, uses the driving forces pressure state impacts response (DPSIR) model of assessment (*see* Dobr s European Environment Assessment Process, Volume 4). This model takes the *pressure-state-response* model one step further by adding the human activities which are the driving forces behind the pressure, and the impacts on human activities and the environment due to the environmental state change (*see* DPSIR (Driving Forces Pressures State Impacts Responses), Volume 4 or the European Environmental Agency WWW site, http://themes.eea.eu.int/showpage.php//?pg• 37183).

The conceptual model we propose integrates these earlier models with the notions of a systems approach to complexity.

The Basis for the Conceptual Model: the Notion of Self-organization

Ilya Prigogine in his Nobel Prize winning work, showed that spontaneous coherent behavior and organization (e.g., tornadoes) can occur and are completely consistent with thermodynamics (Nicolis and Prigogine, 1977; Nicolis and Prigogine, 1989). The key to understanding such phenomena is to realize that one is dealing with open systems with an enduring (not necessarily constant) ow of high quality energy (that is, *exergy*). In these circumstances, coherent behavior appears in systems almost magically. Prigogine showed that this occurs because the system reaches a catastrophe threshold and ips into a new coherent behavioral state. (This is evident, for example, in the vortex, which spontaneously appears when draining water from a bathtub.)

In examining the energetics of open systems, Kay (1984) and Schneider and Kay (1994a) have taken Prigogine's work one step further. An open system with exergy pumped into it is moved away from equilibrium. But nature resists movement away from equilibrium. (This is the second law of thermodynamics restated for non-equilibrium situations.) When the input of exergy and material pushes the system beyond a critical distance from equilibrium, the open system responds with the spontaneous emergence of newly organized behavior that uses the exergy to build, organize and maintain its structure. This dissipates the ability of the exergy to move the system further away from equilibrium. As more exergy is pumped into a system, more organization emerges, in a stepwise way, to dissipate the exergy. Furthermore these systems tend to get better and better at grabbing resources and utilizing them to build more structure, thus enhancing their dissipating capability.

The theory of non-equilibrium thermodynamics suggests that the self-organization process in systems proceeds in a way that: a) captures more resources (exergy and material); b) makes more effective use of the resources; c) builds more structure; d) enhances survivability. These seem to be the kernel of the propensities of self-organization in systems. How these propensities manifest themselves as positive and/or negative feedback loops is a function of the given environment (context) in which the system finds itself embedded, as well as the available materials, exergy and information.

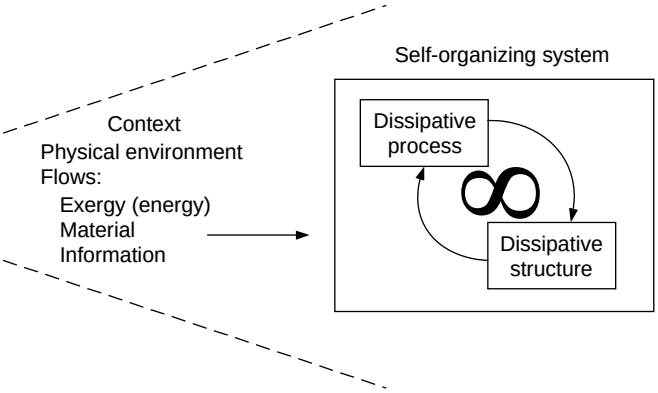

Figure 4 Complex systems as dissipative systems

This conception of self-organization, as a dissipative system, is presented in Figure 4. Self-organizing dissipative processes emerge whenever sufficient exergy is available to support them. The details of the processes depend on the raw materials available to operate them, the information present to catalyze the processes, and the physical environment. The interplay of these factors defines the context for, or the constraints on, the set of processes which may emerge. (Generally speaking, the specific processes that emerge from the available set are uncertain.) Once a dissipative process emerges and becomes established, it manifests itself as a structure.

(In the case of a vortex in the bathtub water, the exergy is the potential energy of the water, the raw material is the water and there is no historical information; the dissipative process is water draining, and the dissipative structure is the vortex. The vortex will not form until enough height of water is in the bathtub and if too much height of water is present, the vortex ips into a different form of ow.)

In an ecological setting, examples of the structures are the individuals of species, breeding populations, forests etc. The processes are reproduction, metabolism, evapotranspiration, etc. The context is the available set of nutrients and energy sources in a physical environment. The information includes the genetic codes and biodiversity at various scales.

The Model

We have integrated the traditional conceptual models with the notion of ecological-economic systems as dissipative complex systems to produce a conceptual model that serves as a monitoring measurement framework (refer to Figures 5–7). In this model, the elements of the landscape (e.g., woodlots, wetlands, farms, neighborhoods) that

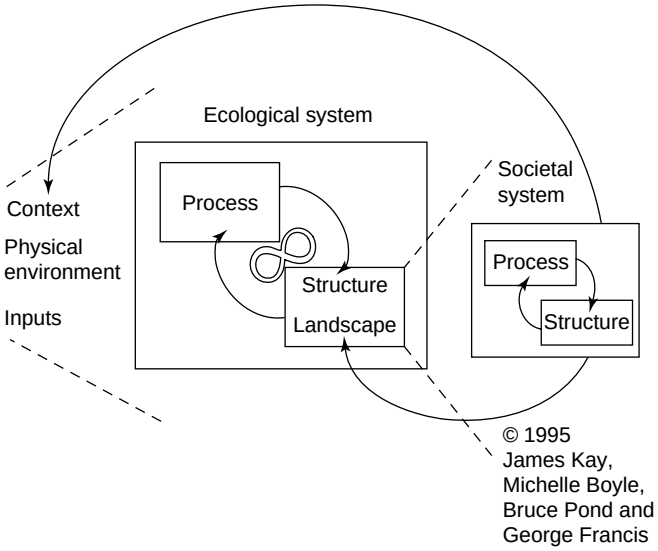

Figure 5 Conceptual model; single horizontal holarchical level

make up the societal and ecological systems, are seen as self-organizing entities set in an environmental context. Self-organizing entities are understood through consideration of their constituent processes and structures, and the relationships between these. (For example, in a woodlot: processes would be evapotranspiration and growth of biomass; structure would be the species that make up the woodlot; and a description of the relationship between these processes and structure would be Holling's four-box model of the ongoing process of birth, growth, death and renewal in ecosystems (Holling, 1986, 1992)). The processes involve the ows of material, energy and information. The structures are the objects (i.e., trees) we see on the landscape. The processes allow for the emergence, and support, of structures, which in turn allow for the emergence of new processes and so on. The recognition of this recursive relationship between process and structure separates this conceptual model from more traditional ones.

Once the relevant processes and structures have been identified, a suite of variables may be specified which can be used to monitor the state of the processes and structures. These variables must be sufficient to define the wellbeing (in the case of ecosystems, the integrity (Kay, 1991; Kay and Regier, 2000)) of the self-organizing entity.

Ecological communities provide exergy, materials and information required for human societies to sustain themselves. This is depicted in Figure 5. The societal system depends on the ow of exergy, materials and information from the ecological system to support its processes and structures. These ows, along with the biophysical environment provided by the ecological systems, are the context for societal systems. The context constrains the possible societal processes and structures in a specific location. While Figure 5 illustrates a single ecological system providing the context for the societal system, the reality is that it is a suite of adjacent ecological systems (for example: woodlots, fields and wetlands adjacent to a farm) that provide this context. Alterations in these adjacent systems will alter the context and thus the possibilities for the system in question.

However, the societal system can also in uence the ecological system in two ways. The first in uence is through changes in the structure of the ecological system (for example: cutting trees down in a woodlot, filling wetlands, and all the human activities which involve removing or dismantling ecological structures on the landscape). Such actions, of course, alter the ows from the ecological systems to the societal systems and thus create a feedback structure on the landscape. This is represented in Figure 5 by the lower arrow back from the societal system to the structure in the ecological system. The feedback to the societal system occurs because changes in the ecological structure change the context for the societal system.

The second in uence occurs when the context of the ecological system is altered by the societal system. For example, the runoff into a wetland or stream may be altered by human activities on adjacent properties. It is depicted in Figure 5 by the upper arrow from the societal system back up to the context of the ecological system. This in uence is qualitatively different than the structural in uence just discussed.

The resulting feedback loop has more steps and accordingly is more indirect. By changing the context of the ecological system, the societal system affects the ecological processes and, in turn, the ecological structure and ultimately the societal system's own context. For example, modifying the runoff into a waterway can dramatically alter the character of the waterway, and hence the type of fish found in it and therefore the sport fishery and associated economic system.

To summarize this discussion, each self-organizing entity resides in an environment that provides: (a) the biophysical surroundings in which the entity exists; and, (b) ows of exergy, material and information that the entity depends upon for the continuation of the self-organizing processes, which maintain its structure. The biophysical surroundings, in conjunction with the ows into the system, constitute the context for the self-organizing entity. It is necessary to monitor this context, since changes in it will effect the processes of the entity.

Referring to Figure 5, the relationship between societal systems and ecological systems is three-fold:

1. Ecological systems provide the context for societal systems. That is, they provide the biophysical surroundings and ows of exergy, material and information that are required by the self-organizing processes of the societal systems.

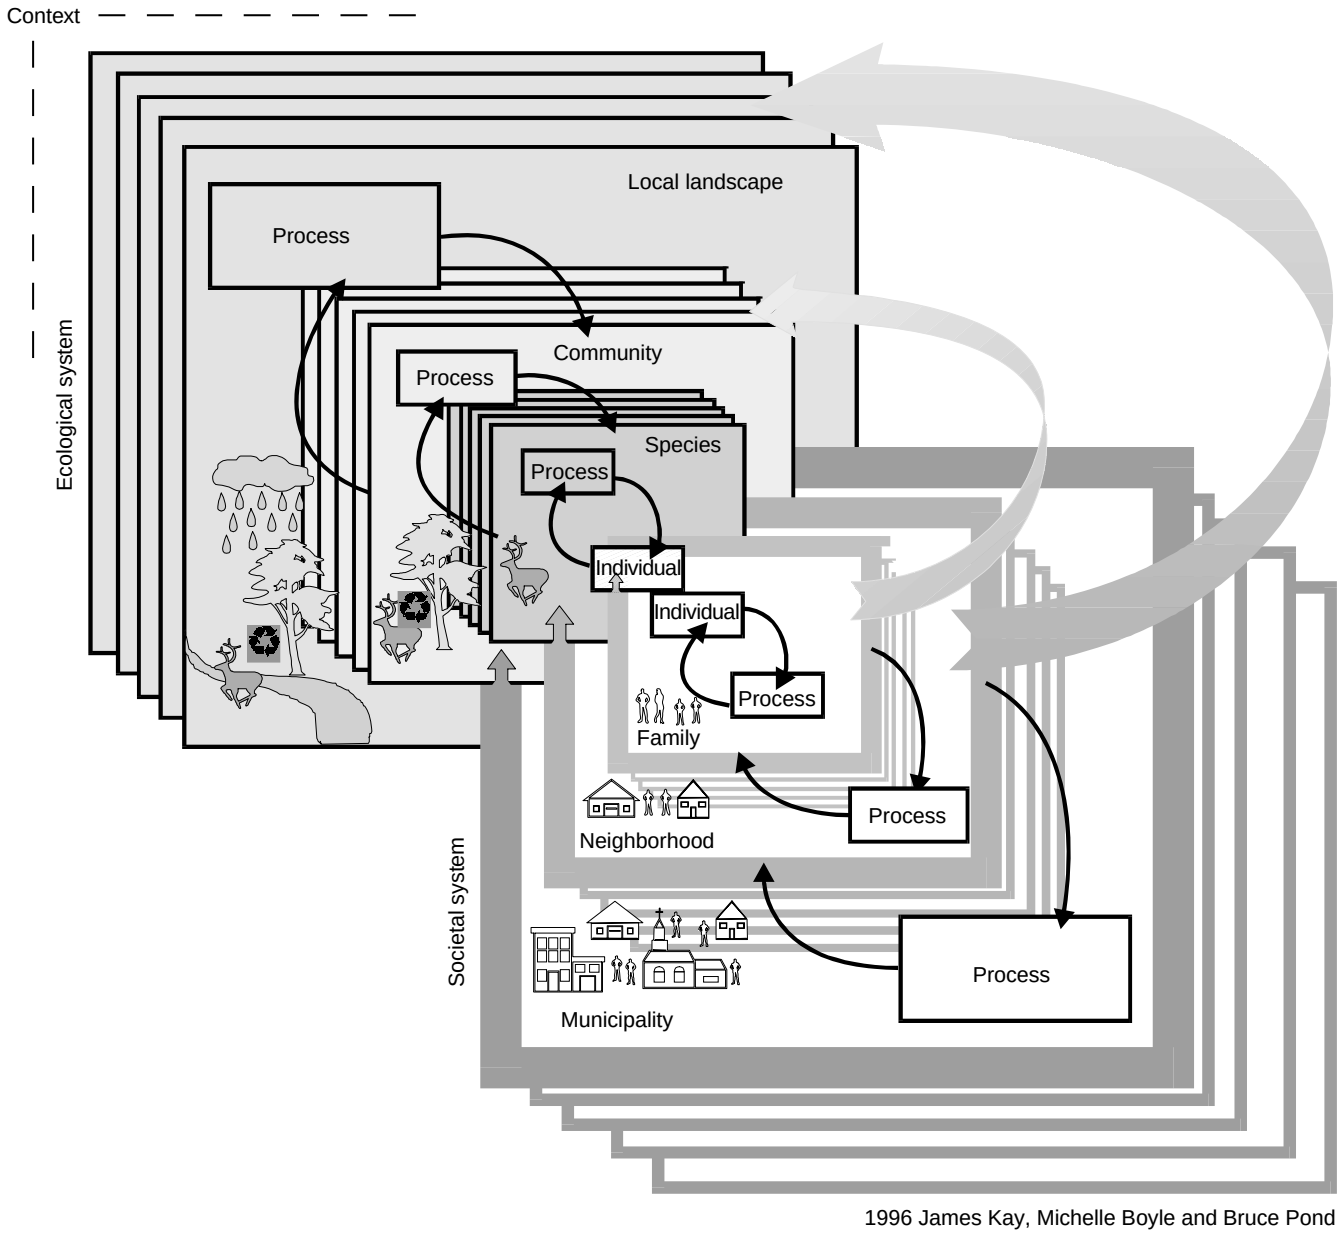

Figure 6 Conceptual model: three levels

2. Societal systems can alter the structures in ecological systems. (For example, cutting down a woodlot, removing beaver from a watershed.) Changes in the ecological structure can then, of course, alter the context for the societal systems themselves.
3. Societal systems can alter the context for the self-organizing processes of ecological systems, e.g., a change in the drainage patterns into a wetland, or a change in the nutrient runoff into a shallow lake from adjacent agricultural fields. Changes in ecological processes can alter ecological structure and consequently the context for societal systems.

Each of these represents a qualitatively different aspect of the relationship between ecological and societal systems that should be considered when monitoring.

The Hierarchical Structure of the Model

Figure 5 applies to one hierarchical level, but as observed earlier, sustainability issues can only be understood in terms of nested holons. Figure 6 illustrates this idea. On the ecological side, *local landscape* can be thought of as a subwatershed, for example. The hydrological cycle is an example of a process in the subwatershed. The structures which make up the subwatershed are the ecological

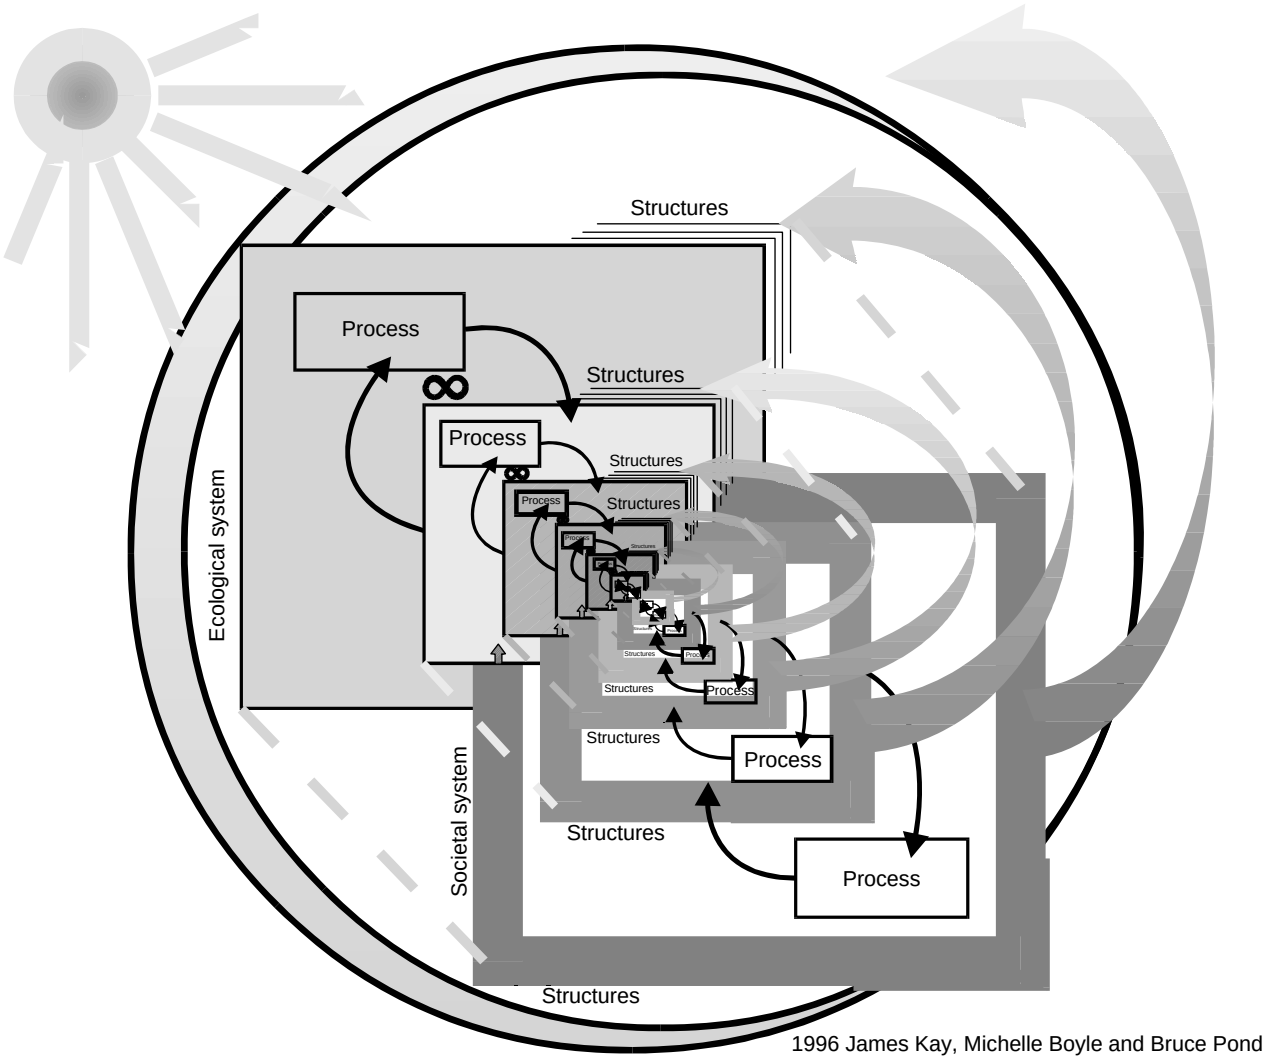

Figure 7 Conceptual model: the big picture

communities (e.g., woodlots, wetlands, open fields, etc.). The communities are in turn made up of species. On the societal side, municipalities are scattered across the local landscape. These in turn are made up of neighborhoods, which are made up of families and businesses.

In many cases, the local subwatershed defines the context for the local municipality. However, the municipality can, and does, directly modify the ecological communities in the subwatershed and thus its own context. Similarly, the context for local neighborhoods is determined by the adjacent ecological communities. Nonetheless, the local neighborhood is quite capable of in uencing ecological communities, through direct structural change (such as harvesting wood from a woodlot), or changing the context of an ecological community (for example, changing drainage patterns into a wetland).

Figure 6 and the examples are meant to be illustrative and not exhaustive, although they do demonstrate that such changes can cascade through the nested holons to ultimately affect individual families and businesses. What is unique about this conceptual model is that it explicitly identifies these connections and relationships and provides a framework for deciding what to monitor.

Figure 7 shows the full conceptual model, which would be used as a template to develop a particular conceptual model in which the important levels, processes, structures, environmental context, and in uence/feedback considerations are specifically identified.

The Conceptual Model and Monitoring

This conceptual model identifies a set of aspects which should be monitored, that is, should have indicators associated with them. These are summarized in Table 3. In effect, Figures 5–7 define different points where a monitoring

Table 3 Aspects of the SOHO system which should be monitored

(a)	State of the wellbeing of the societal and ecological entities:
	measures of self-organizing processes
	– *examples: evapotranspiration, recycling*
	measures of self-organizing structure
	– *examples: biomass, species diversity*
(b)	The context of the societal entities:
	measures of biophysical surroundings
	– *example: average humidity*
	measures of flows into the system
	Exergy: – *example: fuel wood consumed*
	Materials: – *example: aggregate consumption*
	Information: – *example: flow of hormone like chemicals from the environment into food*
(c)	Influences of the societal systems on ecological systems:
	Structural influences
	– *examples: wetlands destroyed, woodlots removed*
	Contextual influences
	measures of biophysical surroundings
	– *example: average temperature*
	measures of flows into the system
	Exergy: – *example: phosphorous loading*
	Materials: – *example: drainage flows*
	Information: – *example: hormone like chemicals into the food chain*

meter should be plugged into the ecological-societal system. A monitoring program should include:

1. Measures of the state of wellbeing of each of the self-organizing entities (ecological and societal). These are represented in the figures by process and structure boxes.
2. Measures of the context for the societal system, that is, the biophysical surroundings and the ows into the societal system from the ecological system. This is depicted in the figures as the societal system in the shadow of the ecological systems.
3. Measures of the contextual and structural in uences of the societal systems on the ecological. These are represented in the figures by the arrows going from the societal system, up one level, and into the ecological structure. These arrows show how societal in uences on the ecological systems, through changes that these in uences cause in the process and structure of the ecological system, can alter the context for the societal system. So the societal in uences on ecological systems are part of a feedback loop which affects the societal systems.

Sustainability is about maintaining the well-being of the combined ecological–societal system. This requires that its self-organizing processes and structures be maintained. This will happen naturally, if we maintain the context for self-organization in ecological systems, which in turn will maintain the context for the continued well-being of the societal systems. This condition for sustainability is incorporated in the conceptual model.

Thus, this conceptual model provides a framework for monitoring for sustainability that is more elaborate than conventional approaches. Traditionally, one would monitor external (usually negative) stresses in uencing the system and its response. In this model, we emphasize the importance of the hierarchical monitoring of:

- both process and structure and their inter-relationship in order to understand the current wellbeing of the system;
- the context of the ecological and societal system in terms of the biophysical surroundings of each, and the ow of exergy, materials and information into the system;
- the contextual and structural in uence of societal systems on ecological systems and hence ultimately on the societal system itself.

Without consideration of each of these aforementioned aspects, we cannot decide where indicators may be placed to most effectively fulfil their purpose. For example, if the intent of a monitoring program is to anticipate future changes in order to make wise management decisions in the present, indicators must be chosen to monitor the factors which in uence the processes and structure of the system. Measures focusing on the current state of the system will only reveal changes that have already occurred and will thus be too late. This is particularly true with regards to monitoring to detect the effects of global change.

Also, monitoring within the boundaries of the defined system of interest is not sufficient to gain an understanding of its dynamics or to anticipate changes, both of which are extremely important in protecting areas or certain land uses. We must broaden our scope to examine the context that constrains or in uences the behavior of the system, and do this from a hierarchical perspective.

When using this model, it is important to bear in mind that self-organization inherently involves internal causality. A self-organizing system has the ability to maintain itself at an attractor despite changes in its environment. So, the environment may change substantially without the system exhibiting major change. Self-organizing systems can respond in a synergistic way to a collection of environmental changes. Thus, changes in the system can rarely be tied unequivocally to a specific environmental, policy or management change. Furthermore, such systems have the capability to generate new behavior that may emerge independently of changes in the environment. The capacity to organize and maintain itself about an attractor is the hallmark of a self-organizing system. It is important to remember that discussions of the behavior of this model cannot

be in terms of one-to-one linkages of contextual elements (i.e., stresses) to the state of processes or structures. Rather, the explanation must be in terms of morphogenetic mutual causality, that is, narratives (Kay and Regier, 1999).

Indicators and their Development

Indicators are often confused with a monitoring program. They are an important part of monitoring, but they must be generated, selected and implemented within the context of all the elements of a monitoring program. Indicators describe the status of different attributes of a system. However, the conceptual model is required to provide a framework that integrates the indicators. As well the data collection and calculation methodologies and a process for synthesizing all the information into a narrative of the system are required if the indicators are to be of any use. Without these elements of a monitoring programme, the indicators cannot be used to describe and assess the overall status of the ecological-economic system in question.

Table 4 Indicator development activities

Generate indicator selection criteria: selection criteria capture the issues and constraints regarding the desired set of indicators are used to screen potential indicators. They must be agreed upon by all those participating in the development of the monitoring program elements
Generate potential indicators: a set of potential indicators consists of possible measures, which emerge from consideration of the issues without regard for constraints. All potential indicators should be recorded and evaluated
Select indicators: Not all potential indicators will meet all the criteria equally well and there will always be trade-offs when choosing some indicators over others. A method must be in place to assess the feasibility of potential indicators and to make a subjective judgement on their evaluation against the criteria

Indicator development consists of three activities: enumerating indicator selection criteria, generating potential indicators and selecting indicators to be implemented for the monitoring program. These activities are summarized in Table 4.

Figure 8 is schematic for organizing information while generating criteria and potential indicators. It delineates a set of considerations that directly or indirectly in uence indicator selection, as well as the relationship between them. For each consideration (box, in Figure 8), criteria for indicator selection and questions to guide the task of generating indicators are formulated. An explanation of the diagram follows, while compiled lists of selection criteria and questions for indicator generation can be found in Tables 5 and 7, respectively.

The development of indicators is motivated by the need to build a narrative of how the ecological-economic system is developing so as to guide human activities. The *sustainability narrative* articulates a vision for the desired development of the system and identifies issues or concerns of import to the users of the indicators. This consideration defines *what we want to know*. As such, it also serves as the entry point for incorporating, into the choice of indicators, changes (over time) in the issues or concerns of users.

The *conceptual model* defines the structural and functional components of the biophysical and societal systems

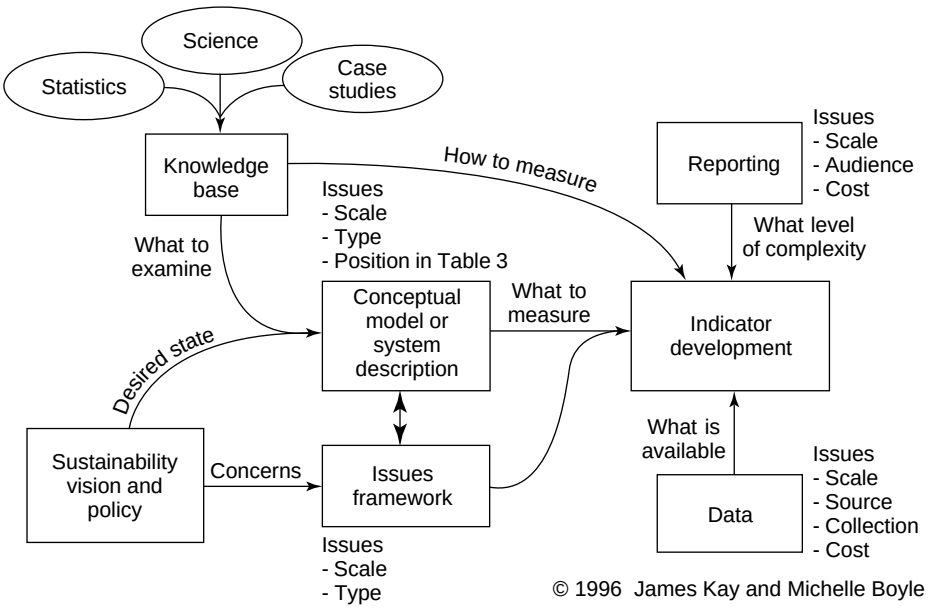

Figure 8 Considerations for indicator development. Legend: • Influence on development of indicators

Table 5 Indicator selection criteria (refer to Figure 8)

Categories of consideration	Indicator selection criteria
Conceptual model of the system	Indicators should: clearly relate to specific societal or ecological elements of the SOHO description
Issues framework	Indicators should be: clearly relevant to specific articulated goals and objectives for sustainability
Knowledge base	Indicators should be: scientifically valid; statistically and analytically sound; demonstrated by case studies to be practical
Data	Indicators should use data that are: available and accessible (easy to obtain and maintain at a reasonable cost); accurate; comparable over time; complete with historical information (to establish baseline conditions and thresholds)
Reporting	Indicators should provide information that is: understandable to potential users; unambiguous; easy to use; at the appropriate scale for decision-making

Table 6 Indicator category

Level I: indicators available for immediate use All essential criteria are met
Level II: indicators with demonstrated potential for use Most criteria are met but, for example, data are not currently being collected, or there is a lack of historical data
Level III: possible indicators There is evidence that these measures would be worthwhile indicators, but further scientific research and/or case studies are required to confirm their utility

Table 7 List of questions for potential indicator generation

(1) What is the sustainability goal or objective?
(2) What are the potential indicators?
(3) Which aspect of the conceptual model does each indicator measure?
(4) At what scale(s) will the indicators be reported?
(5) What is the rationale for each of these indicators (i.e., what does it tell us about the sustainability goals and issues)?
(6) Are there any confounding factors or problems which may limit the use of the indicator?
(7) Data sets: what measurements are required? At what scale will the data be collected? Who is responsible for data analysis and reporting?
(8) Data sources: who has the data set? Who is responsible for its collection?
(9) Which category does the indicator fall into (Level I, II or III)?

and describes the linkages and feedbacks between them. It provides a reference frame, which identifies the appropriate scales at which monitoring should occur and for which indicators are needed. It also provides a framework which shows the relationships between the indicators and some sense of how useful or timely the resulting information will be. The *issues framework* extracts specific management or user concerns and arranges them into a hierarchical framework to associate them with the appropriate scale and type. Thus, the conceptual model and the issues framework are highly interdependent and both facilitate the decision of *what to measure*.

Our *knowledge base* also determines what we elect to monitor. Science, from the perspectives of biology, ecology, geology, hydrology, etc. aids in understanding the processes and structure of the system and the effects of specific in uences or stressors. Complex systems theory adds valuable insight about how we perceive the system and what questions to ask when approaching sustainability issues. Statistics offers rules and standards for sampling and measurement as well as techniques for data analysis and transformation that ensure quality results. Case studies allow us to test chosen indicators and evaluate their utility and feasibility in a practical setting. The amalgamation of these is the body of knowledge that helps us not only to judge *what things are important to examine*, but also *how to make measurements* and *calculate indicators accurately and consistently*.

There are also many considerations attached to the *data* themselves that affect which indicators are chosen. *Data availability* encompasses considerations related to cost, collection, maintenance of databases, accessibility, and who is responsible for each task. The amount (i.e., historical extent) and the quality of data available are also important.

Finally, the development of indicators must be done with an awareness of the *reporting* requirements and the needs of the users. This category provides parameters for the *appropriate level of detail* and *the relative number of indicators*, which affects the aggregation and/or integration of data to compose the indicators.

It should be noted that there are three independent considerations of hierarchy, which are relevant when developing indicators for a monitoring program. We must be concerned with:

1. the scale and type of focus for the situation of interest;
2. the scale of data collection;
3. the scale of reporting the results.

The scale and type of focus may be ascertained from the specific sustainability issue and is re ected in the issues framework. The scale of data collection need not have anything to do with the level of focus for the sustainability issue since information can be aggregated, desegregated, or integrated to be meaningful for decision-making. Likewise, the results may be reported at several different scales.

Indicator Selection Criteria

Using the above considerations as a framework and drawing upon the literature (Boyle, 1998), we generated a list of criteria (Table 5) to be used in evaluating potential indicators. These are properties *each* indicator should possess. Note that these are relatively generic criteria, which apply to many different monitoring initiatives. For a particular project, however, there would be project specific criteria that would be added to this list. Keep in mind that some important characteristics of the information that the monitoring program should provide (for instance anticipatory' or monitoring for specific threats') need not be a quality of every indicator.

There are some criteria that, while desirable, are not necessarily essential. Thus tradeoffs are inevitable. For example, an otherwise excellent indicator may require data which are expensive to obtain, or for which the necessary historical data are not available. Thus, the list of indicator criteria may be used as a checklist to assist in indicator selection. Judgement, and careful consideration of each indicator, is still required. The use of indicator categories is one way to accomplish this.

Indicator Categories

The purpose of grouping possible measures into categories is to distinguish between indicators that are immediately useful (Level I) and those that could potentially be used in the future (Levels II and III). Funding limitations, unavailable data or untested measures are all considerations, which would restrict the immediate implementation of an indicator. Those indicators placed in Levels II and III become a wish list that may become feasible at a later time. This method ensures that these potentially valuable indicators are not completely discarded. For some, the case could be made that the benefit derived from the indicator is worth the extra expense or research required in order for it become a Level I indicator. The final set of indicators is chosen after detailed feasibility investigations for each indicator have been conducted and tradeoffs have been considered. Table 6 defines the three indicator categories.

Note that potential indicators are associated with indicator categories on the basis of an initial assessment. Only those indicators that are known to reasonably meet all the criteria and could be immediately implemented are placed in Level I. If there is some uncertainty about an indicator meeting the criteria, or it is known to be lacking data or scientific validity, it is placed in Level II and III for further investigation. Thus, some potential indicators in Levels II and III may be discovered to be, or developed into, Level I indicators at a future date.

Guiding Questions to Develop Potential Indicators

The considerations described in Figure 8 are synthesized, in Table 7, into a list of questions that will assist in the generation of potential indicators. We have found such a set of questions to be very useful in guiding the process of indicator development and encourage those involved in developing indicators to generate a set of guiding questions appropriate for their own circumstances.

Designing the Remaining Elements

We brie y discuss the design of the remaining elements of the monitoring programme (see Table 2) as they are either very case specific or are the subject of much literature in their own right.

A Methodology for Data Collection and Storage

Carefully laid out procedures that address the practical and technical issues involved in data collection must be established to ensure accuracy, consistency and statistical robustness. This is especially important when different people will be collecting the data over time. An emerging design concern is the technical expertise of those collecting data. Increasingly community groups and volunteers are engaged in data collection. The reliability of the data then, very much depends on the methodology being designed to allow the keen, but technically unsophisticated, to collect the data in ways which are replicable. In any case the design of the methodology must re ect the capabilities of the users of the methodology, if the resulting data is to be useful.

Equally important is the storage of the data, so that they are accessible and usable in the future. Much has been written on this subject, but in essence there must be a way of recording the information that allows someone in the future

(typically a decade) to understand what measurements were taken in the field and to be able to confidently assess their reliability and to repeat them. Failure to do this has often resulted in data being rejected simply because their reliability is unknown, thus effectively wasting the time, effort, and money spent in collecting the data in the first place (Wiersma, 1995). *See also* Data Banks: Archiving Ecological Data and Information, Volume 2; Metadata, Volume 2.

A Methodology for Calculating Indicators

The data collected will have to be manipulated in order to derive values for the indicators. Again, a method to do this accurately, consistently and in a statistically appropriate manner is required. This method must be easily applied by those doing the calculations.

A Process for Synthesis

Synthesizing the information that the indicators provide, into an overall narrative of the status of the system, is essential to completing the central task of the monitoring program, that is, to assess progress towards the human goals and aspirations which motivated the enterprise. The synthesis should in effect bring the conceptual model to life. How one does this is an art form akin to story telling. As such, the form of the narrative is very much dependent on the audience and thus is very case specific.

A Methodology for Reporting

The values of the indicators and the results of the system assessment must be reported to the intended audience or users of the information. While it seems trite to say this, a methodology for presenting it in a clear, purposeful, and timely manner for decision-making is crucial to the utility and success of the monitoring program. Many a monitoring report has collected dust on a shelf because the authors paid no attention to the issue of packaging and marketing it. In fact, generating the report should be treated as a marketing exercise and it should be recognized that a number of different reporting products may be necessary for different audiences. With the advent of the World Wide Web and browsers with capabilities to access GIS and computer-aided drafting software in quite transparent ways, some very exciting possibilities for reporting the results of monitoring programs are emerging (*see* Geographic(al) Information Systems (GIS), Volume 4).

IN CLOSING

We have argued that monitoring needs to be part of an adaptive ecosystem approach if it is to contribute to the sustainability of ecological-economic systems. Monitoring provides feedback to the two other elements of an adaptive ecosystem approach, governance and management. At the core of the approach is a conceptual model (describing the situation in terms of a SOHO systems description) that addresses the issues of complexity, and an issues framework that integrates the hopes, aspirations and concerns of the various actors into a working definition of sustainability. A central tenet of the ecosystem approach is that the path to sustainability is one of tradeoffs. Science can illuminate the tradeoffs but a resolution, that is, the choice of path, is a political decision and in the domain of governance. Thus, an ecosystem approach must bring together science and the socio-political economic realities of the situation in a synthetic and systematic way.

In an adaptive ecosystem approach, governance is seen as the ongoing process of resolving the tradeoffs and charting a course for sustainability. Management is about operationalizing sustainability. Monitoring provides feedback on how the situation is actually unfolding and where it appears to be going.

An adaptive ecosystem approach cannot be undertaken without a monitoring program. The reality of irreducible uncertainty, associated with complex situations, limits our ability to predict how the situation will unfold, and hence where the path to sustainability lies. Thus, any successful approach to sustainability must not only employ traditional anticipatory methods but also methods for adapting to the way in which the situation actually unfolds. The feedback provided by the narrative, which results from a monitoring program, is the source of learning that is required for a successful adaptive approach to sustainability.

In this context the monitoring program must be capable of providing a narrative description of how the ecological-economic system is developing and the implications of this for the path to sustainability. To do this requires collecting information that is clearly tied to the SOHO conceptual model and the issues framework, and reporting this information in a form which can be used for governance and management. Indicator development must be undertaken in this broader system's context, and not as a purely scientific exercise. Otherwise, it is more likely than not to produce yet another set of measures which satisfy disciplinary curiosity, but provide little input to the process of resolving the ecological-economic challenges confronting our society.

A

Adaptation Strategies

see Adaptation Strategies (*Opening essay*, **Volume 4**)

Adaptive Environmental Management

The notion of *adaptive environmental management* (AEM), also termed active adaptive management or experimental management, has evolved over time, but its focus has always been on managing resources under uncertainty. Uncertainties are pervasive in resource management: data are almost always limited and both internal and external processes, including management practices, can cause ecosystem behavior to switch dramatically and unexpectedly (Holling, 1973).

The emphasis placed on reducing such uncertainties distinguishes AEM from other approaches to resource management (Holling, 1978). At their best, these other approaches usually strive for a process of informed trial-and-error through which available knowledge is used to produce a best-guess management strategy. Ongoing scientific research, as well as monitoring the (ecological, social and economic) results of implementing this strategy produce new information, which is then used to refine the best guess. In this process of informed trial-and-error, management operations are typically focused solely on meeting specific socio–economic targets and environmental standards. Efforts to specifically reduce uncertainties occur through standard (reductionist) scientific research, which is conducted at small scales on selected components of the ecosystem. Because this small scale, piecemeal approach ignores component interactions, it is relatively ineffective when used alone at reducing uncertainty in the large scale, operational management of complex ecosystems. In contrast to informed trial-and-error, AEM is a process in which a considerable amount of management's operational effort is intentionally directed at reducing uncertainties. AEM uses operational activities as tools not only to manage, but also to conduct experiments in operational settings (Walters, 1986), and thus test different possible management strategies at operational scales. Thus, in contrast to informed trial-and-error, AEM uses management experiments to supplement standard scientific research in reducing uncertainty.

AEM is most useful when there is substantial uncertainty about the effects of management policies. In certain situations, informed trial-and-error may be more appropriate. Conducting management experiments and constructing monitoring systems over large areas for ecosystems with long and erratic response times is expensive and technically challenging. The large scale of management experiments can also pose unacceptable ecological risks.

Implementing AEM often depends on a shift in awareness of institutions and society to the realization that experimentation at operational scales can be a cost-effective approach to long-term resource management. Bringing about this shift may involve a variety of social, political, and institutional changes (Gunderson *et al.*, 1995; Lee, 1993). Because AEM's management experiments involve both people and institutions affected by the management strategy in designing the experiments and in interpreting the results, AEM has been described by some as social learning (Lee, 1993) (*see* Holling, C S, Volume 2; Social Learning in the Management of Global Atmospheric Risks, Volume 5).

RICHARD A FLEMING AND JAMES A BAKER *Canada*

Agarwal, Anil

(1948-)

Anil Agarwal was trained as a mechanical engineer at the Indian Institute of Technology, Kanpur. He is an environment advocate, journalist and analyst in India. In 1980, he founded the Center for Science and Environment, one of India's first environmental non-governmental organizations (NGOs) to analyze and study the relationship between environment and development and create public consciousness about the need for sustainable development. In 1982, the Center published a pioneering *Citizens' Report on the State of India's Environment*, which provided an overview of the level of degradation and its impact on the people of India.

In 1985, Agarwal co-edited *The Second Citizens' Report on the State of India's Environment*. In 1986, the government of India presented Agarwal with its prestigious Padma Shri award.

In 1986, Prime Minister Rajiv Gandhi invited Agarwal to address the Union Council of Ministers to speak to them about the importance of the relationship between environment and development. Thereafter the Prime Minister asked him to address Members of Parliament on the same issue. He addressed all the 27 Parliamentary Committees, which oversee the work of different Union Ministries.

During this period, Agarwal also chaired the world's largest network of environmental NGOs based in Nairobi, the Environment Liaison Center. In 1987, the United Nations Environment Programme (UNEP) elected Agarwal to its Global 500 Honor Roll for his work both in the national and international arena.

In 1992, Agarwal founded and continues to edit *Down to Earth*, India's first science and environment fortnightly, in order to take environmental issues beyond the limited constituency of environmentalists.

At the national level Anil, among several other things, is the Chairperson of the Society for Environmental Communications, New Delhi, a member of the National Environment Council, Government of India: the Task Force on Control of Air Pollution, Government of Delhi, and the Standing Committee, National River Conservation Authority, Government of India, New Delhi.

At the international level he has been extremely active. Among other things he is Patron, Schumacher College, Devon, UK; Member of the International Working Group on Sustainable Livelihoods, United Nations Development Program, New York, and of the World Commission on Water for the 21st Century, co-sponsored by the United Nations Educational, Scientific and Cultural Organization (UNESCO), the Food and Agriculture Organization (FAO), the United Nations Development Programme (UNDP), UNEP, the World Health Organization and the World Bank.

Agarwal has received a large number of awards from his country, India, as well as from Hawaii and France and from two United Nations Organizations: FAO and UNEP. Anil Agarwal, over the past 20 years, has published 18 books in London, New Delhi, Washington, Rome and Geneva. Some of his books have been translated into French, German and Danish.

His books cover drugs, land, water, energy, food and agriculture, oods and droughts, forests, global warming, women and the landless Aral Sea and environmental economics in addition to his three citizen's reports on the State of Environment in India.

MOSTAFA K TOLBA *Egypt*

Agenda 21

Mary P Williams Silveira
United Nations Economic Commission for Europe, Geneva, Switzerland

Agenda 21 was adopted by the United Nations Conference on Environment and Development (UNCED) in Rio de Janeiro, in 1992, by consensus. As the name implies, it is intended as an Agenda for the 21st century, in which emphasis is placed on decision-making that integrates social and economic concerns with sustainable management of the environment.

Implementation of Agenda 21 is the responsibility of governments, non-governmental actors and individuals. To monitor implementation, the General Assembly established the United Nations (UN) Commission on Sustainable Development (CSD) in 1993. In 1997, the General Assembly carried out a ve-year review of Agenda 21 and adopted a program for the Further Implementation of Agenda 21.

INTRODUCTION

Although efforts had been made by the international community to address major issues of environmental degradation and conservation since the late 1960s, by December 1989, the United Nations General Assembly, in its Resolution 44/228, expressed deep concern at the serious degradation of the global life-support systems and warned of ecological catastrophe. Political understanding of the issues was not keeping pace with scientific knowledge, and environmental issues were largely approached as the provenance of environmentalists.

The General Assembly therefore, in the same resolution, resolved to convene UNCED, in Rio de Janeiro, Brazil, 3–14 June 1992. The conference was to elaborate strategies and measures to halt and reverse the effects of environmental degradation in the context of strengthened national and international efforts to promote sustainable and environmentally sound development in all countries.

Preparations for the conference spanned more than two years. During this period, negotiations began on the documents that would be adopted by the conference, including Agenda 21.

AGENDA 21

Agenda 21 is formally the Programme of Action for Sustainable Development. It was adopted by consensus by the 178 governments that participated in UNCED. Subsequently welcomed by the General Assembly in its Resolution 47/191 of 29 January 1993, Agenda 21 addresses the pressing problems of today and also aims at preparing the world for the challenges of the next century. It re ects a global consensus and political commitment at the highest level on development and environment cooperation. (United Nations Department of Public Information, 1993, Preamble, paragraph 1.3).

Agenda 21 is comprehensive: it addresses needed actions in 39 areas, spanning four clusters of issues: economic and social; conservation and resource management; participation; and implementation.

It is complex: the common thrust throughout is long-term, strategic, integrated and participatory decision-making.

Agenda 21 is inclusive and universal: it places a major emphasis on broad participation not only from governments, the UN and other intergovernmental organizations, but also from nine major groups in civil society (see below).

Agenda 21 is forward looking. It is a program to take the world into and through the 21st century, implicitly founded on the concept of inter-generational equity (see also Principle 3 of the Rio Declaration on Environment and Development, which states that the right to development must be fulfilled so as to equitably meet developmental and environmental needs of present and future generations (United Nations Department of Public Information, 1993).

Agenda 21 is a consensus program. It does not carry the force of international law, but, having been adopted by 178 governments, it does bring with it a strong moral obligation to ensure full implementation.

CONTENTS

Within its 40 chapters, Agenda 21 specifies 115 programs and approximately 2500 actions to be implemented by governments at the local, national, regional and global levels. Each chapter (issue) also identifies priorities, targets, cost estimates, modalities and means of implementation through new and additional financial resources, technology transfer, and strengthening of institutional capabilities at national and international levels.

The economic and social issues are international cooperation (chapter 2), poverty (3), changing consumption patterns (4), demographic dynamics (5), human health (6), human settlements (7), and integrating environment and development in decision-making (8) (the numbers in parenthesis refer to chapter numbers in Agenda 21. Actual chapter titles are more descriptive and longer than the shorthand names provided here).

Issues of conservation and management of resources for development refer to the atmosphere (9), integrated planning and management of land resources (10), combating both deforestation (11) and desertification and drought (12), mountain development (13), agriculture and rural development (14), biological diversity (15), biotechnology (16), oceans and seas (17), freshwater resources (18), toxic chemicals (19), hazardous wastes (20), and radioactive wastes (22), and solid wastes and sewage (21).

Issues of participation are geared toward strengthening the nine major groups listed in Agenda 21 as women (24), children and youth (25), indigenous people and their communities (26), non-governmental organizations (27), local authorities (28), workers and their trade unions (29), business and industry (30), the scientific and technological community (31) and farmers (32).

Finally, the means of implementation are finance (33), technology transfer (34), science (35), education, public awareness and training (36), national mechanisms and international cooperation for capacity-building (37), international institutional arrangements (38), international legal instruments and mechanisms (39) and information for decision-making (40).

IMPLEMENTATION

To review progress at the international, regional and national levels in the implementation of recommendations and commitments contained in, *inter alia*, Agenda 21, the General Assembly, in its Resolution 47/191 of 22 December 1992, established the UN CSD (*see* CSD (Commission on Sustainable Development), Volume 4) as a functional commission of the Economic and Social Council. The Commission meets in regular session once each year and reviews specific issues of Agenda 21 according to a multi-year program of work. To facilitate its review, the Commission has requested governments of all member states to provide, on a voluntary basis, annual reports of their national implementation of Agenda 21.

Agenda 21 calls for its activities to be implemented at all levels and by all local, national and international actors, including governments and local authorities, intergovernmental organizations and non-governmental organizations, other major groups and individuals.

Particular stress is given in virtually every chapter to implementation through national strategies and action plans. One example of implementation is the adoption of National Agendas 21 by 56 governments (this figure is based on national reports submitted by governments annually, on a voluntary basis, to the United Nations Commission on Sustainable Development (UNCSD). The last count was undertaken in 1998, following the sixth session of the CSD), or 30% of the member states of the UN. Many more governments have adopted similar comprehensive strategies for sustainable development at the national level. Governments have also undertaken a broad range of programs and other activities to implement all of the issues raised in Agenda 21. Examples of these are available on the UN system-wide website for sustainable development (this website is maintained by the UN Division for Sustainable Development and is located at the following Internet address: http://www.un.org/esa/agenda21/natlinfo).

Other examples rest at the local level, where local authorities, non-governmental organizations and other major groups have been important catalysts behind the creation of Local Agendas 21. As of 30th November 1996, more than 1800 local governments in 64 countries were involved in Local Agenda 21 activities. An additional 933 municipalities from 43 countries were in the process of establishing Local Agendas 21, and 879 municipalities were just getting started (the information is taken from the Local Agenda 21 Survey, published in February 1997 by the International Council for Local Environmental Initiatives, in cooperation with the United Nations Department for Policy Coordination and Sustainable Development.

Youth have been active in facilitating implementation of Agenda 21. In 1994, a group of international students wrote, designed and published a children's version of Agenda 21. Young people from approximately 100 countries worked together to produce the book that has subsequently sold over 250 000 copies in 17 languages.

REVIEW AND FURTHER PROGRAM

It was understood from the beginning that the objectives and activities of Agenda 21 would need to be revised continuously. The General Assembly decided therefore to conduct a five-year review of the implementation of Agenda 21. This review took place at the nineteenth Special Session of the United Nations General Assembly (UNGASS), in June 1997. UNGASS, in resolution S-19/2 of 19 September 1997, while acknowledging action on a number of fronts, expressed concern over the lack of real progress in the implementation of Agenda 21. It adopted a program for the Further Implementation of Agenda 21 (United Nations Department of Public Information, 1997), which reaffirms that:

> that Agenda 21 remains the fundamental program of action for achieving sustainable development. ••• We are convinced that the achievement of sustainable development requires the integration of its economic, environmental and social components. We recommit to working together – in the spirit of global partnership – to reinforce our joint efforts to meet equitably the needs of present and future generations.

In addition to reaffirming Agenda 21, the program for the Further Implementation of Agenda 21 established a new target by calling for the formulation and elaboration of national strategies for sustainable development that re ect the contributions and responsibilities of all interested parties in all countries by the year 2002. It raised the visibility of certain issues contained in Agenda 21, including energy, transport, sustainable tourism and industry. And it committed governments to undertake the next comprehensive review of Agenda 21 in the year 2002 (United Nations Department of Public Information, 1997, 1–2).

Andersen, Stephen O

(1948-)

Stephen O Andersen, a United States Citizen, born in Logan, UT on 17 January, 1948, is Director of Strategic Climate Projects in the US Atmospheric Pollution Prevention Division. Prior to that Dr Andersen was Deputy Director of the Environmental Protection Agency (EPA) Stratospheric Protection Division.

Andersen studied business administration and economics as an undergraduate and received his PhD in Agricultural and Natural Resources Economics from the University of California, Berkeley (1974).

Prior to joining EPA he worked for environmental and consumer non-governmental organizations (NGOs) including Sierra Club Research, the Environmental Law Institute, and the Consumer Energy Council. He was also a Professor of Economics and Environmental Studies at the College of the Atlantic and the University of Hawaii.

Andersen studied stratospheric ozone depletion and climate change in the early 1970s as a member of the Climatic Impact Assessment Project that investigated the consequences of SSTs. In 1986 he was hired by EPA's stratospheric ozone protection office. His EPA responsibilities included analysis of regulatory impact, cost, and trade, technology cooperation, and sector projects in halons, foams, mobile air conditioning, and military uses.

Steve Andersen (as he is known to his friends) was one of the main pillars in the implementation of the Montreal Protocol on Substances that Deplete the Ozone layer. In 1986 Dr Andersen brought Soviet authorities together with the National Aeronautics and Space Agency (NASA) scientists and EPA senior managers, to gain acceptance for a US ozone monitoring satellite to be carried into space on a Soviet rocket, in order to overcome the loss of access to space resulting from the Challenger accident. He helped organize military support for ozone layer protection including projects to change military specifications requiring use of ozone-depleting substances (ODSs) and three international conferences on the importance of the military to ozone layer protection. In 1992 he helped the North Atlantic Treaty Organization (NATO) take the unprecedented step of writing directly to the United Nations Environmental Programme (UNEP) supporting the proposed accelerated phase-out of ozone-depleting substances. NATO also endorsed technology cooperation, exchange of information regarding halon banks and the harmonization of standards to allow production and maintenance of military equipment without the use of chemicals that deplete the ozone layer.

Andersen also helped organize global technology cooperation including the early phase-out of chloro uorocarbons (CFCs) in refrigerator manufacturing in Thailand and the corporate pledge to help Vietnam avoid increased dependence on ODSs. He served on the team that commercialized no-clean soldering and the team that is phasing out ODSs from solid rocket motors. Dr Andersen helped organized the Halon Alternatives Research Corporation and the International Co-operative for Ozone Layer Protection.

Andersen co-chaired quite a number of the Montreal Protocol Panels, Committees and working groups of the Ozone Assessment Panels. He has actively participated in workshops and conferences concerning the protection of the ozone layer. In recognition of his achievements, Dr Andersen has received several medals and awards from UNEP, the United States, Japan and Brazil.

In 1995 Dr Andersen began work on climate protection by providing the United Nations with a blueprint for undertaking evaluation of the technical and economic feasibility of climate protection including the involvement of experts from industry. In 1996 he successfully negotiated cooperation of electronics manufacturers in Japan, Korea, Singapore, and Taiwan to search for alternatives to the use and emissions of per uoro-compounds as etching agents in semiconductor manufacture.

APN (Asia–Pacific Network)

The Asia–Pacific Network for Global Change Research is an inter-governmental network whose mission is to foster

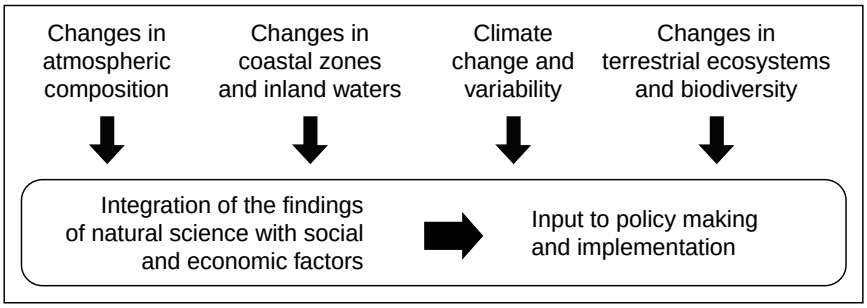

Figure 1 APN research framework

global environmental change research in the Asia–Pacific region, increase developing country participation in that research, and strengthen interactions between the science community and policy makers.

The APN believes that international cooperation among governments and scientists will help increase the understanding of the complex mechanisms and impacts of global environmental change on ecosystems and human society in the Asia–Pacific region. This is necessary to identify and address the problems that may arise from that change.

The vision of the APN is that scientists and institutions within the countries of the Asia–Pacific region will together conduct high quality, cooperative, multidisciplinary research on the region's key global environmental change issues and that the countries will use the results of that research in their policy making processes.

Currently 21 governments participate in the APN (Australia, Bangladesh, Cambodia, China, Fiji, India, Indonesia, Japan, Korea, Laos, Malaysia, Mongolia, Nepal, New Zealand, Pakistan, Philippines, Russia, Sri Lanka, Thailand, Vietnam and the USA) together with scientists throughout the region and the wider global change research community.

The APN was established in response to the 1990 White House Conference on Science and Economics Research Related to Global Change, at which then US President Bush invited the countries of the world to join the United States in creating three regional networks. Those three networks are the APN, ENRICH (European Network for Research in Global Change) and the IAI (Inter American Institute for Global Change Research).

After a series of planning workshops the APN was formally launched in 1996. Its main focus has been the support of global environmental change research projects which cannot be conducted on a national basis and require regional cooperation, and which strengthen research capability at the national and regional levels.

In order to achieve its goals the APN conducts a number of different activities including:

- supporting collaborative research and training activities;
- organizing planning and scoping workshops to develop new research projects;
- disseminating global change information to scientists and policy makers;
- providing opportunities for governments and scientists to discuss regional research priorities and other global change issues.

To date the APN has made direct contributions to 65 global change and capacity building projects, and helped to promote in-kind contributions from a number of countries and organizations for this work. The APN has also initiated and funded scoping workshops, symposiums, an inventory of global change research and a number of other initiatives. It produces a quarterly newsletter and maintains a homepage on the Internet: http://www.apn.gr.jp.

The broad framework of the research interests of the APN is set out in Figure 1. The primary concern of the APN is to provide an input to policy-making through the integration of the natural and social sciences. Accordingly, understanding the human dimensions of global change is at the heart of the APN's concerns. The APN has sponsored research and capacity building activities in areas such as:

- food and water security;
- regional climate modeling;
- land use and cover change;
- urbanization;
- marine and coastal zone studies;
- aerosol data synthesis.

The APN believes that working in partnership with other organizations involved in global change research is essential to maximize the resources available and to deliver the

best possible results. In particular the APN cooperates very closely with START (the System for Analysis Research and Training in Global Change), the International Geosphere Biosphere Program (IGBP), the International Human Dimensions Program (IHDP) and the World Climate Research Program (WCRP). It has also developed links with a number of other regional bodies with an interest in global change research.

Basel Convention

Jennifer Clapp
Trent University, Peterborough, Canada

The Basel Convention on the Control of Transboundary Movements of Hazardous Wastes and their Disposal is an international legal treaty governing cross-border shipments of toxic wastes. The impetus for this convention was the growing export in the 1980s of hazardous wastes from industrialized to developing countries. This practice emerged as a response to rising costs for hazardous waste disposal in rich countries at a time when costs for such disposal in developing countries was minimal. As the nature of this trade became apparent, work began on drafting a global treaty to control it. The United Nations Environment Programme (UNEP) sponsored negotiations on this treaty, which was adopted by 116 governments in Basel, Switzerland, in March 1989. The treaty came into force in May 1992 when it received the necessary 20 rati cations (Tolba and Rummel-Bulska, 1998). As of April 2000, there were 135 parties to the convention. The types of wastes covered by the treaty are those which are toxic, poisonous, explosive, corrosive, amable, eco-toxic or infectious.

The principal objectives of the Basel Convention are to:

1. reduce the transboundary movement of hazardous wastes;
2. encourage hazardous wastes to be treated and disposed of as close as possible to their source of generation; and
3. minimize the generation of hazardous wastes.

To facilitate the achievement of these objectives, the provisions of the original 1989 convention provided a regulatory framework for the movement of wastes (Kummer, 1995; O'Neill, 2000).

There are several cases under which the export of hazardous wastes is strictly forbidden by the convention. Parties are prohibited from exporting wastes to states that have banned its import. This upholds states' sovereign right to refuse waste imports if they so choose. Parties are also to refrain from trade in hazardous wastes with non-parties unless there is a bilateral or regional agreement under which wastes are to be disposed of in no less environmentally sound a manner than that outlined in the convention (Article 11). The purpose of this latter trade restriction is to encourage states to become parties to the convention.

For exports of wastes to states that have not prohibited its import, the principle of prior written notification and consent is to be adhered to (Article 6). This requirement was intended to allow countries to accept or turn away such imports on a case-by-case basis at their own discretion. Parties that intend to export hazardous wastes must notify the importing country in writing in advance of a hazardous waste shipment. If the latter agrees in writing to accept the waste, and provided there is assurance that the waste will be disposed of in an environmentally sound manner, then the transaction is allowed. Waste exports that do not follow these provisions are considered by the convention to be illegal. Parties are asked to only export wastes if they themselves lack the means to dispose of those

wastes in an environmentally sound manner, or if the wastes are considered a raw material in the importing country.

The control system established by the 1989 Basel Convention was criticized by a number of developing countries and environmental non-government organizations (NGOs) as being weak (Puckett, 1992). This was mainly because the convention only sought to control the export of wastes and did not ban their trade between rich and poor countries. Moreover, it did not effectively put a halt to the trade in hazardous wastes destined for recycling operations in developing countries. The issue of whether to incorporate a ban on the trade in wastes between rich and poor countries within the Basel Convention was the subject of heated debate in the early 1990s. In 1994, the conference of parties to the Basel Convention adopted a decision to ban outright the export of hazardous waste destined for both disposal and recycling from the highly industrialised Organisation for Economic Cooperation and Development (OECD) countries to non-OECD countries (Decision II/12). This decision was made on the grounds that developing countries were not capable of disposing of such waste in an environmentally sound manner.

The Basel Convention was formally amended to this effect in 1995, with the ban on waste exports for disposal taking place immediately, and the ban on waste exports for recycling taking effect December 31st, 1997 (Decision III/1). The amendment asks parties listed in Annex 7 to refrain from the export of wastes to countries not listed in Annex 7, once the amendment is ratified. Annex 7 lists members of the OECD, European Commission (EC) and Liechtenstein. To come into force, this amendment requires ratification by 62 parties. As of November 2000, 22 ratifications have been deposited with the Secretary General of the United Nations. The Basel Ban has continued to be a source of controversy amongst the parties, as some have argued that such a trade ban is in contravention of international trade rules enforced by the World Trade Organization (Krueger, 1999).

In 1998, progress was made by the technical working group of the convention in establishing a system for classifying wastes and clarifying precisely which wastes are covered by the treaty. This clarification has gone some way to assure those involved in the global trade in recyclable materials that many of the wastes traded by them are not classified as hazardous, and are thus not controlled by the convention.

In 1999, a protocol on liability and compensation was adopted by the parties. The drafters of the original convention had hoped to include provisions on liability and compensation for damages arising from the transboundary movement of wastes in the original convention, but agreement on these matters was not secured at that time. Instead, Article 12 of the Basel Convention calls on parties to develop such a protocol as soon as practicable. The driving force for the development of this protocol was the concern of developing countries that they lacked funds and the technology to deal with illegal imports of hazardous waste and their impact on their local environments. The protocol thus provides rules for the compensation of countries that are victims of environmental damage due to waste imports, and determines liable parties that must provide that compensation.

Also in 1999, the parties adopted the Basel Declaration on Environmentally Sound Management, which outlines the agenda for the next decade of the convention. This declaration emphasizes the importance of prevention and minimization, as well as the environmental sound management of recycling and disposal of hazardous wastes. This marks a new direction for the convention, as it broadens the focus of the convention as it puts more emphasis on the specific objective of waste management (Clapp, 2001).

Benedick, Richard Elliot

A career diplomat and former Deputy Assistant Secretary of State, Richard Benedick has had a distinguished career in global environmental affairs. Ambassador Benedick was the chief US negotiator and a principal architect of the historic 1987 Montreal Protocol on protecting the ozone layer. His acclaimed book, *Ozone Diplomacy: New Directions in Safeguarding the Planet* (Harvard University Press, 1991, revised 1998), is being translated into Japanese and Spanish and is used in universities around the world.

After serving several years on the International Advisory Board of Battelle, he joined their Washington, DC, office in 1998 as a Deputy Director of the Environmental and Health Sciences Division of Pacific Northwest National Laboratory. He is a Visiting Fellow at the Wissenschaftszentrum Berlin. He has lectured at numerous universities, serves on several boards, and consults for international agencies, governments and industry. From 1990 to 1994, he was Special Advisor to Secretaries-General of both the United Nations Conference on Environment and Development (Rio de Janeiro, 1992) and the International Conference on Population and Development (Cairo, 1994), assisting the negotiations and drafting chapters of Agenda 21 and the Cairo Programme of Action. He has organized or presided over numerous international conferences and negotiations on environment, development, population and science policy.

Benedick served on diplomatic assignments in Iran, Pakistan, Paris, Bonn and Athens. As Deputy Assistant Secretary of State for Environment, Health, and Natural Resources, he supervised policy formation and international negotiations on climate change, biotechnology, ozone, oceans, tropical forests, wildlife conservation, and AIDS. He has also headed policy divisions at the State Department responsible for population affairs and for development assistance, and was selected for the Senior Seminar; the US Government's highest study program. He has led many US delegations and has testified before Congress and foreign parliaments.

Elected a Fellow of the World Academy of Art and Science in 1991, Benedick has also received two of the highest presidential career public service honors (the Distinguished and two Meritorious Service Awards), the State Department's John Jacob Rogers medal, and the 1997 United Nations Tenth Anniversary Ozone Award. Other distinctions include: two State Department Superior Honor awards; visiting fellow, National Center for Atmospheric Research; senior fellow, World Wildlife Fund; awards from the Climate Institute and the Population Reference Bureau; the *Tonisssteiner Kreis*; Phi Beta Kappa; and a citation in *Who's Who in America*.

He received an AB *summa cum laude* from Columbia, an MA in economics from Yale, and a doctorate in international finance from the Harvard Graduate School of Business Administration. He was also an Evans Fellow at Oxford University in metaphysical poetry, and is author of over 90 publications in the US and abroad, including *Industrial Finance in Iran* and *The High Dam and the Transformation of the Nile*.

Blue Plan

In 1975, all the Mediterranean countries, increasingly concerned by the pollution of their common sea, signed the Barcelona Convention and launched their Mediterranean Action Plan (MAP). Since some 80% of marine pollution comes from land-based sources, it was considered necessary to analyze the root causes of this process, to see how it might evolve, and more generally to look for socio-economic development patterns which would avoid environmental degradation in the Mediterranean Basin. This continued systemic and prospective

study of current trends and possible futures is known as the *Blue Plan*.

Using the method of scenarios, the Blue Plan has explored the interactions between development sectors (agriculture, industry, energy, tourism, transport), environmental components (soil, water, vegetation, coastline, sea), demographic dynamics and land occupation changes, in order to suggest avenues towards sustainable development to the Mediterranean countries and the European Commission. Its initial results (Grenon and Batisse, 1989) aroused keen interest in the region. The report revealed how trend scenarios could prove socially and environmentally unacceptable well before 2025, particularly for the countries South and East of the Basin, and outlined the major requirements for a more sustainable future (*see* Mediterranean Sea, Volume 4).

The Blue Plan keeps updating its databases, checking the validity of its scenarios, monitoring changes in the region and publishing thematic studies on a variety of subjects, such as the Mediterranean vision on water, population and the environment presented at the second World Water Forum in The Hague. It now serves as the main support centre for the Mediterranean Commission for Sustainable Development established in 1995, and to this effect prepares reports on such topics as water demand, sustainable tourism, environmental indicators and impacts of free trade.

A major step forward, in line with a main recommendation of the Blue Plan, was the establishment in 1995 of the Euro-Mediterranean partnership, supported by a fund of the European Union called MEDA. The MEDA project on environmental statistics is conducted by the Blue Plan, which also hosts a MEDA project for a regional information system on water.

Blue Plan operations are made possible through a specific non-governmental organization (NGO) under French law and carried out in a regional activity centre located at Sophia Antipolis, near Nice, where a staff of some 15 people works in close contact with experts from all countries in the region. About half of the total annual budget of approximately US$1.5 million is provided by MAP, the rest coming from the European Union (including MEDA) and the French Ministry of Environment.

Future publications will include further issues in the Blue Plan Fascicules series, a comprehensive compendium of indicators, and a new report on environment and development in the Mediterranean to be issued in 2003.

Boreal Forest Carbon Flux and it's Role in the Implementation of the Kyoto Protocol Under a Warming Climate

Kaz Higuchi
Meteorological Service of Canada, Toronto, Canada

Since the signi cant increase in industrial activities in Europe in the mid-1800s, the atmospheric carbon dioxide (CO_2) concentration has exponentially climbed from a value of about 280 parts per million (ppm) to over 360 ppm at present, and is still increasing at a rate of about 1- 1.5 ppm per year. This increase is equivalent to about 2- 3 Pg of carbon (Pg C = 10^{15} grams of carbon) per year in the atmosphere which now contains about 730 Pg C of CO_2. We know relatively well that about 5 Pg C is emitted into the atmosphere every year from various fossil fuel combustion processes. In addition to this industrial source of CO_2, approximately 1.5 Pg C per year is emitted from tropical deforestation. Of these two major sources of CO_2, totaling 6.5 Pg C, it is estimated that about 2 Pg C per year is absorbed by the oceans, while about 3 Pg C per year remains, on average, in the atmosphere. From our present knowledge of the existence of only three major carbon reservoirs in the world (atmosphere, ocean, land biosphere), a carbon sink of about 1.5 Pg C per year is required in the terrestrial biosphere to balance the global carbon budget. A major research activity in the carbon cycle community is to nd out where the sinks are in the land biosphere, and what processes control the net uptake of the atmospheric carbon and how these processes might change under a changing (warming) climate. This scienti c issue is politically important because of its possible in uence on the way the terms of the Kyoto Protocol are implemented by nations such as Canada and the United States. The Kyoto Protocol legally binds countries that signed the agreement to a collective reduction in greenhouse gas emissions below 1990 levels. The Protocol allows countries to use net emissions from land-use change in forestry and agriculture in calculating their compliance with the terms of the Protocol.

To tackle the important but extremely difficult problem of long-term changes in the strengths of the biosphere carbon sinks and sources, scientists usually employ either the *bottom-up* or the *top-down* approach. In the latter case, an atmospheric model, constrained by oceanic carbon dioxide (CO_2) uptake, globally-balanced land biospheric exchange of CO_2, and the observed atmospheric CO_2 concentration measurements from a global CO_2 observing network, is used to estimate spatial and temporal variations in the carbon sources and sinks in the terrestrial biosphere. One of the recent studies using the top-down method has estimated a significant terrestrial sink of about 1.7 Pg C per year in North America during the late 1980s and the early 1990s (Fan *et al.*, 1998). However, climate change impact on net carbon storage in the terrestrial biosphere under an increasing atmospheric CO_2 concentration cannot be made using a top-down approach.

In the bottom-up approach, scientists generally employ the eddy-correlation method using a tower situated in an ecologically homogenous environment to estimate uxes of CO_2 from vegetation. These uxes are then interpreted in terms of daily and seasonal biological and chemical processes taking place in the environment represented by ux measurements. These measurements tell us that the boreal forest in North America has been acting, at least at some locations, as a net sink of about 1–2 metric tons of C hectare $(ha)^{-1}$ $year^{-1}$ (*see* Boreal Ecosystem Atmosphere Study (BOREAS), Volume 2). If one were brave enough to multiply this figure by the boreal forest area in North America of about $2{\bullet}5 \times 10^8$ ha (1 ha = 10^4 m^2), one obtains a North American sink estimate of about 0.25–0.5 Pg C per year. Using a bottom-up approach, it is very difficult however, if not impossible, to make regional and global statements about the spatial and temporal variations in the terrestrial net ux of CO_2 within the context of changing climate. In order to overcome these shortcomings to some extent, the Ameri ux program was initiated in North America to systematically measure CO_2 uxes from as many different ecosystems in North America as possible.

Another approach, called the boundary-layer budget (BLB), has been used by some investigators to estimate average CO_2 uxes over an area of 10^2–10^4 km^2. In this approach, which can be classified as a bottom-up approach, the atmospheric CO_2 concentration in the lower atmosphere is used as an input into a highly simplified atmospheric boundary layer model to calculate the CO_2 ux from the biosphere. This method was used, for example, on a 6-year (1991–1996) record of atmospheric CO_2 concentration values from a mixed boreal forest site (Fraserdale) in Ontario, Canada. Flux estimates were found to be similar in magnitude to those obtained by measurements on ux towers (Shashkov *et al.*, unpublished).

There appears to be some evidence to indicate the existence of a large terrestrial sink in the Northern Hemisphere at the present time, with the North American biosphere possibly playing a significant role. To assess the validity (or reality) of the existence of this terrestrial sink, and to interpret it as a function of various biogeochemical processes within different ecosystems, scientists have started to employ a number of ecosystem models of hierarchical complexity. These models constitute an essential scientific tool to understand how changes in physical environment (such as temperature, precipitation and atmospheric CO_2 concentration) can affect CO_2 exchange between the land biosphere and the atmosphere. Questions we need to ask are: Do these models, which represent mechanisms of carbon cycling in various ecosystems, give net CO_2 ux estimates in agreement with the results obtained from the top-down and/or the bottom-up approaches? What controlling mechanisms governing the carbon ow through the biosphere are important in in uencing the CO_2 ux across the atmosphere-biosphere interface? How are these mechanisms changed as climate becomes warmer with increasing concentration of CO_2 in the atmosphere? A recent study by a group of scientists (Schimel *et al.*, 2000) suggests, based on the results of three different ecosystem models driven by historical meteorological and atmospheric CO_2 concentration data, that for the period 1980–1993 the ecosystems in the United States have been acting as a net sink of about 0.3 Pg C per year, of which about 0.1 Pg C per year is attributed to the CO_2 fertilization of the photosynthesis and warming climate, and about 0.2 Pg C per year to such processes as regrowth on abandoned agricultural and harvested forest lands. (The term *CO_2 fertilization* is used to denote enhanced photosynthesis in plants exposed to a high ambient CO_2 concentration.) These estimates are consistent with carbon inventory models, but are about an order of magnitude lower than those obtained by the top-down approach. Carbon inventory models attempt to keep a running account of carbon ow through various carbon-based products in our society.

The northern high latitude terrestrial biosphere above 50 °N constitutes about 25% of the global vegetated land area, and is composed of about 800–900 Pg C soil carbon and 100–150 Pg C above-ground vegetation carbon. It is dominated by boreal forest ecosystems, of which about 30% are found in Canada. A recent study by a group of British scientists (White *et al.*, 2000) shows that the terrestrial biosphere located north of 50 °N has been accumulating carbon at a rate of about 0.4 Pg C per year, mostly due to the CO_2 fertilization from the increasing CO_2 concentration in the atmosphere. This sink was found to increase, at least in their ecosystem model called *Hybrid* driven by an atmospheric climate model output, to 0.8–1.0 Pg C per year by 2050 under a warming climate. Changes in the physical

climate variables, such as temperature and precipitation, are found to cause the northern high latitude biosphere to become a sink. The above estimates are similar to those obtained in a study using a two-dimensional coupled climate/land carbon cycle model (Chan *et al.*, 1996). In the latter study, the land ecosystem model employed an empirical expression for the soil respiration as a function of soil temperature and carbon content. The study shows that the climate effect alone results in a large soil carbon loss in the northern high latitude regions, causing the biosphere in these regions to become a net source of CO_2. However, inclusion of the CO_2 fertilization effect results in very little change in the soil carbon content in these regions, while producing a relatively large increase in the vegetation carbon content due to enhanced photosynthesis. These estimates are not inconsistent with a net CO_2 uptake estimate for the Canadian forest of about 0.06 Pg C per year over the last few decades. It should be noted that a carbon budget inventory model shows the Canadian forest to be a small source of CO_2. Various values of estimated CO_2 uptake mentioned so far are summarized in Table 1.

Many ecosystem models assume that respiration will increase with an increase in atmospheric temperature. However, some recent findings indicate that soils in high latitude ecosystems may decompose slower than usually assumed in these models, thus reducing the effect of respiration dependence on temperature. In fact, it has been found that forest soils in Finland, for example, increase in carbon content with increase in mean annual temperature.

Given the extreme complexity of the physiological structure and processes of a biological system, it is going to be very difficult to predict how precisely various ecosystems in the terrestrial biosphere will respond in terms of carbon redistribution to a warming climate. It will not be a surprise to find out then that there will be a large variation in the biospheric response to various environmental changes, depending on which ecosystem one is dealing with. There are con icting opinions about the importance of the dependence of respiration on temperature, as well as about the impact of nitrogen deposition. Photosynthetic response to increasing CO_2 concentration and temperature in the atmosphere is not very clear, although there is consensus that it must vary significantly among various vegetative species. Although there appears to be some agreement on the significance of the uptake of the atmospheric CO_2 by the Northern Hemisphere biosphere on a relatively short time scale, with boreal forest ecosystems contributing about 20–30% of the 1.5 Pg C per year missing sink, there is great deal of uncertainty at the present time if the sink will continue on a long time scale under a warming climatic regime. Some scientists believe that soil respiration will begin to dominate over the next 30–50 years, as atmospheric temperature rises more and CO_2 fertilization begins to saturate. If this turns out to be true, then the terrestrial biosphere, now being viewed as a net sink of anthropogenic CO_2, will become a significant source of natural CO_2, adding to the already increasing CO_2 emission from fossil fuels. Reduction of the uncertainty in the net CO_2 ux from the terrestrial biosphere is regarded as one of the top priority activities by the carbon cycle research community.

POLITICAL IMPLICATIONS

Results from such research activities in the global carbon cycle research community will have major global political, economic and social implications. The Kyoto Protocol would legally bind industrialized countries such as the United States, Canada, Japan and the European Union to reduce their overall greenhouse gas emissions by about 5% from 1990 levels during the period from 2008 to 2012. Canada's reduction target is 6%, whereas that of the US is 7%. Article 3.3 of the Kyoto Protocol allows countries to use as credits against their intended emission reduction targets, amounts of CO_2 *saved* by land-use change in forestry via such activities as reforestation (planting of trees on land which was once forested but cleared in the last 50 years) and afforestation (planting of trees on land that has not been covered by forest for over 50 years). However, many unanswered questions related to such basic issues as the definition of a forest, and how to measure changes in the carbon content of various ecosystems have hindered the ratification of the Protocol. In the recent Intergovernmental Panel on Climate Change (IPCC) Special Report: Land Use, Land-Use Change, and Forestry, the IPCC has attempted to address

Table 1 Values indicate net ecosystem uptake of atmospheric CO_2

Model type	Present time (Pg C per year)	Under warming climate (Pg C per year)
Top-down	≈1.7 (N. America, mainly US)	
Bottom-up	≈0.2–0.5 (Boreal forest, Canada)	
Inventory model	Slight source (Canada)	
Ecosystem models	≈0.3 (US)	
	≈0.4 (North of 50 °N, Hemispheric)	≈0.5–1.0 (North of 50 °N, Hemispheric)

some of those unanswered issues (Kaiser, 2000; IPCC, 2000). The IPCC Special Report emphasizes the importance of defining what a forest is, since countries will get carbon credit for trees grown since 1990, or lose credit for trees destroyed since 1990. The IPCC Special Report also notes the importance of distinguishing forests that are harvested commercially and then replanted from forests with increased carbon sequestration from other reforestation activities.

Aside from some obvious moral issues, such processes as the CO_2 fertilization effect will likely induce many countries to start planting fast-growing trees like pine and birch to meet their targets, while possibly altering fossil fuel emission by very little. Indeed, the IPCC Special Report suggests that this is possible. Ecosystem models, which indicate that the terrestrial biosphere north of 50 °N will continue to grow as a net sink for CO_2 over the next 50 years, are supportive of such human-induced land-use change to absorb excess CO_2 in the atmosphere. But what if they are wrong? These models, although complex, are still very primitive. Simply put, the future role of the boreal forest, and indeed the entire global terrestrial biosphere, as a net sink or source of CO_2 seems to depend on the difference between CO_2 fertilization and soil respiration. These processes are very complicated and are governed by many complex interactive biochemical feedback mechanisms that scientists do not understand very well at the present time. Understanding carbon cycling in the boreal forest, as well as in other land ecosystems, has very wide and significant global political and economic implications in the 21st century.

Bourdeau, Philippe F J

Professor Philippe Bourdeau is a former director of environmental science, research and development programs in the Commission of the European Union (CEC), and a past-president of the Scientific Committee on Problems of the Environment (SCOPE) (*see* SCOPE (Scientific Committee on Problems of the Environment), Volume 4), bringing to those organizations the benefit of his very considerable insight into the problems of ecotoxicology. How does the biosphere respond to the stresses imposed on it by the increasing loads of potentially toxic substances dumped into the environment? Do biosphere responses mimic those of humans? Are the effects of multiple toxins additive or multiplicative? These are questions that have interested Philippe for many years.

Philippe Bourdeau obtained his first degree (in agronomic engineering: water and forests) in Gembloux, Belgium in 1949, followed by a PhD in ecology at Duke University in 1954. He then taught at North Carolina State (1954–1956) and Yale University (1956–1962, with a short break from 1958 to 1960 as Dean of Faculty at the University of the Belgian Congo). During his Yale years, Philippe was instrumental with George Woodwell in establishing the Gamma Forest Project at Brookhaven National Laboratory on the ecological effects of nuclear war. In 1962 Philippe became head of the radiobiology service at the Euratom Joint Research Center in Ispra, Italy. Finally in 1971 he joined DG XII of the CEC, where he remained until he retired as Director in 1991; he was in charge of the research programs

of the European Union in environment, marine sciences and technologies, and non-nuclear energy. Since 1971, Professor Bourdeau has been a professor at the Free University of Brussels, where he teaches courses in radioecology, ecotoxicology and agriculture and the environment. He has also chaired an international committee that has sponsored the creation and implementation of a Master Degree Program in Environmental Management across a network of 14 European universities.

Professor Bourdeau has had a distinguished international career. He was President of SCOPE from 1995 to 1998 and earlier he was editor to several of its synthesis volumes in ecotoxicology. Between 1991 and 1994, he was head of a Task Force of the European Community Commission that led to the creation of the European Environmental Agency (EEA) in Copenhagen (*see* EEA (European Environment Agency), Volume 4). He also led the team which produced the EEA Dobris Assessment published in 1995 (*see* Dobr s European Environment Assessment Process, Volume 4) and is author of more than 100 scientific papers. Bourdeau is a Commandeur de l'Ordre de la Couronne (Belgium).

R E MUNN *Canada*

Brinkhorst, Laurens Jan

(1937-)

Laurens Jan Brinkhorst was born in Zwolle, The Netherlands on 18 March 1937. He studied Law at Leyden University (The Netherlands) and received a masters degree in Public Law and Government in 1961 at Columbia University in New York.

He started his career with Shearman, Sterling & Wright, a major law firm in New York, became Lecturer at the Faculty of Law in Leyden and then Professor of European Law at Groningen University (1966). He started his political career as State-Secretary for Foreign Affairs in charge of European Affairs (1973), and later was elected as a Member of the Second Chamber of the Netherlands for Democrats 66 (1977), where he was parliamentary leader in 1981/1982.

Subsequently he pursued a European career: he was Head of the Delegation of the Commission of the European Communities (CEC) in Japan from 1983–1987 and became Director General for Environment and Nuclear Safety (1987–1994). In June 1994, he was elected a member of the European Parliament where he sits in the European Liberal and Democratic group. Brinkhorst is a part-time Professor at the Faculty of Law of Leiden University and is a Visiting Professor at the Law Faculty of the University of Lausanne, Switzerland on International Environmental Law. During his work as Director General for Environment in the European Community (EC), Brinkhorst played a role in the negotiation of the famous Montreal Protocol on the Control of Substances that Deplete the Ozone Layer. He also led the Environment Delegations during the crucial period of negotiations between December 1986 and September 1987, the date of the adoption and signature of the Montreal Protocol.

Laurens Jan Brinkhorst is a board member of His Royal Highness Prince Charles's Business & the Environment Program Cambridge UK, and of the International Institute for Sustainable Development, Winnipeg, Canada.

He has received Decorations from Italy, Denmark, Belgium, The Netherlands and Luxembourg. He has published several books and numerous articles on European Integration and EC Law. He speaks six languages.

MOSTAFA K TOLBA *Egypt*

Bruce, James

(1928-)

James P Bruce, meteorologist and environmental consultant, was born in Toronto, Canada, in 1928. He graduated from the University of Toronto in 1948, was a weather forecaster with the Canadian Meteorological Service and obtained an MA in Physics (meteorology) from Toronto in 1952.

Seconded to the Ontario government in 1955, he established a provincial ood warning system, taught at the University of Toronto and organized a federal hydrometeorological research and applications unit. In 1967 he was appointed founding director of the Canada Centre for Inland Waters and, in 1977, became an Assistant Deputy Minister in Environment Canada with responsibility for the national forestry, wildlife, inland waters and lands directorate programs. In 1980 he transferred back to meteorology as Assistant Deputy Minister responsible for weather forecasts and warnings, national air quality monitoring, atmospheric research and the Canadian Climate Centre.

During the 1970s Bruce helped negotiate Great Lakes water quality agreements with the United States and, for

the International Joint Commission, co-chaired the Science Advisory Board and later the Great Lakes Water Quality Board. He also chaired several intergovernmental boards including the Prairie Provinces Water Board and the Mackenzie River Basin Board. Later he chaired a Canadian scientific steering committee on acid rain and international committees and conferences such as those which negotiated the Helsinki Protocol for sulfur dioxide emission reductions and the 1985 Villach conference on greenhouse gases and climate change.

Leaving government service, Bruce joined the World Meteorological Organization (WMO) Secretariat in Geneva where he served as Director of Technical Co-operation and as Acting Deputy secretary-general from 1986 to 1989. He assisted in establishing the Intergovernmental Panel on Climate Change (IPCC) and later co-chaired an IPCC working group dealing with economic and social aspects of climate change. Returning to Canada, Bruce served as chair of the United Nation's (UN) Scientific and Technical Committee for the International Decade for Natural Disaster Reduction (1990–1994) and of the Canadian Climate Program Board (1992–1997).

In the late 1990s Bruce assisted WMO in advising member countries on the management of their national meteorological and hydrometeorological services and on the feasibility of an international El Nino center in Ecuador. He has provided consultation to the Canadian government regarding assistance to Latin America in disaster preparedness, advised Caribbean countries on dealing with climate change and chaired the UN University's advisory committee on water, environment and health.

Bruce is co-author of the widely used *Introduction to Hydrometeorology* (1967) and has contributed many papers and reports for several books and conference proceedings dealing with climate, water, natural disasters and related issues. He is a Life Member of the Canadian Meteorological and Oceanographic Society and a Fellow and Honorary Member of the American Meteorological Society. In 1986 he was awarded the Patterson Medal for distinguished service to meteorology. In 1994 he was awarded WMO's International Meteorological Organization (IMO) prize for exceptional world-wide contributions in meteorology and hydrology and received an honorary doctorate of environmental studies from the University of Waterloo and, in 1996, the Massey Medal from the Royal Canadian Geographical Society. In 1997 he was made an Officer of the Order of Canada and a Fellow of the Royal Society of Canada.

Bruce currently serves on several Canadian boards, is vice-chair of the Board of the Winnipeg-based International Institute for Sustainable Development and is Senior Associate with Global Change Strategies International, Inc. He lives in Ottawa, Ontario.

MORLEY THOMAS *Canada*

Brundtland, Gro Harlem

(1939-)

Gro Harlem Brundtland, born in Oslo, is recognized for her outstanding contributions towards enhancing international cooperation in environment and development among other remarkable achievements in her continuing career. As a mother of four, married to the renowned political scientist, Arne Olav Brundtland, she is a role model to women in fulfilling their aspirations and convictions.

A medical doctor by profession from the University of Oslo (1963) with a Master of Public Health from Harvard University in 1965, she joined mainstream politics in 1974 when she was appointed to the Norwegian Cabinet as Minister for the Environment. This began a period when she acquainted herself with international issues of increasing concern in environment and development. In 1975, she was appointed Deputy Leader of the Social Democratic Party and in 1981 became the Party Leader and first female Prime Minister of Norway, indeed a post few women had achieved, comparable to Golda Meir, Margaret Thatcher and Indhira Gandhi who Mrs Brundtland held in highest esteem. In her 10 years as Prime Minister she made headlines when she appointed 8 women to her Cabinet out of 18 members. She strongly believed that ••• any cabinet with less than around 40% women will be seen as non-representative of the people . She also persuaded her party to introduce a gender quota in all public appointments.

Gro Harlem Brundtland was appointed Chairman of the World Commission on Environment and Development (WCED) by the Secretary General of the United Nations at a time when environment became a top priority issue in the world's international development agenda. The Commission was established to propose long-term environmental strategies for achieving sustainable development by the year 2000 and beyond, recommend ways whereby concerns for the environment are translated into greater cooperation among nations and define shared perceptions of long-term environmental issues. In her address to the inaugural session of the WCED, Dr Brundtland set the tone by underlining the interdependence of the heretofore discordant themes of sustainability, equity, security and international cooperation. She opined that, ••• the limiting factor is our incapacity to put all together as a guide to future action. At the inaugural meeting of WCED, Geneva, 1984, Gro, as she is known among friends, stated

> We share a world economy; a world environment; and a stake in world development and a decent and dignified human condition of life. We must learn to think globally and in a long-term perspective. The world is shrinking rapidly. No single region or nation can isolate itself from the rest of the world. They share the responsibility of a common future.

The WCED report, *Our Common Future* is recognized for fostering the concept of *sustainable development* and the Commission's recommendations led to the convening of the Earth Summit; United Nations Conference on Environment and Development (UNCED) in Rio de Janeiro in 1992.

As Director General of the World Health Organization (WHO), a post which she took up in 1998 and which brought her closer to her original calling in medicine, she bases her leadership of the WHO on the belief that a healthy and well-educated population is every country's greatest resource. She states that, Good health is a prerequisite for economic growth and social progress. Health issues should be addressed as an integral part of the overall process of economic and social development .

Gro Harlem Brundtland has, over the years, been recognized through many awards among them the prestigious Third World Prize (1988), the Indhira Gandhi Prize (1988), and the Charlemagne Prize in 1994, just to list a few. Her interest in international security, peace, environment and development continues in various other posts that she holds including Vice-President of the Socialist International, Member of the Carnegie Commission on Preventing Deadly Con ict, and Member of the International Task Force On Security Council Enforcement. She previously served as a Member of the Palme Commission on Disarmament and Security.

Her life has touched and changed many in different circles and circumstances and under her leadership, radical opinions on women, politics, development and the environment were rekindled. Her central message has always been ethical and educative:

> ••• to succeed will require a new ethic, a new moral imperative and a new level of international awareness. It will require, more than anything else, a new thinking, a mind-set that has as its basic tenet a commitment to uphold the rights of peoples and nations to participate equitably in the resources of this planet and the development processes that they support.

Cadmium: Management in the Environment, Including Food Chains

see Environmental Cadmium in the Food Chain (**Volume 3**)

Capacity Building

Capacity building is the strengthening of individuals and institutions, as well as the networks and systems in which they operate, so that they function better, are more innovative, and more resilient to threats to undermine them. Thus, capacity building does not only refer to training for individuals, but also to developing the institutional and policy infrastructure, which is essential to their success. Capacity building is a key element in human development, which was defined by the United Nations Development Program (UNDP) in 1990 as a process of enlarging people's choices so that they can lead long and healthy lives, be educated and enjoy a decent standard of living. Continuous capacity building is seen as an integral part of sustainable development.

The International Council for Science (ICSU) has defined capacity building in science as consisting of activities that lead to the strengthening of a corps of qualified scientists with a supporting infrastructure, including facilities and working conditions, which enables them to conduct research, education, training and advisory work. A number of international efforts have been launched to undertake capacity building for the environment and for global change, including Capacity 21 (UNDP); System for Analysis, Research and Training in Global Change Science (START-ICSU); and Leadership for Environment and Development International (LEAD) (*see* LEAD (Leadership for Environment and Development), Volume 4).

These programs recognize that research is not only conducted in universities, but also in government departments, non-governmental organizations and, at local levels, by community organizations. Strengthening the research system will only lead to sound environmental decision-making if there are also trained people and adequate institutions in policy and management to implement the research findings. Much of the focus in capacity building for environment has been in strengthening the national capacities of developing countries. Less attention has been paid to gender equity in science, and to training leaders who can strengthen research and policy systems from within.

ANNE WHYTE *Canada*

Carrying Capacity

Henry Regier
University of Toronto, Toronto, Canada

An organism of a species has natural needs that include food, shelter and a way to dispose of its wastes. A simplistic perspective takes these three considerations as a start from which to calculate the carrying capacity of an ecosystem or landscape for a local population of a particular species.

Basic needs of an organism can be inferred by observing organisms through their life span. Once those needs are known, and provided that the species has little adaptive capability for substituting abundant for scarce goods, the capability of the larger ecosystem to provide for these needs can be assessed. Dividing the measure of an ecosystem's capability by the measure of the needs of an individual organism provides an estimate of the total number of that population which can be sustained indefinitely in the ecosystem. This crude estimate of the total number is the *carrying capacity* of that ecosystem for that species.

In calculating carrying capacity, some particular supply factor necessary for the population may be inferred to be relatively less available than all the others. Such a limiting factor acts as an immediate constraint on the number or size of the population, if the particular species has no way of substituting elements of some abundant factor for the one in short supply. Predation, disease infestation and competition, as demands on the population, may also act as limits. Ecologists with interest in increasing the productivity of a particular species in an ecosystem, say of a species valued by hunters or fishers, may then seek to relax the constraint of a limiting factor through cultural interventions. Such management may include supplying additional food or shelter appropriate to the species, reducing disease infestation, and controlling competitors and predators.

Organisms in general have some self-organizing capabilities that relate to their basic needs. Thus, the life cycle of a species evolves with respect to seasonal availability of elements of these needs. Often some kind of reciprocity emerges between different species to reduce adverse effects on each other, e.g., from competition for scarce resources or other limiting ecosystemic features. Behavioral and social capabilities emerge which may guide an organism so that it does not induce strongly adverse ecosystemic reactions to its activities while satisfying its needs. Hence, it is seldom easy to estimate a species' carrying capacity realistically from a simple factorial analysis within a particular ecosystem. A more realistic measure may be inferable from comparative factorial analyses of different populations of the same species in somewhat different habitats.

A concept of carrying capacity is sometimes applied to the populations of humans in a region or even in the biosphere. Humans have complex behavioral, learning and social capabilities to intervene in the natural system, constructively and destructively with respect to the total number of humans whose basic needs can be accommodated. Malthusians tend to emphasize the destructive and wasteful capabilities while Cornucopians emphasize the constructive and conservative capabilities of humans.

An expert, with an extremely biocentric value-based criterion that satisfaction of human needs should not lead to the extinction of any other species, might assess the carrying capacity of the biosphere for humans as only a small fraction of the current population, i.e., that carrying capacity was surpassed long ago. Alternatively, an extremely technocentric and homocentric expert may guess that many times the present number of humans could thrive in a biosphere that would be almost completely artificial. For example, Caesar Marchetti, a futurist working at IIASA in Austria, once designed life-support systems for a trillion-person world. In the latter case, the limiting factor could be the technical capability for our planet to radiate waste heat to outer space, so that humans don't cook the whole surface of the globe.

Any realistic concept of the interrelationships of a species population and the larger ecosystem is complex. A simplistic notion of carrying capacity may lead researchers and managers astray, especially if applied to humans. Depending on how highly we value non-human nature, and whether we are willing to live at the subsistence level, or insist on an extravagant life style, estimates of the biosphere's carrying capacity may vary from 1 to 100 billion people.

Caspian Sea

see Caspian Sea (*Case study,* **Volume 4**)

CITES (Convention on International Trade in Endangered Species of Wild Fauna and Flora)

The international wildlife trade, worth billions of dollars annually, has caused massive declines in the numbers of many species of animals and plants. The scale of over-exploitation for trade aroused such concern for the survival of species that the CITES was adopted in Washington DC in 1973 to protect wildlife against such over-exploitation and to prevent international trade from threatening species with extinction. CITES entered into force in July 1975, and had 146 Parties in 1999. Its objectives are to ensure, through international cooperation, that the international trade in species of wild fauna and ora does not threaten survival in the wild of the species concerned, and to protect endangered species from over-exploitation by means of a system of import–export permits issued by a management authority under the control of a scientific authority. The Conference of Parties (COP) meets about every 2 years to consider assigning species to one of three appendices. Appendix I prohibits (with limited exceptions) the commercial international trade in wild-caught specimens of species threatened with extinction. Appendix II assigns the responsibility to exporting States to control, through a permit system, such trade in other species, which could become threatened with extinction if there were no such restriction. And Appendix III requires parties to control trade in specimens of still other species, which have been protected in

certain states and listed by those states. The secretariat of CITES is located in Switzerland, with a staff of about 25 and an annual budget of around US$5 million. The convention is governed between its COP and by the CITES Standing Committee which consists of about 16 members representing the major geographic regions and elected at the COP. The work is supported by several scientific and technical committees, including the Animals Committee, Plants Committee, Identification Manual Committee, and Nomenclature Committee; each of these is composed of persons chosen by the Parties. The website of CITES is http://www.cites.org.

JEFFREY A MCNEELY *Switzerland*

Clean Development Mechanism

The *Clean Development Mechanism* (CDM) is defined in the Kyoto Protocol to the United Nations Framework Convention on Climate Change. The CDM will become operational upon entry into force of the Kyoto Protocol.

The roots of the CDM can be found in Article 4.2 of the Convention which includes a provision that parties to the Climate Change Convention may implement policies and measures jointly with other parties.

In the Kyoto negotiations, the CDM evolved from a proposal by the Brazilian delegation for a Clean Development Fund, which would have received levies from parties found to be in non-compliance with their abatement commitments. Instead, the CDM was defined.

Under the CDM, projects are implemented in developing countries. Such projects both contribute to the sustainable development of these countries and generate emissions lower than an appropriately selected baseline, and thus earn certified emission reductions (CERs). Developed countries (listed in Annex I to the Convention) may use such CERs to comply with part of their commitment to limit and reduce emissions.

The CDM is subject to the authority of the Conference of the Parties (COP) serving as the Meeting of the Parties (MOP) to the Kyoto Protocol (COP/MOP) and is supervised by an executive board under the COP/MOP. Emission reductions are certified by operational entities designated by the COP/MOP. Private and public entities may participate in project implementation and acquire CERs. In this regard, it is also envisaged that the CDM would also provide a channel for investment into CDM projects.

A share of the proceeds from certified project activities would be used to cover administrative expenses and to assist those developing countries that are particularly vulnerable to the adverse effects of climate change meeting the costs of adaptation.

The COP, at its fourth session (COP 4) held in Buenos Aires, Argentina, in November 1998, decided that COP 6 (held in the Hague, the Netherlands in November, 2000) should finalize negotiations on principles, modalities, rules and guidelines for the CDM with a view to their adoption by the first session of COP/MOP following entry into force of the Kyoto Protocol. COP 5, held in Bonn, Germany, in October 1999, considered proposals by Parties on a number of such principles, modalities, rules and guidelines, which will be further developed during the period leading up to COP 6. Current work covers such aspects as approaches to project baselines, modalities for the monitoring and verification of projects, for the certification of emission reductions and for the designation of operational entities. Issues such as the composition and terms of reference of the Executive Board, the determination of the share of proceeds for administrative and adaptation costs and ways and means to arrange the funding of project activities, will need to be addressed.

TAHAR HADJ-SADOK *Germany*

Cleaner Production

Osama A El-Kholy
Arabian Gulf University, Manama, Bahrain

In May 1989, the United Nations Environment Program (UNEP) Governing Council asked UNEP to promote the establishment of a network to "allow the transfer of an environmental protection strategy". This was prompted by a growing realization that the cost of dealing with pollution resulting from human activities, particularly in industry and agriculture, after it has been generated (the so-called end-of-pipe approach) has been increasing dramatically over the years since the Stockholm Conference of 1972. A new approach now emphasized that, rather than wait until pollution is generated, it would be more sensible to attempt to prevent it in the first place.

As thinking moved along these lines, the investigation extended to consider other issues not looked into so far. These covered product design, the materials used to produce it, the production processes, and even the very social environment that created demand for such a product or service.

It also became clear that we must continue along this path, always doing better than before, up to the theoretical ideal of zero pollution.

The strategy of cleaner production (note the 'er' in cleaner, and the use of production rather than technology or product) formulated by UNEP to articulate this new approach was launched in a conference in Canterbury in 1990. The strategy is now adopted worldwide and applied in different ways, having shown a remarkable ability to interface and/or assimilate many of the ideas that developed over the last decade or so in environmental management.

FROM POLLUTION ABATEMENT TO POLLUTION PREVENTION

Concern about pollution from modern industry and agriculture in the industrialized countries was the main force behind organizing a United Nations (UN) Conference on the Human Environment held in Stockholm in 1972. This was one of the series of UN-sponsored conferences that dealt with global problems (desertification, water, population, etc.). The Stockholm Declaration at the end of this conference placed pollution at the top of the environmental agenda at the time.

Emphasis in the 1970s was on pollution abatement. Emissions and ef uents had to be treated to satisfy certain requirements before being released to the environment. The major industrialized countries were reported in the 1970s to be spending billions of dollars on the control of industrial pollution. In the then Federal Republic of Germany the share of investment in industrial pollution control between 1971 and 1977 was more than 5% of total industrial investment. In Japan, the ratio was as high as 10.6% in 1973, rising to 17.1% in 1975 under the in uence of more stringent legislation, before dropping to 5% in the early 1980s. In the USA, the ratio was 5.8% in 1975. The expenditure of private industry on pollution control in some industrialized countries varied between 0.8 and 1.7% of the gross national product (GNP) over the period 1972–1986. On average, countries with the most stringent environmental requirements spent about 1.5% of their GNP on pollution abatement. Of this, the manufacturing sector in the USA and Germany accounted for one quarter of this expenditure, or about 0.4% of GNP. A small number of industrial sectors (chemicals, metal products and machinery) accounted for a large part of this expenditure. As for the split between capital investments and operating costs of pollution treatment equipment, recurrent operating costs were in general, much higher, reaching almost five times the capital expenditures in the USA.

The situation was becoming progressively more serious as new legislation on the use of chemicals was promulgated in the mid-1970s. New industrial chemicals now had to go through stringent, expensive, and time-consuming tests before being marketed. Furthermore, the cost of monitoring compliance to the new requirements was mounting as more personnel, both in industry and in government, became involved in monitoring polluting releases. One estimate is that over US$300 billion was spent worldwide each year on environmental projects, most of which was spent on purchasing and maintaining treatment technologies. With the promotion of the *polluter pays principle* by the Organisation of Economic Co-operation and Development (OECD) in 1975, it was the consumer who foot the bill in the final analysis. This situation could not go on for obvious reasons.

During the latter half of the 1970s the concept of low and non-waste technologies emerged, now shifting the emphasis to pollution *prevention* rather than pollution *treatment*. The 1989 decision of UNEP's Governing Council was perhaps in response to this shift of emphasis. The UNEP Industry and Environment Office in Paris assembled a small core group of experts to work out a program for the implementation of the Governing Council decision.

It is both interesting and instructive to look back at the way thinking of the core group developed as work proceeded. First, they agreed that no justifiable distinction can be made between clean and dirty technology. There is no absolutely clean technology: one technology can only be shown to be cleaner than another. This means that there will always be room for improvement to develop still cleaner and cleaner technologies as time goes on. The ultimate ideal goal is a technology that produces no pollution at all, as if the production process is going on inside a bubble into which raw materials are introduced and out of which come only products (the bubble theory). Further consideration led to realization of the need to take into account the pollution a product produces as it is being used (e.g., the exhaust gases from a car). Expansion of the scope of the analysis finally extended both ways, downstream of manufacture and use of a product to its disposal as waste; and upstream to the supply side and the pollution produced in extracting and processing the inputs of raw materials and semi-finished goods. Consequently, the investigation needs to address products also, rather than technologies only. It has to extend across the whole life cycle of products (the so-called *cradle to grave analysis*). It has to investigate product design, production process, and management practices. Cleaner production was finally defined as in Box 1.

There is more to this compact definition than meets the eye:

1. Cleaner production is defined as a strategy, i.e., it extends well beyond technical fixes.
2. It is an all-embracing integrative view of the issue, that does not isolate and concentrate on one aspect only of the problem.

Box 1 What is Cleaner Production?

Cleaner production is the continuous application of an integrated preventive environmental strategy to processes and products to reduce risks to humans and the environment.

For production processes, cleaner production includes conserving raw materials and energy, eliminating toxic raw materials and reducing the quantity and toxicity of all emissions and wastes before they leave a process.

For products, the strategy focuses on reducing impacts along the entire life cycle of the product, from raw material extraction to the ultimate disposal of the product.

For services, it incorporates environmental concerns in designing and delivering services.

Cleaner production requires changing attitudes, responsible environmental management and evaluating technology options.

3. It emphasizes the continuity of the endeavor. We can always do better, *ad in nitum.*
4. The last paragraph means that we must also look into the social environment that created the demand for this product in the first place, and in uenced how it was to be produced.

The complexity of the concept can be more clearly articulated through a hierarchy of substitutions at different levels, taking as an example the motor car:

1. *the process level*: improving the combustion process (combustion chamber design, lean burning, etc.);
2. *the component level*: adding a new component (a catalytic converter to the exhaust pipe, an example of the end of pipe approach);
3. *the sub-system level*: adopting an entirely new technology (the electric car, fuel cells, hybrid engines);
4. *the system level*: adopting a new system (replacing private cars by mass transit, public transport systems);
5. *the value system*: questioning the very premises that created the need for the product (e.g., alternative landscape planning, value systems, work styles).

This hierarchy of substitutions moves the analysis from the purely technical all the way up to the social level, emphasizing the all-embracing, integrative nature of this definition.

UNEP has continued to hold senior level expert group meetings (Paris, 1990; Canterbury, 1992; Warsaw, 1994; Oxford 1996; Seoul, 1998). The meetings take stock of the status of the cleaner production movement worldwide, and review the work of an increasing number of specialized working groups that provide practical technical advice in application of the cleaner production concept as well as in policy formulation, and design practices.

THE CLEANER PRODUCTION STRATEGY IN PRACTICE

On the practical level, it is claimed that a review of the results of applying the cleaner production approach in 500 case studies of industrial firms has shown 70–100% reductions in some air emissions, water discharges and of the production of hazardous and non-hazardous solid wastes, and that the payback period was quite short, ranging from 3 years to less than 1 year. The late 1980s saw an increasing number of programs in many industrial countries, east and west, based on the cleaner production approach outlined above. One pioneering project in Europe is the Project on Industrial Successes with Waste Prevention (PRISMA) initiated in 1985 by the Netherlands Organization of Technology Assessment. When the preliminary results of field research started in 10 companies in 1988 became available, no less than 164 prevention options were identified. These included minor changes in procedures and installations as well as drastic innovations in products or processes. In 30% of the cases these changes were in the category of good housekeeping; another 30% in material and raw materials; 30% in changes in equipment; and the rest in process modifications (Sybren do Hoo *et al.*, 1991). Some good housekeeping measures effected 25–30% reductions in chemicals used. In a number of companies, technological changes resulted in reductions in waste and emissions of 30–80%. Occasionally, it was possible to eliminate a noxious waste ow completely. The use of alternative raw materials resulted in a 100% reduction in emissions of substances such as cyanide (in zinc plating) and solvents (in decreasing parts).

The cost-benefit analysis showed a heterogeneous picture with a few extremely favorable peaks. In one extreme case an investment of DFl 2500 saved the company DFl 124 000 *per annum*. Another company recouped an investment of DFl 800 000 within a year (saving more than DFl 1 000 000 *per annum*). Of the 45 options actually implemented by then, 20 turned out to be cost saving, and 19 to be neutral. It was found, moreover, that these measures had further indirect benefits, such as improvement in product quality.

Within EUREKA (the co-operative research program in Europe), the EUROENVIRON program began promoting Preventive Environmental Protection Approaches in Europe (PREPARE) in 1990 on the basis of the Dutch PRISMA project. PREPARE sought also to catalyze industry/government cooperation and the transfer of information of pollution prevention and cleaner production.

In the United States, prevention teams have been in operation for some years as part of the Technical Assistance Program , helping small businesses in adopting pollution prevention technologies. Groups of external consultants assist industrial firms in formulating and implementing a pollution prevention program. Evaluation of their work indicates that these programs were not only commercially

profitable and environmentally beneficial, but also useful at the macroeconomic level, as well as helpful in clarifying gaps in current knowledge and identifying areas for research.

Mexico and Brazil have achieved some noteworthy successes in organizing efforts for pollution control at various levels of government. The program in Cubatao, home of a large industrial complex in the state of Sao Paulo in Brazil, is one important example of a unique institutional system. Enforcement powers were delegated by contract to the Environment Management Company and an integrated control approach was started in 1984. Some of the results achieved by the end of 1989 in air pollution abatement are summarized in Table 1. Similar success was also achieved in reducing water pollutants.

In China in the early 1990s, UNEP, with funding from the World Bank, joined hands with the National Environment Protection Agency (NEPA) to promote cleaner production throughout China.

In 1993, when the preparatory phase was completed, substantial economic and environmental benefits were identified, even at this early stage of the program:

- Sixty-seven cleaner production options, ranging from managerial changes to process modifications were implemented. Most of these were of the low–no cost type.
- Over US$350 000 saving was achieved for investment of less than US$16 000.
- An average of more than 50% of the chemical oxygen demand in the waste water was eliminated.

In the latter phases, experts were trained to carry out cleaner production activities throughout the country, particularly in small and medium enterprises (SMEs). General and sector specific manuals were published and policy studies carried out. This program has resulted in a gradual shift from investment in end-of-pipe equipment to integrated cleaner production approaches throughout the country.

Many other initiatives in East Europe, the Mediterranean Basin, India, South East Asia, and in Africa could also be cited. The United Nations Industrial Development Organization (UNIDO) cooperated with UNEP in establishing national cleaner production centers (NCPCs). The first batch of eight NCPCs were started in 1994 with funding from European donors and located in Brazil, China, Czech Republic, India, Mexico, Slovak Republic, United Republic of Tanzania and Zimbabwe. NCPCs are spreading gradually worldwide with self-financing in some countries and funding from donors in most cases (Tunisia, Vietnam, Costa Rica, Nicaragua, Croatia, El Salvador, Guatemala and Uzbekistan). A review carried out in July 1998 states that during the period from 1994 up to July 1998, 405 plants participated in in-plant assessments, 1016 consultants and participants were trained, 16 000 persons participated in seminars and more than 7700 attended workshops. The review summarizes the main lessons learnt as:

- A 5-year period is necessary to develop a NCPC into a service-oriented unit.
- A system of certification would enhance the status of cleaner production experts.
- Cleaner production can easily be incorporated into and promoted by other related bodies, such as environmental management systems (EMS) or ISO 14000. (the UNEP/International Chamber of Commerce (ICC)/Fédération Internationale des Ingénieurs-Conseils (FIDIC) EMS Training Resources Kit explains the relationship between EMS/ISO 14000 and cleaner production).
- While the methodology of cleaner production is applicable to all industrial sectors, sector-specific technical expertise needs to be developed.
- An integrated program, rather than a project approach is necessary for sustainable cleaner production implementation.

After almost a decade since the launch of the cleaner production program by UNEP, it is useful to take stock of past experiences and to look ahead into the future:

- There is no doubt that cleaner production has gained remarkable popularity over a short period of time. This is mainly due to the fact that launching cleaner production coincided with a paradigm shift in pollution management from end-of-pipe treatment to pollution prevention. It may seem to have taken a long time to apply the time-honored principle, *prevention is better than cure* but we had to deal with the natural resistance to changing established practices in a functioning establishment. In good economic times, the costs of end-of-pipe treatment could be easily absorbed with other costs. Furthermore, there were no compelling reasons to internalize environmental costs in the total cost of products. It must also be admitted that regulations in the 1970s and early 1980s focused

Table 1 Reduction in atmospheric pollution in Cubatao, Brazil

Pollutant	Initial emissions in July 1984 (kg day^{-1})	Emissions in December 1989 (kg day^{-1})	Actual reduction (%)
Particulates	316 350	77 949	75
Fluorides	2620	400	85
NH_3	8736	205	97
NO_x	61 085	47 561	22
HC	90 000	11 970	86
SO_2	78 353	49 527	37

on end-of-pipe solutions and offered few incentives to pollution prevention initiatives.

- In newly industrializing countries and developing countries, weak monitoring of compliance with environmental regulations, and enforcement mechanisms, mitigated against adoption of cleaner production practices. One could also cite the reluctance of most banks to fund cleaner production projects, due to lack of experience in financial risk assessment of environmental projects.
- However, cleaner production received a tremendous boost once demonstration projects provided concrete evidence of the economic advantages of a host of simple low–no cost actions as mentioned earlier. Pollution prevention came to be considered as a win-win policy. The 3Ps, which stood for the *polluter pays principle* in 1975, now stood for *pollution prevention pays*. Several transnational corporations mainly in the chemical industries, announced their unilateral commitment to reduce the pollutants they discharge by fixed amounts over specific time horizons. Eventually, the law of diminishing returns showed that there is a limit which is reached when the easy, low–no cost options are exhausted. Du Pont revived Pareto's 80/20 principle pointing out that the challenge facing management is to identify the actions that account for the first 20% of costs that achieve maximum environmental benefits.
- Most developing countries still have a long way to go, reaping environmental benefits together with economic benefits through relatively simple, short pay-back periods, low–no cost options. What they now need is the local expertise, enlightened management and relatively small upfront financing of the more complex options that have proven economic benefits. Demonstration projects in developing countries continue to show that application of cleaner production practices, more often than not, yield immediate unmistakable economic and environmental benefits, particularly in SMEs. Unfortunately, and for obvious reasons mentioned earlier, this is exactly where

Box 2 International Declaration on Cleaner Production (adopted at Fifth International High-Level Seminar on Cleaner Production, Korea, 1998)

We recognize that achieving sustainable development is a collective responsibility. Action to improve the global environment must include the adoption of more sustainable production and consumption practices.

We recognize that cleaner production and other preventive strategies such as eco-efficiency, green productivity and pollution prevention are preferred options and require the development, support and implementation of appropriate policies and practices.

We understand cleaner production to be the continuous application of an integrated, preventive strategy applied to processes, products and services to reduce risk and to pursue economic, health, safety and environmental benefits.

To this end we are committed to:

Transparency sharing our cleaner production experience:

- by fostering and promoting dialogue on the implementation of this strategy;
- through communication of the benefits to external stakeholders.

Integration encouraging the integration of preventive strategies:

- into all levels of our organization;
- through EMS, and tools such as environmental performance evaluation, and cleaner production, environmental impact, and life cycle assessments.

building cleaner production capacity:

- by developing and conducting awareness, education and training programs to facilitate the practice within our organization;
- by encouraging the inclusion of the concepts and principles into educational curricula at all levels.

Creating innovative solutions:

- by promoting a shift of priority from end-of-pipe to preventive strategies in our research and development policies and activities;
- through the development of products and services which are environmentally efficient and meet consumer needs.

Leadership using our influence:

- to encourage the adoption of cleaner production and sustainable consumption practices through our relationships with stakeholders.

Implementation taking action to adopt cleaner production:

- with continual improvement by setting challenging goals and regularly reporting progress through established management systems;
- by encouraging new and additional finance and investment in preventive technology options, and promoting cleaner technology cooperation and transfer between countries;
- through work with UNEP and other partners and stakeholders to support this declaration and review the success of its implementation.

cleaner production has not yet penetrated on any significant scale. Positive technical/financial support on an adequate scale is necessary. Such intervention is cost-effective and arrangements could, and have been, concluded with enterprises to pay back part, if not all, of the resulting savings to cover the cost of implementation.

- Cleaner production has stood the test of time. The original definition has demonstrated its compatibility with, and even ability to take under its wing, new ideas in sound environmental management (e.g., eco-efficiency, resource accounting, sustainable consumption, ISO 14000 standards or life cycle assessment and eco-labelling, etc.).
- Although cleaner production has become something of a buzz word in common use, there are clear signs that it is often used in restricted senses that deprive it from its all-embracing advantage. The most common form of misuse is equating it to pollution prevention particularly in production processes. Perhaps the social aspect of consumption patterns is the one field that has not yet been investigated in depth in operationalizing the definition formulated by UNEP a decade ago.
- With the launch of the International Declaration on Cleaner Production (Box 2), cleaner production has entered a new phase, aimed at creating a multi-stakeholder partnership. It is hoped that this will increase proper understanding and awareness of cleaner production, as well as increasing demand and renewed commitment of cleaner production practitioners. Led by the UNEP Executive Director and the Korean Environment Minister, 64 ministers, CEOs directors of environmental agencies, NGOs and academic institutions signed the Declaration which continues to attract more signatories.

Climate Change: an Emerging Issue in the Global Agenda

Michael Zammit Cutajar
United Nations Framework Convention on Climate Change, Bonn, Germany

This article discusses developments with respect to the UN Framework Convention on Climate Change up to early 2001. Climate change is a quintessentially global issue. The global climate system is a mega-resource that humanity - especially agrarian humanity - has taken for granted for millennia. It is being destabilized by the economic and demographic growth of the last two centuries. Emissions of carbon dioxide and other heat-trapping gases from all sources and all social origins - wasteful emissions and survival emissions alike - mix indiscriminately in our common atmosphere. There they enhance the natural greenhouse effect, making the world warmer than it should naturally be.

The international response to climate change is a negotiating process, from which a strategy is emerging, so far embodied in the 1992 United Nations Framework Convention on Climate Change, and its 1997 Kyoto Protocol. The first step, the Convention, is an agenda-setting framework, based on principles. Its objective is to stabilize greenhouse gases in the atmosphere at safe levels. It provides for: cooperation and exchange of information; leadership by industrialized countries in modifying long-term emission trends; financial and technological support for the efforts of developing countries; and responses to vulnerability. It has been in force since 1994 and, with over 180 parties, is nearly universal. The Protocol would take a significant further step by binding industrialized countries to verifiable emission limitation and reduction targets. Its first commitment period aims at an aggregate reduction of greenhouse gas emissions of some 5% below 1990 levels, in the period 2008- 2012.

THE DYNAMICS OF NEGOTIATION

The negotiating process is driven primarily by the scientific assessments of the independent Intergovernmental Panel on Climate Change (IPCC), the third of which (2001) confirmed evidence that distinguishes the human contribution

to global warming from natural climate variability. The message of the mainstream scientists, in summary, is that the global climate is changing as a result of human activity (*see* Intergovernmental Panel on Climate Change (IPCC): an Historical Review, Volume 4).

There is some dissent from these findings of the IPCC. This is vocal but limited. In some cases, it is discredited by association with vested economic interests that have much to lose from action to use fossil fuels less wastefully.

Perhaps more disturbing is the wait-and-see approach advocated by many business and industry groups, allied to predictions of job losses. This defensive attitude does not give due weight to the costs of doing nothing – the costs of the impacts of climate change on vulnerable ecosystems, communities and economies. The vulnerable segments of global society do not wield economic clout, it would seem.

It is encouraging, however, to note that the *precautionary principle* (*see* Precautionary Principle, Volume 4), which is enshrined in the Convention, is attracting an increasing number of adherents from within the industrial and business sectors. The insurance industry took the lead in this direction, accompanied by companies with an interest in promoting energy conservation, and producers of solar and wind power. Even within the fossil fuel industry, natural gas producers have tended to favor action to limit emissions of carbon dioxide, since their product contains less of this greenhouse gas than coal or oil. And major petroleum companies based in Europe have shifted towards a precautionary approach.

The message of the IPCC has difficulty getting through, beyond those involved in the climate negotiations (mainly in environment ministries), to the economic policymakers, public and corporate. Admittedly, it is sometimes difficult to see through the scientific clothing in which the message is wrapped. More needs to be done to deliver it clearly and loudly. More fundamentally, though, the long-term nature of the problem makes it difficult to engage political and public attention. Few citizens, and even fewer politicians, are concerned with a problem that will face their grandchildren's grandchildren.

Thus, the effort must continue to convince Northern policymakers that they cannot buy their way out of the problem without making the necessary structural adjustments in domestic production and consumption. For their part, Southern policymakers need to be convinced that mitigating and adapting to climate change should figure in their present priorities for sustainable development. The message to both is that action now will cost less than action later. A further message to the South, sadly familiar, is that it is the poor countries who are most vulnerable and who will bear the burden of adverse climatic impacts.

POSITIVE STRATEGIES

In both cases, North and South, it is possible to identify actions that make economic sense for the countries concerned while also addressing climate change by limiting greenhouse gas emissions (*see* No Regrets Principle, Volume 4). This approach, known as no regrets enables climate strategists to address the problem without basing the justification for action on climate science alone. Thus, for example, one can seek emission reductions by promoting policies to deal with more tangible environmental problems such as urban air quality, traffic congestion and the spread of transport infrastructure – problems that voters and taxpayers recognize more readily as their own problems, here and now. Local governments and municipal authorities can be lead players in such a strategy.

Beyond the no-regrets approach, one senses that, behind its defensive walls, industry is exploring possibilities for making money out of cleaner, climate-friendly technologies. Regular articles in the press about experimental low-emission motor vehicle engines are perhaps the most important indicator of this technological exploration, automobile transport being the source of the most rapid growth in carbon dioxide emissions. A climate-friendly technology fix does not contradict economic growth, provides opportunities for profitable investment and bridges North/South economic interests. Consequently, technology – its development, application and transfer – is a regular theme in discussions under the Convention though, so far, little has been done to move beyond debate in this area. Positive measures to promote transfer, through public-private partnerships, are likely to be needed.

CONSUMPTION PATTERNS

Less is heard about consumption patterns and lifestyles. On the one hand, the American way of life is held sacred and it is considered to be political suicide to tamper with it. On the other hand, this same way of life is being globalized through the exponential spread of communications, despite the fact that it is not replicable on a global scale at forecast levels of population and given present technology.

Discussion under the Convention does not neglect the consumption aspect totally. Proposals have been tabled concerning technical standards for consumer goods and fiscal measures that stimulate changes in consumption habits. However sensible such proposals may be, they are caught up in a negotiation where some (such as the European Union) argue that such measures should be adopted by all industrialized countries in order to maintain a level playing field in international trade, while others (such as the United States) press for maximum exibility to

each country to choose how best to achieve reductions in emissions.

MAKING COMMITMENTS EFFECTIVE

While the first phases of negotiations have concentrated on action by industrialized countries to limit their emissions, it is clear that the objective of the Convention – the stabilization of atmospheric concentrations of greenhouse gases at a safe level – cannot be achieved by the presently developed countries alone. They are obliged to take the lead in cutting emissions and modifying long-term emission trends, because of their historical contribution to concentrations and their high emissions per head. However, their efforts could be negated by the growth of emissions from developing countries, needed to meet the needs of these countries for material well-being.

Yet developing countries will only consider limiting their emissions in ways that would not place a new constraint on their economic growth, and even then not until they are convinced that developed countries are serious about cutting theirs. The evidence so far is not convincing; no Organization for Economic Co-operation and Development country achieved the initial target under the Convention (returning emissions to 1990 levels by the year 2000) on account of policies explicitly addressing climate change. Some such as the UK and Germany achieved the target for other reasons. One can argue that it does not matter how they achieve the aim as long as they do so, but a happy accident is not a rational strategy and will not be replicated. Currently (early 2001) negotiations are under way on ways of putting teeth into the Kyoto commitments of developed countries. These, in turn, are experimenting with domestic measures and economic instruments aimed at achieving emission limitation at minimum economic and social cost.

FUTURE NEGOTIATIONS

The forward vision that can be derived from these early steps is of a series of negotiating rounds among the parties, leading to progressive degrees of commitment and institutional development – not unlike the history of trade negotiations since 1948. The commitments will be differentiated according to responsibility and capacity. The strategy will be implemented by the parties themselves; several multilateral and regional agencies and programs will support them.

Efficiency in limiting future emissions of greenhouse gases is vital for success in achieving the ultimate objective of the Convention. Equity in distributing responsibility for these limitations is vital for political engagement. Visions of the economic opportunities of a climate-friendly future would transform the language of negotiation from burden sharing to win-win.

This linkage with the economy relates the climate change scenario to that of globalization and global sustainable development. Climate change is a by-product of two centuries of economic growth, so action to address it must pass through the economy of the 21st century. Greater efficiency and cleaner technologies are needed in the energy, transport and industrial sectors, among others. This can be a driver of technological change, green jobs and green profits. The international response can also generate a new push in favor of the transfer of technology and know-how to developing countries and capacity-building.

A novelty of the emerging strategy is its use of international economic instruments. The mechanisms of the Kyoto Protocol would allow industrialized countries to meet part of their emission targets offshore, through economic transactions. One mechanism – *emissions trading* (*see* Tradable Permits for Greenhouse Gases, Volume 4) – would permit an industrialized country to acquire part of the emission allowance of another. The other two mechanisms *joint implementation* (*see* Joint Implementation, Volume 4) and the *clean development mechanism* (CDM) (*see* Clean Development Mechanism, Volume 4) – allow the acquisition of credits for emissions averted by investments in climate-friendly projects in industrialized or developing countries. Together, the three mechanisms would create a new tradable commodity, namely carbon; a new service industry: the verification and certification of transactions in the carbon market; and a new motivation for foreign direct investment in low-carbon technologies.

One of the two project-oriented mechanisms, the CDM, also has the aim of assisting developing countries in achieving sustainable development and generating finance to help them adapt to the adverse effects of climate change.

All three mechanisms seek to engage the private sector in advancing the international strategy. They are thus in tune with the spirit of the times.

Climate Change Assessment, United States

see Climate Change Assessment, United States (*Case study*, **Volume 4**)

Club of Rome

Ricardo Diez-Hochleitner
President, The Club of Rome, Madrid, Spain

The Club of Rome is a global think tank and center of innovation and initiative. As a non-pro t, non-governmental organization (NGO), it brings together scientists, economists, businessmen, international high civil servants, heads of state and former heads of state from all ve continents who are convinced that the future of humankind is not determined once and for all and that each individual can contribute to the improvement of our societies.

Founded in Rome 1968, the approach of the Club of Rome to the solution of the world problematique is the identification of problems, their analysis in a global, interdisciplinary and long term perspective, the research of future alternative solutions and the elaboration of scenarios for the future. The results of this work are communicated to public and private decision-makers and to the general public. The methods for such communications are reports, conferences, and the internet. The Club of Rome's essential mission is thus to act as an independent, global, non-official catalyst of change.

The first report commissioned and published by The Club of Rome was *The Limits to Growth*, a book which produced a world-wide impact (more than 12 million copies have been sold in 37 languages). Its thesis was interpreted in many different ways. It stressed above all, for the first time, the importance of the environment, and the essential links with population and energy. This was a particularly striking illustration of what is meant by the global problematique. It was understood as a break and change of paradigm.

The Club of Rome is governed by three complementary principles:

1. A global perspective in examining issues with the awareness that the increasing interdependence of nations and the globalization of problems pose predicaments beyond the capacity of individual countries.
2. Holistic thinking and the seeking of a deeper understanding of complexity within the contemporary problems – political, social, economic, technological, environmental, psychological and cultural – which the Club of Rome terms the world problematique.
3. An interdisciplinary and long-term perspective focussing on the scenarios, alternative choices and policies determining the destiny of future generations, because this perspective is too often neglected by governments and other decision-makers on account of short term interests.

The report *The Limits to Growth*, a seminal one for the Club, has been followed by 26 other reports, on problems ranging from education, energy, the impact of microelectronics on society, to governance, the role of NGOs in development and the environment. Several others are under preparation.

It is important to emphasize that, in addition to their role as information sources, these reports must also serve two essential functions. First, they represent the starting point of a process and not its culmination. Their publication allows the Club, which has no claim to possessing the truth, to launch wide-ranging debates to discuss the conclusions and so share with a variety of audiences, from governments to universities and the media, its thinking and suggestions for resolving the problems affecting the world. Secondly, they are the starting point for certain initiatives implemented at the highest levels of decision-making, both public and private, with a view to fostering changes to strategic factors.

Every year, the Club of Rome holds its Annual Conference in a different region of the world. In addition to the working sessions reserved for members of the Club, these meetings bring together personalities from the region or the world who are invited to take part in discussions on a particular aspect of the world problematique. These meetings have established fruitful inter-personal relations with leaders and activists in the region, enabling a better understanding of the region's specific problems and its perception of global issues and the role it would like to play in them. Beside these annual meetings, the Club of Rome organizes occasionally regional meetings on regional aspects of the world problematique.

However, the Club itself tends normally to adopt a low profile, and the passionate debate sparked by *The Limits to Growth* has been the only and unexpected exception to this desire to operate discreetly. We believe that we are sometimes more effective when we work behind the scenes.

Coastal Zone Management

Mahmoud Kh El-Sayed
University of Alexandria, Alexandria, Egypt

Coastal zones throughout the world have historically been among the most heavily exploited areas because of their rich resources. If these coastal resources are to be maintained and restored, effective action is urgently needed. To

answer this need, a management system has been designed: integrated coastal zone management (ICZM).

ICZM is a process of governance consisting of the legal and institutional framework necessary to ensure that development and management plans for coastal zones are integrated with environmental (including social) goals and are made with the participation of those affected. The purpose of ICZM is to maximize the bene ts provided by the coastal zone and to minimize the con icts and harmful effects of activities upon each other, on resources and on the environment (World Bank, 1996).

It is worth noting that the terminology of coastal zone management (CZM), ICZM, integrated coastal and marine areas management, and coastal resource management, are all used interchangeably.

The coastal zone is generally understood to be the place where the land meets the ocean, comprising significant marine and terrestrial areas. The limits of the coastal zone are often arbitrarily defined, differing widely among nations, and are often based on jurisdictional limits or bounded by reasons of administrative ease.

Coastal areas contain some of the world's most productive and diverse resources. These resources are used and exploited for economic and social objectives. Population pressure, particularly the growth of urban areas, combined with the rapid expansion of industry and tourism associated with services, utilities and activities has created a worldwide concern about sustainable development of these areas.

These sectoral activities produce combined environmental impacts resulting in marine and fresh water pollution, air pollution, loss of marine resources, loss of natural land resources and land degradation, destruction of historic and architectural heritage, loss of public access to the coast, noise and congestion. Natural risks and hazards, such as earthquakes, forest fires and oods, pose additional hazards to coastal areas (United Nations Environment Program, 1995). In addition, serious environmental problems are likely to arise in association with potential impacts of expected climate change and sea level rise in coastal and deltaic areas worldwide. Policy makers are faced with the challenge of ensuring economic development while limiting the adverse impacts of such development on natural areas and protecting human life and infrastructure. Sectoral development interests, which prevail in coastal areas, make decision-making even more difficult and require mechanisms for cross-sectoral cooperation.

In both developed and developing countries, the coastal zone is likely to undergo the most profound change in the near future. Already more than 60% of the world's population lives within the coastal areas and many of these people may have to cope with significant rises in sea level before the end of the century. Consequently, unless careful environmental management and planning are instituted, severe con icts over coastal space and resource utilization are likely, and the degradation of natural resources will close development options (World Bank, 1996).

A basis for action, objectives, and activities related to Integrated Management and Sustainable Development of Coastal and Marine Areas, including Exclusive Economic Zones were presented in Chapter 17 (para 17.3–17.7) of Agenda 21. Recognizing the intensifying threats and the environmental pressure in coastal areas, the United Nations Conference on Environment and Development (UNCED) in Rio de Janeiro, 1992, emphasized that:

> The marine environment – including the oceans and all seas and adjacent coastal areas – forms an integrated whole that is an essential component of the global life-support system and a positive asset that presents opportunities for sustainable development; and that the coastal area contains diverse and productive habitats and ecosystems important for human settlement, development and local subsistence.

The Conference recommended that a new integrated approach to marine and coastal area management and development, at the national, subregional, regional and global levels be developed to minimize con icts and to provide for optimal sustainable resource use.

The concept of developing CZM plans, guidelines and principles was therefore considered as priority for most of the coastal nations all over the world.

Since the directives, priorities and the decision-making process differ from national, regional and global perspectives regarding sustainable development; there are many definitions of CZM. However, integration, sustainability and the socio-cultural dimension remain as common subjects in most definitions.

The World Coast Conference '93 Statement defines ICZM as a continuous and evolutionary process for achieving sustainable development, that involves the comprehensive assessment, setting of objectives, planning and management of coastal areas and resources, taking into account traditional cultural and historical perspectives and con icting interests and uses.

The common elements of the CZM process are:

- problem identification and assessment;
- program design and preparation;
- program adoption and financing;
- program implementation;
- monitoring and evaluation.

In all of the above stages, strong political will and commitment at all decision-making and stakeholder levels are needed if the CZM process is to be carried out successfully.

The development and enforcement of a CZM plan requires an adequate implementation structure, which needs to be defined in terms of the following dimensions:

- institutional;
- legislative;
- financial;
- human resources.

Common but Differentiated Responsibility Principle (Stockholm/Rio)

The *common but differentiated responsibility principle* (Stockholm/Rio) is a significant product of the United Nations Conference on Environment and Development (UNCED). The principle affirms that developed nations accept that they bear primary responsibility for the present state of environmental degradation, and in the meantime all nations must cooperate to prevent further degradation. Principle 7 of the UNCED Rio Declaration (1992) asserts:

> States shall cooperate in a spirit of global partnership to conserve, protect, and restore the health and integrity of the Earth's ecosystem. In view of the different contributions to global environmental degradation, States have common but differentiated responsibilities. The developed countries acknowledge the responsibility they bear in the international pursuit of sustainable development in view of the pressures their societies place on the global environment and of the technologies and financial resources they command.

The principle is also embedded in the Framework Convention on Climate Change and The Convention on Biological Diversity (both signed during the UNCED). The principle of differentiated responsibility has also been articulated in previous international agreements; for example the 1972 Stockholm declaration.

KEVIN S HANNA *Canada*

Conference of Parties

When a convention/treaty/protocol is adopted by a plenipotentiary conference, i.e., a conference of government representatives who are officially authorized to adopt the convention, it is then open for signature together with what is called the *nal act*. The latter records what happened at the time of adopting the convention, who attended and any reservations made. To the final act, is annexed the treaty itself. Government representatives may sign only the final act or may sign the final act and the treaty/convention. After signing the convention it goes through the process of ratification. Ratification means endorsement by the relevant authority in the country. This is generally the parliament but could be a revolutionary council or a high committee of the party in the single party system countries.

A specific number of ratifications are required for the treaty to enter into force. This varies from one convention to another and the number is stipulated in the body of the convention. Once the required number of instruments of ratification is deposited with the depository, the treaty enters into force. Countries which ratify the treaty constitute the *Conference of the Parties* which meets regularly, normally every one or two years, to follow up on the implementation of the convention, take the necessary steps for its amendments, approve the budget for its secretariat and so on.

Convention on Biological Diversity

Jeffrey A McNeely
IUCN, The World Conservation Union, Gland, Switzerland

The 1992 United Nations Conference on Environment and Development (the Earth Summit) put biological diversity on the international agenda when its participants signed the Convention on Biological Diversity (CBD). The CBD entered into force on the 29th December 1993 and by the end of 1999 had 178 State Parties. Its secretariat is based in Montreal, Canada, with some 34 staff and an annual budget of US$9.7 million (E-mail: secretariat@biodiv.org). The CBD commits the nations of the world to the objectives of conserving biological diversity, using biological resources sustainably, and sharing equitably the bene ts arising from the use of genetic resources. Its objectives thereby bring together elements that address biological, economic, and ethical concerns. It is the rst global agreement to address comprehensively all levels of biodiversity, from genetic resources to species and ecosystems.

The idea of such a convention began at the Third World Congress on National Parks, held in Bali, Indonesia, in October 1982 and was developed further by International Union for the Conservation of Nature's (IUCN's) Environmental Law Centre over the following several years. In August 1988, United Nations Environmental Programme (UNEP) Executive Director Mostafa Tolba convened a high level panel of experts to advise him on whether a global biodiversity convention was timely, and if so, what it should include. UNEP then convened a series of intergovernmental meetings to develop the CBD for signature at Rio de Janeiro. The CBD is a landmark legal instrument in that it takes for the rst time a comprehensive approach to the conservation of biodiversity and sustainable use of biological resources. It recognizes the justi cation for conservation on the basis of ethics, economic bene t and human survival. However, the CBD goes beyond conservation and sustainable use to encompass such issues as ensuring access to genetic resources, sharing of bene ts arising from the use of genetic material, dealing with potential hazards of biotechnology, and promoting access to information and technology.

The CBD also implicitly recognizes that biodiversity is unevenly distributed on our planet. While the economically prosperous industrialized countries are typically relatively poor in biological wealth, the developing countries of the tropics have many more species and much greater genetic diversity. Thus the responsibility for conserving biodiversity lies especially with the actions to be taken in tropical countries, at the very time when the use of these biological resources may be critically important for developing their domestic economies. The CBD recognizes that it is in the enlightened self-interest for the industrialized countries to provide nancial and other kinds of support to the tropical countries to enable them to carry out their obligations under the convention and thereby provide global bene ts in terms of better management of biological resources.

The CBD is also innovative in its construction as an umbrella agreement, leaving it up to individual Parties to determine how its provisions are to be implemented while providing advice on how this might be accomplished. Containing no lists of species or sites to be protected, the articles of the convention express overall goals and policies rather than elaborated obligations and targets.

CONTENTS OF THE CONVENTION

The CBD defines biological diversity as the variability among living organisms from all sources including, *inter alia*, terrestrial, marine, and other aquatic ecosystems and the ecological complexes of which they are a part; this includes diversity within species, between species, and of ecosystems . While biodiversity has many definitions, the fact that nearly 180 governments have accepted this one gives it particular power. The CBD also recognizes the principle in international law, that states have the sovereign right to exploit their own resources according to their own environmental policies, but that they also have the responsibility to ensure that activities within their jurisdiction or control do not cause damage to the biodiversity of other states. It calls for the parties to cooperate with others both directly and through international organizations on issues of biodiversity, and to involve the private sector in doing so.

Article 6 of the CBD builds the framework for national implementation by calling on each party to prepare a national biodiversity strategy and action plan; to include biodiversity concerns into the plans and policies for other sectors such as agriculture, fisheries, forestry, and tourism; and to incorporate biodiversity into cross-sectoral matters such as land-use planning, trade and economic policy. By the year 2000, nearly 150 countries had either published their national biodiversity strategy or were actively engaged in preparing it.

BUILDING THE KNOWLEDGE BASE

Knowledge is the foundation upon which action in the field of biodiversity can be based. Therefore, Article 7 of the convention encourages parties to identify and monitor genes, species, and ecosystems that the party considers particularly important (because of special economic, social, or biological value to the country), and to identify and monitor its activities that may have significant adverse impacts on biodiversity. The information generated will enable countries to determine their own priorities for conserving biodiversity and using biological resources sustainably, and foster international exchange of information. However, consistent with the notion of a precautionary approach, parties also recognize that lack of knowledge is not a valid reason for not taking appropriate action to conserve biodiversity.

IN SITU CONSERVATION

Conserving ecosystems and species in their natural settings is the essence of the convention. Parties are encouraged in Article 8 to emphasize *in situ* conservation through actions such as: establishing and managing a representative system of protected areas; conserving and sustainably using biological resources within and outside protected areas; promoting environmentally sound and sustainable development in areas adjacent to protected areas; rehabilitating degraded ecosystems and promoting the recovery of threatened species; controlling alien species and the risks associated with genetically modified organisms; protecting threatened species and populations, and regulating processes and activities that may adversely affect biodiversity. Article 8 thus seeks an appropriate balance between preservation and sustainable use. It also specifically calls for cooperation between countries in providing financial or other support to developing countries to implement the measures called for by the CBD. By the end of 1999, Parties to the CBD had agreed actions on forests, alien invasive species, and coastal marine systems.

EX SITU CONSERVATION

Since *ex situ* conservation takes place outside natural habitats, for example, in zoos, botanical gardens, and seed banks, it is meaningful primarily for genes and species as a complementary effort to *in situ* conservation. Under Article 9, parties are encouraged to implement appropriate *ex situ* measures in support of conserving ecosystems and natural populations of species, preferably implementing these measures in the country where the genes or species originate.

SUSTAINABLE USE

The CBD defines sustainable use as the use of components of biological diversity in a way and at a rate that does not lead to the long-term decline of biodiversity . It thereby moves beyond the traditional focus on the species being harvested to instead address the system affected by any harvest. Under the CBD, parties are also encouraged to promote the sustainable use of biological resources by integrating conservation and sustainable use into national decision-making. Adopting measures for using biological resources which avoid or minimize adverse impacts on biodiversity, supporting local populations to develop and implement remedial action in degraded areas, and encouraging cooperation between government and the private sector in developing methods for the sustainable use of biological resources.

INCENTIVES FOR CONSERVING BIODIVERSITY

Biodiversity often is lost by accident, as an unintended consequence of other activities, such as building a dam or a road, converting a forest into a plantation, or extending agriculture into habitats that previously had been used for other purposes. Such development activities are often heavily subsidized, while the incentives for conservation tend to be much weaker. Therefore, the Convention encourages the adoption of economically and socially sound measures which act as incentives, such as proper pricing of biological resources to re ect true cost and the use of tradable rights in their management. Such measures can be effective means for encouraging the conservation of biological diversity and the sustainable use of biological resources.

RESEARCH, TRAINING, PUBLIC EDUCATION AND AWARENESS

Recognizing the importance of generating new information on biodiversity, the parties agree to promote active programs for research, scientific training and technical education in fields related to biodiversity. The CBD urges countries to cooperate in applying new scientific information to conserving biodiversity and using biological resources sustainably, with particular attention given to developing countries. Parties recognize that biodiversity will only be conserved if the general public is aware of its value and supports actions being advocated under the convention to promote public understanding of biodiversity issues, and to cooperate internationally in developing appropriate educational and public awareness programs in this field.

ASSESSING IMPACTS

Environmental impact assessments and strategic environmental assessments can be useful tools in determining how development projects are likely to affect or be affected by biological resources and to identify the options for minimizing these effects. The parties agree to introduce appropriate procedures for assessing the environmental impact of projects, programs, and policies that could significantly affect biodiversity, to seek to avoid or minimize any negative impacts on biodiversity, and to facilitate appropriate public participation in these procedures. The CBD also calls for states to exchange information about activities, which are likely to damage biodiversity and to promote arrangements for emergency responses in such cases.

ACCESS TO GENETIC RESOURCES

Genetic materials of plant, animal, microbial or other origin often have economic value. Seeds of agricultural crops, particular animal breeds, and genes from bacteria form important components of biodiversity and provide the foundation for a number of commercial activities, including the development of improved agricultural varieties and pharmaceuticals. Recognizing the sovereignty of states over their natural resources, the CBD encourages parties to facilitate access to genetic resources within their jurisdiction for environmentally sound use, under mutually agreed terms and with prior informed consent. These latter terms are difficult to define and have fostered new approaches to national legislation that ensure fair access and equitable sharing of benefits.

TRANSFERRING TECHNOLOGY

Fulfilling many of the convention's objectives will require that developing countries have access to appropriate technology. Parties are encouraged to provide or facilitate access to these technologies, including genetic engineering techniques, conservation technologies, and methods of habitat rehabilitation. Developing countries are to be extended fair and most favorable financial terms in this regard. Access to and transfer of technology is to be consistent with the protection of *intellectual property rights* (IPRs): no simple matter. Benefits from genetic resource based technologies are to be shared with the parties providing the genetic resources. The convention also includes elements relating to safe trade, handling and use of living modified organisms (LMOs). The first protocol of the CBD was negotiated to address these latter issues. The so-called Cartagena Protocol, named after the Colombian city where detailed negotiations began, was adopted as a formal Biosafety Protocol during a special session of the Conference of Parties (COP) held in Montreal, Canada, in January 2000 and has far reaching implications for trade in biotechnology. This protocol is the first international treaty to comprehensively address genetically modified organisms. The protocol will enter into force when 50 countries have formally ratified it.

Transfer of technologies relevant for the conservation and sustainable use of biological diversity, continues to be a major area of unfulfilled expectations of most developing country parties. Technology is an important tool for *in situ* and *ex situ* management of biodiversity. For example, new agricultural technologies have the potential to increase yields to feed the growing human populations while reducing unintended adverse environmental impacts. Modern biotechnology could provide tools for understanding the living world and thus may greatly aid in assessing and monitoring biodiversity at the national, regional and global levels. Transfer of relevant technologies will be facilitated and enhanced through the involvement of the private sector in the area of bioprospecting and biosafety in joint ventures with national institutions or local private sector entities.

EXCHANGING INFORMATION

The CBD encourages its parties to exchange information about biodiversity. The CBD also recognizes that many indigenous and local communities have a close and traditional dependence on biological resources and that their knowledge and practices can make a significant contribution to the conservation of biological diversity and the sustainable use of biological resources. Parties are therefore encouraged to protect and recognize customary use of biological resources in accordance with sustainable traditional practices. The CBD also encourages the maintenance and wider application of relevant indigenous knowledge, innovations, and practices as well as the equitable sharing of benefits arising from their use. They have established an internet-based clearing house mechanism for helping to do so.

PROVIDING FINANCIAL RESOURCES

Each Party to the CBD undertakes to provide within its capabilities the necessary funds and incentives for national activities undertaken to implement the Convention. It also recognizes that developing countries may require additional financial assistance to enable them to implement the convention and benefit from its provisions. Under the convention, the developed countries are called upon to provide new and additional financial resources to developing countries. One response has been the use of the financial resources of the Global Environment Facility (GEF), which was established and is operated by the World Bank, the

United Nations Development Programme, and the UNEP to provide the incremental costs necessary to assist developing countries in dealing with global environmental problems: the GEF, *inter alia*, the financial mechanism for implementing the CBD. The GEF spends over US$100 million per year in this endeavor, while many developed countries also provide considerable funding directly to developing countries amounting in total to several hundred million dollars per year. The CBD is therefore one of the relatively rare international conventions that also directly results in substantial economic incentives in support of its implementation.

THE WORKINGS OF THE CONVENTION

The CBD established a COP (*see* Conference of Parties, Volume 4) that meets on a regular basis. By mid-2000, it had met five times, as follows:

1. COP1: Nassau, Bahamas (November–December 1994);
2. COP2: Jakarta, Indonesia (November 1995);
3. COP3: Buenos Aires, Argentina (November 1996);
4. COP4: Bratislava, Slovakia (May 1998);
5. COP5: Nairobi, Kenya (May 2000).

The COP is advised by its Subsidiary Body on Scientific, Technical and Technology Advice (SBSTTA) which meets between sessions of the COP, normally in Montreal. The COP establishes *ad hoc* working groups to address particular issues. Noteworthy in this regard has been its work to implement Article 8(j), which addresses the issue of indigenous peoples and traditional knowledge. The CBD offers the only effective international mechanism where these issues can be discussed at a substantive and technical level; this helps integrate emotive human rights issues within the environmental issues affecting biodiversity.

As an umbrella agreement, the CBD is able to address a wide range of important issues. During its third meeting, the COP reasserted its aspiring role as a focal point in relation to other relevant international instruments and processes, especially on issues such as forests, intellectual property rights (IPRs), and agriculture. The degree of these interactions and the leadership level adopted by the COP are variable. Perhaps the issue where interaction is strongest is agriculture: the CBD addresses land resources; water resources; plant, animal and microbial genetic resources; wildlife; air and climate; farm inputs; wild sources of food; traditional knowledge; marketing conditions for agricultural products; land-use pressures; and agroforestry. The COP has staked out a leading position in the field of agricultural biodiversity, taking the opportunity to link concerns regarding biodiversity conservation and sharing of benefits with the mainstream economy, drawing on balanced attention to the three objectives of the CBD. The COP sent a message to the December 1996 session of the Food and Agriculture Organisation Commission on Plant Genetic Resources for Food and Agriculture (PGRFA) to negotiate the revision of the Convention on the International Undertaking on Plant Genetic Resources in harmony with the CBD. It also specified COP's willingness to consider a protocol on PGRFA under the CBD.

Consistent with its mandate under the CBD, the COP has also sought to in uence intergovernmental discussions on forests to ensure that forest biodiversity concerns are addressed covering issues such as the underlying causes of biodiversity loss, analysis and mitigation of human impacts on forest biodiversity, economic valuation of biodiversity components, and development and use of criteria and indicators for biodiversity. The work program for forest biodiversity includes development of technologies necessary for conservation and sustainable use of forest biodiversity, it takes an ecosystem approach, and incorporates traditional systems of conserving biodiversity in forests. The COP has also called for scientific analysis of the ways in which human activities, especially forest management practices, in uence biodiversity and sought ways to minimize or mitigate negative in uences arising from such practices.

Through its COP, the CBD has also stimulated considerable progress on biodiversity in the seas. For example, COP2 adopted the Jakarta Mandate on Marine and Coastal Biodiversity. It provided a checklist covering five areas in which CBD Parties should take actions for conservation and sustainable use in these habitats: integrated marine and coastal area management; marine and coastal protected areas; sustainable use of marine and coastal living resources; mariculture; and alien species. Major international bodies were invited to improve their existing activities and develop new actions, which promote the conservation and sustainable use of marine and coastal biodiversity, taking into account the recommendations contained in the Jakarta Mandate. A three-year process will elaborate the recommendations for action in the above five areas, and possibly others. To assist in the implementation of the process, the CBD Executive Secretary has established a roster of experts, and he draws upon a wide range of inputs from governments, intergovernmental organizations (IGOs), nongovernmental organizations (NGOs) and others.

Many people believe that conserving biodiversity and using biological resources sustainably will benefit all of society. However, conserving biodiversity, using biological resources sustainably, and equitably sharing the benefits of such use, all involve social costs and benefits that are borne unevenly across segments of society. Therefore, the CBD calls for policies to promote the equitable sharing of these costs and benefits in ways that improve the wellbeing of the poor and weaker sections of society. Activities to implement the Convention thus need to be supported by

all sectors of society, including local communities, NGOs, the scientific community and industry. The CBD offers a unique opportunity for this diverse mixture of interests to work toward the same broad objectives. This desired international consensus can be attained if all sectors of society contribute to the agreed goals of the CBD.

The CBD website is found at http://www.biodiv.org/.

Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES)

see CITES (Convention on International Trade in Endangered Species of Wild Fauna and Flora) (**Volume 4**)

Convention on Long-range Transboundary Air Pollution (LRTAP)

Lars Björkbom
Stockholm, Sweden

The LRTAP was signed in Geneva in November 1979 by 34 member states of the United Nations Economic Commission for Europe (UNECE), which also includes Canada and the US. The Convention came into force in 1983 and today (early 2000) has 45 parties out of 55 of the UNECE members. The growth of number of parties over the period is mainly a re ection of the geo-political changes that have taken place, but also re ects the growing awareness of international interdependence when trying to achieve national environmental goals in minimizing negative effects to ecosystems and human health of various airborne pollutants, which are transported long-range over national borders.

The LRTAP is a framework convention focusing on information gathering and exchange of knowledge to support parties in their air pollution abatement policies. Its foremost scienti c tool from the start was the incorporation of the European Monitoring and Evaluation Programme (EMEP), which had been built up as part of the preparatory process. Later, other expert groups have been established on effects of air pollutants and information gathering and assessment of abatement technologies.

*The LRTAP countries would, at the time, not allow any legal provisions for extending international cooperation to mutual abatement efforts in the form of protocols. There is still no such provision in the framework agreement but today there are de facto eight protocols, ve of which are in force. One of the protocols (1984) regulates the nancing of the EMEP. The others deal with reductions of separate pollutants (sulfur dioxide 1985 and 1994, nitrogen oxides 1988 and volatile organic compounds (VOCs) (*see *Volatile Organic Compounds, Biogenic (VOCs), Volume 2) 1991). The later protocols regulate groups of compounds with similar characteristics and effects, e.g., protocols on heavy metals (HMs) and on persistent organic pollutants (POPs) (1998). The latest protocol to abate acidi cation, eutrophication and ground-level ozone, signed in 1999, further regulates reductions of emissions of sulfur, oxidized and reduced nitrogen and VOCs, which all interact in different ways to create environmental and human health problems in the three effect areas listed in the name of the protocol. None of the protocols has all LRTAP Parties as parties or signatories. Also, the cluster of countries is not the same for each country's protocol, which re ects the fact that different countries have different priorities on different ecological and health issues.*

The LRTAP had its roots in the East–West tension during the Cold War, the Principle 21 adopted at the 1972 United Nations (UN) Conference on Man and the Environment in Stockholm, and Scandinavian concerns about low resistance of waters and soils (low buffering capacities) to acidifying pollutants, whose main sources were sulfur emissions in continental Europe and the British Isles. In the Final Act of the Conference on Security and Cooperation adopted in Helsinki in 1975 during a temporary thaw in East–West relations, UNECE countries agreed to cooperate in a number of areas: disarmament, human rights and economic affairs, which included environmental affairs. When the thaw again disappeared in the late 1970s, the only area that was not considered too dangerous for cooperation was environment. A proposal from the Soviet Union in late 1976 to the UNECE to cooperate in the field of the environment (and also in the field of energy) was, however, acceptable to the western countries. When discussing what particular problems should be dealt with, Sweden and Norway saw their chance to bring acidification on to the agenda as being a transnational problem and also a test of the implementation of Principle 21, which states that although nations have sovereign rights over their own environment, they are not allowed to pollute their neighbors or the environmental commons. After more than a year of tough negotiations, a high-level meeting of UNECE members in November 1979 adopted the LRTAP.

Within the convention, parties agree to cooperate, in exchange for information relating to national emissions of air pollutants that might have transboundary effects, and measures that they are taking to abate such emissions. The objective laid down in article 2 is to endeavor to limit and, as far as possible, to gradually reduce and prevent air pollution including long-range transboundary air pollution. Parties shall develop ••• policies and strategies which, shall serve as a means of combating the discharge of air pollutants (art 3) and exchange information on, and review, their policies, scientific activities and technical measures aimed at combating ••• the discharge of air pollutants (art 4) and exchange available information on national, subregional and regional policies and strategies for the control of sulfur compounds and other major air pollutants (art 8).

The LRTAP is served by the UNECE secretariat, but the UNECE has no decision-making power. This rests with the executive body (EB), which is the Conference of the Parties to the LRTAP (*see* Conference of Parties, Volume 4).

The initial central scientific tool related to the convention is the Cooperative Programme for Monitoring and Evaluation of the Long-range Transmission of Air Pollutants in Europe (EMEP), which was in existence already in 1977, but became an integral part of the LRTAP when it came into force. A number of subsidiary bodies to the EB have successively been established, relating to various articles under the LRTAP or to separate Protocols or EB decisions, relating to research on effects, assessment of emission abatement techniques, negotiation and review of protocols and implementation of protocols. All these subsidiary bodies have, through EB decisions, over time and as needs have arisen, established (and, less frequently, concluded) international coordinating programs, centers and Task Forces (TFs) to support the quality of their advisory role to the EB. (For the 1999 organization of work and how it has been developing over time, see Figure 1).

During the negotiations of the LRTAP, a few countries (in particular Norway and Sweden) pressed for a more action-oriented agreement, which would include specific international emission-reduction obligations for parties. The time was, however, not ripe in 1979 for such proposals. It was not even possible to get a provision in the LRTAP that could form a legal base for developing protocols to reduce emissions of air pollutants. It is interesting to re ect on the fact that today (early 2000), four such Protocols are in force and a further three adopted and signed by a large majority of LRTAP parties that regulate quantitatively defined reductions in emissions of the most important air pollutants, which are transported over national boundaries within (and in certain cases beyond) the UNECE region. There is also a Protocol on the financing of EMEP.

From a legal point of view, each Protocol is an independent international agreement. None of the Protocols (already in force or expected to come into force) has all LRTAP parties as parties (or signatories) and the composition of parties (or signatories) to each Protocol differs for different protocols, which re ects different priorities of parties to problems regulated in each Protocol. There has been, however, a growing tendency over time that more and more LRTAP parties also become parties to the Protocols. This might re ect a growing awareness among all LRTAP parties that most of the problems related to transboundary air pollution can not be effectively attacked without common international abatement responsibilities, but also the fact that later Protocols have allowed for differentiations of national abatement obligations, when they are based on scientific assessments of each party's contribution to the problems.

The first three substantive Protocols on emission reductions of sulfur (1985), nitrogen oxides (1988) and VOCs (1991), respectively, are often called protocols of the first generation. Their common characteristic is a at rate approach, meaning that each party shall implement the same percentage of emission reductions of the polluting compound over the same given period of time.

In the 1985 Protocol on the Reduction of Sulfur Emissions or their Transboundary Fluxes, all contracting parties were obliged to reduce their emissions of sulfur dioxide by at least 30%, by 1993, based on their emissions in 1980.

In the 1988 Protocol concerning the Control of Emissions of Nitrogen Oxides or their Transboundary Fluxes, the general rule is that parties should freeze their emissions by 1994 to the emission levels of 1987. There was, however, some exibility introduced in this Protocol. The US was allowed to have 1978 as the base year for calculating their emissions in 1994 because they could demonstrate, relative to other parties, early introduction of three-way catalysts to curb exhausts from cars, which were then and still are a dominant source of emissions of nitrogen oxides.

In the 1991 Protocol concerning the Control of Emissions of VOCs or their Transboundary Fluxes, the general rule was to reduce emissions of VOCs by 30% by the year 1999 based on assessed emission values from a choice of a year between 1984–1990. Some parties from countries in Central and Eastern Europe (CEE) with relatively small total emissions were allowed to freeze their emissions based on the same optional base year. Parties with areas larger than 2 million km^2 could choose a limited part of their territories as management areas. Canada and Norway chose this option when ratifying the Protocol. Norway was allowed to include its vast marine area allotted to them under the Law of the Seas agreement, where Norway has large offshore oil and gas production, which is an important source for VOC emissions.

All three Protocols were considered as a first step to control and reduce emissions of the relevant pollutants. In the 1988 NO_x Protocol, the review article prescribed that a revised or second step protocol should *inter alia* be based on the *critical load* approach (*see* Critical Load, Volume 3). This has also been the case for two of the second-generation protocols, which have dealt with the same pollutants (plus ammonia) as the earlier ones. The critical load is a quantified value of how much deposition of a pollutant a receptor can accommodate without losing its buffering capacity. A similar value for concentrations of pollutants in the atmosphere is applicable for effects of ground-level ozone to *inter alia* crops and human health, and is called the *critical level*. The critical load concept has so far, however, not been applicable to the two Protocols, which regulate the control of POPs and heavy metals (HMs), both adopted in 1998, where alternative methods of scientific risk assessments of the various effects of the various chemicals and metals on ecosystems and human health have been criteria for banning or severely restricting their production and/or use. Common to all protocols of the second generation is the fact that they are guided by

scientific considerations, where up-to-date knowledge of the negative effects of the controlled pollutants is the key characteristic. Another common feature of these protocols is that they allow differing emission reductions or other obligations for individual parties, the goal being to use optimal cost-effective solutions.

The 1994 Protocol on Further Reduction of Sulfur Emissions can today be considered as a first test to apply the critical load's approach. Based on information of emission sources and volumes, atmospheric trajectories and data on depositions (*see* RAINS (Regional Air Pollution Information and Simulation), Volume 4), critical load maps produced on different ecosystems' sensitivity to sulfur depositions in 150 • 150 km grid squares covering all of Europe west of the Urals, and cost curves for emission abatement measures in different countries, optimized integrated assessment scenarios were produced that could give guidance to negotiators on the most cost-effective way, on a regional scale, to reduce sulfur emissions. The long-term objective was to achieve depositions below critical loads for sulfur all over Europe, to abate acidification. It was realized that this goal could only be reached in a series of steps. The Protocol covered a first step, aiming at a 50% closure of the gap of exceedances of critical loads between 1990 depositions and critical loads in each grid square, translated into emission reduction quantities for each country by the year 2000 based on 1980 emission values. Although this ideal gap closure scenario was modified in the final negotiating phase (as expressed in Annex II to the Protocol) owing to political and economic concerns expressed by some delegations, the critical load or effect-related approach proved its value to all participating governments. An option was open to parties with areas of more than 2 million km^2, to meet their requirements within a defined sulfur dioxide management area that contained emissions that had significant impacts beyond their national boundaries. This option was used by Canada only.

The approach was, however, considered a half-measure. After all, acidification is not caused by sulfur deposition only, but also by nitrogen, both oxidized and reduced. Therefore, the EB considered that the objective should be to abate acidification and eutrophication, and given the fact that NO_x, together with VOCs, under exposure to sunlight produce ground-level ozone, this effect area should also be attacked in the new NO_x Protocol (see Figure 2). This multi-effect/multi-pollutant approach was embarked upon in 1994. This required much further research on deposition and concentration effects on ecosystems, materials and human health, as well as laborious refinement of the integrated assessment model used for the 1994 Sulfur Protocol. Much work to establish reasonably accurate emission inventories for the relevant

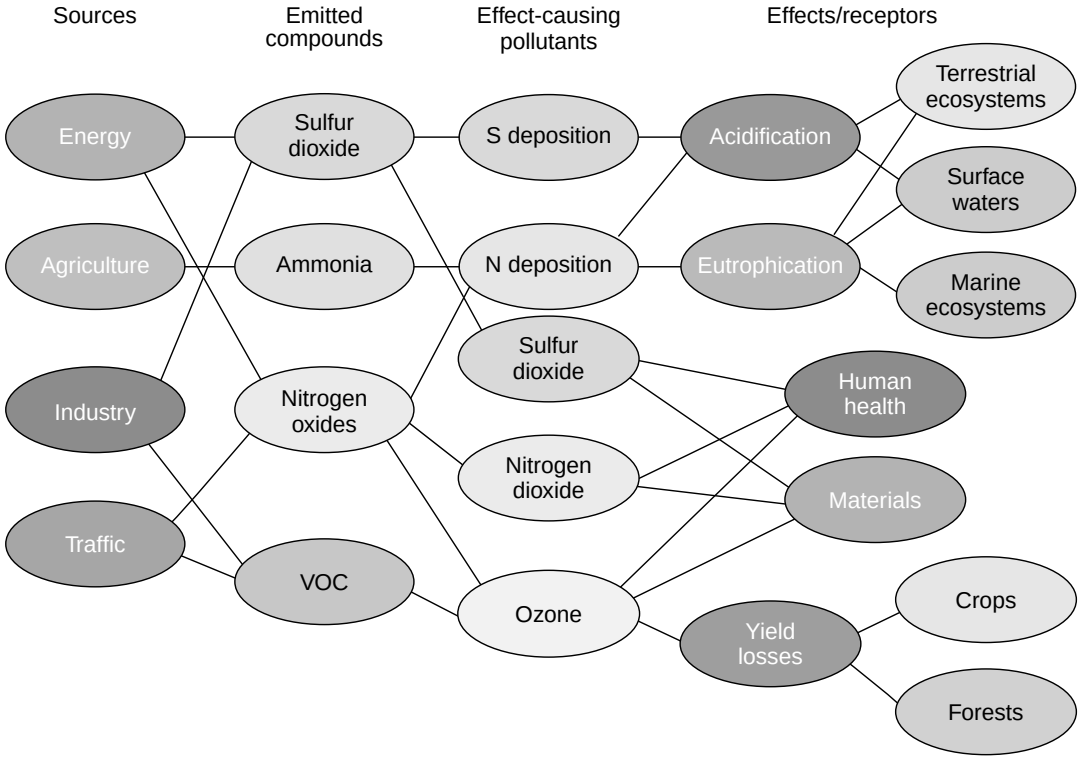

Figure 2 The interrelationship between sources of air pollution, emitted compounds, effect-causing pollutants and effects receptors. (Reproduced by permission of IVL)

pollutants and assessment of abatement costs for the many emission sources involved also had to be done. New insights into the atmospheric chemical processes leading to ozone formation, and the behavior of ammonia when released to the air and when deposited in ecosystems, were developed. With this impressive knowledge base, a Protocol to abate acidification, eutrophication and ground-level ozone was ready to be adopted in late 1999. Parties will be legally obliged, in a first step, to make substantial reductions of all pollutants involved (defined in absolute volumes in Annex II to the Protocol) in relation to their national contributions to the effects area by the year 2010, based on the emission levels of 1990. When implemented, exceedances above critical loads for acidification and eutrophication will be limited to the most sensitive areas in Europe, and the reduction of background ozone concentrations will significantly relieve pressure on human health, crops and semi-natural forests. However, in 2010 there will still be large areas with depositions above critical loads and several million people will live in areas where critical levels for oxidants will be exceeded. Further steps towards the final objective of the Protocol, to reduce deposition of acidifying and eutrophying pollutants below critical loads and concentrations below critical levels in the UNECE region, are to be negotiated within the framework of the Protocol after periodic reviews assessing the relevant scientific development and new techniques and other measures to further abate the pollutants. By using this integrated approach, it is calculated that the overall abatement costs will have been reduced by more than 30%, in comparison with the at-rate pollutant-by-pollutant approach used in the first generation of protocols under the LRTAP.

Two further Protocols on HMs and on POPs were developed in a parallel exercise and both were adopted in 1998. The HMs Protocol regulates emissions of cadmium, lead and mercury. The objective of the Protocol is to minimize effects on human health and adverse effects on the environment. Its central obligation is to curb emissions by applying strict limits to the major source categories emitting metals that can be achieved by using *best available techniques, not entailing excessive costs* (BATNEEC), which are quantified and described in a number of annexes. Efforts to ban metals in products were less successful, owing to con icting international trade rules. Phasing-out of leaded gasoline over a period of years is, however, required and will have its main effects in CEE countries. The Protocol also introduces measures to lower emissions of mercury from products. The Protocol includes provisions for adding other metals to the Protocol if international action is deemed necessary.

The objective of the POPs Protocol is to control, reduce, or eliminate discharges, emissions and losses of POPs to the environment. Three measures are used as obligations. For some substances, production and use are eliminated, and for others, use is severely restricted. For those substances which are formed unintentionally as a result of combustion or processing activities, total annual emissions are reduced from a reference year, applying stiff limits using BATNEEC. The 16 substances listed in the present Protocol are aldrin, chlordane, chlordecon, dichlorodiphenyl, trichloroethane, dieldrin, dioxins and furans, endrin, heptachlor, hektachlorobenzene, hexachlorocyclohexane, hexabromobiphenyl, mirex, polycyclic aromatic hydrocarbons, polychlorinated byphenyls and toxaphene. A process included in the Protocol allows for substances to be added or current obligations to be modified as new information is obtained. This regional POPs Protocol is seen as a major step towards global control of these substances, which are presently under negotiation under the UN Environment Programme umbrella.

With the latter three Protocols, the most important known air pollutants, which are transported over national borders, are now controlled within the framework of the LRTAP. These Protocols are designed to stand the test of time, and have provisions for regular reviews and amendments. Both effective implementation and cost-optimal abatement measures need to be based on the most up-to-date scientific knowledge. Preserving the impressive scientific network that has been built up during the 20 years of development under the LRTAP is a key to the future effectiveness of the Convention. It has been an inspirational and legal focal point for both international and national air pollution abatement in the UNECE region. The implementation record has so far been impressive. Substantive reductions of sulfur emissions have been recorded, but also reductions in absolute terms of nitrogen oxides and VOCs emissions have taken place over the period and with the new Protocols in force, there will be forceful management instruments to achieve the objective laid down in article 2 of the LRTAP to gradually reduce and prevent transboundary air pollution in the UNECE region. Of course, this does not mean that air pollution in the region has reached sustainable levels, but the work under the LRTAP indicates that this goal can be reached through revisions of the Protocols foreseen over the next few decades. Its effectiveness so far should be an inspiration to other regions in the world.

CSD (Commission on Sustainable Development)

The Economic and Social Council of the United Nations (UN) established the CSD as a functional commission of the Council on the 12th February 1993, in response to a resolution of the UN General Assembly. The resolution of the General Assembly on 29th January 1993 endorsed the recommendations of the UN Conference on Environment and Development (UNCED) in particular, the chapter of Agenda 21 concerning Institutional Arrangements which, *inter alia*, recommended the establishment of the Commission.

The Commission is composed of 53 members elected from among state members of the UN and members of the specialized agencies for a term of office of three years.

The Commission meets annually for a period of 3 weeks, now reduced to two.

The Commission was established to ensure effective follow-up to the UNCED Conference, as well as to enhance international cooperation, and rationalize the intergovernmental decision-making capacity for the integration of environment and development issues, and to keep under review the implementation of Agenda 21, recognizing that it is a dynamic program that could evolve over time, and make recommendations, as appropriate, on the need for new cooperative arrangements related to sustainable development.

The Assembly also decided that the Commission, in the fulfillment of its functions, will also monitor progress in promoting, facilitating and financing, as appropriate, access to and transfer of environmentally sound technologies and corresponding know-how, in particular to developing countries, on favorable terms, including concessional and preferential terms, as mutually agreed, taking into account the need to protect intellectual property rights as well as the special needs of developing countries.

The Commission has already met seven times. Part of each meeting (lasting for two to three days) is attended by high-level ministers. The Commission is endeavoring to coordinate activities of the UN system covering areas of sustainable development, which include economic growth, social development, and environmental protection and management.

Cumulative Environmental Assessment

R E Munn
University of Toronto, Toronto, Canada

A cumulative environmental assessment (CEA) is an assessment of the cumulative environmental effects over decades of a proposed development (e.g., a power station or waste dump), including:

- *the cumulative environmental effects of the development itself (e.g., slow release of heavy metals into ponds or the atmosphere);*
- *the multiplying effects on the local environment of other developments that may subsequently be attracted to the area (e.g., construction of an electricity-generating station may attract industry to the area);*
- *the interactive effects on the local environment of long-term regional and global environmental and socioeconomic changes (e.g., climate change, globalization, free trade agreements). (In many jurisdictions, however, CEAs are not required to include the effects of such large-scale changes.)*

The causes of local change may be environmental (e.g., drainage of wetlands), socioeconomic (e.g., population growth, highway construction) or both. Often, the changes are piecemeal over decades (sometimes referred to as *nibbling*), and thus difficult to predict. Overlapping political

responsibilities may sometimes contribute to the problem (CEARC/NRC, 1985).

Some engineers and planners think that the preparation of a CEA is an impossible task. Nevertheless, more and more jurisdictions require that developers submit CEAs in addition to environmental impact assessments (EIAs), (called environmental assessments, EAs in some jurisdictions). In Canada, for example, Bill C-13 (the 1992 Canadian Environmental Assessment Act) includes the clause that consideration be given to any cumulative effects that are likely to result from the project in combination with other projects or activities that have been or will be carried out. This Act does not include assessment of the effects of long-term large-scale change, although a hydrological development, for example, is usually designed to operate successfully for 100 years, during which time the rainfall regime might change drastically.

Factors to be considered in the selection of methodologies to be used in CEAs include the following:

- The assessor must be concerned with effects that may not become apparent for several decades, and in some cases, more than a century into the future.
- The spatial scales of interest must be much larger than in the case of an EIA. For example, a CEA of a proposed recreation area to be located in a rural setting must include not only the area but also the transportation corridors to and from urban centers.
- Because of the complexities of socioeconomic and ecological systems, an ecosystem approach (*see* Monitoring in Support of Policy: an Adaptive Ecosystem Approach, Volume 4) must be used. As examples, CEA study boundaries, wherever possible should coincide with those of naturally occurring ecological zones such as watersheds. Post-construction monitoring systems should be directed towards detecting changes in the stresses operating on the system as well as on the environmental effects.
- The CEA should include consideration of relevant long-term regional and global change factors such as urbanization and climate change.
- As interest in cumulative effects extends further and further into the future, the uncertainty factor increases more and more, due to:

1. The inherent uncertainties in socioeconomic and political scenarios, for even 10 years ahead, e.g., the unexpected rise in oil prices in the 1970s, and the fall of the Berlin wall in the late 1980s.
2. The failure of simulation models to predict many kinds of cumulative effects due to non-linearities, feedbacks, and incomplete knowledge of initial and boundary conditions.
3. The lack of methodologies to test model performance. Historical analogues are usually difficult if not impossible to find, and even if an environmental audit is performed 10 or 20 years after a development has been launched, there is no way of telling whether a better site could have been selected for the development.

With these concerns in mind, several CEA methodologies are being used, but it is still too early to recommend any single one of them.

1. *Risk assessment methodologies*: the risk assessment field contains a rich panoply of methodologies, some of which might be useful for assessing long-term cumulative effects.
2. *Multiple scenario construction*: because the future is so uncertain, it may be useful to select a range of future scenarios, to study the environmental effects of each, and to bracket the possible range of environmental effects that might ensue. See, for example, Stigliani *et al.* (1989) and Policy Exercises: a Tool for Solving Environmental Policy Dilemmas, Volume 4.
3. *Adaptive management strategies*: planners are well aware of the fact that long-term predictions of future land use are often wrong. They therefore periodically update their plans as new information comes in. Holling (1978) has recommended that this approach be used in EIAs. Of course, once a reservoir, for example, has been built, it is very difficult to make changes to its design. Wherever possible, however, options should be kept open as long as possible in preparation for the unexpected.

Demand Management

A P Lino Grima
University of Toronto, Toronto, Canada

Careless technology and lack of adequate policy instruments have made it possible for producers and consumers of environmental and natural resources to avoid part of the costs of production and consumption by passing these costs to others. These costs (e.g., water and air pollution) are referred to as technological externalities in environmental economics (Baumol and Oates, 1979). One way of reducing these externalities is to invoke regulation and prohibition. Indeed in the case of highly noxious pollutants, outright prohibition is called for. However, in most other cases there are several economic incentives and legal mechanisms for reducing these externalities (e.g., regulation, transferable emission permits, liability for compensation as in the US Superfund provisions). How can the demand for goods and services that deplete scarce resources or pollute our environment be reduced while respecting consumer choice (and, by implication, an economically ef cient allocation of capital and labour)? Demand management (sometimes referred to as demand-side management, or demand design) is one such exible policy tool to enhance conservation and move toward sustainable development within a market system based on consumer sovereignty. Demand management refers to policies designed to in uence consumer behavior by setting the price of a good or service (e.g., municipal water) to the level of producing and delivering it. In more recent literature the term has been used to include any technical, institutional, or educational effort to encourage resource conservation.

In general, the emphasis in environmental and natural resource management has been on the supply fix, i.e., increasing the supply (for example, of municipal water or electricity or highways or paper products) by expanding the infrastructure to meet the requirements for water, electricity, and so on. This emphasis on the supply fix re ects the view that supplies of environmental and natural resources are plentiful and that the demand for goods and services based on such resources are fixed. Indeed demand is often described as need or requirements. In this mind-set the supply fix becomes the only fix; and prohibition or regulation through improved technology becomes the only forms of environmental management. This mind-set is slowly changing to the view that higher levels of material production and consumption are compatible with sustainable resource use (WCED, 1987).

In an early empirical study of *demand management* through marginal cost pricing (Grima, 1972, 5), the first mention of the terms demand engineering or demand management was traced to a 1960 report by the US Senate Select Committee on National Water Resources, 1960. Demand management aims to in uence consumer choices by making the consumer pay a price that is as close as possible to the incremental cost of production, including any costs borne by others (e.g., health costs caused by air pollution). Like other environmental management options, demand management has its strength and weaknesses and the choice among the wide range of options should not be made on purely ideological grounds.

One limitation should be emphasized right at the outset: demand management and other economic incentives and legal mechanisms for reducing externalities complement rather than replace a regulatory and monitoring framework. To state an obvious example, residential electricity demand management requires metering, an appropriate pricing schedule and regular billing. So in a third-world city that lacks metering and billing facilities, residential demands for water or electricity are not amenable to demand management. This example leads to another limitation of price-dependent demand management: it is more relevant to reducing pressure on resources in af uent countries than in less developed countries.

Demand management works best for resource-based services that exhibit rising incremental costs (i.e., economies of scale have been exhausted or the cost of resources is rising) or services that exhibit daily or seasonal peak demands (e.g., for municipal water, energy for heating or cooling and highway use). Meeting peak demands requires higher levels of investment (e.g., for water storage towers) and at

least some higher operating costs (e.g., energy for pumping the water). It is therefore reasonable that the users of services during peak periods should pay for these increased costs. In addition, consumer choice is allowed and the policing/monitoring of peak pricing is not likely to be expensive. For example, it should be administratively easy to impose higher prices for water use during the summer or to require higher prices for transportation users during the rush hours. These higher costs to the consumers would provide a continuing incentive to reduce peak use and therefore increase the efficiency of the water (or public transport) system.

One of the positive aspects of demand management is that it enhances conservation by giving consumers correct signals and helping them to avoid policy traps. For example, in Canada in the late 1990s, more than half of the new vehicles on the road were relatively speaking gas-guzzling mini-vans and sport utility vehicles. These new car owners were faced with steeply rising gasoline prices in late 1999 and early 2000. However, adjusting to these higher energy costs in the short term is difficult or costly or both because of the long lifetime of vehicles. If an appropriate gasoline tax had been imposed to meet the costs that energy users impose on society as a whole in the form of NO_x and CO_2 new car owners would have received a more appropriate signal. Another example where a smaller pay-off may be expected is the deposit for the returnable beer bottle in Ontario (as opposed to the recyclable glass for wine and the aluminum can for pop). The average beer bottle in Ontario is used 20–30 times with small but not negligible savings in energy, litter and cost. It is particularly important that consumers in developing economies are given appropriate signals in order to avoid costly policy traps. In this sense, demand management is quite relevant to less af uent countries.

Demand management requires that the consumer of energy, water and other resource-based goods and services face costs (i.e., prices) at the correct level. If electricity at peak seasons and time costs more to produce and deliver, then electricity rates should re ect this. If energy use imposes costs on society in the form of climate change, then prices should re ect this too. Consumers would still have the choice to pay the higher price or reduce consumption, presumably through the adoption of more energy-efficient technology.

In most cases, prices are set by a number of producers who compete for market share and a number of consumers who seek to find the lowest price possible. So prices are set at the intersection of the demand and supply curves without too much administrative interference or collusion. Any deviation from this model would be a deviation from perfect competition and also a deviation from the ideal (i.e., efficient or optimal) allocation of the factors of production. However, most water and electricity rates and mass transportation prices are prices set by monopolies that provide municipal water, electricity, mass transport, etc. So how does one compare the prices with respect to the optimal allocation of resources that the market system aims to achieve?

In a market economy, incremental (or marginal) utility that consumers derive from a good or service is equal to the price per unit of a good or service. On the production side the volume of the good or service offered for sale is such that the incremental cost of producing the last (or marginal) unit is equal to the revenue, i.e., the price charged to the consumer. In brief, both the level of consumption and production are adjusted in such a way that the cost of the last unit produced and the utility of the last unit consumed are both equal to the price. Under these conditions, producers would not want to produce more or less of the good or service and the consumers would not want to consume more or less of it. In economic terms, we have an efficient allocation of scarce labor, human-made capital and natural resources. One should put in the usual disclaimer that it is necessary to make assumptions of perfect competition and the absence of externalities for this argument to be tenable. In addition, one has to assume a fair distribution of wealth and income before one accepts economic efficiency to be also ethically acceptable. However, the absence of perfect competition or a fair distribution of income and assets, is not a good reason to throw out the pricing system, which in general works much better than any central planning. The lack of perfect competition and social equity should, however, act as a spur to improve the market system. Demand management meets this criterion because ideally demand management sets consumer price equal to the incremental price of production, taking into account any external costs imposed by consumers on society and any costs of meeting peak demands.

Much of the early work on demand-side management focused on correct pricing and this type of mechanism is still a very useful step. However, later work by Brooks and others (Brooks, 1994; Grima and Paine, 1985) have expanded the concept especially with respect to its application to less developed countries. For example, marginal cost pricing (or even sensible pricing) of irrigation waters would free water for higher value uses such as municipal water. However, in economies where metering is non-existent and where it is politically and socially sensible to keep farmers on the land, emphasis on the conventional equimarginal principle is probably misplaced. Instead the focus needs to be directed towards technical, institutional and educational efforts to conserve water in the current uses.

To summarize, regulation and prohibition are no longer considered to be the only tools for achieving environmental goals. Market-oriented policy options such as demand management (coupled with appropriate monitoring and regulatory regimes) could play a key role in the transition from a consumer society to ecologically sustainable economic

development. The more rational prices that would face consumers could reduce the rate of depletion of non-renewable natural resources and could also reduce the rate of environmental degradation. Recent work on demand-side management has tended to include a broader range of conservation strategies in addition to the original emphasis on marginal-cost and peak-responsibility pricing.

Dematerialization and Sustainable Development

see Dematerialization and Sustainable Development (*Opening essay*, **Volume 4**)

Dematerialization of the Economy

Dematerialization is a shorthand term for significantly reducing the materials intensivity of the economic system. The need for this arises from a series of related propositions that are increasingly salient. Firstly, the world economy, as currently structured, is extremely materials intensive, in that the rich countries extract, process and discard far greater tonnages of materials than do the poor and developing countries. Secondly, economic growth in the past has also been based on mechanisms (such as the substitution of machines powered by fossil fuels for human and animal muscles) that are inherently materials intensive. Moreover, this mechanism, together with economies of scale, is still important for increasing labor productivity. Thirdly, some materials, like metals, are recyclable but others (especially fossil fuels) are not. Most materials extracted from the environment automatically become wastes and pollutants in a relatively short time; this is a simple consequence of the law of conservation of mass (Ayres and Kneese, 1969; Ayres, 1989). Fourthly, the waste assimilative capacity of the earth is becoming overloaded. In many respects, it is the scarcest resource. Finally, the developing countries must exploit many of the same growth mechanisms that the industrial countries did in reaching their present state of af uence. It follows that, to allow scope for economic growth in the developing world without triggering irreversible environmental degradation, it will be necessary for the advanced industrial countries to adopt fundamentally different policies and approaches. In brief, these changes require far more strict conservation of materials (including redesign to facilitate repair, renovation and remanufacturing), and development and exploitation of renewable sources of energy (especially solar power). Apart from reducing their own demand for raw materials and fossil fuels, this change of direction is important because the new materials-conserving and non-polluting renewable energy technologies that must be developed by the industrialized countries are also the technologies that will also be adopted in the developing countries as they grow.

Desertification Convention

Martin Williams
Adelaide University, Adelaide, Australia

At the United Nations (UN) Conference on Environment and Development (Earth Summit) held at Rio de Janeiro in June

1992, deserti cation was de ned as: " land degradation in arid, semi-arid and dry sub-humid areas resulting from various factors, including climatic variations and human activities" (UNCED, 1992). Until then, the de nition used by the United Nations Environment Programme (UNEP) attributed all deserti cation to human activities and excluded climate as a causal factor. Under this scenario, deserti cation was regarded simply as " land degradation in arid, semi-arid and dry sub-humid areas resulting from adverse human impact" (UNEP, 1990). Another important initiative to emerge from the 1992 Earth Summit was a request to the UN General Assembly to establish an intergovernmental committee for negotiating a convention on deserti cation. The General Assembly (47th session, 1992) established such a committee, the negotiations were successful, and the Deserti cation Convention was duly signed by 87 countries in Paris on 14- 15th, October, 1994. The full title of the convention is as follows: United Nations Convention to Combat Deserti cation in those Countries Experiencing Serious Drought and/or Deserti cation, particularly in Africa. To appreciate the need for such a convention, it is useful to understand some of the reasons for the inclusion of drought in the title and for the particular emphasis on Africa.

PRELUDE TO THE DESERTIFICATION CONVENTION

As long as desertification was considered to be a result of adverse human actions in arid and semi-arid areas, there was little incentive to consider an international approach to the problem. The prevailing view until the early 1970s was that desertification re ected inappropriate forms of land use (Aubréville, 1949), and that its impact was highly localized (Mainguet, 1994; Thomas and Middleton, 1994). The responsibility for managing desertification must therefore reside within the countries affected, so that desertification was seen to be a matter for national, but not for international, concern. All this changed with the 1968–1974 Sahel drought. This drought, which began in the Sahel region of Africa in 1968, brought below-average rainfall to every country immediately south of the Sahara for the ensuing fifteen years (Hare and Ogallo, 1993). More than any other single factor, the Sahel drought was the catalyst in focussing world attention on the reality of severe and widespread drought as a cause of famine and extreme social distress (Kassas, 1975a). Droughts had af icted other parts of the world besides Africa, but nowhere else in the world at that time had the scale and severity of the drought been so great (Tucker *et al.*, 1991; Middleton and Thomas, 1992, 1997; Williams and Balling, 1996; Williams, 2000).

The UN responded very belatedly to the famine in Africa and held a conference on desertification in Nairobi in 1977. This conference produced a plan of action to combat desertification that was endorsed by the UN General Assembly later that year and entrusted to the UNEP for implementation. In the years that followed, it soon became apparent that the plan of action was not achieving its aims and that desertification was becoming an increasingly severe problem, particularly in Africa (Darkoh, 1989; Dregne *et al.*, 1991; Glantz, 1977, 1987; Grainger, 1990). Reasons for the failure include a lack of political commitment by individual countries, inadequate infrastructure and financial support, and failure to involve local communities.

IMPEDIMENTS TO SUCCESS IN THE COMBAT AGAINST DESERTIFICATION

Table 1 lists a number of the more important reasons for past and present failures in dealing with desertification. Some relate to a lack of adequate monitoring procedures, some to inappropriate forms of participation, some to inadequate resources and poor use of existing resources, and some to awed planning.

Frustrated by the lack of substantive progress in dealing with desertification in Africa, the African environment ministers met in November 1991 in Abidjan in order to prepare a common position paper for Africa for presentation to the 1992 Earth Summit. In particular, they were unanimous in requesting that a new convention to combat desertification should be a specific recommendation to be included in Agenda 21. They were successful. They also enjoyed the support of many other countries facing similar problems of desertification, including China (China's Agenda 21, 1994; Ci Longjun, 1998). Chapter 12 of *Agenda 21* is entitled: Managing Fragile Ecosystems: Combating Desertification and Drought. It contains a very useful analysis of the causes and consequences of desertification, and a set of highly practical action plans for use at a variety of national and international scales (UNCED, 1992). Paragraph 12.40 (p. 104) provided the impetus for what followed and deserves to be cited in full:

> The General Assembly, at its forty-seventh session, should be requested to establish, under the aegis of the General Assembly, an intergovernmental negotiating committee for the elaboration of an international convention to combat desertification in those countries experiencing serious drought and/or desertification, particularly in Africa, with a view to finalizing such a convention in June 1994.

The General Assembly acted swiftly and established the International Negotiating Committee. The committee met five times and was able complete the final draft of the convention in time for the June 1994 deadline; a remarkable achievement given the complexity of the issues and the diversity of opinions represented within the committee (UNEP, 1995; Kassas, 1995b; Williams *et al.*, 1995; Chasek, 1997). Table 2 is a brief outline of the Desertification Convention.

Table 1 Possible impediments to past anti-desertification measures[a]

Planning/policy
Lack of national plans addressing control measures in development planning
Lack of prioritization due to conflicting demands on financial resources
Inadequate identification of social and economic causes
Poorly designed conservation works and over-emphasis on technical solutions
Disincentives of government pricing policies
Over-optimistic goals
Failure to address increases in human and livestock populations, which exacerbates the processes of desertification
Resources
Global economic recession, reduced financial resources and exacerbation of exploitative land use activities
Lack of external funding for UN in fulfilling the plan of action
Inadequate human resources or appropriate education at national levels
Lack of scientific machinery for management and assessment of desertification
Participation
Inadequate involvement or consideration of local knowledge, experience and skills in planning and implementation of management strategies
Forcing management upon local people who may not willingly accept external interference
Inadequate co-ordination or development of integrated approaches from independent government departments
Failure to combine efforts of UN agencies for interdisciplanary approaches
Monitoring
Lack of effective monitoring mechanisms for degradation processes and assessment status
Lack of follow-up observations on management impacts
Lack of maintenance of projects
Inadequate enforcement of stock limitations and control of grazing to maintain balance between livestock and plant cover

STRENGTHS AND WEAKNESSES OF THE DESERTIFICATION CONVENTION

The strengths and weaknesses of the Desertification Convention re ect the very diverse perspectives of those involved in negotiating the convention (Kassas, 1995b; Chasek, 1997) as well as the lack of scientific knowledge relating to the interactions between desertification and climate (Williams and Balling, 1996). The developing countries in particular were disappointed over the lack of any additional financial resources to cope with some of the fundamental issues such as poverty alleviation and food security (Table 3). The developed countries have

Table 2 Outline of the Desertification Convention[a]

Part 1 Introduction: includes terminology, objectives and guiding principles
Part 2 General provisions: addresses obligations of affected country parties; the priority for Africa; and relationships with other conventions
Part 3 Action programs, scientific and technical cooperation and supporting measures
Section 1 covers action programs at national, sub-regional and regional levels; the importance of international cooperation; the need for support and coordination for both elaboration and implementation of programs; and regional implementation annexes
Section 2 focuses on information collection, analysis and exchange; research and development; and transfer, adaptation and development of technology
Section 3 centers on capacity building, education and public awareness; and financial resources and mechanisms
Part 4 Institutions: provides for the conference of the parties, the permanent secretariat and the committee on science and technology; and stresses the importance of networking of institutions, agencies and bodies
Part 5 Procedures: focuses on communication of information; measures to resolve questions and settle disputes; status of annexes; amendments to the convention and the annexes; and the right to vote
Part 6 Final provisions: includes, inter alia, information on signature, ratification, entry into force and withdrawal
Annexes 1–4: Regional implementation annexes for Africa, Asia, Latin America and Caribbean, and the northern Mediterranean

[a] *Source:* adapted from UNEP (1995).

Table 3 Key aims decided at the Desert Margins Initiative, Nairobi, January 23–26, 1995[a]

Overall goal
To contribute to sustainable food security and poverty alleviation
Overall objective
To promote innovative and action-oriented dry land management research to arrest land degradation
Specific objectives
Understanding land degradation
Assessing dry land management practices
Evaluating the role of livestock in the rangeland/arable land continuum
Designing policies, programs, and institutional options
Improving natural resource management
Fostering domestication of tree species
Formulating drought management strategies
Enhancing institutional capacities
Exchanging technologies and information

[a] *Source:* author's notes and International Crops Research Institute for the Semi-arid Tropics, February 1995.

persistently argued that issues as broad as this should not be part of a legally binding convention (Chasek, 1997). The impasse persists.

Perhaps the most useful aspect of the convention is that it has brought desertification into the international arena as a problem transcending national boundaries, and has encouraged individual countries to prepare National Action Plans (China's Agenda 21, 1994).

It seems fitting to conclude with the words of Baba Dioum, a conservationist from Senegal in Africa: In the end we will conserve only what we love, we will love only what we understand, and we will understand only what we are taught.

Distance Learning and Environment

Jane Dougan

Nova Scotia Southeastern University Oceanographic Center, Dania Beach, FL, USA

Distance learning - planned education or learning in which one or more learners are physically separated, or at a

distance, from the person or source providing instruction, and often also from one another - is not new, but it is undergoing a revolution in reach and form, fueled largely by the explosion in use of information and communication technologies (ICTs), particularly the internet and the world-wide web. In 1981, there were an estimated 213 Internet hosts (computers with a direct connection); by January 1989, there were approximately 80 000. January 2000 surveys estimate that there are now over 72 million Internet host sites worldwide (predominantly in North America, Europe and Asia/Paci c), of which more than six million are educational (Internet Software Consortium, • http://www.isc.org•). This brings new opportunities for learning and new challenges.

With ICTs, learners are not so much at a distance but part of a virtual (cyberspace) learning community. Students (and teachers) can learn independently or as part of a virtual classroom; can access and discuss course materials with other learners in synchronous (real-time) or asynchronous learning networks (ALNs); and can collaborate on real-world or computer-simulated activities and materials locally and remotely. Increasingly, the learning need not be distant (i.e., isolated); instead, it may be distributed or connected learning.

While technology is a key driver, arguably the most challenging considerations involve the intent and content of the materials, and how learning at a distance happens. The hoped-for democratization of the Internet has the potential to further the development of learning communities; incorporating dynamic, interdisciplinary, constructivist, learner-centered approaches that transcend borders of geography and time, altering traditional notions of where formal learning begins and ends. Anyplace, anytime delivery is particularly appropriate in meeting the increasing demand for exible lifelong learning. In June 1999, G8 nations adopted the Cologne Charter - Aims and Ambitions for Lifelong Learning, which identi ed the importance of distance learning, particularly through ICT networks, as a key building block. In terms of environmental sustainability, the ability of the teaching materials to travel to the learner reduces the ecological footprint created by necessitating travel to a central learning institution. The increasing mobility is intellectual, rather than fossil fuel dependent. There are environmental, social and economic bene ts; people can learn while they remain in their community, within their bioregion and close to family and work.

At the same time, there are challenges. Effective distance learning requires ongoing supportive infrastructure at the production and delivery level, as well as relevant, appropriate content. Technology and content alone cannot be sustained without supportive and ongoing regulatory frameworks and distance education policies. Technology-intensive learning materials are time-consuming to prepare. As the global reach of distance learning expands, there is a corresponding need for increased local participation in the production of distance learning materials, particularly those involving multimedia. Distance learning materials predominantly originate within an urban, industrialized world, with English as a lingua franca. At the same time, the use of multimedia and ICTs provides increasing opportunities to incorporate and exchange knowledge of the cultural and social perspectives and ecological realities of the learners. In the context of global change, these are critical considerations, especially if learning is to play a role in supporting environmental, social and economic sustainability at a local as well as global level.

HISTORY AND EVOLUTION OF DISTANCE LEARNING

Distance learning has always evolved in response to global change and transition; re ecting economic and social changes in how and where we live and work, and technological changes in how we communicate and learn. The urge to develop and use tools to interpret and communicate how we live within the environment can be traced back more than 22 000 years, to a time when our ancestors recorded their observations of nature on cave walls. Since then, the tools have increased in breadth and sophistication, as has our knowledge base, and the challenges we face in learning to live sustainably.

Before distance learning, there was learning by correspondence, similarly fueled by a combination of technological innovation (a mechanized printing process, the infrastructure of roads and railways, the organization of the post office) and social change. As literacy and public education increased, so did demand for education by correspondence: in some countries, partly in response to a high concentration of people moving to cities; in others, to educate a population highly dispersed throughout remote areas.

The late 1800s were a time of experiment and individual initiative. In England, Isaac Pittman taught far-away students shorthand by postcard; in Sweden, when a student moved away, Hans Hermod taught him by letter and the resulting correspondence program (Hermods-NK1) is now part of the national educational system. Gradually, correspondence learning was incorporated into national formal educational systems. It expanded during World War II (in large part, to educate service personnel, even within Prisoner of War camps). From then on, learning by correspondence increasingly incorporated radio (e.g., Korea Air-Correspondence Junior College; University College in Nairobi's air-correspondence courses for teachers in rural areas; Madureza Project in Brazil.) In the early 1970s, Britain's Open University used prime-time television broadcasts along with radio and print correspondence,

and provided a successful and innovative model for other countries. Educational broadcast television learning programs have been used with great success worldwide, particularly in Latin America; e.g., Telesecundaria (Mexico), Telecurso 2000 (Brazil). Broadcast school education was also used in widely spaced settlements in Australia.

There are thousands of accredited distance learning programs and courses, and their number is increasing exponentially. Emergence of the Internet as a widely available international network has transformed the ability and means to access, process and share information. The boundaries between traditional and distance learning are dissolving, and distance education courses and even online undergraduate and postgraduate degrees are increasingly seen as credible. Distance learning programs and institutions accredited under Generally Acceptable Accreditation Principles (GAAP) are listed in the World Guide to Higher Education, the Commonwealth Universities Yearbook, or at: http://www.degree.net. On-campus courses offer distance learning components; distance learning courses incorporate real-world local learning activities. Virtual universities challenge the need for a physical campus. The African Virtual University (AVU) (www.avu.org) is a World Bank sponsored satellite-based telecommunications education network using videotape and broadcast to deliver lectures to 24 universities in 16 countries of Sub-Saharan Africa, and developing an extensive digital library. The Virtual University of the Monterrey Institute of Technology (Mexico) delivers university-level courses through live and prerecorded television broadcasts, and incorporates Internet communication for faculty and students. Universidad EAFIT (Colombia) is embarking on Project Virtual Classroom, exploring the use of shared virtual environments as tools for distance education. Project CONEXIONES is aimed at creating a virtual space for children to share ideas and learning with others nationally and internationally (http://sigma.eafit.edu.co/• virtualc/main_eng.htm.).

The JASON Project is an award-winning interdisciplinary online distance learning program allowing student interaction worldwide with year-round virtual scientific expeditions (http://www.jasonproject.org/). Digital Earth is a work in progress towards a seamless virtual representation of the planet that will allow people to explore and interact with the vast amounts of natural and cultural information gathered about the Earth (http://www.digitalearth.gov). Among numerous other environmental courses available by distance learning, Britain's Open University (http://www3.open.ac.uk) offers a postgraduate diploma in Environmental Decision Making with an emphasis on helping students clarify their thinking in the face of complex issues and incorporate environmental considerations into everyday decision making . The University of London Wye College External Programme has been running MSc programs in environmental management and environmental assessment, wholly by distance learning, since 1993. These are just a few examples of the increasing range and number of environmental distance learning courses and programs available.

There are expanding numbers of web sites for teacher training materials and knowledge sharing. The World Links for Development (WorLD) program provides training in the use of technology in education for teachers and students in developing countries, and links students worldwide in collaborative on-line learning projects (www.worldbank.org/worldlinks). Education Network Australia (EdNA) is a exible Internet-based Australian schoolteacher education program focusing on new technologies in learning (http://rice.edn.deakin.edu.au/CurrCorp/Currcorp.htm). Global Learning and Observations to Benefit the Environment (GLOBE) is a network of research scientists, students and teachers from over 8000 schools in over 85 countries working together to understand the global environment (http://www.globe.gov/). Leadership for Environment and Development (LEAD) is:

> a global, independent, education foundation [providing] continuing professional education for outstanding mid-career individuals•••introducing them to issues of environment and development•••with a guiding philosophy•••rooted in the ethical value of caring for our planet and all life that it sustains now and in the future (www.lead.org).

Its mission is accomplished in part by linking over 1000 associates and fellows worldwide via the internet-based network LEADnet, and providing a multi-language search engine LEADcat (http://www.leadcat.org) (*see* LEAD (Leadership for Environment and Development), Volume 4).

From an environmental and social perspective, distance learning via information and communication technology (ICT) can change our notions of community, connecting learners across borders and overcoming traditional political and national knowledge hierarchies. Networks of learning are becoming decentralized. The Association for Progressive Communications (APC) is linking over 50 000 non-governmental organizations (NGOs) in 133 countries to build strategic communities and initiatives•••to equitable human development, social justice, participatory political processes and environmental sustainability (http://www.apc.org).

THE DIGITAL DIVIDE

Learning at a distance has always attempted to reach groups and individuals who might be excluded from formal learning; women, low-income, immigrants, adult learners. The impersonality and reach of correspondence learning overcame more than geographic barriers: e.g., those of race, socio-economic level, gender, age, education-level, and

physical disability. Today, a major challenge is to overcome a digital divide in access to learning and information. The typical Internet user is a young (under 35) college-educated urban male, with a higher than average income and uent in English (the language of 80% of web sites). While access to computers and connectivity is increasing, the gap between the haves and the have-nots remains wide. The number of Internet hosts has more than doubled (from • 30 million to • 70 million) within three years, but it may be a considerable distance to the nearest telephone line; an estimated two-thirds of the world's people have never used a telephone. Even if there is access to networks, the cost may be prohibitive or restrictions in bandwidth (the amount of information that can be sent through a channel) may limit access.

Concerted efforts are being made to bridge global gaps in access, quality and delivery of education, with an increasing focus on the potential of distance learning. International meetings and forums on education and knowledge are attempting to resolve these challenges. For example, the Global Knowledge 1997 Conference (Toronto) and the Second Global Knowledge Conference (Malaysia, March 2000) have strengthened the Global Knowledge Partnership (www.globalknowledge.org). Similarly, the 1990 World Conference on Education for All (EFA) led to the establishment of an International Consultative Forum on EFA (www.unesco.org/education/efa), with further global meetings in Paris (1991), New Delhi (1993), Amman (1996), and a World Education Forum (2000) (http://www2.unesco.org/wef). The May 2000 symposium titled, *Shaping the Network Society: The Future of the Public Sphere in Cyberspace*, sponsored by Computer Professionals for Social Responsibility (www.cpsr.org), resulted in the Seattle Statement (www.scn.org/cprs/diac-00/seattle-statement.html), which calls for active, informed citizen participation and has now been signed by over 150 people from 20 countries. The United Nations Scientific and Cultural Organisation's (UNESCO) Education 21 initiative is embracing adult and distance learning within its quest to strengthen education in support of sustainable development, and their Learning without Frontiers (LWF) program (http://www.unesco.org/education/lwf/) is concerned with issues of access and lifelong learning at a community and individual level. The LWF program was pivotal in the Joint Initiative on Distance Education taken by nine high-population countries (Bangladesh, Brazil, China, Egypt, India, Indonesia, Mexico, Nigeria, Pakistan). More recently, a close collaboration has evolved between UNESCO and the Learning Development Institute (http://www.learndev.org.) towards consolidating and expanding the LWF program.

Online newsgroups and electronic mailing lists devoted to distance learning increasingly focus on issues such as equity and democracy in information-sharing and knowledge-building, and environmental sustainability.

For many countries and regions, especially rural areas, wireless technologies offer the best solution to joining a linked world of learning. Innovative methods of unwiring the World are being explored (http://www.media.mit.edu/unwired/) via international research and partnership. The Telecommunication Development Bureau (BDT) of the International Telecommunication Union (ITU) has developed a virtual training center (http://www.itu.int/VTC) as the base for a networked Global Telecommunication University/Global Telecommunication Training Institute (GTU/GTTI): a virtual university based on distance learning principles, with the aim of overcoming the technology training gap in developing countries. Further, ITU/BDT affirms that:

> the protection of our environment is essential for sustainable world development. Application of modern telecommunication technology to remote sensing, meteorology and telemetry programs can assist humanity to ensure efficient surveillance and management of the Earth's limited resources: water, forests, the atmosphere and organisms and plants that constitute biodiversity.

Accordingly, ITU/BDT organized an international symposium (Tunis, 1996) on the potential role of telecommunication technologies in environmental protection, and has launched a series of related pilot projects. Relatively inexpensive methods of wireless communication can increase accessibility for remote regions and poorer communities. Geographic information systems (GIS) technology is a collaborative tool for sharing maps and data related to environmental learning and natural resource management (*see* Geographic(al) Information Systems (GIS), Volume 4). Digital satellite links and high bandwidth satellite networks are on the horizon. Computers alone are not the solution; a reliable telecommunications infrastructure is required, emphasizing community access; e.g., telecenters in easily accessible locations such as libraries, post offices, clinics. These can offer a broad range of support and access to multimedia services, including distance learning.

As the world's information systems and learning become linked, ethical and economic questions arise surrounding ownership of intellectual property in electronic course materials, and there are disturbing indications that some distance learning courses may become tools for marketing products.

This brief article provides merely an overview of issues surrounding distance learning and environment in the context of global change. There are dozens of new and innovative approaches to environmental learning by distance, and no doubt more just over the horizon. The following is a guide to further sources of information on global change

and distance learning activities, in addition to those already mentioned.

INTERNATIONAL DISTANCE LEARNING ORGANIZATIONS

The American Center for the Study of Distance Education (ACSDE) (http://www.ed.psu.edu/acsde/) publishes the American Journal of Distance Education (AJDE) and a monthly electronic journal, The Distance Education Online Symposium (DEOS). DEOS-L is an interactive listserv, and DEOSNEWS serves approximately 5000 subscribers in more than 80 countries.

Center for Research in Distant and Adult Learning at the Open University of Hong Kong (http://www.ouhk.edu.hk/cridal/) (hosted the first Conference on Research in Distance and Adult Learning in Asia, June 2000).

Commonwealth of Learning (COL), (http://www.col.org/), an international organization created by Commonwealth Heads of Government to encourage the development and sharing of open learning/distance education resources and technologies .

The Development Education Program (http://www.worldbank.org/depweb/) provides teacher and student materials, case studies, and outreach activities related to social, economic and environmental sustainable development.

European Association of Distance Teaching Universities (http://www.eadtu.nl/content.htm).

The Global Distance Education Net (DistEdNet) (http://www.globaldistancelearning.com/) is an online multilingual knowledge guide to distance education targeted for developing countries. There is a core site located at the World Bank, with regional sites elsewhere.

The Inter-American Distance Education Consortium (CREAD) (http://www.cde.psu.edu/DE/CREAD/cread.html) is a network of individuals and institutions throughout North, Central and South America, joining resources and expertise to redefine educational partnerships in the 21st century .

The International Center for Distance Learning (http://www-icdl.open.ac.uk/icdl/), affiliated with the Open University UK, promotes distance learning related research, teaching, consultancy, information and publishing activities, primarily in Commonwealth countries, including an extensive database.

South African Institute for Distance Education (SAIDE), (http://www.saide.org.za/) including Southern Africa Global Distance Education Net.

United Nations Development Programme (UNDP) INFO21 site (http://www.undp.org/info21/sectors/s-edu.html) provides information and links to a variety of issues, including distance education and protection of the environment.

Virtual University (http://www.vu.org/), a non-profit worldwide learning community and the largest educational portal on the Internet today .

Virtual-U (http://virtual-u.cs.sfu.ca/vuweb/) incorporates the Global Educators Network, TeleLearning Network, and Virtual Learning Environments.

Women's International Electronic University, (http://www.wvu.ed/), multilingual, promotes ways for women to learn and women's ways of knowing , including cybercourses.

NEWSGROUPS AND ELECTRONIC MAILING LISTS

ACPACOMX is an international learner discussion list (listserv@mitvma.mit.edu).

INTED-L for learners, educators, trainers interested in international education (listserv@uwwvax.uww.edu).

INTER-L for learners, educators, trainers interested in international education (listserv@vtml.cc.vt.edu).

DEOS-L part of DEOS established by the American Center for the Study of Distance Education, DEOS-L is a moderated listserv for discussion of current issues in distance education (listserv@lists.psu.edu).

Distance Learning and Developing Countries (DLDC): a discussion list for researchers, teachers and students. For information, see http://www.egroups.com/group/dldc/info.html.

Global Knowledge for Development (GKD) discussion list is administered by the Global Knowledge Partnership, consisting of public, private and not-for-profit organizations committed to sharing information, experiences and resources to promote•••knowledge and information as tools of sustainable equitable development . See http://www.globalknowledge.org/discussion.html. To subscribe, contact majordomo@mail.edc.org.

(1922-)

Professor James Clement Ignatius Dooge was educated in his home country of Ireland and in the US, in civil engineering, uid mechanics and hydraulics.

Jim Dooge's life has moved along four intense and parallel streams, each of which complements the others and each of which could easily fill a single life for most human beings. Thus, Jim Dooge's life has been filled with a large and warm family; teaching and research; key positions in his country's political life; and contributions made to a variety of important international organizations. It has been his unique and multiple talents, energy, commitment, and skills as a leader in so many different areas which has allowed this unusual and rich combination to ourish.

Jim Dooge began his career during the war years as a junior engineer on sewage treatment and river improvement schemes in Ireland, and for eight years after 1946 he was the design engineer at the Civil Works Department of the Electricity Supply Board in Dublin. In 1956 he spent two years pursuing academic studies as a research associate at the University of Iowa, and upon returning to his country he began a long and distinguished academic career in Ireland, at University College Cork. Here he was a Professor of Civil Engineering from 1958 to 1970, and then at University College Dublin, where he was Professor of Civil Engineering from 1970 to 1984. He then became consultant hydrologist to several Irish universities as well as a much sought-after consultant and adviser to numerous international organizations.

Jim Dooge's contributions to his country's academic life have been recognized by various honors, including membership and presidency of the Institution of Engineers of Ireland and the Royal Irish Academy, and honorary membership of the Irish Meteorological Society and the Royal Dublin Society.

At the same time (1948) as the beginning of his academic career, Jim Dooge embarked on a political career when he was elected a member of the Dublin County Council of which he became chairman during two different periods in the early 1950s. After his return from the United States, and while pursuing his career as a Professor in Dublin, he was elected a member of the Irish Senate, having been nominated by the Institution of Engineers of Ireland. In 1965 he was reelected to the Senate and was also elected its deputy chairman. In 1973 he was reelected for a third term and was elected chairman of the Senate. During the period to 1977 he was also member of the three-person Presidential Commission, which exercised the functions of the head of state during any presidential absence or vacancy.

In 1977 Jim Dooge attempted to retire from public life in order to devote more time to academic concerns and to international cooperation in science and engineering. This retirement was not to last for more than four years, as in 1981 he was nominated to the Senate by the Taoiseach, who also appointed him minister of foreign affairs. In 1982 he was reelected to the Senate and became leader of the house and leader of the opposition. In 1983 he became a member of the New Ireland Forum established to pursue the quest of a lasting peace and stability in Ireland. In 1984 he was made chairman of the Ad Hoc Committee of Representatives of the EEC Heads of Government on Institutional Affairs and European Union. In 1987 he was finally able to step down from formal participation in public service, although he has never stopped being an in uential member of Irish life, even as a private citizen.

Parallel to all these accomplishments in Ireland, Jim Dooge began to participate in international scientific and engineering activities. In the mid-1950s he became a member of the International Association for Hydraulic Research and member and later president of the International Association for Hydrological Science. In the mid-1970s he began what was to be a long and important participation in the life of the International Council for Science (ICSU), first through the International Union for Geodesy and Geophysics, and later through ICSU itself, as president of the ICSU-UATI Committee on Water Research. He was secretary-general, and finally president of ICSU from 1993 to 1996. During this period Jim Dooge contributed to a large variety of ICSU's actions, especially in the climate research area, and in the involvement of the scientific community in the preparations for the 1992 United Nations Conference

on Environment and Development. During that year Jim Dooge also served as the chairman of the International Conference on Water and the Environment, held in Dublin. He also served as chairman of the organizing committee of the Second World Climate Conference (1990) and member of the United Nations Educational, Scientific, and Cultural Organization (UNESCO's) Scientific Advisory Committee set up in 1997. He has also served on a variety of committees to advise the European Union's scientific programs.

Jim Dooge has been given numerous honors for his international activities, including the prestigious 1983 Prize in Hydrology, membership in numerous scientific societies and academies of other countries and four Doctorates *honoris causa* from prestigious universities.

In the midst of all this activity, as a family man, a prominent figure on his country's political stage and on the international stage, Jim Dooge managed to keep up an active research and lecturing career. He has given lectures on research results in systems hydrology in a large number of countries on all continents and has served as external examiner in many of these. He began publishing his scientific research as early as 1947, and is still productive, publishing on issues ranging from water sciences, natural disasters, global change to climate issues.

It is difficult to imagine the development of Irish political life, the progress made in hydrological sciences and in international cooperation in science without the remarkable contributions during the past 50 years of the exceptional Professor J C I Dooge, whose personal qualities match his professional accomplishments.

JULIA MARTON-LEFEVRE *USA*

Dowdeswell, Elizabeth

(1944-)

Elizabeth Dowdeswell, came to prominence in international environmental circles during preparations for the United Nations Conference on Environmental and Development (the so-called Rio or UNCED Conference). She was then Canada's principal delegate to the Intergovernmental Panel on Climate Change (IPCC) and she became the co-chair of the working group on mechanisms within the Intergovernmental Negotiating Committee on the Framework Convention on Climate Change.

Ms Dowdeswell was brought up in rural Saskatchewan in the Canadian Prairies. She obtained an undergraduate degree in home economics and a teaching certificate from the University of Saskatchewan before doing a graduate course in behavioral science at Utah State University in the USA. Then she began a career in education as a high school teacher, university lecturer and educational administrator at the local level.

Her rise in Saskatchewan public affairs was meteoric. Ms Dowdeswell achieved the rank of Deputy Minister of Culture and Youth in her early thirties and set national benchmarks on cultural and heritage policy. Ms Dowdeswell then became a management consultant to the Canadian federal government and served as a leader of several public enquiries into politically delicate issues such as Canada's unemployment, benefits scheme. She was also Canadian Chair of the Great Lakes Water Quality Board in the framework of the Canada-US International joint Commission. This led to Ms Dowdeswell being appointed Assistant Deputy Minister at Environment Canada and head of the Atmospheric Environment Service. This position automatically made her Canada's Permanent Representative to the World Meteorological Organization (WMO) and immediately thrust her into global environmental politics. She served two terms on WMO's executive council and became intensively involved in the climate change debate.

In 1992, Ms Dowdeswell was elected by the United Nations Third General Assembly to succeed Dr Mostafa K Tolba of Egypt as the third executive director of the United Nations Environment Programme (UNEP). She took up her appointment in January 1993, and served to the end of 1997. Included in her UNEP legacy were renewed regional networkings and new foci for UNEP's relationships and partnerships within the UN family, particularly the World Bank, UNEP and the Global Environmental Facility.

On leaving UNEP, Ms Dowdeswell returned to Canada. She currently lives in Toronto.

DPSIR (Driving Forces–Pressures–State–Impacts–Responses)

As an acronym, DPSIR refers to a framework for structuring environmental information. It is a further development of the P–S–R (pressures–state–responses) model initially proposed by the Organization for Economic Co-operation and Development (OECD).

Driving forces, or drivers, designate human activities, which consume resources or generate pollution, nuisances and other disturbances of the environment. They may be grouped into economic sectors (agriculture, industry, energy, transport, tourism, other services, etc.), or in social categories (households, governments, private enterprises, etc.). *Pressures* describe, qualitatively and quantitatively, emissions and waste, as well as the utilization of resources. *State* expresses the modifications of the state of the environment (air and water quality, water resources, habitat destruction, etc.) resulting from the pressures. *Impacts* represent the effects of state modifications on human health and well-being, on ecosystems and on natural resources. *Responses* are measures taken to counter these negative impacts, mostly by public authorities (regulations, economic and fiscal instruments, education, etc.) but also by industry (codes of conduct, reporting, environmental management systems, etc.) and non-governmental organizations (NGOs).

The five elements of the scheme are connected in various ways. There is a causal chain from D to R and there are direct links between R and each of the other elements inasmuch as they constitute the target of the measures taken. If R is aimed at one of the D's, the scheme forms a loop: the D thus affected will presumably reduces the pressures it exerted, the state of the environment will improve and the negative impacts will be mitigated.

The DPSIR model is a useful analytic tool. It presents information in an integrated form, bringing out the complexity of the main environmental issues. It is helpful in developing indicators, whether they be descriptive, performance or efficiency indicators. It facilitates the identification of the most efficient and cost-effective measures to take. Applied dynamically, it provides the means to assess the performance of implemented policies. It brings out the advantages of integrating environmental concerns in sectoral policies (considered as driving forces) as the best way to strive for sustainable development.

PHILIPPE BOURDEAU *Belgium*

EF

EA (Environmental Assessment)

Environmental assessment is an activity that operates at the interface between scientific research and policy formulation. EAs range in size from local (e.g., proposed construction of a power station or reservoir) to global (e.g., control of greenhouse gases). In some countries, an assessment of a local development such as a power station is called an *environmental impact assessment* (EIA). Complex scientific issues such as climate change and biodiversity losses are long term, contain considerable uncertainty and involve many stakeholders, including potential winners and losers; particularly in such cases, an EA (when summarized in easily understandable language) helps policy makers to formulate options and trade-offs.

R E MUNN *Canada*

ECA (Economic Commission for Africa)

ECA is the regional arm of the United Nations (UN), mandated to support the economic and social development of its 53 member states, foster regional integration, and promote international co-operation for Africa's development. Established in 1958 and based in Addis Ababa, Ethiopia, ECA is one of five regional economic commissions under the administrative direction of the UN headquarters. It reports to the UN Economic and Social Council (ECOSOC) through the Conference of African Ministers Responsible for Economic and Social Development and Planning, and convenes a number of intergovernmental organs and committees. The commission has a staff of some 850, comprising professionals with a wide range of expertise, as well as general support and field service.

Since 1995, ECA has embarked on major institutional and managerial reforms. This renewal process has resulted in a new strategic focus defined by five core programs and two cross-cutting themes. The core programs are: Facilitating Economic and Social Policy Analysis; Ensuring Food Security and Sustainable Development: Strengthening Development Management; Harnessing Information for Development; Promoting Regional Cooperation and Integration; Fostering Leadership and Empowerment for Women in Africa; and Enhancement of ECA Capacities.

During its 40-year history, the commission has made a number of significant contributions to African development. The Commission was instrumental in setting up the African Development Bank (ADB), which is the continent's leading multilateral development financier today. It facilitated the establishment of a number of sub-regional organizations, including the Economic Community of West African States (ECOWAS) and the Preferential Trade Area for Eastern and Southern Africa (PTA), now the Community of Eastern and Southern Africa (COMESA). It was instrumental in building some 30 technical institutions to buttress the socio-economic development of Africa, encompassing such fields as technology, banking and finance, minerals and remote sensing, and planning and management. Notable among these is the Eastern and Southern African Management Institute (ESAMI) and the African Institute for Economic Development and Planning (IDEP). The commission also played a key role in the articulation of landmark economic strategies, such as the Lagos Plan of Action and the Cairo Agenda for Re-launching Africa's Development. ECA continues to provide member states with technical assistance in many fields and to foster the development of civil society groups, including non-governmental

organizations (NGOs), professional associations and intellectual networks.

MOSTAFA K TOLBA *Egypt*

ECLAC (Economic Commission for Latin America and the Caribbean)

The ECLAC was originally established as the Economic Commission for Latin America (ECLA) by resolution 106 (VI) of the United Nations (UN) Economic and Social Council (ECOSOC) in 1948; it was redesignated as ECLAC in 1984 by ECOSOC resolution 1984/67, and is headquartered in Santiago, Chile with sub-regional offices in Mexico and the Trinidad and Tobago and national offices in Argentina, Brazil, Colombia, Uruguay and Washington, DC.

ECLAC is one of the five regional commissions of the UN established by the UN to coordinate policies, promote economic and social development and foster regional and international trade within their respective regions. ECLAC's initial focus was Latin America, but it has subsequently expanded its geographical scope to include Caribbean countries.

Membership of ECLAC is open to member States of the UN from North, Central and South America as well as the Caribbean. There are a number of European countries, namely, France, Italy, the Netherlands, Portugal, Spain and the United Kingdom, which are also members due to their strong historical, economic, and cultural ties to the region. A number of non-self-governing territories in the Caribbean region have become associated members. In sum there are 41 members and seven associate members.

In 1996, ECLAC's mandate was updated by ECOSOC resolution 553 (XXVI) in an effort to increase the relevance of activities sponsored in the region. In accordance with this new mandate, ECLAC acts as a center of excellence to aid its member States in the integrated analysis of the development process. This includes formulating, evaluating, and following up public policy measures as well as providing assistance in areas of specialized information. ECLAC experts also offer advice, training and support for regional and international cooperation and coordination.

The meetings of the Commission are held every two years, with a Committee of the Whole meeting in between sessions. At each biennial meeting representatives of ECLAC member States debate topics affecting the Latin American and Caribbean region's economic and social development, review its activities for the previous biennium, and approve its work program for the next biennium for execution by its secretariat, which is headed by an executive secretary.

Eco Taxes

Kevin S Hanna
Wilfrid Laurier University, Waterloo, Canada

By integrating economic and environmental decision making, economic instruments work within the marketplace to make environmentally positive decisions more attractive. Economic theory suggests that if environmental damage is brought into the market and a value is assigned to negative activities, then it is possible to establish a charge equal to the value of the impact. This discourages unsustainable behavior. But the concept can be dif cult to put into operation, and assigning a monetary value to environmental degradation is in itself a contentious issue. Eco taxes, or green taxes, are one way of providing incentive for environmentally positive behavior, and for internalizing some environmental costs.

In the realm of environmental management, economic incentives generally fall into two primary categories, tax instruments and non-tax instruments. Tax instruments can include tools such as environmental charges, incentives, and combinations of charges and incentives. Environmental charges, or taxes, are usually designed to change behavior by placing a monetary charge on activities that impact the environment. *Eco taxes* are often discussed in the context of a Pigovian tax (named after the economist Pigou), which is also called a pollution tax, where a polluting firm pays a tax based on the cost of damage. The term eco taxes, however, has come to encompass a broader range of tax instruments.

Charges can be applied in several ways; in conjunction with regulations by applying a charge to emissions that

exceed a certain level, application to the total amount of discharge, or to actual amounts of a specific ef uent. Or, instead of applying charges to emissions, they can be applied to inputs or products. Tax incentives modify behavior by rewarding environmentally positive activities, or by penalizing poor behavior. They can include preferential income tax treatment for particular producers, exemptions and deductions, or tax benefits to investors in specific projects and activities. By combining incentives and charges, the two approaches work together by providing a tax on an activity, such as emissions, while providing a rebate or tax credit for introducing new technology. Behavior can be modified while allowing policy makers some exibility to develop ways of offsetting any inequities or costs that may be associated with taxes.

Other options that can function like a tax include user charges, deposit refunds, or even compliance bonds. Deposit refund programs are applied to instances where products can be recycled or reused. A surcharge is applied and refunded when the product or packaging is returned to a collection system. The effect, ideally, is to increase the recovery and reuse or recycling of selected products. Compliance bonds are an option where activities that have environmental impacts are subject to regulation. Such bonds are easily applied to resource extraction activities such as logging and mining, and help insure compliance with reforestation or reclamation requirements. In instances of non-performance the bond is forfeited and applied to remediation.

Tax incentives are often discussed in the context of production activities, with an emphasis on particular emissions or by-products. But specific tax instruments can also be related to land use conservation. For example, tax deductions or credits for contributions relating to conservation, tax deductions for specific uses, and tax exemptions for environmentally positive uses.

EXAMPLES OF ECO TAX INSTRUMENTS

Creating new taxes, or raising existing ones, presents a range of implementation challenges. In most regimes, tax instruments are usually not administered by environmental agencies. In order to put such tools into practice, the cooperation of other departments often has to be secured. Most mechanisms also require support from the political level, and in some instances the general *revenue trap* would have to be addressed. The latter refers to the problem that some agencies have with respect to the monies they generate. In most fiscal systems, funds collected by government are often given over to general revenue, and then reallocated through a budget process. In instances where a conservation agency collects revenue for environmental work, it would have to be certain that it could dedicate these funds to environmental projects either through the budget process or through special purpose accounts.

Regardless of the implementation issues, taxes have long been the traditional and preferred way of raising revenue for most governments. Two main criteria should be considered in eco taxes. Economic efficiency dictates that the net benefits to society should be maximized when the funding mechanism is introduced. Equity, in the economic sense, dictates that the charges, taxes, or fines, should directly re ect or be related to the costs that are imposed on society by the action. Both criteria are based on economic principles and can be measured to varying degrees depending on the instrument and the context. Both equity and efficiency are aspects of overall cost allocation principles. The three basic principles that apply to any evaluation of new taxes and fees are the *polluter pay principle*, the *user pay principle*, and the *bene ciary pay principle*.

The *polluter pay principle* is related directly to the deterioration of the environment and natural resources. Simply defined, it holds that the polluter should bear the cost of measures to reduce pollution decided upon by public authorities to ensure that the environment is in an acceptable state (Opschoor and Vos, 1989). Efficiency is served because the cost of polluting is re ected in the taxes or charges applied, and the market can allocate these to consumers and producers alike. Ideally, there is a clear indication from the market of the cost of environmentally unsustainable activity. Equity is served because the cost is borne by the producers and consumers of the product or service causing the problem (*see* PPP (Polluter Pay Principle), Volume 4).

The *user pay principle* simply holds that the consumer of an environmental benefit bears the cost of consumption. Therefore society does not subsidize the recreation or resource using activities of others. Equity and efficiency is served by allocating costs to those who use the environmental resource. The costs imposed on the environment, such as remediation, restoration, maintenance and related services, are borne by those who use a specific service.

The *bene ciary pay principle* allocates costs based on consumption of a benefit. Those who benefit from a resource pay for its maintenance, restoration or provision. The difficulty in this principle is the process of allocation. While user-pay and polluter-pay principles can be directly applied, the beneficiary pay principle is based on the theoretical willingness to pay for a resource. Willingness to pay, ability to pay, and actually paying are also issues inherent in implementing a tax or fee based on a beneficiary-pay principle. Identifying who benefits from a resource presents significant administrative and technical issues in implementation and feasibility; especially when the benefit is indirect

or not explicitly sought by the recipient. User fees and beneficiary fees are discussed in more detail below.

Some of the products that are provided though the work of conservation agencies can also be considered joint products. Joint products benefit not just the general public in a tangible or intrinsic way, but they also constitute a direct benefit to industry or special interest groups. Clean water, for example, benefits firms that need it for manufacturing. Water quality also affects recreation, the commercial fisheries, and other amenities that often have measurable benefits. The preservation of wilderness and habitat benefits hunting, fishing, and other recreational activities. Habitat and general environmental quality can be related to the desirability of a community as a place to live or as a place to locate business. Governments provide many of these amenities through direct program activities, and indirectly through regulation or other incentives.

Taxes in General

Taxes cover a broad range of instruments applicable to the general public. These can include direct taxes such as property taxes (both *ad valorem* and tangible), taxes on business receipts, business income taxes, personal income tax, and death or gift taxes. Indirect taxes are applied to transactions and expenditures. The value-added taxes common in Europe and North America are applied to virtually all goods and services at most stages of production and to retail sales. Sales taxes, applied to goods sold at the retail level, are common in many regimes. The semantics of taxation overlap and the distinction between some labels can be subtle. Most national governments use many of these methods.

In some instances a special surcharge or surtax could be added to support environmental programs, or a portion of existing receipts could be dedicated to conservation work. These charges can be applied selectively only to residents, transactions, or goods within a defined area. Most tax options have to contend with issues of political and administrative feasibility. Public support may depend on designing carefully targeted taxes that are applied directly to activities or entities that have a direct impact on the environment.

Surtaxes and Surcharges

A surtax, or conservation tax, implies a dedicated increase that is applied to an existing tax, fee, permit, or license. The additional revenue is ideally allocated directly to predetermined program activities. Governments at all levels administer common agents such as commercial fishing and hunting licenses, research permits for animal and ora collection, parks fees, resource royalties, discharge permits, and even highway tolls. Such permits and fees lend themselves to a surtax to support environmental objectives.

Surtaxes can realize significant revenues. Surtaxes are also applicable to income tax. There are examples where healthcare objectives and the application of a minimum required tax are implemented through relatively small surtaxes. British Columbia's Forest Renewal Program is supported by a surtax on timber royalties, the surtax raises about CDN$400 million per annum for forest management programs.

Special Sales and Service Taxes

This category refers to taxes that may apply to the general public as a whole but are added to specific products and services. They are selective and are directly applied to goods and services that relate to a well-defined environmental problem, region, or in support of a specific program. For example, new taxes can be added to fees for hotels, campgrounds, and other accommodation, automobile and recreation fuel, garbage and other disposal services, and products such as pesticides and fertilizers.

Implementing such options often requires integration of efforts among different levels of government, and in some contexts local government might have a significant role. Issues such as the geographical extent of such taxes can also be important. But the potential benefits for the environment can be significant. Additional taxes can be dedicated to environmental work, and publicizing this purpose can make the addition of the tax more palatable to the public and decision makers. The public may accept small increases in consumption taxes if the proceeds are dedicated to environmental work, and monetary dedication is consistent and well stated.

Transaction and Other Unique Charges

Transaction charges do not apply to the general population but are applied to exchanges that directly affect environmental quality. Charges can be applied to land severances, and to production materials used to manufacture chemicals, plastics, and wastes. Transaction charges may also be levied on the transport and disposal of wastes associated with environmental degradation. Complementary waste taxes can be applied to storage, volume of production, and level of toxicity of wastes. The issuance of development permits, the carrying out of inspection visits and similar transactions are also amenable to such charges, which can be applied on almost any level to activities that impact the environment.

User Fees and Beneficiary Fees

User fees, or user charges, are applied to those who use a specific resource or environmental service. Beneficiary

fees have the advantage of being selective and relatively precise. The potential application of user fees is broad and can be applied to recreation, such as parks, water, wildlife, or fisheries, or it can be industrial, agricultural or urban such as the withdrawal of water, sewage or storm water treatment, solid or liquid waste disposal, or even infrastructure use. User fees imply a structure that is ideally designed to capture the full cost of service delivery. They help bridge the information gap by showing consumers that there is a monetary cost associated with specific actions. Ideally, user fees provide an incentive for the sustainable use of resources, and can also act to improve revenue collection for the provision of environmental services, or remediation and clean up.

User fees apply directly to those who access a specific service, and beneficiary fees apply to those who directly or indirectly benefit from an initiative. For example, a beneficiary fee could be applied to fishing licenses within a jurisdiction to support fish stocking or habitat programs, because all license holders potentially benefit from such programs. Or a beneficiary fee can be applied to fishing in a specific lake or bay where a restocking program has been initiated, or shoreline cleanup has been initiated. In instances of fees for special areas, a license can be sold that entitles the holder to fish or hunt within a defined area. The proceeds from a location specific fee or license sur-tax can be dedicated to conservation efforts within that area.

User fees now apply to many services provided by government. Many agencies are gradually introducing and increasing such charges to recover the costs of services they provide, and to generate additional revenue. In most locales, fees are applied at national parks, and many governments are implementing or considering cost recovery methods that are, in essence, user fees. In North America, these are being increasingly extended to the use of selected services, facilities, inspections, licenses, and legal services such as property title transfer, many of which have been previously paid for entirely, or have been subsidized, from general taxes.

Ecosystem Approach

see Ecosystem Approach (**Volume 2**)

Ecosystem Health

Ecosystem health may broadly be defined as the state or condition wherein ecosystem functions are not compromised by human activity. Ecosystem health may be viewed from ecological (biophysical), socio-economic, human health, and policy perspectives. From an ecological perspective, healthy ecosystems are characterized by the absence of distress syndrome, by their resilience to perturbations, and by their characteristic organization and productivity. The absence of distress syndrome refers to the absence of commonly exhibited signs of ecosystem pathology under stress including: alterations of biotic community structure to favor opportunistic species, exotic (non-native) species, and life forms of smaller size; increased disease prevalence; loss of biodiversity; and alteration of productivity. Resilience refers to the capacity of the ecosystem to recover from natural perturbations (e.g., forest fires, oods, etc.). Resilience can be measured in terms of both the time for recovery and the extent of recovery. Organization is assessed in terms of the structure of the biotic and abiotic components. Productivity is measured in terms of both primary and secondary production.

Healthy ecosystems supply an abundance of nature's services, such as potable water, renewable resources, etc. Curtailing these services often has severe economic and human health consequences. Economic consequences may include: fisheries lost owing to habitat destruction and/or overharvesting; forests lost to acidification, chemical smog, overharvesting, etc. Human health consequences may include: water-borne diseases that thrive in disturbed ecosystems, respiratory diseases enhanced by chemical smog, new diseases resulting from human interference with ecological integrity (e.g., Lyme disease), etc. Ecosystem health can also be assessed in terms of public policy: in healthy ecosystems, safeguards are in place to prevent human activities from becoming a stress on natural environments. Effective policies regulating land use, waste residual discharges to air and water, overharvesting, and the introduction of exotic species are essential for maintenance of ecosystem health.

DAVID J RAPPORT *Canada*

Ecosystem Integrity

A living system exhibits *integrity* if, when subjected to disturbance, it maintains an adaptive organizing capability to recover toward a goal that is normal and good for that system. Some authors reserve the meaning of integrity to relate only to ecosystems that have not lost, to a significant degree, their natural pristine organization, identity and goal-directedness. Ecosystems that have been transformed through human activities to a different, but desirable, self-organizational complex may be said, by them, to be *healthy* (*see* Ecosystem Health, Volume 4) but not to possess natural integrity. Other authors use the term integrity in both cases, but then bear an onus to specify some benchmark state according to which such integrity may be assessed.

Goals or end-states other than the pristine or naturally whole may be taken by some authors to be normal and good from some human perspective.

Disruptions can arise external to an ecosystem and thus impact it from outside. Climatic surprises and invasions by destructive humans are common examples of such external disruptions. But disruptions can also arise internally in an ecosystem, such as eruptions of species that usually have only a sparse presence, or the collapse of an abundant dominant species. Sometimes external and internal disruptions are interrelated, with an internal disruption triggered by an external event. If the disruptions and stresses are too intense, an ecosystem can disintegrate into a disorderly mess mostly of species that we find useless or offensive, or into a barren area with a few tough life forms.

To maintain systemic integrity in order to survive and thrive, a living thing must maintain an appropriate balance between partial openness to its external environment and partial closedness, in order to manage its internal features. Single-celled and multi-celled organisms create and maintain semi-permeable membranes to serve as a selective barrier within which each can maintain identity, self-organization and goal-directedness as well as other attributes of integrity. The barrier permits good things to enter the living system and bad things to be expelled from it. In humans the skin, lungs and gut are part of this membrane which includes as sensing organs our visual, olfactory, gustatory, auditory and tactile senses.

At higher levels of organization, a population, a species or an ecosystem does not create a biotic physical barrier around itself as a living entity, though some may be constrained geographically by some abiotic discontinuity in their external environment. If we knew how to perceive and measure it, we might find a complex organizational boundary at the space–time edges of a population

or ecosystem. And it might have some analogues to the sensing organs mentioned above. However, this might well extend an organismal analogue of an ecosystem too far.

An ecosystem's external environment may change gradually and cyclically, as with the seasons. Alternatively, it may change abruptly and violently as with storms, droughts and human interventions. The internal system also changes incessantly, in part due to its own goal-directed activities that emerge and change through evolution, and in part due to some irreversible adaptations to external in u-ences. Hence maintaining integrity usually does not involve only simple, stereotypical processes; instead exible and reciprocal adaptation occurs between an ecosystem and its systemic environment. For an ecosystem, such adaptation in turn involves reciprocal rearrangements within its network of nested elements of populations and organisms.

Because self-maintenance of ecosystem integrity may involve emergence of new ecological phenomena, it may not be possible to measure an ecosystem's integrity fully in a deterministic way. Some of an ecosystem's structures and processes that are related to its integrity can be measured. From comparative studies it may have been inferred that some species populations are particularly vulnerable to collapse or eruption when an ecosystem is stressed to an extent that may trigger its disintegration or transformation to another phase. Such integrative indicator species can then be monitored to provide partial insight into the status of an ecosystem's integrity or health.

Other indicators and indices of ecosystem integrity are used in practice. In freshwaters the concentration of the phosphate ion in the spring season is helpful in characterizing the water body as oligotrophic with little phosphate or eutrophic with much phosphate, each of which may be taken to be a state of ecosystemic health or integrity. With intermediate levels of phosphate concentration, the ecosystem may be in a turbulent transitional ux exhibiting less integrity than with either the oligotrophic or eutrophic phase.

HENRY REGIER *Canada*

EEA (European Environment Agency)

EEA is a legally independent body of the European Community with a mandate to provide timely, targeted, relevant and reliable information to support the environmental policy process and sustainable development. Established by European Community Regulation (1210/90) and revised in 1999 (Council Regulation 933/1999), the Agency started working in Copenhagen in 1994. In carrying out this mandate the Agency has two main objectives. First, to assist the European Community and member countries to identify, frame, prepare and implement sound and effective environmental policy measures and legislation, and to monitor, evaluate and assess environmental achievements and outcomes. Second, to establish and coordinate the European environment information and observation network (EIONET) for the collection, analysis and assessment of data shared with EC services, EEA member countries and international organizations, and through this to work toward a simplified and streamlined production of European environmental information.

All European Union (EU) countries are members of the EEA, but other countries may join who share the concerns of the EU and member states and the objectives of the agency. Non-EU member countries currently include Iceland, Liechtenstein and Norway. Thirteen new members are expected to join the EEA very soon; among them, ten Central and Eastern European countries together with Cyprus, Malta and Turkey.

The EEA works in all areas enabling it to describe the present and foreseeable state of the environment from the point of view of environmental quality and sensitivity, pressures on the environment and the socio-economic dimension.

The EEA works with national monitoring centers and other bodies in a network which the agency was mandated to set up and coordinate. This European environment Information and Observation Network, based on existing national networks, includes so-called Topic Centers (groups of expert institutes in the member countries under contract to the EEA) which the EEA uses to gather and process information in the different themes of interest. To ensure the broad dissemination of this information and to keep the public properly informed, the EEA publishes regular assessments of the state and outlook of the European environment every 3–5 years (e.g., EEA, 1999), and more frequent indicator-based assessments of the environment (EEA, 2000). Information is also made available to the public directly in a Reference Center accessible through the Internet (http://eea.eu.int).

EIS (Environmental Impact Statement)

An EIS is a summary of an environmental (impact) assessment written in plain English for the various non-specialists involved in the environmental assessment process (including citizen interveners at public hearings).

The contents of an EIS usually include:

1. a description of the proposed development or activity (where will it be located/occur? What are the basic engineering and other facts? Who will benefit? Who may lose?;
2. a discussion of alternatives (e.g., different sites, different forms of energy production) that might meet the same development goals;
3. baseline environmental conditions (a factual account of current environmental conditions and recent trends);
4. a description of the scoping and bounding conditions used to reduce the number of variables/factors considered;
5. predictions of future conditions with and without development (during construction, operation and decommissioning);
6. estimates of the significance of the environmental changes expected;
7. recommendations (not applicable in some jurisdictions):
    - for acceptance, provisional acceptance (acceptance with modifications), rejection; or postponement of a decision until more baseline data are collected and analyzed;
    - for approval of proposed monitoring and inspection procedures to be undertaken during the life of the project.

Emerging Environmental Issues

see Emerging Environmental Issues (*Opening essay*, **Volume 4**)

Emissions Trading

Emission trading is a market-based approach to controlling emissions of air pollutants through the buying and selling of allowances to emit a specified pollutant over a specified period. In contrast to the *command and control approach*, where the maximum allowable emission from each source is regulated and is usually based upon the best available technology, in emission trading a limit (i.e., the total number of emission allowances) is placed upon the aggregate emissions from those sources involved in the trading. The sources may then trade amongst themselves. Ideally the only restrictions would be that the total number of allowances is not exceeded and that environmental requirements such as local air quality standards or maximum rates of acidic deposition from the atmosphere are met. Some sources may create surplus allowances by reducing their emissions or even purchasing surplus allowances from other sources. In some trading schemes, surplus allowances may be banked for use at a future, more advantageous time, or for sale. Those selling their surplus allowances can make a profit if the initial cost of creating the surplus allowances (either through control measures or through the initial purchase) is less than the sale price. On the other hand, if other sources anticipate a shortfall of allowances to cover future emissions (perhaps because of an expansion or more stringent environmental requirements), they may wish to purchase allowances if the purchase cost is less than the cost of reducing emissions. Through trading, therefore, the cost of maintaining or reducing emissions may be less than that of the command and control approach, and managers of individual sources may have more exibility in meeting air pollution requirements. Emission trading has been most extensively used in the United States for controlling the lead content of gasoline, chloro uorocarbons to reduce the destruction of the stratospheric ozone layer, and sulfur dioxide to reduce acid precipitation.

Endangered Species

Jeffrey A McNeely
The World Conservation Union, Gland, Switzerland

An endangered species (EN) is a species of plant or animal whose population is so low that it is in danger of becoming extinct unless urgent remedial action is taken. Many countries have their own lists of EN that are protected under national law, but the international authority is the World Conservation Union's (IUCN's) Red List Programme: see the 1996 IUCN Red List of Threatened Animals, and the

*1997 IUCN Red List of Threatened Plants (*see *World Conservation Union (IUCN) Red List of Threatened Species, Volume 4).*

IUCN's has three levels of endangerment within its structure of categories of threat to species (Figure 1). It uses five general criteria for assessing level of endangerment based on variables closely associated with extinction risk. These criteria include:

1. declining population (past or projected);
2. small distribution and decline or uctuation;
3. small population size and decline;
4. very small population or very restricted distribution;
5. quantitative analysis (such as population viability analysis).

A population of plants or animals is considered *vulnerable* (VU) when it has an observed, estimated, inferred or suspected population size reduction of at least 30% over the past 10 years or three generations, whichever is longer, and where the causes of the reduction are not demonstrably reversible, or not clearly understood, or may not have ceased, or could recur. *Endangered* (EN) are those whose populations have declined by 50% over the same time, while *critically endangered* (CR) species are those that have suffered a population size reduction of 80% or more over the same time period. Table 1 summarizes the current totals of threatened species.

Most experts consider this list to be very conservative, because it is based on IUCN's very strict criteria and only

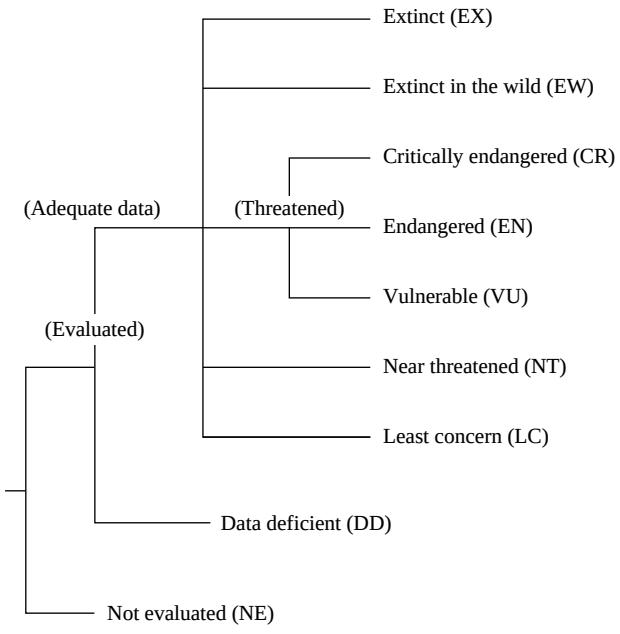

Figure 1 IUCN categories of threat

Table 1 The current totals of threatened species[a]

Taxon	CR	EN	VU	% Threatened
Mammals	169	315	612	22.8
Birds	168	235	704	11.1
Reptiles	41	59	153	3.2
Amphibians	18	31	75	2.6
Fishes	157	134	443	2.7
Insects	44	116	377	
Plants	371	6522	7951	12.5

[a] No percentage is given for invertebrates because the estimate of total insect species numbers is so approximate.

in the case of mammals and birds are there adequate data. A consensus of field biologists working on endangered (EN) has concluded that about 20% of reptiles, 25% of amphibians, and 34% of fishes (mostly freshwater) are under some threat of extinction. The current information on the status of threatened species is heavily biased towards terrestrial vertebrates. Relatively few invertebrates have been assessed, making it difficult to estimate the percentage that are threatened; because the invertebrates are the most numerous species, they are the ones that are projected to lose the greatest number of species.

The IUCN Red List Categories provide an explicit, objective framework that can be applied consistently and widely to classify species according to their extinction risk. This enables comparisons to be made across different taxa, provides a clear understanding of how species are threatened, provides a basis for planning conservation actions, and enables the monitoring of recovery efforts. The criteria are most appropriate when applied at the global level and assigning a taxon to a category may be different when the criteria are applied at the regional or national level. For example, a species that is globally endangered may be common in a country where it is effectively protected; conversely, a species that is common and widespread at a continental level may be endangered in a given country, especially if that country is at the edge of the distribution of the species.

Countries with a strong scientific research capacity often have the largest numbers of EN, especially of the taxa that are difficult to study. For example, Australia, US, and South Africa are among the top four countries with the most EN of reptiles, amphibians, and invertebrates, though none of them makes the top five for mammals or birds. For vertebrates, Indonesia, China, Brazil, and India are among the top five for threatened species of both birds and mammals; but of course these countries are also very rich in species numbers. Some taxa have very large percentages of EN. For example, both species of elephants are endangered, as are all the species of rhinos, a quarter of the species of primates, and seven of the 23 species of crocodiles. Among the birds, albatrosses and grebes have nearly 20% of their species endangered. Among the fish, over half the sturgeon

are endangered. The freshwater mollusks are another group that is highly endangered, especially the species that are endemic to one or a few islands.

EN often are rare, genetically impoverished, of low fecundity, dependent on patchy or unpredictable resources, extremely variable in population density, persecuted, out competed for habitat by alien invasive species, or otherwise prone to extinction as a result of human dominated changes to landscapes. The most significant proximate cause for endangerment is undoubtedly related to habitat, including reduction in area, fragmentation, and overall degradation. Habitat loss or degradation is specifically identified as one of the main reasons for species becoming endangered for 75% of mammals, 44% of birds, 68% of reptiles, 58% of amphibians, 55% of fishes, 52% of crustaceans, 47% of insects, 95% of bivalves, and 50% of gastropods. Many scientists consider these figures to underestimate the proportion of species that are threatened due to impacts on their habitats, but these figures clearly indicate the importance of maintaining intact ecological systems for the conservation of biodiversity.

Another major factor of endangerment is the introduction of alien invasive species that may lead to hybridization, competition, predation, disease, parasites, and the alteration of ecological relationships between species; thus the introduction of these alien invasive species may threaten entire ecological communities, on both islands and mainland areas. Aquatic systems are especially vulnerable to such impacts. Direct exploitation affects at least some species of mammals (such as rhinos and tigers) and reptiles (such as crocodiles).

One objective of putting a species on the endangered list is to foster its recovery, so many governments prepare recovery plans to bring the species back to a population sufficient to remove it from the endangered list. A recovery plan for an EN will accurately diagnose the factors causing the decline of that species and define the measures for counteracting those factors.

Detailed information on globally threatened species can be found on the internet at http://www.wcmc.org.uk/data/database/rl**.** anml**.** combo.html.

Environmental Assessment of Major Development Projects

Robert Goodland
World Bank, Washington, DC, USA

Environmental assessment (EA) is that part of economic development planning which seeks to promote sustainability by improving environmental management and decision making. EA is a process which conserves environmental services and prevents delays, while reducing environmental damage and risks, especially to the poor. EA parallels the feasibility phase, often takes at least a year, and feeds into the nal project design. The most important part of EA is a fully budgeted schedule of implementation of the measures designed to prevent, mitigate or compensate for the predicted impacts during construction and operation. Responsibility is assigned to implement the schedule. Capacity strengthening and training is normally essential to implement the mitigation and to monitor results. EA ends with decommissioning and clean up.

EA, an integral part of economic development planning, seeks to promote the sustainability of such development. EA is basket of tools to improve environmental management and decision making. Primarily, EA is designed to conserve or improve environmental services, and to reduce risks. Secondarily, EA reduces and compensates for the adverse environmental impacts of a proposed project. EA reduces costs by preventing damage, especially that harming the poor, and by reducing delays. If the EA is prepared in parallel with the feasibility study of the project, there will be more agreement on the final design, thus reducing

dissent. If a project is prepared without an EA, which has to be added later, the project will be delayed, expensive design changes may be necessary, and delays will be inevitable.

The EA process normally starts as soon as the project has been identified in general terms, but before it has been designed in detail. Typically, to take a highway example, the need for a highway from A to B is identified, but the details (precise routing, width, etc.) have not yet been specified. The process begins with EA *scoping* what will be needed to carry out the full EA, which disciplines will be needed, for how long and when. The main potential impacts are predicted in general terms based on prior experience and a review of the literature about a project of this nature.

The impacts are then screened in order to focus on potentially major impacts and not to waste resources on minor ones. For example, if a proposed highway may run near a hospital or community center, a noise pollution specialist may be needed on the EA team. If the highway may run in or near a National Park, a biologist will be required. Stakeholder views are sought to this stage, often by means of community meetings, requesting comments by publishing an outline of the project in the local newspaper. Radio information and requests for comments are effective for illiterates. Comments received in whatever form are consolidated and the suggestions used to improve design.

A useful part of the early EA process is the ruling out (*screening*) of potential impacts, together with the reasons why they are ruled out. In a reservoir project to site A, for example, if water-borne diseases were to be ruled out, the justification might be that Dr X, an expert from the World Health Organization, with long experience in malaria, writes that neither malaria nor any of its vector mosquitoes, has ever been recorded in this country and that the nearest malaria is 1200 km away at site B, which is sufficiently far for its occurrence at site A to be very unlikely. The water in the proposed reservoir is of such a type that vector breeding is not a big risk. Then similar findings should be sought for other water-related diseases. If a water-borne disease is not mentioned in the EA, stakeholders, especially affected people, rightly ask if it has been overlooked, which means the whole EA is questionable. Such transparency out fosters confidence, hence consensus, by stakeholders. The EA has to be comprehensive at the beginning, gradually eliminating potential issues, so that most attention can be allocated to the more likely impacts. Ruling out of non-issues, and the justification for ruling them out, is a major and important part at the outset of EA.

Following scoping and screening, an interdisciplinary team of environmentalists of appropriate specialties is assembled in the project area and starts work on predicting the nature of impacts, working with the engineering design team to prevent as many impacts as possible by design improvements. The team then devises mitigation for those impacts which cannot be designed out. The EA team and the project design team work closely together for the entire duration of the design phase, often called the *engineering feasibility study*, for a year or more.

At least one year is needed to complete many EAs partly because many environmental impacts may be seasonal (e.g., animal migration such as migrating caribou herds in the Alaska pipeline case), so all seasons need to be monitored. As the frequency of some impacts exceeds annual seasonality, and as many environmental features vary greatly from year to year, more than a single year of monitoring is often necessary.

Implementation of the EA recommendations results in improved project design and a set of safeguard measures to reduce adverse impacts. This preventive approach adjusts the design of the project, such as by re-routing the highway around a sensitive site. The second means to improve the project is the implementation of a series of specified mitigatory measures. The third means is by monitoring during construction and subsequent operation of the development in order to assess the extent to which the design and mitigatory measures are working. Adaptive management adjusts the environmental precautions taken. Escrow accounts or performance bonds may be necessary to pay for cleanup and decommissioning costs after the project, even if it has different owners.

Proper design can prevent most potential impacts, and the remainder can be reduced to acceptable levels, but there will always be a residue of minor impacts which are not predicted, or which are not fully mitigable. If the EA team judges that to be the case, the EA should recommend *offsets*. These are measures to compensate for unmitigated impacts to ensure that the environment is unambiguously better off in net terms with the project. This is in addition to impact prevention and mitigation.

Environmental Data Report

Mostafa K Tolba
International Center for Environment and Development, Cairo, Egypt

The UNEP Environmental Data Report series is designed as a critical review of currently available environmental data and related information. More speci cally, through its mix

of tabular and textual presentation of material, it serves a number of functions, namely:

- *identi cation of the principal sources and compilers of environmental data sets;*
- *provision of extracts or summaries of key data sets in tabular form;*
- *highlighting the de ciencies in the available information base, not only in terms of information gaps and the quality of the existing data, but also in terms of relevance to policy-making;*
- *highlighting the ongoing efforts to correct the de ciencies in the information base;*
- *provision of an overview of the signi cant and emerging environmental trends; and*
- *attempts to relate environmental conditions to human activities or pressures on the environment.*

Environmental information (whether as data, statistics, appropriately packaged synthesis or qualitative materials) is becoming increasingly recognized as an essential component of national development plans. National activities, such as transportation, agriculture, energy production or use, waste management, forestry and fisheries have a potential for direct and indirect impacts on the environment. The United Nations Conference on Environment and Development (UNCED) held in Rio de Janeiro in June 1992, stressed the need to integrate environment and development in future policy formulation. Reliable environmental data are therefore necessary for use by governments, as well as by industrial, public and private sectors, to frame policy, to set priorities and to assess results. The improvement and use of available environmental information is a major requirement for the development of national and international policy.

The need for sound information at all levels, from that of the senior decision maker at the international level to the field worker at the national level, was also highlighted at UNCED. The action plan, commonly known as *Agenda 21*, which was adopted at the conference, identified two program areas needing better implementation to ensure that decisions are based increasingly on sound information: bridging the data gap, and improving information availability (UN, 1992).

The absence of data from a number of developing countries, especially in a regional context, hinders national environmental protection and national development and planning, as well as the evaluation of regional and global effects. To achieve cost-effective data collection and assessment, users and their requirements need to be more clearly identified. In addition, ways of transforming existing information into forms more useful for decision-making are essential, together with targeting the information at different user groups.

Governments must have at their disposal not only their own national data upon which to assess the impact of their policies, but also international data to aid their development of sound environmental action plans. In order to disseminate better environmental data at regional and international levels of relevance to management needs, UNEP (United Nations Environment Programme) established, in the mid 1980s, its own biennial Environmental Data Report series. The *UNEP Environmental Data Report* is a source volume of carefully checked, verified and annotated data that provides a basis for detailed environmental assessments at the national and international level. The reports also cover environmentally-related sectors such as transport, energy, human health and industry to satisfy the needs of decision makers. Effective linkages between the different sectors or environmental concerns are made in each report. It is not possible for any one of the reports in this ongoing series, to contain all the data and information which are available for a particular sector or topic. Therefore, in each report, data are chosen to illustrate selected topical issues, geographical concerns, transboundary issues and global data collections.

Examples of data included in the latest editions come from the UN agencies and their cooperating organizations, particularly WHO (World Health Organization), WMO (World Meteorological Organization) and FAO (Food and Agriculture Organization), as well as other international and regional organizations, economic institutions and national State of the Environment Reports (SOE).

Environmental and environment-related data in the Environmental Data Report is organized as follows:

- *The state of the environment*: the first section describes the state of the global environment in terms of environmental contamination, climate change and the status of the natural resource base (Parts 1 to 3).
- *Human and economic activity*: these chapters describe significant trends in the pressures on the global environment. These include population growth and economic development (Part 4), energy production and use (Part 6), industrial activity and transport (Part 7). The problems associated with the generation and disposal of wastes are outlined in Part 8. The impacts of natural and man-made hazardous environmental events (Part 9) and human health issues (Part 5) are also addressed.
- *Policy responses*: the final section outlines some of the regional and global measures taken to protect the global environment and assesses their effectiveness (Part 10).

Each chapter comprises tabular material (presented as a continuous block at the end of the chapter) plus supporting text and graphics. The supporting texts identify the principal data sources, discuss the quality of the existing data sets and summarize key environmental trends, and the footnotes

to the data tables provide information of a more technical nature and full details of the original data sources.

Although each edition of the *UNEP Environmental Data Report* contains a central or core set of data tables which are updated each time (these are identified by a green-colored background), many of the data and supporting information presented in successive editions are new. This material is carefully selected to re ect topical and emerging issues. Owing to space restrictions, it is not possible to provide full coverage of every topic in each edition; some issues are thus covered in alternate editions. However, within the supporting texts, extensive cross-referencing is made to earlier editions and to other chapters. For convenience, references in the text are given after each individual subsection and the key findings are highlighted in a summary paragraph at the beginning of each chapter. Inset boxes provide more detailed discussions of specific issues or a particular study and, where appropriate, examples of environmental indicators.

For more information, consult UNEP, PO Box 30552, Nairobi, Kenya.

Environmental Education

Mohamed Kassas
Cairo University, Giza, Egypt

Environmental education was one of the principal topics on the agenda of the UN Conference on Human Environment held in Stockholm (Sweden) in 1972. Recommendation 96 of the Plan of Action adopted by the Conference required the United Nations Educational, Scienti c and Cultural Organisation (UNESCO) and the United Nations Environmental Programme (UNEP), together with interested international bodies, to establish an international program on environmental education. UNESCO and UNEP collaborated in planning and developing a world cooperative program. The preparatory process included an international workshop in Belgrade, 1975, followed by regional symposia held during 1975- 1977 in: Europe (Helsinki), Africa (Brazzaville and Lagos), Arab States (Kuwait), Asia (Bangkok), Latin America (Bogota), North America (Ottawa), East Europe (Prague). The outcome of these worldwide consultations provided materials for an intergovernmental conference held in Tbilisi in 1977 that launched the International Environmental Education Program (IEEP). In 1987, 10 years after Tbilisi, a second international conference (the Moscow Congress on Environmental Education and Training) produced the International Strategy for Action in the eld of Environmental Education and Training in the 1990s. We note that training was added to education. The Agenda 21 adopted by the UN Conference on Environment and Development (Rio de Janeiro, 1992) contained Chapter 36 on environmental education, which outlined three principal programs: (a) reorienting education towards sustainable development; (b) increasing public awareness; and (c) promoting training.

The UN Commission on Sustainable Development, that monitors progress in implementing Agenda 21, reviewed in its fourth session (1996) progress and constraints related to Chapter 36 of Agenda 21. Environmental education acquired a new form: education for sustainability. For a review of the UN led endeavor in this eld, see Smyth et al. *(1997).*

ENVIRONMENTAL EDUCATION: DEFINITIONS

The following four definitions are not synonymous, they re ect priorities related to various objectives and operational purposes.

1. *Environmental education* is the process of recognizing values and clarifying concepts in order to develop skills and attitudes necessary to understand and appreciate the inter-relationship between humans, their culture and his biophysical surroundings. Environmental education also entails practice in decision-making and self-formulating codes of behavior about issues concerning environmental quality (IUCN, 1972).
2. Environmental education is the process dealing with the relationship between humans and their natural and human-modified surroundings, and includes the relation of population to pollution, resource allocation and resource depletion, conservation, transportation, technology and urban and rural planning and to the total human environment (*US Public Law 91-516, the Environmental Education Act, 1970*).
3. Environmental education is aimed at developing a world population that is aware of, and concerned about, the environment and its associated problems, and which has the knowledge, skills, attitudes, motivation and commitment to work individually and collectively towards solving current problems or prevention of new ones (*International Workshop on Environmental Education, Belgrade, 1975*).
4. Environmental citizenship: environmental education and education for sustainability attempt to create an environmentally responsible population that contributes to sustainable development. The related components of environmental citizenship include information, awareness, concern, attitude, beliefs, education and training,

knowledge, skills, literacy and responsible behavior (Hawthorne and Alabaster, 1999).

Related to environmental education is the concept of *worldview*.

> The expression environmental worldview is typically used to describe beliefs, values and concepts that collectively make up the individual's perception of the environment and humankind's relation to it.
>
> Disignes and Tomsen (1995)

Environmental education aims at: instilling in the learners a positive perception of the environmental worldview, and cultivating in the society, through educational institutions, a broader environmental worldview.

Lucas (1980) recognizes three approaches to environmental education: education in the environment, education about the environment, and education for the environment. While environmental education seeks the goal of understanding the environmental issues, environmental training is to provide selected people with the necessary skills to monitor, assess and manage the environment and the interactions between environment and development.

ENVIRONMENTAL EDUCATION: OBJECTIVES AND GUIDELINES

The Tbilisi Conference (1977) concluded that environmental education was to create and develop the following attributes:

- awareness, to help individuals and social groups acquire awareness and sensitivity to the total environment and its allied problems;
- knowledge, to help individuals and social groups acquire basic understanding of the total environment, its associated problems and the responsible presence of humanity in it;
- attitude, to help individuals and social groups acquire social values, strong feelings of concern for the environment and the motivation for actively participating in its protection and improvement;
- skills, to help individuals and social groups acquire the necessary skills to solve environment–society problems;
- evaluation ability, to help individuals and social groups evaluate environmental measures and education programs in terms of ecological, political, economic, social, aesthetic and educational factors;
- participation, to help individuals and social groups develop the sense of responsibility and urgency regarding environmental problems so as to ensure appropriate action to solve these problems.

The Tbilisi Conference endorsed the guiding principles for environmental education included in the Belgrade Charter (A Global Framework for Environmental Education) produced by the International Workshop of 1975. The principles included:

- consider environment in its totality, including natural and human-modified, technological and social aspects (including economic, political, technological, cultural, historical, moral, aesthetic);
- begin environmental education at the pre-school level and continue through all formal and non-formal stages, making it a continuous lifelong process;
- draw on the specific content of each discipline in making possible a holistic and balanced perspective in order to be interdisciplinary in its approach;
- examine major environmental issues from local, national, regional and international points of view so that students receive insights into the concept of an environmental worldview;
- promote the value of, and need for, local, national and international co-operation in the prevention and solution of environmental problems;
- while taking into account the historical perspective, focus on current and potential (future) environmental situations;
- explicitly consider environmental aspects in plans for development and economic growth;
- enable learners to have a role in planning their learning experiences and provide an opportunity for making decisions and accepting their consequences;
- develop environmental sensitivity, knowledge, problem-solving skills and clarification of values at every age, but with special emphasis in early years on environmental sensitivity to learner's own community;
- help learners discover the symptoms and the real causes of environmental problems, emphasize the complexity of environmental problems and the need to develop critical thinking and problem-solving skills;
- utilize diverse learning environments and a broad array of educational approaches to teaching and/or learning about and from the environment, with due stress on practical activities and first-hand experience.

ENVIRONMENTAL EDUCATION: ETHICS

All through history, humankind was aware of its intimate relationships with nature. The culture of kinship with other creatures on Earth is old, spiritual environmental ethics was part of ancient civilizations that was fostered through teachings of religions. This may have been subdued through societal transformations associated with industrialization and urbanization, processes that have apparently blurred the sense of intimacy with, and dependence on, nature: its

air, water, land and biota. Rural habitats remained closer to nature.

New environmental awareness was initiated in response to environmental damage caused by various forms of pollution and deterioration of life-support systems that became particularly evident during the second half of the twentieth century. Environmental groups of concerned citizens and advances in the sciences of ecology and environment created worldwide feelings that Man has the duty to protect the environment. Environmental education became a tool for nurturing environmental ethics and for instilling prudent attitudes and practices towards nature, its health and its resources.

By the 1990s the concept of sustainable development became prevalent, almost a widely held belief. This has added a future dimension to environmental ethics: responsibility of the present generation towards the well being of the future generations and their environment. *The IUCN-UNEP-WWF (1991): Caring for the Earth: a Strategy for Sustainable Living* calls for worldwide adoption of an ethic for sustainable living, under which every person takes responsibility for his or her impacts on nature, and each generation undertakes to leave to the future a world as diverse and prosperous as the world it inherited. The institutions of religion have an effective role in promoting environmental ethics. For instance, Harvard University initiated a program on religion and environment that included a series of conferences on major religions and environment. See the series of papers in Volume 5 on religion and the environment, for several of the world's religions. Civil society organizations, through initiatives like the green consumer movement, the green-belt movement, etc., are effective tools in cultivating environmental ethics. Professional associations are keenly interested in the roles of its membership in conserving the environment. For instance, the World Federation of Engineering Organizations, through its Committee on Engineering and Environment, produced and adopted in its Annual Plenary Session, New Delhi, 5 November 1985 a *Code of Environmental Ethics for Engineers*. Business, industry and commerce are responding positively to requirements of environmental concerns. Prior to 1980s, industry seemed to regard environmental issues as a peripheral nuisance, but during recent decades the process of greening the corporate boardrooms is spreading. The World Business Council for Sustainable Development is an example. For a review on this subject, see Tolba *et al.* (1992).

ENVIRONMENTAL EDUCATION: IN THE SCHOOL

The formal education system is conceived as comprising four stages: pre-primary, primary, secondary and tertiary. At the pre-primary level, education addresses the child's emotional orientation to nature and to the environment of home and neighborhood. In rural areas in most developing countries, pre-primary schooling is not available, environmental education has no formal structure but is gained through helping at home, in the field and in play; sensitivity to the environment (elements of nature, cycle of the seasons, etc.) comes naturally. In more fortunate urban habitats some nursery and kindergarten schools exist. In developed countries, pre-primary schools are better equipped and trained teachers are available.

Children at primary school can accept integrated knowledge especially in subjects related to health, nutrition and sanitation. Mental perception of the environment seems to develop at the age of 9/10 years. Formal environment education may be introduced as a subject in primary school curricula or as an added element of subjects like natural history, population, hygiene, etc. Adequately trained and motivated teachers are cardinal for success. In large countries with a wide diversity of habitats, teachers need to be capable of framing teaching and teaching materials to suit local environmental conditions. Well-trained and inspired teachers are key elements of success.

The secondary stage (age: 11/12–17/19 years) is in some countries one 6-year school, in others it comprises an intermediate school followed by a secondary school. This is the age of being capable of comprehending the synthetic nature of environmental knowledge. Secondary education is usually oriented to traditional disciplines, and there seems little room in the curricula to accommodate integrative environmental elements. Two approaches are widely debated, but seems to be favoured. (1) Environmental issues may permeate each element (discipline) of the student's learning. (2) Environment with its ramifying aspects may be set as an element in the curricula. In either form, environmental education has become a worldwide feature in secondary schools.

The substance of environment in the school processes may combine in-school basic environmental knowledge (ecology, natural resources, population dynamics, problems of habitat degradation, etc.) and out-of-school activities, involvement in community activity, problem-solving projects, etc. The latter reminds us of Lucas (1980) approach: education in the environment; for this purpose field stations, teaching facilities in biosphere reserves, etc., could provide invaluable support.

Environmental education, as other aspects of environmentalism, does not enjoy easy acceptance. Critics in the USA charge that environmental education is attempting to turn school children into overzealous, unthinking environmentalists ; turning children into environmental crusaders . Two elements are blamed: teaching materials being scientifically weak and politically motivated, and teachers trying to impart their own values to learners. In 1997 an Independent Commission on Environmental Education

(ICEE) carried out a survey and evaluation study on environmental education in US schools; see Disinger (1997) for a review. The ICEE noted that environmental topics were generally infused into other subject areas, mostly science and that environment-focused teaching and learning materials often do not provide a framework for progressive building of knowledge. The importance of the relationship between environmental concerns and development of good citizenship was noted and approved. ICEE recommended, school should consider teaching environmental education as an upper-level multidisciplinary capstone course integrating what students have learned in science, social science, and other upper-level courses . ICEE emphasized that teachers of environmental education need substantive preparation in science, economics and mathematics, and that teaching materials need to be scientifically accurate and well balanced.

ENVIRONMENTAL EDUCATION: TERTIARY LEVEL

Environmental education seeks to provide learners in tertiary institutions with two attributes: environmental literacy and environmental professionalism. Evolution of university programs seems to move from the initial concern with nature conservation (applied ecology) to the wider concern of interactions of development and environment.

Environmental literacy means, apart from the sensitivity required by environmental citizenship, that learners at the tertiary level should obtain basic knowledge of the interactions of society and environment in the processes of resource development and management of human habitat. Here, professionally trained engineers, agriculturalists, physicians, economists, lawyers, etc., need to be fully cognizant of the likely impacts of societal activities and development schemes on the health and quality of the environment. For this purpose, a broadly based general program in environmental sciences may be introduced into the undergraduate curricula. This program may include a first part, available to all students, on the basic interactions within the biosphere and a second part comprising case studies that relate to the professional areas included in the curricula, that is, tailored according to the interest of the class.

Tertiary institutions are required to produce professionals for a variety of job requirements. These include:

1. technicians for environment monitoring;
2. managers of environment schemes;
3. research scholars in fields of environment;
4. school teachers for environmental education;
5. technicians for programs of awareness.

Two lines seem to prevail: institute a university first degree (BSc, etc.) in environmental sciences, or institute postgraduate courses (diploma, MSc, etc.) in environmental sciences. The latter seems to be more widespread, and may be a general (university) degree or a specialized degree (environmental engineering, occupational health, environmental accounting, environmental legislation, environmental education, etc.).

ENVIRONMENTAL EDUCATION: COMMUNICATION AND MEDIA

Success in implementing schemes for conservation of natural resources, protection of the environment, reversing environmental degradation, etc., requires support and positive participation of people. This requires programs of non-formal education that disseminate environmental knowledge, cultivate public awareness and motivate active participation. This component of environmental education has two principal thrusts: cognitive skills that make people understand the environment and appreciate the consequences of action and of inaction and the intimate interdependence between society and environment; and work skills that enable people to participate meaningfully in implementing corrective measures.

The press is an effective tool for education in general. Radio has been and is likely to remain a principal medium for non-formal education in rural areas in developing countries. Television, video and cinema have become widespread media with great potentials for bringing home the environmental message. It can present real environmental scenes or graphics that dramatically mimic natural scenes. These media especially radio and television have the advantages of:

1. presenting messages in series that are regularly transmitted and become part of the daily programs of recipients;
2. combining news (documentaries) with expert comments and explanations;
3. being used for programs of group education (in country clubs, community organizations, etc.) and hence allow for group interactions. They can also have a useful role in the school.

Developments in media interactions with audience and in methods for assessing impacts of media programs provide useful guidance for improving effectiveness and reach.

Non-formal environmental education, through media and community organizations, need to be supported with ow of materials. The International Institute for Environment and Development (IIED, London) created a body (Earthscan) in the early 1970s to provide this support. UNEP and its associates produce a series (OUTREACH) of dossiers, each providing basic information on an environment issue

and variety of means for its narrative and graphic presentation. A dossier is meant to provide raw material that could be remolded to suit various media. OUTREACH is produced in several languages and has now produced (more than 100 issues) a most valuable set of reference materials.

See also: Distance Learning and Environment, Volume 4.

SUMMARY

In the 1970s the concept of environmental education reached the world agenda, in the 1980s it was expanded to environmental education and training, in the 1990s it was transformed to education for sustainable development. This evolution of concepts related to evolution of perception of the role of education in understanding and in managing the relation of mankind and the environment.

Environmental education is a lifelong process that extends from the pre-school stage throughout life. It aims at providing learners with knowledge of, and instilling feelings towards, the environment, and at providing learners with skills that enable them to participate in managing the environment, and in conserving its quality and resources.

Environment education is provided through formal channels (school system with its various grades), and non-formal channels (media, community organizations, etc.).

Environmental education needs trained and inspired teachers and media staff, and teaching and communication materials that are based on correct science and effective presentation.

Environmental (Eco) Labeling

Osama A El-Kholy
Arabian Gulf University, Manama, Bahrain

Labels serve many purposes. They identify the contents of a package, the manufacturer or supplier of a product, its brand name, composition, certain properties, method of use, warnings, approval or certi cation by a regulatory authority, claims of some advantages, or citation of names of high pro le users.

Labels and trade marks can be registered so as to restrict their use to the original owners. They are protected by law against use by unauthorized persons.

Environmental (Eco) labels provide information, either about a product's, or a service's, eco characteristics (e.g., low energy consumption or low emissions of wastes, absence of certain undesirable ingredients, safer disposal after use, etc.), or its impact on the environment, in general.

Currently, there are three types of eco-labels. Type I labels are voluntary, multiple criteria labels awarded by a third party to products in a particular category. Type II are self-declared claims by a manufacturer, importer, distributor or retailer who stands to benefit from the claims. Type III are based on the results of a process called *life cycle assessment* (LCA).

Experts at a 1991 United Nations Environment Program (UNEP) conference agreed that programs dealing with eco labeling are making the positive statement that a product or service that is to be used for a particular purpose is less harmful to the environment than similar products or services. Consequently, as consumers became more concerned with eco issues, eco-labels became an important marketing tool.

Starting in the late 1980s, eco-labels bearing different names and logos were issued in an increasing number of countries. Since these were being granted using different criteria by a variety of governmental, non-governmental, and business organizations, there were worries that national

labeling schemes could become barriers to international trade, particularly for developing countries. In fact, the prevailing view until quite recently was that eco-labeling was not working. Consumers became skeptical and started to doubt the integrity of eco-labeling schemes. It soon became clear that there was a need for international eco labeling standards. Developing such international standards depends on LCA. This analyses the impact of a product or service on the environment throughout the whole of its life cycle.

Standardizing this process worldwide would lead to internationally acceptable eco-labels. The International Standards Organization is working on developing such international standards for LCA and eco-labeling.

ECO-LABELS WORLDWIDE

The oldest eco-label is Germany's Blaue Engel (Blue Angel), first issued in 1978. Since then the Blue Angel symbol has appeared on a steadily increasing number of German, as well as foreign, products. In 1998, it covered some 4500 products in about 80 product categories from almost 1000 manufacturers. Approximately 13% of the manufacturers, and 15% of the products awarded the label are foreign, coming from 13 European countries together with China, Japan, Korea and the USA.

Authority for the label to appear on a certain product was entrusted, by a private law contract, to the German Institute for Quality Control and Labeling. The label is issued by an eco-labeling jury on the basis of criteria set up by the German Ministry of the Environment, Natural Conservation and Nuclear Safety. The procedures for application and the development of criteria are quite elaborate and involve the Federation of German Industries, Consumers' Association, and the Federal Environmental Agency.

It is worth noting that the Blue Angel is not the only eco-label in Germany. There is competition from smaller programs, but Blue Angel has maintained steady growth over the last few years.

There are national eco-labeling systems in many countries, both developed and developing (e.g., Singapore, India, Zimbabwe). Rather than list them, it is more useful here to dwell on attempts to develop transnational eco-labeling systems that attempt to address the main difficulty with national schemes, viz. the use of different criteria and procedures for issuing an eco-label. The first such initiative came from the Nordic countries. In 1989, Finland, Iceland, Norway and Sweden, later joined by Denmark, launched the Nordic Swan eco-label. Governments subsidize the program which has issued more than 500 licenses covering some 1500 products in just under 50 product groups. The scheme enjoys popularity amongst Nordic consumers not yet matched by other eco-labels in other countries. The Nordic agencies responsible for the program have been appointed as competent bodies for the European Union (EU) eco-label.

The EU eco-label, a ower logo, was started in 1992. This label is intended to replace existing national labels in the member states. Under the EU regulation setting up the system, member states must establish a competent body to run the eco-labeling process. All member states are involved in establishing ecological criteria for product groups. This process is elaborate and goes through six phases before criteria are adopted by a decision of the European Commission. This approach is gathering momentum slowly and some 200 products from under 30 manufacturers have enrolled. Criteria for just over 10 product groups were developed by 1998 and another 10 are in the pipeline. Adopting an EU eco-label means eventually abandoning national labeling schemes in favor of a unified European one.

In North America, the Canadian Environmental Choice Program was established in 1988 by the Federal Government and administered by an environmental services consultancy. The USA Green Seal was established in 1990. The focus of the Canadian program has been in the professional procurement market. Companies that obtained Green Seal certificates in the USA include a number of multinationals. The focus is again on the institutional purchasing sector. The Canadian and US programs joined hands to form the Global Eco-labeling Network (GEN).

GEN, a voluntary not-for-profit association of eco-labeling organizations founded in 1994, sets criteria and certifies products and services. It aims at improving, promoting and developing eco-labeling of products and services. At present, 14 eco-labeling organizations from Europe, Asia, North and South America are members. The GEN secretariat is located in Canada and has an office in Japan.

The year 1999 witnessed growing opposition in Europe to food products made with, or containing, genetically modified organisms. Although such products have been widely consumed in the USA for a number of years, this has changed recently and there seems to be growing opposition to the consumption of such products in the USA as well. This has resulted in the call for eco-labeling of genetically modified food products. There is strong resistance in the USA to unilateral action in this and similar areas. This emphasizes the need for internationally accepted labeling and monitoring procedures (Hasiberger, 2000).

Environmental Policies for the World Oceans

Gunnar Kullenberg
International Ocean Institute, Gzira, Malta

Major ocean issues of great concern to humankind which environmental policies of the world ocean must address include:

- *coastal zone degradation and physical disturbances resulting from multiple, and often con icting, uses by an increasing coastal zone population: coastal erosion, sea level changes, physical alterations in the water and of critical habitats, in particular coral reefs, mangroves, seagrass beds;*
- *marine pollution, mainly of the coastal zones and shelf seas, but also affecting remote areas through long-range atmospheric transport of persistent pollutants; (The major source of marine pollution is land-based activities of society; pollution from shipping has been reduced and is reasonably controlled through environmental policies adopted in the framework of International Maritime Organization (IMO); dumping and incineration at sea have likewise been controlled reasonably well through environmental policies adopted in IMO);*
- *over shing in about 2/3 of all shing areas according to the Food and Agriculture Organization (FAO), and the alterations of marine biological diversity due to disturbances from habitat destruction, pollution, including eutrophication and changes of nutrient balances, shing and transfer of species through shipping and aquaculture developments;*
- *the role of the ocean in global change, including climate change, in the balance of emission and absorption of greenhouse and other gases, e.g., water vapor, carbon dioxide (CO_2), oxygen, changes in ocean circulation and of large-scale perturbations such as El Niño phenomena, frequency and strength of storms and storm-surges;*
- *the exploitation of non-living marine resources, including building material, oil and gas, hydrates, renewable energy through ocean thermal energy conversion, waves, tides, ocean currents;*
- *the exploitation of recently discovered deep-sea ecosystems associated with sea-bottom vents, for medical pharmaceutical and other purposes;*
- *the very limited understanding we have of ocean processes, conditions, resources, biological diversity and ecosystems, with the related considerable uncertainty as to consequences and impacts of changes (e.g., rather sudden changes in the deep ocean conveyor belt), be they natural or human induced;*
- *the transportation of goods by shipping, and the related handling transfers and interfaces, especially in ports, but also safety at sea, and transfer of non-indigenous species;*
- *the recreation and tourism industry, depending on the ocean and coastal zones as major environmental components.*

The importance of the ocean for the global balance of biogeochemical cycles, the climatic variability and stability for the global food production, and thus for global change cannot be over emphasized. A stable sea level over the last 6000–7000 years has been very important for coastal development.

Additional challenges facing environmental policies for the ocean are that oceanic problems are closely inter-related and need to be considered as a whole, that almost all sectors of society in one way or another are dependent upon the ocean or the marine environment, and that currently most national and international institutions are sectorally oriented and are unable to deal with ocean issues in a comprehensive fashion. This means that even in cases where comprehensive international environmental policies for the ocean exist, their applications are fragmented and insufficiently coordinated.

International policy instruments have been adopted which, if they were to be implemented would address several of the issues.

The Third Law of the Sea, the United Nations Convention on the Law of the Sea (UNCLOS) and the results of the Rio Conference, the United Nations Conference on Environment and Development (UNCED) 1992, when taken together, constitute a comprehensive international environmental law for the ocean and a means of its implementation. Chapter 17 of Agenda 21 comprises seven major program areas, which spell out modes of implementation of several parts of the Law of the Sea. The adoption of the Law of

the Sea and its entering into force in 1994 have produced a comprehensive perspective of the ocean, beyond being a body of water and a means of transportation, by focussing attention on the life, production, resources and environmental dimension of the ocean.

Part XIII of UNCLOS establishes a consent regime for marine scientific research, and puts science on an equal footing with economics, law and other major sectors of society.

An important element of the regime for research is cooperation. The need for cooperation is fully recognized and is even made mandatory: states shall cooperate. This, when implemented, will stimulate cooperation also in other circumstances than research. UNCLOS provides stimulus for technology transfer, human resources and institutional development, and capacity building, which is very necessary for the implementation of UNCED-related agreements or any environmental policies for the world ocean.

The global conventions and agreements, signed on the occasion of or resulting from UNCED 1992, addressing climate change, biological diversity, fisheries management, the marine pollution from land-based activities and the desertification issues, are pushing in the direction of developing adequate global observing and early warning systems based partly on the precautionary principle. There is need for adequate data delivered in a timely and reliable fashion for forecasting and compliance monitoring. This is also reason for the development of the Global Ocean Observing System (GOOS), its modules and regional components. Very considerable advances have been made since the inception of GOOS in 1989/1990.

Fundamental pillars of UNCLOS are the Common Heritage Principle and the Exclusive Economic Zone (EEZ). These policy instruments provide a means of achieving greater equity among nations than presently is the case.

Through the EEZ concept, coastal states are given full rights of the resources, but also full responsibility for management, for environmental conditions, pollution, etc. This provides the potential for a focussed and identified management. However, we know that it does not yet work as it could. There is a need to build capacity and provide for education and joint programs. Interdisciplinary and applied research is required; including integration of the results, making integrated assessments, linking natural, social and economical perspectives.

The environmental policies dealing with shipping include the International Convention for the Prevention of Pollution from ships, the Marine Pollution convention (MARPOL) of 1973, with so far six Annexes. Following several tanker accidents in the 1970s, the Conference on Transfer Safety and Pollution Prevention was held at IMO in 1978. It adopted a Protocol on ship design and operation which was incorporated into the Convention on the Safety of Life at Sea (SOLAS) of 1974; and a Protocol related to marine pollution from oil, the 1978 MARPOL Protocol. This Convention is called MARPOL 73/78. The other Annexes of the Convention address various aspects of pollution from ships, the latest being air pollution (Annex VI). The IMO is still working on regulations regarding management of ballast water in order to prevent spreading of non-indigenous species, and of anti-fouling paints harmful to the environment.

Dumping and incineration at sea is regulated through the London Convention of 1972 with various protocols. This is also managed in association with IMO. Special attention has been given to the release of radioactive material into the ocean. The international policies are dealt with through the International Atomic Energy Agency (IAEA).

The complexity of the world ocean makes it attractive to address the environmental concerns through regional mechanisms, which can be harmonized both with global environmental policies and with national ones, and also can address regional priorities. These are often different from region to region.

Since the Stockholm Conference on the Human Environment 1972, the regional approach has been pursued in a systematic fashion with respect to formulation, reaching consensus and creating required mechanisms for implementation of marine environmental policies. This has included the North Eastern Atlantic regions, where the International Council for the Exploration of the Sea (ICES) has served as scientific advisory body external to the regional environmental conventions, which are HELCOM (the Helsinki Commission–Baltic Marine Environment Protection Commission) and OSPARCOM (Convention for the Protection of the Marine Environment of the North–East Atlantic) for the North Sea. The latter took a significant step towards an integrated regional marine environmental policy through its revision in 1992/94, when the Oslo and Paris Conventions, dealing with seaborne and land-based sources of pollution respectively, were combined.

For other major regions of the world ocean, regional environmental policy development has been pursued by the United Nations Environment Programme (UNEP), in its Regional Seas Programme. UNEP has cooperated with all United Nations (UN) Agencies involved in marine affairs in this development. Currently ten Regional Seas Conventions or Agreements are in existence. They are all based on the same principles: overall legal instrument, protocols dealing with specific regional problems, participation of governments through the ministry of the environment and shared costs; with a regional secretariat as coordinating mechanism for implementation of actions agreed by contracting parties. Capacity building including equipment, development of methods for monitoring and surveillance, establishment of early warning systems, training and public awareness creation are important elements of the regional action plans. However, other major components of an integrated policy

Box 1 Acronyms relating to the marine environment, mentioned in this paper but not specifically referenced elsewhere

EEZ:	Exclusive Economic Zone
HELCOM:	Helsinki Commission – Baltic Marine Environment Protection Commission
ICES:	International Council for the Exploration of the Sea
MARPOL 73/78:	Marine Pollution Convention
OSPARCOM:	Convention for the Protection of the Marine Environment of the North–East Atlantic
UNCLOS:	United Nations Convention on the Law of the Sea

for the ocean are not included, e.g., shipping, fisheries, tourism and exploitation of non-living resources.

Only in one region, the Mediterranean Sea, have the contracting parties taken the step towards a comprehensive marine environment policy. This includes establishment of a regional Commission for Sustainable Development.

The fisheries policies are of particular importance (*see* Policies for Sustainable and Responsible Fisheries, Volume 4).

Implementation of environmental policies for the world ocean is governed at the international level through the UN system. The Commission on Sustainable Development, created after UNCED 1992, meets every year and reports through the Economic and Social Council (ECOSOC) to the General Assembly on the implementation of Agenda 21. Interagency mechanisms exist for dealing with the ocean issues, including the Joint Group of Experts on Scientific Aspects of Marine Environmental Protection (GESAMP) created in 1969, and the Administrative Committee on Coordination (ACC) Subcommittee on Ocean and Coastal Areas, created in 1994 as a result of UNCED 1992.

The implementation of UNCLOS is considered annually in a specific agenda item by the General Assembly, on the basis of an UN system-wide report prepared by the Secretary General.

Environmental non-governmental organizations play an important role in focussing attention on issues and in pushing for the establishment of adequate environmental policies for the ocean. Greenpeace International, Friends of the Earth, the International Union for the Conservation of Nature–World Wildlife Fund and the International Ocean Institute must be specifically mentioned for their pioneering efforts (see also Box 1).

Environmental Refugees

Norman Myers
Oxford University, Headington, Oxford, UK

There is a new phenomenon in the global arena: environmental refugees. These are people who can no longer gain a secure livelihood in their homelands because of drought, soil erosion, deserti cation, deforestation and other environmental problems. In their desperation, they feel they have no alternative but to seek sanctuary elsewhere, however hazardous the attempt. Not all of them have ed their countries, many being internally displaced. But all have abandoned their homelands on a semi-permanent if not permanent basis, with little hope of a foreseeable return.

In 1995 these environmental refugees totaled at least 25 million people, compared with 23 million traditional refugees, or people eeing political oppression, religious persecution and ethnic troubles. The environmental refugees total is expected to double by the year 2010, and to increase steadily for a good while thereafter as growing numbers of impoverished people press ever harder on overloaded environments. When global warming takes hold, there could be as many as 200 million people overtaken by sea-level rise and coastal ooding, by disruptions of monsoon systems and other rainfall regimes, and by droughts of unprecedented severity and duration.

INTRODUCTION

Of the 25 million environmental refugees in 1995, there were roughly five million in the African Sahel, where a full 10 million people had ed from recent droughts, only half returning home. Another four million, out of 11 million refugees of all types, were in the Horn of Africa including Sudan. In other parts of sub-Saharan Africa, (where 100 million people are considered to be semi-starving), seven million have been obliged to migrate in order to obtain relief food. In China, with its 120 million internal migrants, at least six million deserve to be regarded as environmental refugees, having been obliged to abandon their farmlands due to shortages of agricultural plots in the wake of decades of population growth. In Mexico there are one million new environmental refugees each year; some become assimilated in cities, and a few return home, leaving

a cumulative total, as a bare minimum, of two million. Finally, there are those people displaced involuntarily by public works projects, notably large dams, increasing in number by 10 million every year (with a cumulative total of 50 million in just China and India). Most of them resettle elsewhere, but the number remaining in a refugee-like situation totals one million.

THE HAITI EXPERIENCE

For years Americans have watched streams of Haitian boat people heading towards Florida. Not only have these people been eeing political oppression, they have been driven by the rundown of the environmental resources on a grand scale (soil, water, trees) that underpin their agricultural economy.

Almost three-quarters of the populace depends directly on agriculture. Only one-third of all land is considered suitable for farming, but population pressures cause three-fifths to be cultivated. Two-thirds of the farmland is on slopes of more than 20°, yet have to support farmers at densities of over 270 km^{-2}, as great as in the most heavily populated agricultural areas of India. The soils are thus exceptionally prone to erosion, half of all farmlands being so eroded that they may be unreclaimable. In some places much of the landscape has lost virtually all its soil, exposing large stretches of bare rock.

The combination of environmental rundown with population growth (Haiti's is the second highest in the Caribbean) means that *per capita* grain production is only a little over half what it was 40 years ago. Many Haitians enjoy only 80% of an acceptable calorie intake: they are chronically malnourished (jargon for semi-starving). One child in ten dies before the age of five. Since 1980, the average cash income has been declining, until today it is just over \$400 $year^{-1}$.

Primarily as a result of all these environmental travails, at least 1.3 million Haitians or one in five of the populace have left their homelands, 300 000 of them heading for the United States. In former times, some of them were driven by political oppression and government corruption, but for most, the predominant factor has been environmental, and to that extent these people deserve to be called environmental refugees.

Even though their country now enjoys a measure of political democracy and economic freedom, many Haitians still lack adequate food. Many more environmental refugees will leave from Haiti for the United States. This migration poses high costs in the destination states. State and local governments in Florida have paid out as much as \$250 million $year^{-1}$ to cater for Haitian aliens, more than 17 times the \$14 million the Agency for International Development has been spending annually for environmental safeguards throughout the Caribbean.

ENVIRONMENTAL REFUGEES WORLDWIDE

The estimate of 25 million for the 1995 total of environmental refugees is cautious and conservative. Scattered throughout the developing world are 135 million people threatened by severe desertification, and 550 million people subject to chronic water shortages. While certain of these people will have been included in the 25 million figure, many could well have been driven to migrate without being counted as environmental refugees.

Of the nearly one billion additional people added to the global population during the 1990s, a good proportion will have been among communities with a cash income of \$1 day^{-1} or less. They include the people most likely to be subsisting, or rather struggling to survive, in environments too wet, too dry or too steep for sustainable agriculture. In sub-Saharan Africa, these environments will have needed to support an extra 150 million people within the 1990s, and a similar total in India.

Poverty serves as an additional push factor associated with the environmental problems displacing people. Other factors include population pressures, malnutrition, landlessness, unemployment, over-rapid urbanization, pandemic diseases and government shortcomings, together with ethnic strife and conventional con icts. In particular, it is sometimes difficult to differentiate between refugees driven by environmental factors and those impelled by economic problems. In certain instances, people with moderate though tolerable economic circumstances at home feel drawn by opportunity for a better livelihood elsewhere. They are not so much pushed by environmental deprivation as pulled by economic promise. This ostensibly applies to many Hispanics heading for the United States. But those people who migrate because they suffer outright poverty are frequently driven also by root factors of environmental destitution. It is their environmental plight as much as any other factor that makes them economically impoverished. This generally applies to those refugees who migrate to areas where economic conditions are little if any better than back home, as is the case with many people who migrate within sub-Saharan Africa and the Indian subcontinent. In this instance, with poverty and life on the environmental limits as the main motivating force, it matters little to the migrants whether they view themselves primarily as environmental or economic refugees.

In short, there is a gradient of factors at work. At one end are those who are driven by environmental problems outright, and at the other end are economic migrants who are voluntary opportunists rather than refugees. In between is a gray zone where one category sometimes tends to merge into the other. The assessment to date is no more than a first-cut effort, albeit preliminary and exploratory, to come to grips with a prominent and fast growing problem that is all too real for those who endure it, however much the purists may argue about final definitions.

On top of all these sub-problems is the lack of official recognition, whether on the part of governments or international agencies, that there is an environmental refugee problem at all.

THE FUTURE OUTLOOK

How many environmental refugees can we realistically anticipate in the future: or rather, how many people are likely to become vulnerable to environmental problems that could force them to migrate? Let us consider the outlook for the year 2010. The population of developing countries is projected to grow by more than one billion people, a 24% increase in just 15 years. Sub-Saharan Africa's total will have expanded by some 240 million, a 42% increase, and the Indian subcontinent's by 377 million, 32%. The numbers of people in absolute poverty are predicted to swell from 1.3 to 1.6 billion. The 135 million people affected by severe desertification could well increase to 180 million. The populations of water short countries, 550 million today, are expected to surge to more than one billion. If the 1985 onwards plateauing of crop yields continues, there will be more, and more widespread, shortfalls in food production (especially in sub-Saharan Africa and the Indian subcontinent), while international tradable stocks will be increasingly unable to keep up with fast burgeoning demand.

The 25 million environmental refugees in 1995 had mostly become obliged to migrate since 1980, when their numbers first started to climb rapidly. In light of patterns and trends of environmental decline and associated problems such as spreading poverty and population increase, it is probable that by 2010 there will be at least another 25 million such refugees if only because the impelling factors will continue to be at least as prominent for the communities concerned. (This supposes too that there will be few preventive measures of sufficient scope.) In fact, the increase could well be more than 25 million because of increasingly degraded environments coupled with growing numbers of impoverished people.

For a specific instance of the problem's scope to expand, consider the prospect for sub-Saharan Africa until the year 2010. This is already the region with half the world's traditional refugees and at least a similar proportion of environmental refugees. Despite some advances in soil conservation (Kenya, Ethiopia), small scale agriculture (Nigeria, Zimbabwe), reforestation (Tanzania, Malawi), anti-desertification (South Africa), and population planning (Kenya, Zimbabwe, Botswana), the outlook is unpromising. The region's population is projected to increase to over 800 million people, fully 42% more than in 1995. Severe desertification may well affect more than 100 million people, half as many again as today. Ten countries are expected to be experiencing chronic water shortages or even acute water scarcity, with collective populations totaling well over 400 million people. Without greatly expanded efforts to tackle the region's lack of development, *per capita* Gross National Product (GNP) will probably stagnate in real terms at around $500.

Most important of all will be the region's incapacity to feed itself. Some twenty countries with a projected collective population of 440 million are expected to experience up to 25% shortfall in food supplies, and a further eight countries with a projected 75 million people face more severe deficits. *Per capita* food production is scheduled to decline even below the meager 1990 level, possibly as much as 20% below. The total number of malnourished people could grow to 500 million, with 100 million destitutes obliged to live for the most part off imported food (in just southern Africa there were 20 million people dependent on relief food in 1992). The food deficit could well rise to as high as 50 million tons. Due to its exceptional poverty the region will be increasingly unable to compete in the global grain market. Food aid worldwide in 1995 was only 7.5 million tons, enough to make up the diets of only 10 million semi-starving people.

On the global scale, there will be problems of climate warming. Due largely to sea-level rise and ooding of coastal zone communities, but also to increased droughts and disruptions of rainfall regimes such as monsoonal systems, global warming could threaten large numbers of people with displacement by 2050 or earlier. Preliminary estimates indicate the total of people at risk of sea-level rise in Bangladesh could be 26 million, in Egypt 12 million, in China 73 million, in India 20 million, and elsewhere, including small island states, 31 million, making a total of 162 million. At the same time, at least 50 million people could be at severe risk through increased droughts and other climate dislocations.

All in all, the issue of environmental refugees promises to rank as one of the foremost human crises of our times. To date, however, it has been viewed as a peripheral concern, a kind of aberration from the normal order of things, even though it is an outward manifestation of profound deprivation and despair. While it derives primarily from environmental problems, it generates problems of political, social and economic sorts. As such, it could readily become a cause of turmoil and confrontation, leading to con ict and violence. Yet as the problem becomes more pressing, our policy responses fall further short of measuring up to the challenge. To repeat a key point: environmental refugees have still to be officially recognized as a problem at all.

At the same time, there are limits to host countries' capacity, let alone willingness, to take in outsiders. Immigrant aliens present abundant scope for popular resentment, however unjust this reaction. In the wake of perceived threats to social cohesion and national identity, refugees can become an excuse for outbreaks of ethnic tension and civil disorder, even political upheaval. This is already the

case in those developed countries where immigrant aliens increasingly prove unwelcome, as witnessed by the experience of Haitians in the United States and North Africans in Europe. Almost one-third of developed countries are taking steps to further restrict immigrant ows from developing countries.

Yet measures to relieve the plight of refugees of whatever kind have drastically diminished in relation to the growing scale of the problem. Although the annual budget of the United Nations High Commissioner for Refugees has recently been boosted to $1.3 billion, the agency is increasingly unable to supply food and shelter for refugees of traditional kind alone, much less to invest in rehabilitation or repatriation of these refugees. Meanwhile, the world's refugee burden is borne primarily by the poorest sectors of the global community. In 1995 the 20 countries with the highest ratios of official (traditional) refugees had an annual per capita income of only $750.

POLICY OPTIONS

There is much scope for preventive policies, with the aim of reducing the need to migrate by ensuring an acceptable livelihood in established homelands. First of all, we need to expand our approach to refugees in general in order to include environmental refugees in particular. We cannot continue to ignore environmental refugees simply because there is no institutionalized mode of dealing with them. If official standing were to be accorded to these refugees, this might help to engender a recognized constituency, e.g., those 900 million people who endure some degree of desertification, four million of whom have become environmental refugees in the Sahel alone. While desertification entrains costs of $42 billion year^{-1} just through the loss of agricultural produce, the United Nations' Anti-Desertification Action Plan would cost no more than $10 billion year^{-1}. Yet the amount subscribed so far is less than $2 billion, ostensibly on the grounds that arid land dwellers have no constituency and hence lack political leverage.

Second, we need to widen and deepen our understanding of environmental refugees by establishing the root causes of the problem; not only environmental causes but associated problems, plus the interplay of the two sets of forces. There are many conceptual gray areas as proximate concerns and ultimate causes, the contributory roles of population pressures and poverty, the linkages to ethnic tensions and conventional con ict, and so forth. Suppose, for instance, there had been a better understanding and hence a better anticipatory response on the part of the Philippines government when the agricultural frontier closed in the country's lowlands during the late 1980s, bringing on a sudden increase in landlessness and an upsurge of migration into steep country in search of land. The problem could have been somewhat relieved through before-the-event measures to redistribute existing farmlands, to improve rural infrastructure and to supply more off-farm employment, thereby reducing the need to migrate out of the lowlands.

Consider too the root causes of famine. If a famine has been human-made, it can be human-unmade, whereas natural factors can only be managed and accommodated. Just as the recurrent droughts in sub-Saharan Africa cannot all be blamed on climate, so the recurrent famines cannot all be blamed on drought. Drought has often served to trigger famines by disrupting the social, economic and political processes that would normally ensure sufficient access or entitlement to food.

Probably most important of all is that there can be little advance except within an overall context of what has come to be known as *sustainable development*. This applies notably to reliable access to food, water, energy, health and other basic human needs, the lack of which is behind many environmental refugees' need to migrate. In big picture terms, sustainable development represents a sound way to preempt the environmental refugee issue in its full scope over the long run. As a prime mode to tackle the issue, then, there would be a handsome payoff on investment to foster sustainable development in developing countries through greater policy emphasis on environmental safeguards, together with efforts to stem associated problems such as poverty, population and landlessness.

However, only select parts of sustainable development measures address the particular problem of environmental refugees. Especially pertinent, for example, would be the Anti-Desertification Action Plan as applied to the Sahel and arid sectors of the Horn of Africa, both being sources of large numbers of environmental refugees, whether present or prospective. Also warranting closely targeted responses are food-short regions within sub-Saharan Africa and the Indian subcontinent.

Much could be achieved too through better targeting of foreign aid. The annual budget of the main source of multilateral aid, the United Nations Development Programme, has declined so much in recent years that it is now little more than that of the United Nations High Commissioner for Refugees ($1.3 billion in 1995), meaning that the United Nations' main response in this regard tends to be as reactive as proactive. Worse, the 10 developing countries with well over two-thirds of the world's poorest of the poor receive only one-third of foreign aid and it is impoverished communities that serve as the source of most environmental refugees. India has 20% of all people in absolute poverty worldwide, yet it receives only five percent of total foreign aid. Were foreign aid to be more closely directed at impoverished people in the main countries and regions concerned, it could help to relieve the problem while it is still becoming a problem, i.e., before it becomes entrenched.

Equally to the point, developing countries and aid organizations alike devote only around 10% of their development expenditures to priority human needs such as water and sanitation, nutrition, and health, the lack of which is often a contributory factor to the environmental refugee problem. The communities most deficient in these essentials are the 1.3 billion people in absolute poverty. The challenge could be largely surmounted if the funding proportion were to be doubled to 20%. The additional annual cost for the United States would be no more than $2 billion, or $7.7 per American (the price of a beer every three months). Alternatively, the sum could readily be made available by restructuring the US aid program of $9 billion year^{-1}.

There is much more that developing countries themselves can do, and at no great cost. According to the United Nations Children's Fund (UNICEF), to eliminate deaths from famine would cost only a little more than $0.5 billion year^{-1}; to cut malnutrition among women and children (who make up a disproportionate share of environmental refugees), less than $2 billion; and to reduce hunger among the poorest households, little over $6 billion. All of these measures would help to reduce prime pressures generating environmental refugees. The total cost would be less than $9 billion, or $7 for each of the 1.3 billion people in absolute poverty: these being the communities that are a main source of environmental refugees. By contrast, developing countries spend an annual average of $40 citizen^{-1} on military activities. In 1991 Ethiopia assigned 13% of GDP to this purpose, four times the global average, even while it featured some of the largest numbers of environmental refugees in proportion to population size.

ESCAP (Economic and Social Commission for Asia and the Pacific)

The United Nations (UN) ESCAP is one of the five United Nations Regional Commissions, the others being Africa, East Europe, Latin America and the Caribbean, and West Europe and others.

ESCAP was established in 1947 in Shanghai, China, as the Economic Commission for Asia and the Far East to assist in post-war economic reconstruction. The Commission moved its headquarters to Bangkok in January 1949. The name was changed in 1974 to re ect both the economic and social aspects of development, and the geographic location of its member countries. ESCAP has been the main UN economic and social development center for Asia since 1977.

ESCAP is the largest of the five UN Regional Commissions, comprising 51 members and nine associate members and representing some 60% of the world's population, or 3.5 billion people.

ESCAP members include Japan and Australia; the dynamic tiger economies (Republic of Korea, Singapore, Thailand, Indonesia, Malaysia), and seven new Republics of Central Asia, which are undergoing rapid economic transition. Thirteen of the world's least developed countries make up one-quarter of ESCAP's full members, and 19 small Pacific island developing countries account for over one-third of ESCAP's total membership. The smallest country is Niue with a population of 2000. The largest is China with a population of 1.2 billion people.

ESCAP spawned two of the region's vital institutions – The Asian Development Bank and the Mekong River Commission.

The main legislative organ of ESCAP is the Commission, which meets annually at the ministerial level and reports to the UN's Economic and Social Council. It provides a forum for all governments of the region to review and discuss economic and social issues and to strengthen regional cooperation.

EU (European Union)

The European Union (EU) was established by the Treaty of Maastricht, signed on the 7th of February 1992, and further defined by the 1997 Amsterdam Treaty. It currently includes

the 15 countries belonging to the European Communities: Austria, Belgium, Denmark, Finland, France, Germany, Greece, Ireland, Italy, Luxemburg, Netherlands, Portugal, Spain, Sweden, and the United Kingdom, totaling 370 million citizens.

The Union, which is grounded in the European Communities treaties, has the task to organize, in a manner demonstrating consistency and solidarity, relations between the member states and between their peoples.

The Union's objectives are:

- to promote economic and social progress which is balanced and sustainable, in particular through the creation of an area without internal frontiers, the strengthening of economic and social cohesion and the establishment of economic and monetary union;
- to assert its identity on the international scene, in particular through the implementation of a common foreign and security policy;
- to develop close cooperation on justice and home affairs.

The Union is served by a single institutional framework including the following:

- the European Parliament, directly elected, with legislative power and the task to control the use of executive power;
- the council of the EU, representing the governments of the member states, which sets political objectives and coordinates national policies and shares legislative power with the European Parliament;
- the European Commission, with three basic functions: initiator of proposals for legislation, guardian of the Treaties and manager and executor of Union policies and of international trade relations;
- the Court of Justice, which provides the judicial safeguards to ensure that the law is observed in the interpretation and the application of the Treaties;
- the Economic and Social Committee, representing the various categories of economic and social activity and advising the commission, the council and the European Parliament;
- the Court of Auditors, the European Investment Bank, the Committee of the Regions, the European Central Bank and the European Ombudsman.

The EU is in charge of common policies in the areas of trade, agriculture, fisheries, transport, research and technological development, environment, etc. It sets basic minimum standards in environmental protection, which must be applied in the member states, and it has the duty to integrate environmental concerns in the definition and implementation of sectoral policies in order to promote sustainable development.

The European Commission is headed by a College of Commissioners, one of which is responsible for environment policy and oversees the Directorate General Environment.

The budget allocated to this Directorate General is used for the implementation of action programs, the preparation of new legislation, the funding of projects aimed at improving the environment in the member states (LIFE and Cohesion programs). A special appropriation is made for the European Environment Agency, located in Copenhagen, whose mission is to provide comprehensive information on the state of the European environment and the effectiveness of policies. Environmental research is managed by the Directorate General Research, which funds large multinational projects in support of the relevant EU policies.

FAO (Food and Agriculture Organization)

The FAO was founded in October 1945 with a mandate to raise levels of nutrition and standards of living, to improve agricultural productivity, and to better the condition of rural populations.

Today, the FAO is the largest autonomous agency within the United Nations system with 180 member nations plus the Economic Union (EU) (member organization) and more than 4000 staff members around the world. Following recent efforts to decentralize, the FAO's staff includes almost 2200 people at headquarters and more than 1800 working at decentralized offices and field projects. The organization's 2000–2001 biennial budget is set at $650 million. FAO assists developing countries through agricultural and rural development projects with about US$300 million per year with funding obtained from donor agencies, governments and its own regular programme; half of this assistance is for technical assistance and support and half for emergency assistance.

Since its inception, the FAO has worked to alleviate poverty and hunger by promoting agricultural development, improved nutrition and the pursuit of food security – the access of all people at all times to the food they need for an active and healthy life. The organization offers direct development assistance, collects, analyses and disseminates information, provides policy and planning advice to governments, and acts as an international forum for debate on food and agriculture issues.

The FAO is active in land and water development, plant and animal production, forestry, fisheries, economic and social policy, investment, nutrition, food standards and commodities and trade. It also plays a major role in dealing with food and agricultural emergencies.

A specific priority of the organization is encouraging sustainable agriculture and rural development, a long-term strategy for the conservation and management of natural resources. It aims to meet the needs of both present and future generations through programs that do not degrade the environment and are technically appropriate, economically viable and socially acceptable.

G

GATT (General Agreement on Tariffs and Trade)

The GATT was created in 1947 as a draft agreement on rules for trade in goods between then only 23 contracting parties. In order to service the GATT agreement and facilitate trade negotiations, an *ad hoc* organization known as GATT was established alongside the GATT agreement. The GATT was not a fully- edged international organization, having no legal personality, but was rather a revolving contractual agreement. This status persisted through the 1986–1994 Uruguay Round of world trade talks, during which contracting parties negotiated additional agreements for trade in services (General Agreement for Trade in Services, GATS) and intellectual property (the Agreement on Trade-related Aspects of Intellectual Property Rights, TRIPs). An agreement was also made during the Uruguay Round to establish the World Trade Organization (WTO), which came into being as an international organization on 1st January 1995.

The WTO was established as an intergovernmental organization to administer all the trade agreements under its auspices, and accession and adherence to those agreements. The WTO's main decision-making bodies are councils and committees in which all members can participate. With its secretariat in Geneva, and current membership of 140 countries, the purpose of the WTO is to regulate governments' interventions into international trade according to a negotiated rules-based system, to settle trade disputes between parties, and to organize trade negotiations. Administrative and technical support is also provided by the WTO.

While GATT no longer exists as an institution, the GATT agreement continues to exist in an amended form as a principal WTO agreement. Moreover, the GATT agreement's key principles of non-discrimination, transparency and predictability have been incorporated into the agreements on services and intellectual property, and are now widely recognized as key principles in all other WTO agreements. The GATT, GATS and TRIPs agreements, and their related subsidiary agreements, today make up core agreements that are administered by the WTO and are subject to a single system of rules for resolving disputes. All WTO members adhere to core agreements and some adhere to various additional WTO plurilateral agreements.

Although the WTO has no specific agreement dealing with the environment, a number of the WTO agreements include provisions dealing with environmental concerns. Following the Uruguay Round, members created the WTO Committee on Trade and Environment (CTE) to study the relationship between trade and the environment. The CTE has the responsibility, inter alia, to make recommendations to the WTO General Council about any changes that might be needed in WTO trade agreements for environmental purposes.

GEO (Global Environment Outlook)

The State of the Environment Assessment unit of the United Nations Environment Programme Division of Early

Warning and Assessment has the core mandate to keep under review the state of the global environment and identify emerging issues that require international attention. A major activity of the unit is the preparation, through a collaborative, participatory process, of the GEO reports. These reports provide comprehensive assessments of the state of the global environment and reviews of policy responses as well as outlooks for the future.

The global environment assessment process, through which the GEO report is produced, is cross sectoral and participatory, incorporating regional views and perceptions and building consensus on priority issues and actions through dialogue among policy-makers and scientists at regional and global levels. Input is solicited from an extensive array of sources throughout the world: regional and thematic collaborating centers, United Nations organizations, and independent experts. The first GEO report (GEO-1) was published in January 1997(OUP/ISBN 0 19 521349 1), the second (GEO-2000) was published in September 1999 (Earthscan/ISBN 1 85383 588 9), and the third (GEO-3) is due to be published in time for the 2002 World Summit on Sustainable Development.

The main GEO report is underpinned by numerous technical and regional reports. Other by-products have been developed out of the GEO process, including overview booklets, which provide a brief synopsis of the main reports. A training manual is being used to train collaborators and others involved in integrated environmental assessment and reporting around the world. A GEO-for-youth report, *Pachamama: Our Earth, Our Future*, was published in October 1999 (Evans Brothers/ISBN 0 237 52119 9). Most of these products are available in more than one language.

GEO reports can be accessed through http://www.unep.org. Further information can be obtained from geo@unep.org.

MARION CHEATLE *Kenya*

Geographic(al) Information Systems (GIS)

Paul Longley
University College London, London, UK

Measurement, simulation and modeling of environmental change entails a multitude of geographic problems that range from the routine to the monumental. Yet the solutions to diverse environmental problems share common characteristics since they almost always involve aspects of location. Thus, for example, a mineral extraction business is concerned with locational problems when it determines where to dig, how to route access roads, and how subsequently to institute land ll and landscaping activities. In similar vein, a farmer needs to solve locational problems in order to make better decisions about the amounts of fertilizer and pesticide to apply to a eld system. Location is also fundamental to environmental impact assessment.

Longley *et al.* (2001), from which this discussion is adapted, classify locational problems according:

- *Scale* (level of geographic detail): the effects of human activity upon the environment may be assessed at a range of scales from the architectural to the global.
- *Intent*: while some problem-solving is driven by human curiosity and the quest for greater scientific understanding, others problems are much more solution-oriented and practical in nature.
- *Timescale*: some geographic problems are manifest over short time periods, while others assume greatest importance over the long term.

Geographic information systems (GIS: often termed geographical information systems in Europe) provide a framework for locational problem solving across all geographic scales, in scientific as well as application-driven contexts, and can support both short- and long-term decision-making. Some aspects of the development of GIS applications may be much more straightforward than others. The handling of geographic information often begs unique, complex and difficult choices, although application is more straightforward if the objects of study are crisp and well defined. The cost of creating reliable and robust geographic information is often great, yet there are few technical obstacles to subsequent reproduction and distribution of it to other users. Many environmental questions cannot be solved with reference to just a single source of information, yet it can be straightforward to process or merge different information sources. If these and other challenges can be met with both rigour in generalization and sensitivity to context, GIS allows us to assess how the world looks, the forms it takes, how it works, and the natural and human processes that fashion it (Longley *et al.*, 2001).

The specific form of the world varies geographically, and every surface (or near surface) environment is unique. However, the effects of processes upon surface environments are much more general – for example, the effects of greenhouse gas emission on the environment are similar irrespective of where on the Earth the source is. GIS is unique in that it allows us to gauge the effects of general processes upon specific environments. Thus, for example, the effects of acid rain upon forests in Scandinavia

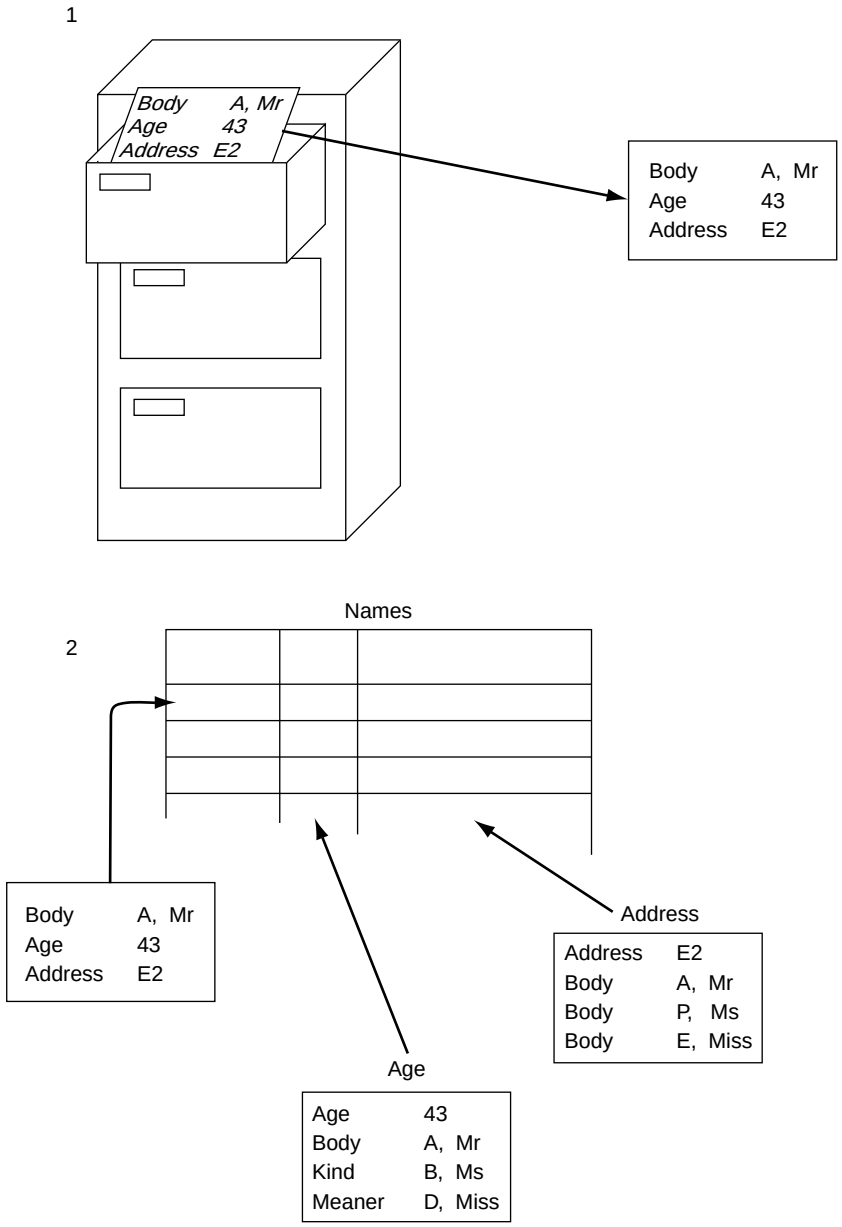

Figure 1 A GIS can be thought of as a digital filing cabinet of maps (Martin, 1996)

might be identified by applying general models of atmospheric dispersion and circulation to the specific air pressure systems prevailing over the North Atlantic and Baltic in a particular study period.

In many geographic problems, there is no simple relationship between a single process and an observed outcome. Rather, a range of factors may conspire to produce an observed outcome in a particular instance, as with the combined impact of climate, bedrock geology, aspect and slope angle upon rates of soil erosion following deforestation. A second unique property of GIS is that it enables the relative importance of a range of different factors to be assessed and incorporated in location-specific models of process. GIS can be adapted to circumstances in which such factors may not be expressible in commensurate terms, or where it is necessary to accommodate multiple goals and objectives.

GIS is conventionally deemed to comprise:

- software, designed to perform well-defined functions (GIS software);
- digital representations of aspects of world (GIS data);
- a community of people who use these tools for various purposes (the GIS community);
- applied problem-solving or scientific investigation (doing GIS).

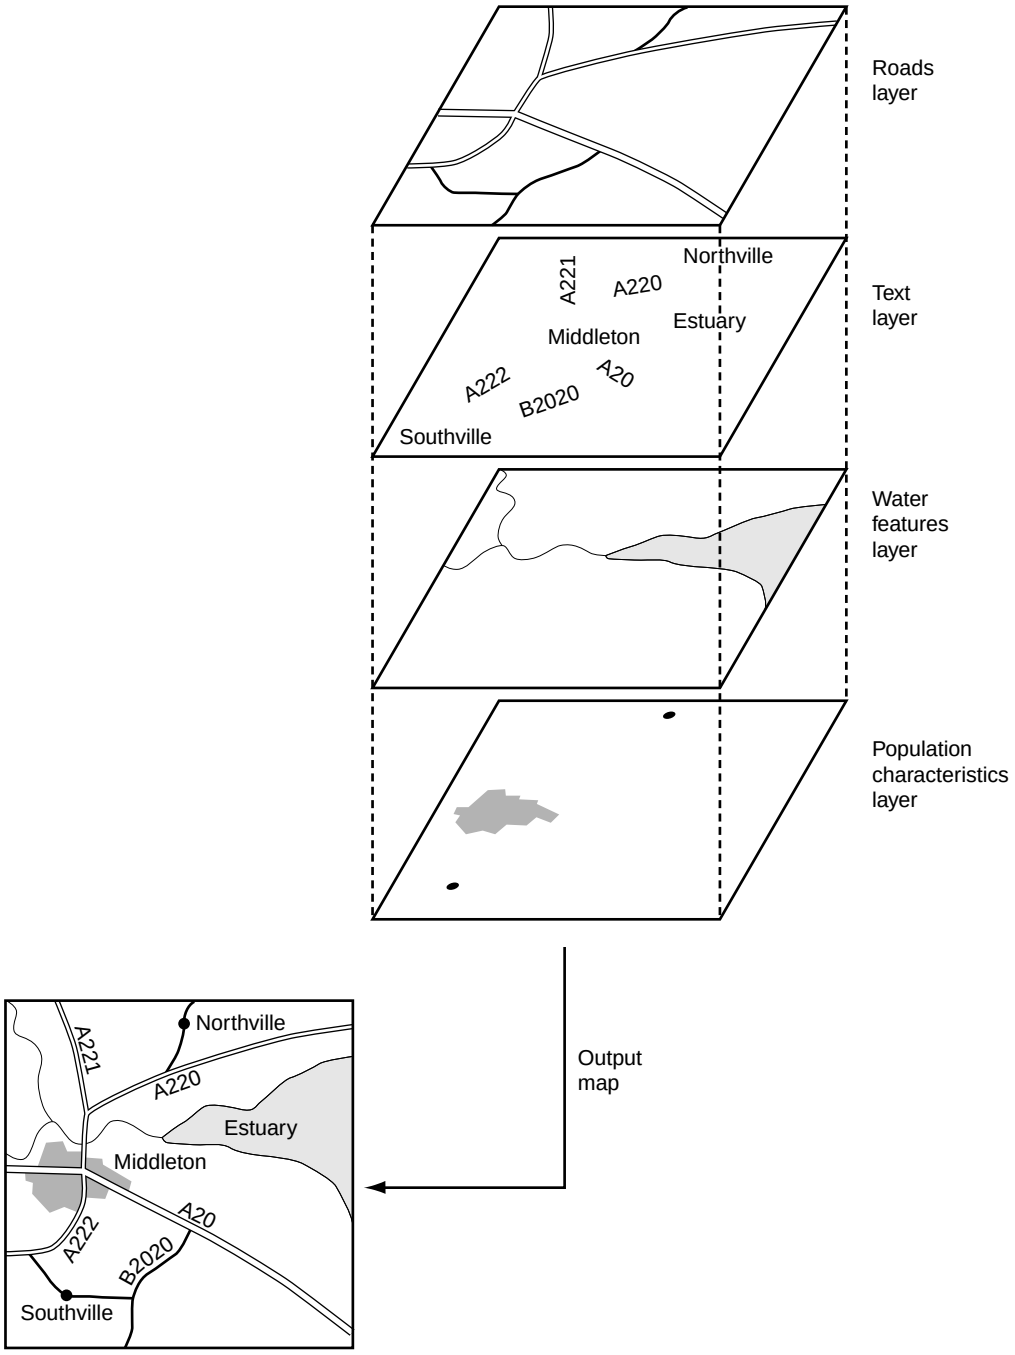

Figure 2 GIS can be used to create composite maps

There are many ways of defining GIS (see Longley *et al.*, 2001). Perhaps most straightforwardly, a GIS can be thought of as a digital version of a filing cabinet of maps (Figure 1: adapted from Martin, 1996). However, GIS is much more than this, because data from different sources can be brought together in order to create composite maps (Figure 2), which can be used directly to inform decision-making. In this sense, a second definition of GIS is as an environmental decision support system. Natural resource managers often need to know where spatial objects are. A third way of considering GIS is as a mechanized inventory of geographically distributed features or objects. A fourth definition of GIS emphasises the integrating role of GIS, as a scientific tool for revealing attributes of composite datasets (such as those shown in Figure 2) that are invisible in any one of the constituent themes. Finally,

GIS may be considered as providing a toolkit of basic techniques for performing operations on geographic data that are too tedious or expensive or inaccurate if performed by hand.

The first GIS was the Canada Geographic Information System, designed in the mid 1960s for natural resource management. In an unrelated development in the late 1960s, the US Bureau of the Census developed dual independent map encoding in order to support automatic referencing and aggregation of census records. It was not long before the early GIS developers identified that common solutions were applicable to the widest range of application areas, and soon generic computer software was being developed for computer mapping (Foresman, 1998). An early distinction was between software written to manipulate a regular grid of cells known as a *raster*, each element of which of which takes a numerical attribute value, and the vector data structure that comprises points, lines, nodes, segments and polygons (Figure 3). The development of raster GIS has also been associated with the development of satellite remote sensing (*see* Remote Sensing, Volume 2). The modern history of GIS dates from the early 1980s, when the price of sufficiently powerful computers fell to the point at which larger numbers of smaller organizations could adopt the innovation.

Today's GIS is a complex of software, hardware, people, institutions, networks, and activities. The major software vendors (such as ESRI Inc., Intergraph Corporation, etc.) provide distinct products to serve very different needs. These range from the geographically enabled spreadsheets that are available as adjuncts to popular word-processing packages, through simple systems for viewing, analyzing, and mapping data, to software for supporting GIS-oriented Web sites and sophisticated software systems that support the widest range of spatial analysis operations.

A GIS will normally comprise some or all of the following component parts.

- *Hardware* to enable the user to interact with the computer software – typically through typing, pointing, clicking or speech. Hardware may be configured as desktops, laptops, personal data assistants, in-vehicle devices, cellular telephones and a range of other devices.
- *Software*, that is the suite of interrelated computer programs that allows a range of spatial data operations to be performed.
- A *database*, which may have been created for a particular purpose, but in many environmental applications will likely have been created to fulfil a range of purposes (generic data, such as framework data: Rhind, 1997).
- *Network* connection for rapid communication or information sharing – typically the Internet and/or the intranets of large organizations. In so-called client-server GIS, the network connects the user's hardware device (the client) to one or more servers of data and/or software.
- *People* who design, program and maintain the GIS, who supply it with data, and who interpret the results of GIS-based analysis.

Huge industries have developed around each of these component parts. The GIS data industry accounts for the greatest proportion of the estimated US$ 7 billion annual sales value of GIS (1999 prices), and is involved with the acquisition, creation, maintenance, dissemination and sale of GIS data. The GIS software industry directly employs several thousand programmers, software designers, systems analysts, application specialists, and sales staff. The provision of GIS hardware is part of the information technology mainstream, and also supports specialized vendors of geographically enabled devices such as global positioning system receivers. The innovation of the Internet also led to the development of the GIS service industry, in which businesses, agencies and the public are provided with remote access to data services in return for subscription and/or advertising revenues. Education in GIS is also a significant business in itself, and GIS is taught through thousands of university programs, through on-line programs (e.g., ESRI Inc.'s Virtual Campus at http://www.esri.com) and through in-service training.

Representative GIS applications in the environmental realm focus on topics such as the conservation of wildlife

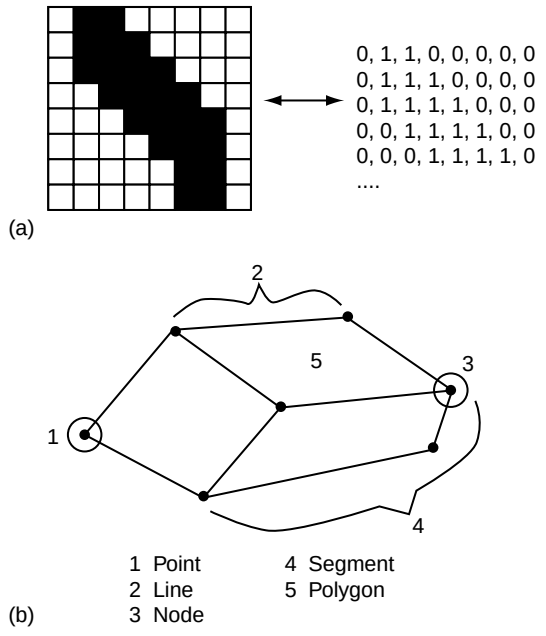

Figure 3 (a) The raster data structure comprises a regular grid of cells; while (b) the vector data structure comprises points, lines, nodes, segments and polygons

and biodiversity, planning and management of nature reserves, interpretation and protection of scenery, and management of relationships between different land uses (Aspinall, 1999). The integrative power of GIS allows the wider geographical context of designated sites to be considered, and approaches based on co-operation have replaced a focus on competition between land uses. This has been given immediate relevance by initiatives related to sustainable development and the maintenance of biodiversity. Sustainability also emphasizes the interdependence of human populations and environmental resources, and GIS is an important tool for evaluating the broad remit of wide-area conservation initiatives. GIS is also increasingly used as a decision support tool to monitor environmental change in real time (Larsen, 1999).

Geographic information systems are undoubtedly useful tools for measurement, modeling and analysis of global environmental change. Yet their usage also raises frustrating and profound questions, such as:

- how does a user know whether apparently significant results are robust and defensible?
- What is the most appropriate spatial and temporal scale for assessing change?
- What principles might help a GIS user to design better maps?
- How may representations of physical, environmental and social systems, and the interactions between them, best be integrated?
- How can user interfaces be made readily understandable by novice users?

Resolution of these questions is central to the developing field of *geographic information science* (GISc) (Goodchild, 1992). GISc studies the fundamental issues arising from the creation, handling, storage and use of geographic information, as a well-defined class of information in general. The related terms *geomatics*, *geoinformatics*, *geocomputation*, *spatial information science*, and *geoinformation engineering* all suggest similar scientific approaches to the fundamental issues raised by the use of GIS and related technologies.

Today's GIS is much more than a single piece of software residing on a single computer, and the practice of GIS has been revolutionized by the development of the Internet. Some applications, including those in the environmental realm, have been criticized for their ethically questionable motives, and it is important to remain cognizant that while any technology may appear neutral, it is always used in a social context. GIS remains a rapidly developing field, yet its core organizing principles, techniques and management practices will be much more enduring than the particular proprietary software systems that are used to put it into practice (see Longley *et al.*, 2001 for details).

GESAMP (Joint Group of Experts on the Scientific Aspects of Marine Environmental Protection)

GESAMP is an advisory body sponsored by the International Maritime Organization (IMO), the Food and Agriculture Organization (FAO), the United Nations Educational, Scientific and Cultural Organization (UNESCO) and its Intergovernmental Oceanographic Commission (IOC), the World Meteorological Organization (WMO), the World Health Organization (WHO), the International Atomic Energy Agency (IAEA), the United Nations (UN) and the United Nations Environment Programme (UNEP). Members of GESAMP are appointed by the sponsoring organizations and serve in their personal capacity. The activities of GESAMP fall into two broad categories:

1. preparation of periodic reviews on the state of the marine environment; and

2. evaluation of specific scientific issues relevant to the protection of the marine environment.

GESAMP has defined *marine pollution* as introduction by Man, directly or indirectly, of substances or energy into the marine environment (including estuaries) resulting in such deleterious effects as harm to living resources, hazards to human health, hindrance to maritime activities including fishing, impairment of quality for use of seawater and reduction of amenities. This definition provided the basis for a legal definition of marine pollution in most international conventions dealing with the protection of the oceans, including the United Nation Convention of the Law and Sea (UNCLOS). GESAMP actively participated in the preparatory process leading to the United Nations Conference on Environment and Development (UNCED).

Since it was established in 1969, 69 reports and studies have been published in GESAMP reports and studies series. In addition to two global assessments of the state of the marine environment (GESAMP, 2001a), studies published in the last decade include topics such as: review of nutrients as potentially harmful substances; evaluation of the hazards of harmful substances carried by ships; some aspects of pollution modification of atmospheric and oceanic processes and climate; atmospheric input of trace species to the world oceans; long-term consequences of low-level marine contamination; coastal modeling: global strategies for marine environmental protection (GESAMP, 1991); significance of carcinogens as marine pollutants; impact of oil, individual hydrocarbons and related chemicals on the marine environment; environmental consequences of anthropogenically discharged sediment to the coastal zone; guidelines for marine environmental assessment; biological indicators and their use; monitoring of ecological effects of coastal aquaculture wastes; invasion of the ctenophore *Mnemiopsis leidyi* in the Black Sea; sea-surface microlayer and its role in global change; contributions of science to integrated coastal management; patterns, threat and development of a strategy for conservation of marine biodiversity; hazard assessment of ships' cargoes; safe and effective use of chemicals in coastal aquaculture; and land-based sources and activities affecting the quality and uses of the marine environment (GESAMP, 2001b).

For further information see http://gesamp.imo.org/.

Global Environmental Change and Natural Disasters

Jim Bruce
Ottawa, Canada

Rapidly escalating disaster losses have been the most striking and disturbing consequence of global environmental change. Land use changes and increased exposure to the risks have undoubtedly played the major role, but there is also increasing evidence that intensity and frequency of extreme weather events in a changing climate are contributing to the rising disaster toll.

DISASTER LOSS DATA

The global increases in losses from great natural disasters are truly alarming. In the mid-1960s, losses averaged about $5 billion per year, rising until in the 1990s they were about $50 billion per year in constant dollars (an estimated $93 billion total loss in 1998) (Munich Re). These loss estimates are based on informed extrapolation of insured losses. During this period with a 10-fold increase in disaster loss, global economic production has increased three to four times and the global population has doubled. Thus, the gross global data on population and economic activity exposed to risks cannot begin to explain the increase in economic damages in disasters.

A very important factor, which has contributed to the increasing losses, has been the migration of populations to vulnerable regions, particularly the growth of large urban areas on the world's coasts and along river valleys and growth of squatter settlements near cities. Increasing wealth in many urban communities also has increased the exposure to risks. However, reinsurance industry spokesmen consider that these factors alone cannot account for the rising toll of losses. The Red Cross-Red Crescent Society's report on 1998 disasters also concluded that total losses exceeded $90 billion in 1998, that natural disasters and environmental problems were responsible for 58% of the world's refugees and that some of the increase is due to climate change.

SIGNIFICANCE OF DISASTER TYPES

It must also be recognized that while individual earthquakes and volcanic eruptions can cause significant loss of life and local devastation, e.g., Northridge, CA, 1994, Kobe, Japan, 1995, their global total impacts are far less than that for the more numerous weather or climate related disasters; i.e., storms, floods and droughts. The World Disaster Report of the International Federation of Red Cross and Red Crescent Societies (1996) provides global statistics from 1970 to 1994. Of the 138 000 people killed each year on average, 82% were due to climate/weather disasters; of five million made homeless on average per year, 93% were from floods, droughts and storms; and of the 124 million people affected, 98% suffered through climate-related disasters. The human impact of disasters falls very unevenly on regions of the world. Some 87% of those affected (1965–1992) were in Asia, and more than 90% of deaths were in Asia and Africa. Even on a *per capita* basis, disaster sufferers per unit of population in Asia are six times that of North America and 42 times that in Europe.

On the economic side, *Information Paper 4 for the World Conference on Natural Disaster Reduction, Yokohama,* May 1994, presented a compilation of information from a number of sources, particularly the Center for Research on Epidemiology of Disasters, University of Louvain, on events which were classified as *major* disasters. Major was defined as more than 1% of annual gross national product (GNP) of country(s) affected, more than 1% of population affected, or more than 100 deaths. For events from 1963–1992 causing significant damages (more than the 1% of GNP threshold) 84% were storms floods and droughts, 10% earthquakes and 6% other disasters (landslides, volcanoes, etc.) Thus, by all criteria, on a global basis, climate related disasters have caused and continue to cause by far the most damages, suffering and deaths. However, it must be recognized that for individual disasters, the average amount of direct economic loss is greatest for earthquakes.

Another significant outcome of the analyses provided at the Yokohama Conference was that the number of disasters from 1963–1992 causing significant economic losses has risen three to five times more rapidly for climate-related disasters than for earthquakes. Could this be due entirely to some preferential increase in exposure to the risks for storms, floods and droughts than for earthquakes? This seems unlikely to be the only factor at work since some of the world's most vulnerable coastal zones with population growth are susceptible to both geological and weather/climate disasters (e.g., Japan, USA (CA)).

LAND USE CHANGES

The relationship between floods and landslides and the removal of forests and other vegetation on the slopes of watersheds is well understood. Flood peaks and landslides are substantially increased by loss of vegetation on hillsides. This is especially true in smaller watersheds. In large basins, the effect of land-cover changes tends to be masked by many other factors.

In addition, the expansion of cities with accompanying increases in paved and roofed area results in higher runoff rates and greater floods in urban and suburban areas. For example, in one study in southern Ontario, the percentage of rain and snowmelt that runs off immediately, increased from 10 to 43% with urbanization of the watershed. Thus, with rapidly growing cities, human actions are undoubtedly increasing the percentage of rain or snowmelt that runs off quickly, causing floods.

In the case of droughts, studies in the Sahelian region and elsewhere have shown that while drought periods are caused by large-scale changes in the general circulation of the atmosphere, local actions can prolong the dry periods and make their effects more devastating. Removal of vegetation for firewood, or by grazing animals, changes the albedo of the land surface and the surface roughness, both leading to prolongation of dry weather and its adverse effects. Losses of vegetation can also reduce the penetration of water into the soil, accelerating runoff and leaving little flow for the dry season. It is evident then that human actions in affecting

land uses and vegetation are already having significant effects on severity of floods and droughts.

The growth of cities results in vegetation loss and soil changes in their area of urban sprawl, and large cities can cause devastation far beyond their boundaries. For example, urban demand for fuel wood often leads to clear-cutting of nearby forests that had served local populations for generations. To illustrate, Delhi, India, needs 612 tons of firewood per day, and much of this wood now comes from forests as far as 700 km away (Kreimer and Munasinghe, 1992).

CLIMATE FACTORS

Are climate extremes becoming more frequent and severe, to at least partially explain observed disaster trends? If so, are they likely to continue to increase?

Unfortunately, understanding is far from complete of the natural variability of the climate system or of changes in the frequency of extreme events due to increasing greenhouse gases and aerosols in the atmosphere from human activity. These are matters of active research.

Recent developments in that research tend to support the view that extreme events will increase with continued human induced greenhouse gas forcing of climate and have already begun to do so in some regions. Predictions of future climate are made with global mathematical models. Most recent models have interactive atmosphere–ocean–land surfaces. They are run with realistic assumptions of continued emissions of carbon dioxide and other greenhouse gases and take into account the regional cooling effects of aerosols (especially sulfate particles). It should be noted that commitments to emission limitations in the Kyoto Protocol (1997) to the United Nations Framework Convention on Climate Change, even if fully implemented, would only slow, to a modest extent, the rate of global increase of greenhouse gas emissions. A doubling of carbon dioxide (CO_2) equivalent from preindustrial levels would probably occur in the second half of the 21st century without more vigorous controls.

Such global change models (GCMs) have been used by research groups in a number of countries to project not just the evolution of the warming trends over the coming century, but in some cases changes in extremes. When the models project a change in frequency or intensity of some type of event, researchers then ask whether recent data, with greenhouse forcing to date, show trends consistent with the model projections. Among the most studied of these trends is that for heavy rainfall intensities.

HEAVY RAINFALL INTENSITIES

A number of different GCM model runs with a doubled CO_2 atmosphere have been examined to assess projections of future frequency of heavy rainfall events. A comparison of five such model results concluded that there would be a decrease in return period (i.e., increased frequency) of extreme short period (• 1 day) rainfall events in five regions studied. Similar results were reported from the CSIRO (Australian) GCM and the UK high resolution model, which showed a mean intensity increase of 10–30% at most latitudes, in a doubled CO_2 atmosphere, but with the heaviest 10% of rain events increasing by more than 50%. The Canadian Climate Model projects that 20-year return-period heavy rainfalls will on average become 10-year rainfalls over much of the world (Zweirs and Kharin, 1998).

In a number of studies, down-scaling of the grid size from the GCMs was achieved with limited area models nested within GCMs. Several of these, for Australia, the Central Plains of North America and the Indian monsoon region, other tropical land regions, and northern mid-latitudes, project greater frequencies of heavy one-day rainfalls. The Intergovernmental Panel on Climate Change (IPCC) summarized the situation in 1995 by saying With increasing greenhouse gas concentrations, many models suggest an increase in the probability of intense precipitation. This tends to confirm the earlier IPCC (1992) conclusion that a warmer climate will be one in which the hydrologic cycle will in general be more intense leading to more heavy rain events.

Among the regionally observed trends, well confirmed by long-term reliable data, are increases in the frequency of extreme rainfall events in USA, Japan and northern Australia, and the northwest coast of India. For example, Tom Karl of US National Climate Data Center and colleagues, reported in *Nature* (Karl *et al.*, 1995) that there was a highly significant (20%) increase over the USA in the summer season in the proportion of rain occurring in heavy rain days (• 50.8 mm) over the period 1911–1992. In another paper these authors showed that the proportion of the USA that has had a much greater than normal amount of precipitation in extremely heavy one-day events (• 50.8 mm) has steadily increased over the 20th century. They calculate that this latter result has a less than 1 in 1000 chance of occurring in a quasi-stationary climate and thus is very probably a manifestation of a changing climate. (Karl *et al.*, 1996) These analysts more recently found similar but less pronounced trends over shorter period records to 1996, for China and the former Soviet Union. Thus, trends in observed rainfall data are in several regions consistent with the model projections.

Increasing frequency of high intensity rainfall would result in more flash floods, more frequent overflow of storm drainage facilities, greater soil erosion and higher risk of landslides in unstable areas. These studies tend to support the conclusions of the Red Cross-Red Crescent Society

that a changing climate is contributing to the increases in disaster losses.

OTHER EXTREME CLIMATE EVENTS

Other studies have shown that the frequency of very intense winter storms in the Northern Hemisphere would increase with greenhouse forcing of climate and have done so since the 1970s (Lambert, 1996). Hail, lightning-set wildfires, and tornadoes all are related to warmer conditions in the atmosphere's surface layers, although other conditions must be present as well. Consistent data on these small-scale phenomena are extremely difficult to obtain for trend analyses. However, their frequencies correlate positively with observed higher surface temperatures, especially higher minimum temperatures at night, a phenomenon widely observed in the warming climate of recent decades.

TROPICAL CYCLONES

For tropical cyclones, no clear trends emerge from the data, nor are they projected by models for the future, except for trends related to the El Nino Southern Oscillation (ENSO) phenomenon.

Data from the World Meteorological Organization (WMO) yield no evidence of changes in frequency and intensity on a global basis. However, the frequency of North Atlantic hurricanes declined over the period 1970–1987 while those in the western Pacific increased. These changes are much more likely to be due to the relatively intense and persistent warm El Nino events of the past two decades, than due to greenhouse forcing of climate although these two may be related. ENSO events tend to depress Atlantic hurricane activity and change the distribution of tropical cyclones in the Pacific.

Modeled future tropical cyclone activity under human-induced climate change, is also ambiguous. A comprehensive analysis by Lighthill *et al.* (1994) suggests that present climate models are inadequate to address the problem. On physical grounds, however, it has been argued that while there will likely be little change in numbers or in average intensities of tropical cyclones, it is highly probable that there would be an increase in the intensity of the most severe cyclones (Emanuel, 1996).

ENSO PHENOMENA

Large scale floods and droughts are associated with naturally oscillating modes of the climate system, the El Nino, La Nina (ENSO) events of the equatorial Pacific Ocean, the North Atlantic Oscillation and its close relative the Arctic Oscillation. The most devastating flood and drought conditions in tropical and sub-tropical regions are associated with the ENSO events. Abnormally high sea surface temperatures off the equatorial coast of western South America (El Nino) or lower than normal temperatures (La Nina) both have profound effects on global circulation patterns, but with especially strong signals in subtropical and tropical zones. El Nino conditions are typically associated with storms and floods in western South America, droughts in northeast Brazil and much of the southwest Pacific, floods in parts of Africa and southern China and severe storms in California. La Nina conditions are not a complete mirror image of this pattern but are mostly the reverse.

El Nino events have been increasingly more persistent and intense over the past 80 years and especially the past 30 years. An important question is whether that trend is a natural one, or has been forced by increased surface heating due to greenhouse gas accumulations. Some scientists claim that recent trends to 1995, are part of an ENSO cycle of 100 years or so (Rajagopalan *et al.*, 1997). On the other hand modeling work at both the Princeton Geophysical Fluid Dynamics Laboratory (Knutson and Manabe, 1998) and the Max Planck Institute, Hamburg (Timmerman *et al.*, 1999) gives strong support to the theory that greenhouse forcing has influenced the observed trend. This research also indicates that as greenhouse gas concentrations due to human activities increase over the coming decades, El Nino-like conditions are likely to be more frequent and intense, but still interspersed with La Nina periods. This in turn means that alternating flood-drought cycles would increase in severity in much of the world. These findings are consistent with a growing view among climate researchers that climate change will be manifest mainly through increased intensity of the warm phases of the natural modes of variation of the climate system, rather than through just a steady rise in mean temperatures.

SEA LEVEL RISE

Added to these effects, mean sea level, which has risen 10–20 cm in the last century, is projected to increase two to five times as rapidly this century due to continued expansion of warming ocean waters and melting of glaciers (IPCC, 1995). This will further exacerbate flooding in estuaries and increase the effects of storm surges in low-lying coastal areas. Higher storm surges with tropical cyclones can have particularly devastating effects on many small island states, and countries such as Bangladesh.

SUMMARY

This review of statistics on disasters, land use changes and climate, and projections of future climatic extremes and sea level rise, leads to the following points:

- Global losses, both human and economic, in natural disasters, mostly climate-related, have risen rapidly in the past three decades.
- While increased populations and infrastructure exposed to the risk is likely the main cause, changes in land use and climate appear to have been contributing factors.
- With population growth, land use changes which increase ood and drought impacts will continue.
- Increases in heavy rainfalls in some regions and greater frequency of other severe climatic events have been observed, are consistent with model projections of climate change, and are likely to continue to increase.
- Observed increases in frequency and intensity of El Nino conditions will probably continue with accompanying ood and drought conditions over many regions.
- Observed and projected sea level rise adds to ood and coastal storm damages.

Ironically, as the International Decade for Natural Disaster Reduction (1990–1999) came to a close, disaster loss prevention measures were ever more urgently required. Reduction of the rates of land use and climate changes through adoption of more environmentally sustainable policies could assist in slowing the trend. Disaster loss mitigation measures as an adaptation response to climate change and variability, must receive increasing support.

Global Forest Watch

Dirk Bryant

World Resource Institute, Washington, DC, USA

*Global Forest Watch is an international data and mapping network, combining on-the-ground knowledge with the power of the Internet and advanced digital technology to provide accurate information about the world's forests to a global audience. Global Forest Watch is currently working with more than 75 partners around the world to document activities inside remaining intact forests (who is behind these activities, and how well these actors are abiding by national laws) - in effect, enforcing transparency on the global forest products industry. Global Forest Watch information is available in hardcopy, as well as through the Internet at www.globalforestwatch.org. Global Forest Watch is currently housed within the World Resources Institute (WRI), but will eventually become a separate non-government organization (NGO) (*see *WRI (World Resources Institute), Volume 4).*

CURRENT EVENTS

On February 29th, 2000, Global Forest Watch was officially launched at the National Press Club in Washington, DC. At this event the first three Global Forest Watch reports, *Canada's Forests at a Crossroads: an Assessment in the Year 2000*; *An Overview of Logging in Cameroon*; and *A First Look at Logging in Gabon,* were released as well as the Global Forest Watch Website (see Figure 1 for the Global Forest Watch logo).

As of January 2001, Global Forest Watch is working in 10 countries – Cameroon, Canada, Gabon, Indonesia, Chile, Romania, Russia, Venezuela, the US, and the Democratic Republic of Congo. The Global Forest Watch network of 75 partners represents NGOs, universities, and research groups. Supported by 12 WRI staff who provide Geographic Information Systems (GIS) mapping expertise and backstopping for day-to-day operations, Global Forest Watch works closely with scientists, governments, and industry to validate results through an extensive peer review process before they are published.

During 2001, Global Forest Watch reports will be published for Chile, Indonesia, Russia, and Venezuela with the goal of working in 21 countries over the next three years, covering some 75% of the world's remaining intact forests.

MARKET IMPACT

Recent endangered forest-free purchasing commitments by major US and European wood products companies – including Home Depot, IKEA, Lowes, and others – offer a huge potential to shift the timber industry out of the world's last intact natural forests. Activist groups are pursuing an innovative strategy to protect these areas by pressuring major wood users to stop sourcing from intact forests. This approach will help build demand for well-managed certified forest products, as supplies are squeezed within intact forest areas. Several of these companies have stated they will favor supplies certified by the Forest Stewardship Council (FSC) or equivalent wood suppliers. However, there is a huge shortfall of certified wood. In addition, several companies have committed themselves to purchasing only from those suppliers in compliance with environmental laws and regulations, which will help curb demand for illegally harvested wood. To assure the protection of intact forests, demand must be shifted from cut-and-run and illegal harvesting of these areas to sustainable, certified supplies, increasingly sourced from secondary and plantation forests.

Currently, no mechanisms exist for the implementation of these commitments. Until they are put into place, these commitments will remain empty promises.

Global Forest Watch, through its international network of partners, will provide the tools and information that companies need to turn these commitments into purchasing practices. Within the next three years, with Global Forest Watch information, corporate and other users will be able to track, for the first time, where wood products originate.

Figure 1 Global Forest Watch logo

AUDIENCE AND PRODUCTS

Global Forest Watch's audience includes policy makers, corporations, civil society, and consumers. While Global Forest Watch will publish hardcopy reports documenting forest development in countries throughout the world, many products will be web-based and available through the Global Forest Watch Website. Products will include interactive and static maps, and a searchable database that will allow users to determine the name of a company that is operating in any given forest logging concession area.

GOVERNANCE STRUCTURE

Global Forest Watch is governed by an international steering committee that includes one representative per country, the Global Forest Watch director, and one representative from WRI. The steering committee provides overall guidance on Global Forest Watch's direction. The Global Forest Foundation is a separate organization, serving as a funding entity and a visionary body for Global Forest Watch.

DEVELOPMENT

Global Forest Watch grew out of WRI's 1997 publication, *The Last Frontier Forests: Ecosystems and Economies on the Edge* (Bryant *et al.*, 1997). This publication, conducted in consultation with 90 forest experts from around the world, found that only 20% of the forests that once covered the earth remain as large tracts of intact natural (frontier) forest. These areas provide islands of habitat for ora and fauna, key life support functions critical to human survival (such as storing vast amounts of

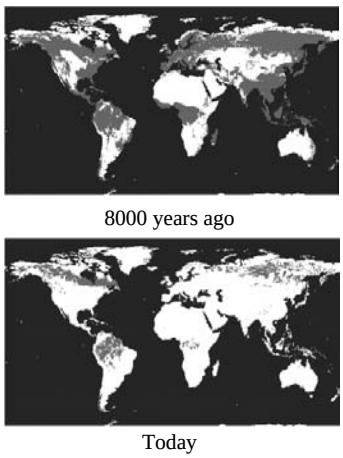

Figure 2 Frontier forest image

carbon (C) to offset the threat of global warming), and are home to the world's traditional indigenous forest peoples. However, outside of far-northern regions, three-quarters of this remaining frontier forest is threatened, and will likely be cleared or degraded in the next 10–20 years at current rates of exploitation. Unsustainable logging practices pose the primary threat to these forests. In tropical countries, much of the timber is harvested illegally (the Brazilian government estimates over 80% of logging in the Amazon Basin is illegal). In Canada and other northern countries, the remaining forest is being clear-cut to feed demands for wood products (Canada – the world's largest wood exporter – harvests 90% of its timber from old growth and primary forests) (see Figure 2).

The analysis for *The Last Frontier Forests* publication was conducted at a coarse scale (1 : 8 000 000) which provided a global perspective of the issue, but was far too coarse for far-reaching discussions about which areas within a country are under threat, and which should be off limits for development. Through this work, however, WRI became acquainted with organizations around the world that were working on forest issues in their countries. At the same time, technologies, such as satellite imagery and GIS mapping, became more available and useful for documenting development activities within forests. Coupled with an expressed interest on behalf of other environmental organizations, corporations and scientists, has led WRI to pursue its mapping to a finer scale, resulting in the creation of Global Forest Watch.

Goldemberg, Jose

(1928-)

Professor Goldemberg had a very uncommon evolution of his career, from purely academic research in experimental nuclear physics to general science to involvement in public affairs and then to administration. The highlight of his career was his efforts to improve support for science activities and the protection of human rights of scientists in Brazil during the period of military government (1964–1984). The future role of nuclear energy in Brazil marked his transition toward a growing interest in energy alternatives and renewables. His management skills were harnessed when he acted as the rector of the University of Sao Paulo and then as a cabinet member in the federal government. He played a very significant role in defusing the nuclear race between Argentina and Brazil.

His grandparents arrived in Brazil at the turn of the century and settled in a small town. In 1935 they moved to Porto Alegre, where public educational facilities were better. He attended a good public high school established in the previous century. The school's approach combined a strong belief in rationalism with hierarchy. There, he developed a craving to find the ultimate causes of the events around us and to understand the structure of matter.

Professor Goldemberg graduated with a Bachelor of Sciences from the Universidade de Sao Paulo, carried out graduate work at the Physics Department, University of Saskatchewan, Canada and the Physics Department, University of Illinois, USA and got his PhD in Physical Sciences from the Universidade de Sao Paulo (1954). He served as Assistant Professor, University of Toronto, Canada, and Professor of Physics, and Director of the Institute of Physics at Universidade de Sao Paulo. He served also as Associate Professor at the University of Paris

(Orsay) (1964); Senior Research Associate (1977–1982) and Visiting Professor (1993–1994) Princeton University, USA; Visiting Professor at the International Academy of the Environment, Geneva, Switzerland (1995) and President of the Brazilian Association for the Advancement of Science (1979–1981).

He received the DSc Honoris Causa from the TECHNION, Israel Institute of Technology (1991); was co-winner of the Mitchell Prize for Sustainable Development, USA (1991); he established the José Goldemberg Chair in Atmospheric Physics at Tel Aviv University in 1994. He is a member of the Brazilian Academy of Sciences and the Third World Academy of Sciences. He is the author of many technical papers and books on nuclear physics, the environment and energy in general.

His best known publications of include: *Energy for a Sustainable World*; *Energy for a Developing World*; *How to Stop Global Warming*; *Energy Needs in Developing Countries and Sustainability*; *Energy, Environment and Development*.

MOSTAFA K TOLBA *Egypt*

Goldman Prize

see International Environmental Prizes (**Volume 4**)

Goodman, Gordon

Professor Gordon Goodman has been active internationally in the fields of environment and development since the early 1960s, initially as a scientific researcher and later as the developer of environment/development institutions. In the 1960s, when he was general secretary of the British Ecological Society, he founded its Industrial Ecology Group, with an international membership, and helped to pioneer the application of ecology to the management of urban industrial environments. Under the auspices of the Scientific Committee on Problems of the Environment (SCOPE), which he helped to establish, he was the senior author and editor of a technical report for the United Nations (UN) Conference on the Human Environment: which was accepted by governments as the basis for the first Global Environmental Monitoring System (GEMS).

As Professor of Applied Biology in the University of London, Gordon Goodman was a member of UK Government environment committees on air pollution, water pollution, waste management, and environmental health. He was the founding director of the international Monitoring and Assessment Research Center (MARC) at the University of London, designed to support the UN Environment Program's Global Environment Monitoring System. He was invited to Sweden to establish the Beijer Institute (Royal Swedish Academy of Science) an international institute for energy, resources, and the human environment. Subsequently he was invited by the Government of Sweden to establish the Stockholm Environment Institute as its founding executive director and later, the chairman of its international board.

Professor Goodman has acted as an adviser on polluted land reclamation for local government and the private sector. He has also advised governments, the UN Specialized Agencies (United Nations Educational, Scientific and Cultural Organization (UNESCO), World Health Organization and World Meteorological Organization), the 1972 Stockholm Conference, the 1987 Brundtland Report, and as special scientific adviser, the 1992 Rio Conference' Preparatory Group, on problems of energy, environment and development.

His research interests include food-web chemistry (atmosphere-soil-plant-animal transfers and ecotoxicology) of environmental degradation and reclamation (techniques for restoring grass and trees to heavy-metal contaminated land in the Lower Swansea Valley, developing a moss-bag technique for the quantitative monitoring of atmospheric heavy-metal pollution in South Wales), energy risk management, global warming/climate change, and energy/resource problems of developing countries. He has authored or edited several books and written numerous scientific and technical papers on these subjects. He played an important role in developing and establishing the Rockefeller Foundation's Leadership for Environment and Development (LEAD) in 12 countries/regions worldwide and was responsible for producing its training curriculum (*see* LEAD (Leadership for Environment and Development), Volume 4). He was also the inaugural president of the International Service for the Acquisition of Agri-Biotech Applications (ISAAA) devoted to agricultural biotechnology training and genetically modified (GM) crop studies in developing countries.

Professor Goodman currently sits on the panel for the Volvo Environment Prize and is a member of the Earth Council. He is a foreign member of the Royal Swedish

Academy of Sciences (RSAS). His honors include the Older Linnaean Gold Medal of this Academy, honorary doctorates in science from the University of York, UK and Clark University, US, and Commander (First Class) of the Swedish Royal Order of the Polar Star.

Green Investment

Rory O'Brien
University of Toronto, Toronto, Canada

*Green investment refers to an economic investment strategy in which investors make corporate environmental performance the major focus in their role as shareholders in a company. Though the term is often used interchangeably with socially responsible, or ethical, investment, green investment is in effect a sub-set of it, with a speci c emphasis on investment that has mainly environmental, as opposed to social, consequences (*see *Socially Responsible Investment, Volume 4).*

Research has shown that environmentally responsible companies tend to perform better nancially than their industry peers. As a result, green investment has been growing rapidly in the last 10 years. Through the use of screening criteria, stock is purchased or sold by investors in order to push companies toward more sustainable business practices. Increasing numbers of investors are also promoting corporate change through the use of shareholder activism. A key factor in investor empowerment is standardizing and disclosing corporate performance measurements.

CORPORATE ENVIRONMENTAL BEHAVIOR AND FINANCIAL PERFORMANCE

In 1999 the Dow Jones sustainability group index (DJSGI) launched the first global stock index intended to track the performance of 200 major companies selected on the basis of high measures of environmental, social and economic sustainability. Using data on company stock price between 1994 and 2000, the DJSGI showed a small but significant out-performance of the larger Dow Jones global index (DJGI), comprised of 2000 companies throughout the world.

The DJSGI results support research done in the past decade on the relationship between a company's environmental performance and share price. Most studies have shown either a positive correlation between superior environmental management and the price of stock, or at the very least, a neutral effect, thereby putting to rest the unsubstantiated but persistent belief that investors had to accept a lower rate of return on their social investments.

This fact has not gone unnoticed by individual investors, who have been rapidly pouring money into hundreds of newly created socially responsible mutual funds and unit trusts. Of these, many are green funds, with a focus primarily on the environment. Social and environmental funds have recently proven to be strong performers – in the United States, for example, a significantly larger percentage of them was given higher ratings by three major investment tracking agencies than the rest of the mutual fund industry for the period between 1997 and 2000. These institutions, like other green investors, use social and environmental screens in their stock selection as well as screens based on financial performance.

GREEN SCREENS

In 1999, $1.2 trillion, or four-fifths of the $1.5 trillion in the United States estimated to be invested using socially responsible screening criteria, was subject to green environmental screens. In some instances, investors screen out entire industries perceived to be detrimental to the environment, such as the nuclear industry. In many cases, however, a best-of-sector approach is taken, wherein top performers in an industry, those that are exemplary in their environmental practices, are rewarded with investors' money. Green screens promote investing on the basis of positive corporate performance and deter investment in negatively performing cases.

Examples of positive screens include, among others, having enhanced pollution prevention policies and programs, environmentally friendly products and services, energy efficiency programs and alternative energy sources, and re-use and recycling of materials in operations.

Negative screening criteria include such things as repeated violations of environmental laws and regulations, hazardous waste production, nuclear energy, production of ozone depleting substances, excessive emissions of greenhouse gases, and unsustainable practices in resource industries such as deforestation and over-fishing.

A handful of firms such as Ethical Investment Research Service (EIRIS) in the UK, Investor Responsibility Research Center (IRRC) and Kinder Lydenburg and Domini (KLD) in the US, and Michael Jantzi Research Associates (MJRA) in Canada track the social and environmental activities of companies on the basis of screening criteria, maintaining extensive databases on hundreds of publicly traded corporations. Their clients include institutional investors and investment management firms, particularly those who do not maintain in-house research expertise in this area.

SHAREHOLDER ACTIVISM

Not all green investors will sell their shares in a company that is found to be harming the environment. An increasing number are becoming shareholder activists, seeking to engage corporate directors in dialogue and raise awareness of issues. In many cases, such low-key pressure, particularly from larger institutional investors such as pension funds, is sufficient to create change. In cases where corporate leaders are not amenable to such an approach, the more public route of formal submission of a shareholder resolution at the company annual general meeting is the only viable alternative. Such resolutions are growing in number, especially as environmental advocacy groups become increasingly aware of this tactic. In 1999, the environment was the most common category of shareholder proposal in the US. In the UK and Canada, however, such resolutions remain relatively rare, as the legal framework in those countries makes it much more difficult to circulate social or environmental resolutions to shareholders.

CORPORATE ENVIRONMENTAL REPORTING

To adequately evaluate corporate behaviour, green investors must have detailed and reliable sources of information. Government regulation has greatly contributed to the amount of public disclosure of corporate activities, with strict reporting on such things as toxic waste production or pollution emissions providing a basis for judging environmental performance. More progressive companies have gone beyond what is legally required and have adopted even higher standards.

Among green investors, one of the more highly regarded sets of standards is known as the Coalition for Environmentally Responsible Economies (CERES) Principles. Created in the aftermath of the disastrous Exxon Valdez oil spill in 1989, the CERES Principles were developed by a coalition of major US environmental groups and socially responsible investors, including several large public pension funds, in order to provide business with guidance on sound environmental practices. The principles, which have been endorsed by over 50 companies, among them several large multinational corporations, are as follows:

- protection of the biosphere;
- sustainable use of natural resources;
- reduction and safe disposal of wastes;
- energy conservation;
- risk reduction to employees and communities;
- safe products and services;
- environmental restoration;
- informing the public about harmful actions;
- management commitment to these principles;
- audits and reports on environmental practices made public.

A related joint initiative of the CERES coalition and the United Nations Environment Programme (UNEP) that is gaining acceptance worldwide is the global reporting initiative (GRI). The GRI is promoting the use of Sustainability Reporting Guidelines, which are intended to act as comprehensive standards for corporate environmental reporting. Universal deployment will greatly aid investors in evaluating and comparing companies on social and environmental, as well as financial, grounds.

The ISO 14000 family of standards from the International Organization for Standardization is another useful tool. In continuous development throughout the 1990s, these standards were designed to help improve a company's environmental management system, providing guidelines for monitoring, evaluating and communicating corporate environmental performance. The ISO and GRI should be of particular help to management in presenting environmental audit reports to shareholders.

Green investment grew rapidly throughout the latter half of the 1990s, and has shown itself to be both a cause and result of trends toward improved corporate environmental practices and increased public awareness of environmental issues. As more firms and investors become cognizant of the linkage between greener operations and higher share prices, we should see an increase in green investments, fueled in no small measure by enhanced corporate environmental reporting.

GRID (Global Resource Information Database, of the United Nations Environment Programme (UNEP) Division of Early Warning and Assessment)

UNEP, as the environmental voice of the United Nations, analyzes the state of the global environment, assesses global and regional trends, and provides early-warning information on environmental threats and policy advice based on the best scientific and technological capabilities available. As part of this mandate, UNEP maintains a network of cooperating centers around the world to provide environmental data and information to enhance the scientific basis for decision-making.

GRID is a system of cooperating centers within UNEP that is dedicated to making environmental information more readily accessible to environmental analysts as well as international and national decision makers. Its mission is to provide timely and reliable geo-referenced environmental information and access to a unique international data service to help address environmental issues at global, regional and national levels in order to bridge the gap between scientific understanding of earth processes and sound management of the environment.

There are 15 GRID centers around the world, some with regional focus and others having a thematic focus. GRID centers have an active program dealing with the integration and analysis of data sets from multiple sources to derive policy relevant information about such pressing issues as the status of the world's freshwater, the loss of biodiversity, changes in land cover and population–environment interactions. Some recent activities include:

- catalyzing the development of global data sets related to land cover, river basin boundaries, topography and population distribution;
- monitoring environmental hot spots around the world using satellite data;
- early warning of emerging environmental threats in Africa;
- assessing risks and threats to human health associated with the degradation of ecosystems;
- assessing the status of the world's remaining closed forests;
- responding to environmental emergencies;
- assessing environmental vulnerability;
- assessing river basins in an integrated manner;
- developing an Internet-based project tracking and mapping system;
- the World Atlas of Desertification;
- the African Elephant Database;
- vector-borne diseases in Africa;
- assessing impacts of climate change.

Following is the list of the GRID network of centers:

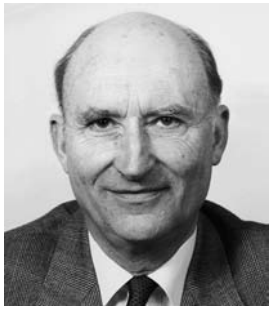
Holdgate, Martin



(1931-)

Sir Martin Wyatt Holdgate, CB, PhD, Fl Biol, was born on 14 January 1931, graduated from the University of Cambridge in 1952 with a 1st Class Honors BA in Natural Sciences, followed by an MA and PhD in Insect Physiology in 1955. The years 1955–1966 were spent as a research fellow, Queens College, Cambridge (1955–1956), lecturer in Zoology, Manchester University (1956–1957), lecturer in Zoology, Durham University (1957–1960), assistant director of Research, Scott Polar Research Institute, University of Cambridge (1960–1963) and chief biologist, British Antarctic Survey (1963–1966). These formative years of teaching and research provided Dr Martin Holdgate with scholarly experiences in biology, ecology of Tristan da Cunha Islands and the southernmost parts of Chile, and the biogeography of the Antarctic and Sub-Antarctic (maritime) regions, and a worldwide perception of the global environment.

During the 22 years (1966–1988) he combined and maintained the functions of a chief scientist at home and a chief architect of international endeavors in several environmental fields. At home he was deputy director (research), of the Nature Conservancy (1966–1970); director, of the Central Unit on Environmental Pollution, Department of Environment (1970–1974); director of the Institute of Terrestrial Ecology (1974–1976); director general of research and deputy secretary of the Department of Environment (1976–1981) and chief environment scientist for the Departments of Environment and of Transport (1981–1988). At the international level Dr Holdgate was a leading member of the International Council for Science (ICSU) Scientific Committee on Antarctic Research (SCAR), convened the Second SCAR Symposium on Antarctic Biology (1969) and edited its proceedings. He coordinated international programs of biological research by nations active in Antarctica and drafted the *Agreed Measures for Conservation of Antarctic Fauna and Flora* (adopted in 1974). He was also a member of the Scientific Committee for the International Biological Programme (IBP, 1964–1970), an active member of the ICSU Scientific Committee on Problems of the Environment (SCOPE) and joint author of its first global review (*Environmental Issues, SCOPE 10, 1977*). He led UK delegations to numerous international meetings preparatory to the UN Conference on Human Environment (1972), and to the Governing Council of the United Nations Environment Programme (UNEP).

Between 1983–1984 he was president of the council and part-author and joint editor of the two UNEP comprehensive reports on the state of the global environment (1982 and 1992). Between 1993 and 1996 he was a member and rapporteur of the UN Advisory Board on Sustainable Development.

From 1988 to 1994 he held the post of Director General of the World Conservation Union (IUCN), the world's largest association of states, government agencies and non-governmental organizations concerned with conservation and sustainable use of natural resources. During these years at the helm of this in uential institution, he was the principal administrator and the principal scientist, a combination very rarely attained. When he retired from this international commission he was recognized with special honor at home, being knighted. His post-retirement activities include: chairman of the UK Government Energy Advisory Panel (1993–1998), co-chairman of the UN Intergovernmental Panel on Forests (1995–1997), member of the UN Task Force on Environment and Human Settlements and president of the Zoological Society of London.

Sir Martin Holdgate is the author, co-author and/or editor of some 10 books and numerous research papers.

IAI (Inter-American Institute for Global Change Research)

The IAI was created through an intergovernmental agreement signed by 16 nations of the Americas in May 1992, in Montevideo, Uruguay. Its mission is to augment the scientific capacity of the region, to better understand global change phenomena and their socio-economic implications, and to promote the dissemination of the emerging information. The Institute pursues the principles of scientific excellence, international cooperation, and the full and open exchange of scientific information relevant to global change.

To function as a regional entity and to conduct research that no one nation can undertake on its own, the IAI was designed as a network of research institutions collaborating to implement the Science Agenda (Figure 1). The IAI is governed by the Conference of the Parties, currently composed of 18 countries, which meets every year. Between conferences, the IAI's activities are directed by an Executive Council and managed by an Executive Director, whose office is located at 1758, Avenida dos Astronautas, Sao José dos Campos, SP, 12227-010, Brasil (Fax: • 55-12-341-4410, E-mail: iaibr@dir.iai.int). A Scientific Advisory Committee of 10 scientists makes recommendations regarding the Science Agenda, develops long-term plans and assesses the scientific results obtained by the Institute. The Science Agenda includes four broad themes: (1) understanding climate variability in the Americas; (2) comparative studies of ecosystems, biodiversity, land use, and water resources; (3) changes in the composition of the atmosphere, oceans and fresh waters; (4) integrated assessments, human dimensions and applications.

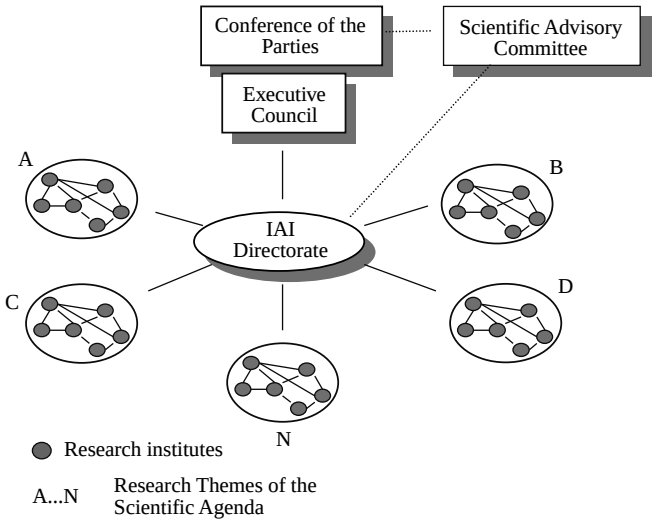

Figure 1 IAI, multinational distributed network of research institutions

IAI's strategy to implement global change research involves a three-step mechanism: (1) funding planning activities through start-up grants, specifically designed to encourage investigators to begin collaboration on proposals for long-term projects that will serve as the core for future research networks; (2) augmenting on-going activities in research, training and education, and data and information collection through initial science programs of up to 3 years duration, involving institutions from three or more member countries; (3) implementing collaborative research networks around themes of the Science Agenda by supporting up to 5-year projects involving institutions from at least four member countries. Proposals are selected based on: (1) their scientific excellence; (2) their multinational/multidisciplinary structure, and (3) the relevance of the research to on-going or future policy actions. Information emerging from IAI's research is published in scientific journals and/or presented in scientific meetings and symposia. An updated list of these publications can be found in the IAI homepage (http://www.iai.int). An IAI newsletter is also published quarterly at the Departamento de Ciencias de la Atmosfera, UBA, Pabellon II, 2do piso, Ciudad Universitaria, 1428 Buenos Aires, Argentina (Fax: • 54-11-4576-3356, E-mail: iainews@at.fcen.uba.ar).

The IAI also has a Summer Training Institute on Interdisciplinary Global Change Science located at the University of Miami, USA (e-mail: http://www.rsmas.miami.edu/IAIUM). The Institute activities are organized each year around a regionally important global change theme of

societal relevance and involve the participation of 20–25 early-career natural and social scientists of the Americas. The IAI has signed and implemented several cooperation agreements with regional and international organizations linked to global change and with National Councils for Research and Technology of IAI member countries.

ICSU (International Council for Science)

The ICSU is a non-governmental organization, founded in 1931 to bring together natural scientists in international scientific endeavor. ICSU has recently (April, 1998) changed its name from International Council of Scientific Unions to International Council for Science , although the acronym ICSU remains unchanged. [Throughout this encyclopedia, the term International Council for Science will be used.] Its national membership comprises 98 multidisciplinary bodies (scientific research councils or science academies) and 26 international single-discipline scientific unions, to provide a wide spectrum of scientific expertise, enabling members to address major international interdisciplinary issues which none could handle alone (ICSU also has 28 scientific associates).

The council seeks to break the barriers of specialization by initiating and coordinating major international interdisciplinary programs, and by creating interdisciplinary bodies which undertake activities and research programs of interest to several members. A number of bodies set up within ICSU also address matters of common concern to all scientists such as capacity building in science, environment and development and the freedom in the conduct of science.

The council acts as a focus for the exchange of ideas and information and the development of standards. Hundreds of congresses, symposia and other scientific meetings are organized each year around the world, and a wide range of newsletters, handbooks and journals are published.

The principal source of ICSU's finances is the contributions it receives from its members. Other sources of income are the framework contracts from the United Nations Educational, Scientific, and Cultural Organization (UNESCO), and grants and contracts from other United Nations bodies, foundations and agencies, which are used to support the scientific activities of the ICSU unions and interdisciplinary bodies. The total budget of the whole ICSU family amounts to over US$ 15 000 000 a year. One of ICSU's greatest strengths, however, is the time contributed freely by the thousands of scientists committed to the objectives of the ICSU.

The ICSU headquarters is located in Paris, France (51 Blvd de Montmorency, Paris 75016, Secretariat@icsu.org).

R E MUNN *Canada*

IDNDR (The International Decade for Natural Disaster Reduction)

In the late 1980s, the United Nations General Assembly (UNGA) was becoming increasingly alarmed about rapidly increasing human and economic impacts of natural disasters. There was also a growing awareness that much could be done to reduce losses and suffering through preventative measures (e.g., strengthened buildings, land use planning to avoid vulnerable areas), and through warning and preparedness systems. Dr Frank Press of the US National Academy of Sciences proposed that a decade be declared, to more fully use scientific and engineering knowledge to reduce losses worldwide. In 1989 the UNGA adopted a resolution declaring the 1990s the IDNDR. The word loss should have been present between disaster and reduction to avoid future confusion, but it would have made the designation even longer than IDNDR.

By some measures, the IDNDR was a failure. Disaster losses increased throughout the Decade. Economic losses have increased some 10 times between the 1960s and the

late 1990s. However, loss of life, in the industrialized world did not increase, probably due to improved warning and preparedness systems during the Decade. Numbers of people affected averaged more than 130 million per year between 1971 and 1996. The Red Cross–Red Crescent Society reported that 1998 global losses exceeded $90 billion and that 58% of refugees in the year were due to environmental and natural disasters. The experience of disaster loss increases is attributable to population increases, increased vulnerability due to occupation of hazardous areas, increased infrastructure at risk, land use change and climate changes (*see* Global Environmental Change and Natural Disasters, Volume 4).

On the other hand, it may be useful to examine whether during the 1990s decade, some mechanisms were put in place that could limit future losses.

In the UNGA Resolution of 1989, a Scientific and Technical Committee (STC) was called for, as well as a Secretariat. All costs were to be supported by voluntary contributions mainly from United Nations (UN) member countries. From the beginning, the UN lodged the secretariat in a succession of agencies responsible mainly for relief and response rather than those that would be concerned with prevention as a measure towards sustainable economic development. This, in part, led to lack of resource commitment by those UN agencies that housed' the secretariat and a general unwillingness on the part of donor countries to make the expected substantial contributions. Some key countries, especially Japan and Germany, UK and Nordic countries, made modest contributions.

The STC in the early part of the decade defined three main targets to guide efforts and as a means of assessing progress. They called for each country to complete by 2000:

1. a comprehensive risk assessment;
2. mitigation measures addressing the risks built into sustainable development planning;
3. access to global, regional and local warnings, and preparedness systems in place.

In addition the STC, which met at least annually, and the secretariat put strong emphasis on establishing national committees or key focal points in each country to achieve these targets; these were formed in more than 100 countries. A major successful effort in securing political commitment for disaster loss prevention was through the 1994 UN World Conference on Natural Disaster Reduction, Yokohama, Japan. The scientific community, mobilized mainly by the World Meteorological Organization, UN Educational, Scientific and Cultural Organization and the non-governmental International Council for Science, undertook many valuable decade projects to develop new capabilities and to apply existing knowledge to disaster loss mitigation.

At the IDNDR Programme Forum, Geneva, July 1999, many countries, international and regional organizations presented success stories. Measured against the targets, how much progress was made?

1. Risk is a product of two factors, probability of the hazard, and vulnerability to the hazard. *Hazard assessment* for all types of natural hazards, climatic, hydrologic and geological, was carried out effectively in many countries, and regionally in several cases (e.g., North America, Mexico, USA and Canada). However, *vulnerability assessment* proved much more difficult with adequate techniques still under development.
2. Mitigation, or pre-disaster preventive and preparedness actions, increased. For example, USA is now committed to provide 15% of disaster loss payouts to such actions. Some other countries have undertaken similar steps. The UN Development Programme and World Bank both established units with a disaster loss prevention responsibility.
3. Warning and preparedness systems were established or strengthened for cyclones in the SW Pacific region, SW Indian Ocean and the Caribbean and for 10 volcanoes. Warnings of eruption of Mt Pinatubo in the Philippines saved many lives.

In addition, the countries of the world signed several important Conventions during the 1990s which when implemented, will reduce disaster losses. These include:

1. The UN Framework Convention on Climate Change which, in requiring adaptation to climate extremes, could address the majority of disaster losses;
2. The Convention on Biological Diversity which in protecting forests and coral reef ecosystems, will also reduce disaster impacts, and;
3. The Convention on Desertification and Drought to help reverse drought disaster impacts especially in Africa.

Thus, for the new millennium, there have been put in place during the IDNDR, at least partly due to the Decade, a number of mechanisms that should assist in reducing natural disaster impacts. At the same time, it must be recognized that human populations and megacities are likely to continue to become more vulnerable (currently an estimated one billion people live in temporary towns at the outskirts of cities). Hazards are likely to continue to increase due to global changes. It will be a major challenge to minimize human and economic losses in future; vigorous efforts are increasingly needed in the post-Decade era.

JIM BRUCE *Canada*

IDWSSD (International Drinking Water Supply and Sanitation Decade)

The Water Decade, officially called the IDWSSD, was conceived during the United Nations Water Conference at Mar del Plata in 1977, and was launched at the United Nations General Assembly in New York during November 1980, at the recommendation of the World Health Organization (WHO). The basic goal of the Water Decade was safe water and sanitation for all. This was an ambitious goal, even if the most basic services for safe water and sanitation were to be provided. In 1980, less than 30% of people in rural areas of developing countries had access to safe potable water supplies (Traoré, 1992, 3.9). In contrast, in urban areas the comparable number was just under 80%. For sanitation facilities, some 35% of rural people and 66% of urban people were satisfactorily serviced. As a result of this situation, the WHO had estimated that diarrhea was causing the death of six million children each year, and that parasitic worms infected nearly 50% of the entire population of developing countries (Traoré, 1992, 3.7).

While these figures indicated that the need to improve drinking water supplies and sanitation was a huge task, they did not reveal the even greater disparities existing in the least developed nations, or the needs of the poorest people in such countries. On a regional basis, the need was greatest for the rural people in countries of Western Asia, where, on average, only 22% of the population was serviced, and in Africa south of the Sahara where 23% of the rural population had access to water supply services. For Africa as a whole, 30% of the people had access to safe water. Regarding sanitation, the poorest levels of service occurred in Southeast Asia and in the eastern Mediterranean region. These patterns indicated that, in 1980, about 1.65 billion rural people at a global scale did not have access to a safe water supply, and about 1.47 billion did not have access to safe sanitation for disposal of human wastes.

The overriding motivation of the Water Decade was to improve health and therefore overall living standards. Indeed, Barbara Ward had stated that the number of drinking water standpipes per person was perhaps the best indicator of quality of life of rural people in developing countries. For her, provision of safe potable water and sanitation facilities was the one initiative which could have the greatest impact at a global scale to improve overall well being. By the end of the Water Decade, significant progress had been made, with 60% more people having access to a safe water supply source compared to the 1970s, and 140% more having access to satisfactory sanitation. In absolute terms, these percentages translate into over 1.5 billion additional people being provided with safe water supplies and 750 million people receiving access to safe sanitation facilities during the 1980s. However, despite these improvements, over one billion people were still without safe water supply and nearly 1.8 billion people did not have adequate sanitation at the end of the water decade (World Health Organization, 1991).

The main explanation for the shortfall was that during the 1980s the global population increased by about 750 million people. As a result, in many regions of the world, but especially in rural areas of developing countries, basic human needs for water use were not being satisfactorily met by the end of the Water Decade. Prospects for the future are not encouraging. For example, population projections at the beginning of the 1990s showed that in the following decade the global population was expected to increase by almost 900 million people. By late 1999, the human population on the Earth had been officially documented by the United Nations as having reached six billion people.

IFIAS (International Federation of Institutes for Advanced Study)

IFIAS is an international grouping of leading research institutes, originally established in 1972 on the initiatives of the Rockefeller and Nobel Foundations. It was part of a ourishing of innovative institutions in that period, which included international think tanks, new cooperative ventures in the sciences and social sciences, as well as various institutes for advanced study. IFIAS was designed to pool the resources of the international scientific research community to examine long-term, cross-disciplinary, and controversial issues.

Originally situated in Sweden, IFIAS moved its headquarters to Toronto, Canada in 1986, and is currently hosted by the Institute for Environmental Studies, University of

Toronto. At various periods in its history, it has had offices in Washington, DC and Maastricht, in the Netherlands. Its membership has ranged from 20–40 institutes at various times, covering a wide range of advanced research in everything from ekistics (i.e., the study of building form), to coastal waters management.

Because of its mandate, IFIAS has often been at the forefront of identifying issues that have subsequently become more widely appreciated. In the 1970s, IFIAS worked on early climate change research (contributing to the basic work of the World Climate Programme); energy and self-reliant development at the local village level in developing countries; hazards research including the dynamics of drought; biotechnology; and Islam and the West. IFIAS also took a lead in a number of large-scale international probes, such as the Analyzing Biospheric Change program, initiated in 1981, which examined a whole range of rapid changes, including urbanization, agricultural degradation, and coastal waters pollution. Project Ecoville, in particular, was a path-breaking attempt to apply systems thinking to rapid urbanization around the world.

In the late 1980s and 1990s, IFIAS was one of the originating partners in the founding of the International Human Dimensions of Global Change Programme (HDGCP) along with the International Social Science Council, the United Nations University, and the United Nations Educational, Scientific and Cultural Organization. This was designed to be a social science complement to the International Geosphere–Biosphere Programme; and the HDGCP has undergone various transformations and name changes since that period – now the International Human Dimensions Programme.

As with many other international collaborative scientific institutions, IFIAS has struggled to maintain its activities and presence in an era of cutbacks and the loss of the initial visionary impetus that accompanied the founding of so many innovative networks in the 1960s and 1970s. In spite of this, IFIAS's more recent activities and initiatives have included work on technological change and innovation, an international coastal cities initiative (a project of the Institute for Environmental Studies at the University of Toronto); the Gender, Science, and Development Programme which contributed significantly to the Beijing Women's Conference; and continuing work on the future of international science.

The history of IFIAS can be studied in two works: Stahle *et al.* (1988) and Timmerman (1999). Further information concerning IFIAS can be obtained from http://www.ifias.ca.

IHDP (International Human Dimensions Programme on Global Change)

The IHDP is an international, interdisciplinary. social science program to promote and coordinate research aimed at describing, analyzing and understanding the human dimensions of global environmental change (GEC), i.e., the way people and societies (a) contribute to GEC; (b) are in u-enced by GEC; and (c) mitigate and adapt to GEC.

In 1996, the International Social Science Council was joined by the International Council for Science as co-sponsors of the IHDP. While strengthening the IHDP itself, this also facilitated collaboration with the International Geosphere–Biosphere Program (IGBP) and the World Climate Research Program. The IHDP established a strengthened secretariat in Bonn, Germany, and is guided by a Scientific Committee representing different geographic and scientific backgrounds. National Human Dimensions Committees are an essential component of the IHDP's research strategy emphasizing a bottom-up approach. The IHDP collaborates with over 30 of these Committees, and communicates with them through a quarterly newsletter, and a web page.

For the IHDP, the human dimensions of GEC encompass the full range of social and natural sciences disciplines necessary to analyze and understand people's role as both the possible cause and target of GEC. IHDP Science Projects are a key mechanism used to generate IHDP research activities in priority areas, to promote international collaboration of researchers, and to link policy makers and researchers. Projects evolve from proposals by the Scientific Committee or via proposals to the IHDP made directly by one or more National Human Dimensions Committees or programs. There are presently four IHDP Science Projects:

- Land Use and Land Cover Change (co-sponsored with IGBP); *see* IGBP Core Projects, Volume 2;
- GEC and Human Security;
- Institutional Dimensions of GEC;
- Industrial Transformation.

RAMINE V SHAW *Germany*

IIASA (International Institute for Applied Systems Analysis)

The IIASA, located in Laxenburg, Austria, is an independent, non-governmental, interdisciplinary research institution that specializes in natural and social scientific research methods and models for use by policy makers, the scientific community, and the public worldwide. The Institute currently concentrates its research efforts within the following core themes: Environment and Natural Resources, Energy and Technology, and Population and Society. IIASA is renowned for its expertise in transboundary air pollution, energy management and conservation, land use, forest resources management, water management, technological evolution, population dynamics, risk analysis and economic transition. Continued concerns about human welfare have added two related areas to the research program: the future of social security systems and implications of future catastrophic events on society and its institutions. The Institute has also made major inroads in advancing the theories and methodologies used to tackle these applied and policy-relevant issues, including the construction of large databases and sophisticated models. For example, several of the Institute's databases, such as those on carbon dioxide (CO_2) mitigation technologies, European forest resources, global climate and land use and land cover, are among the most comprehensive in the world. Governments and private institutions in Europe, Asia, and the Americas draw upon these data resources, as well as on IIASA-developed software, for modeling such issues as transboundary air pollution and water quality management. Since its inception in 1972, IIASA has fulfilled its strategic goal: to conduct international and interdisciplinary scientific studies to provide timely and relevant information and options, addressing critical issues of global environmental, economic, and social change, for the benefit of the public, the scientific community and national and international institutions. After three decades, IIASA continues as a center for innovative research; international, interdisciplinary collaboration; conferences and workshops; and networking with other organizations of scientists worldwide. IIASA's funding comes from sponsoring member organizations in 15 countries throughout North America, Europe and Asia. In addition, a valuable source of funding and direction for IIASA's research projects comes from various grants, sponsorships, or partnerships in both member and non-member countries. Governments throughout the world must address unprecedented changes in the world's social, economic, and environmental conditions. To fashion effective policies, national leaders must understand the complex problems associated with global change and recognize their interrelationships. Providing this insight is precisely the mission of IIASA.

IMO (International Maritime Organization)

IMO is a specialized agency of the United Nations (UN) with headquarters in London, UK. It was established in 1948 as the Inter-governmental Maritime Consultative Organization (IMCO). Its name was changed to the IMO in May 1982, following an amendment of its convention.

IMO consists of the assembly, the council, the maritime safety committee, the marine environment protection committee, the legal committee, the technical cooperation committee, the facilitation committee, and a number of sub-committees. It has a secretariat headed by a secretary general.

IMO's principal objective is to

> Encourage the general adoption of the highest practicable standards in matters concerning maritime safety, efficiency of navigation and the prevention and control of marine pollution from ships; and to deal with legal matters related to (these) purposes.

One of its functions is to provide for the drafting of conventions, agreements, or other suitable instruments •••.

IMO has adopted many treaties and other instruments on maritime safety, prevention and control of marine pollution from ships, and liability, and on compensation for vessel-source pollution. Among these are conventions on safety of life at sea; prevention of collisions at sea; training and certification of seafarers; prevention of marine pollution from ships; intervention in cases of marine pollution casualties; civil liability for environmental damage caused by ships; and international compensation funds for pollution damage. Non-treaty instruments include codes for the construction and equipment of ships, international code of maritime signals and traffic separation schemes.

IMO performs secretariat and other functions in respect of the 1972 London Dumping Convention. It is recognized

by the UN Convention for the Law of the Sea as the competent international organization on navigation, including pollution from vessels and by dumping.

Headquarters: 4 Albert Embankment, London SE1 7SR. Tel.: • 44-(0)20-735-7611.

Indicators on Environmental Quality and Sustainable Development

Allen L Hammond
World Resources Institute, Washington, DC, USA

Indicators are quantitative measures that simplify and help interpret large amounts of data and analysis. For example, the performance of a national economy is usually summarized by indicators such as the gross domestic product (GDP), the in ation rate, and the unemployment rate. Indicators such as the Dow Jones industrial average or the S & P 500 are often reported to summarize the performance of the US stock market. In a complex age, indicators perform an essential communication function. They help decision-makers and ordinary citizens alike to quickly grasp important trends.

So far, however, there are very few environmental indicators in widespread use, especially indicators that would summarize at a national scale whether environmental conditions were getting better or worse. Moreover, there is growing interest in indicators that could summarize progress (or the lack of progress) towards sustainable development, encompassing national performance in economic, environmental, and social conditions.

Such interest is motivated in part by the belief that indicators are crucial to informed decision-making. In the business world, this attitude is often expressed by the adage, " If you can't measure it, you can't manage it." Without appropriate indicators, decision-makers may not focus adequately on environmental or social problems, and public awareness may not generate the pressure that, in democracies, is often crucial for signi cant policy changes.

ENVIRONMENTAL INDICATORS

Over the decade of the 1990s, efforts to develop environmental indicators have proceeded on many different fronts. Work by Environment Canada led to a system of indicators describing environmental pressures such as pollution, the state or condition of the environment, and the social or institutional response to the problem (Environment Canada, 1991). This pressure/state/response framework was applied to a number of specific environmental issues in environmental indicators developed and reported by the Organization for Economic Cooperation and Development (OECD) for its member states (OECD, 1994). The government of the Netherlands developed an integrated set of environmental pressure indicators that could be aggregated or combined to give a single, summary indicator that it reports publicly on a periodic basis (Government of the Netherlands, 1991; Adriaanse, 1993). The US Environmental Protection Agency developed an indicator of toxic releases that aggregates data from more than 100 different chemicals and tens of thousands of industrial facilities (EPA, 1993).

Publication of these indicators has sometimes led to significant changes in policy or behavior. In the Netherlands, for example, publication led to new and stricter regulation of acidifying gases and to voluntary compacts for reduction of toxic pollution with industry. In the US, the Toxic Release Inventory stimulated voluntary commitments to drastic reductions in toxic pollution by many major chemical companies.

The concepts of a framework that shapes a system of indicators and of aggregation to summarize or simplify a set of indicators into a single measure that is more easily communicated are widely used in the indicator literature.

More recent work on environmental indicators has explored additional approaches. Research at the University of British Columbia led to an indicator of the environmental footprint of consumption patterns, measured in terms of the amount of land that would be required to support that consumption (*see* Ecological Capacity, Volume 3). A detailed analysis of the ow of all materials through industrial economies by the Wuppertal Institute and an international collaboration of research institutes led to a number of aggregated indicators – such as total materials requirement and total pollution output – to describe and summarize those ows and their potential environmental consequences (Adriaanse, 1997). Similar materials ow studies have now been completed for many OECD countries; the resulting indicators are sometimes described as *throughput measures*.

In addition to statistical indicators, work by the World Resources Institute and its collaborators developed spatial indicators (digital maps) of the state and the stresses or potential degradation of coral reefs and other ecosystems (Byrant *et al.*, 1998). Such spatial indicators show the patterns of environmental threats across an ecosystem as well as giving quantitative summary measures such as the percent of the habitat at high risk of degradation.

Although adoption of environmental indicators is proceeding slowly, there is some evidence of progress

and a growing richness of analytical work in indicator development.

SUSTAINABLE DEVELOPMENT INDICATORS

Efforts to develop not just environmental indicators but more comprehensive measures of sustainable development are spreading, although relatively few indicators of this type have been published or widely adopted. One impetus for such efforts has been the UN Commission on Sustainable Development, which has actively encouraged the development and testing of indicators. A second impetus is the growing conviction among some researchers that existing indicators of economic growth such as the GDP give a distorted sense of progress – that it is not more economic output but rather increased human welfare that is essential to sustainable development.

One approach to sustainable development indicators has been to modify economic indicators or to group existing economic indicators with environmental and social indicators. The World Bank, for example, has developed and calculated for most nations an experimental indicator of economic, natural, and human capital, all measured in economic terms. Supplementing this wealth indicator is a corrected GDP measure called *genuine savings* that takes into account such dissavings as degradation of natural resources and pollution clean-up expenditures while adding in as investments such things as educational expenditures (World Bank, 1996). An informal group of indicator experts is exploring an approach that would cluster several indicators for each of economic, environmental, and social aspects of sustainability (*see* Natural Capital, Volume 2).

A second approach is to develop new frameworks – and perhaps radically new indicators – that offer fresh insights into what sustainable societies might require. One example of this approach was developed by an interagency task force within the US government. It incorporates such concepts as *endowments* (the inherited stock of natural resources, built capital, and human capabilities) and processes (from industrial processes that transform matter to educational processes that increase human capacity) as well as a tentative list of indicators (US Government, 1998).

Progress towards sustainable development indicators remains slow (Moldan and Billharz, 1997). Part of the difficulty is that the underlying concept of sustainable development lends itself to many different interpretations, and may well be dependent on the state of development of a country as well as being scale-dependent. Indicators useful for industrialized countries, for example, may not be appropriate for developing countries still highly dependent on natural resources; measures applicable at a continental scale may bear little relation to those appropriate for an urban area or a rural community. Furthermore, there are unresolved basic measurement issues: practical ways to measure the social capital of a society – for example, the strength and flexibility of its institutions or the richness of informal social connections or the prevalence of corruption – do not exist. As a result, an extended period of experimentation and research may be necessary before widespread adoption of sustainable development indicators takes place.

Industrial Ecology

Industrial ecology (IE) is an evolving field of study that deals with materials and energy flows and transformations, both within an economic system and also across its

boundaries with the natural world. The term was first used in Japan (1972) but was revived in a well-known article by Frosch and Gallopoulos (1989) as an intentional metaphor to suggest an industrial system of diverse specialized firms that imitates a natural ecosystem to the extent of utilizing material wastes as a natural ecosystem recycles nutrients. IE, which emphasizes transactional relationships among production units (firms) can be distinguished from *industrial metabolism* (IM), which emphasizes materials/energy flows and transformations (Ayres, 1989). However, there is considerable overlap and the two concepts are used somewhat interchangeably. Other related concepts include *life-cycle analysis* (LCA) (sometimes called a *life cycle assessment*), *mass flow analysis* (MFA), *substance flow analysis* (SFA), *recycling*, *remanufacturing*, and *dematerialization*. In reality the IE metaphor is flawed. A natural ecosystem depends upon primary producers, which are photosynthetic green plants. In addition, it includes a hierarchy of animals and microorganisms: plant-eaters (grazers), several trophic levels of carnivores and omnivores, plus a variety of parasites and decay organisms. By contrast, the current industrial system has two kinds of primary producers. One category utilizes organic inputs from agriculture and forestry. The other category of producers utilizes abiotic inputs: minerals, metals and fossil fuels. There is a superficial resemblance to the food chain, in that firms higher on the chain utilize the products of firms lower on the chain.

A natural ecosystem, taken as a whole, generates neither products nor wastes. It merely endures and provides a stable microenvironment that permits its components to reproduce themselves and thus the system. It exchanges raw materials on a continuing basis with natural reservoirs (air, water and soil).

Reprocessors and recyclers in the industrial system are only roughly analogous to parasites and/or decay organisms. In the natural system their function is preprogrammed (behavior). In the industrial ecosystem, by contrast, their role, if any, is determined by economic incentives (prices, demand) and regulations. The industrial system differs fundamentally from an ecosystem in that the former depends essentially on exploiting natural capital (minerals and fossil fuels) put in place eons ago, whereas an ecosystem utilizes only current or recent primary production.

Industrial Responses to Stratospheric Ozone Depletion and Lessons for Global Climate Change

see Industrial Responses to Stratospheric Ozone Depletion and Lessons for Global Climate Change (*Opening essay*, **Volume 4**)

Integrated Assessment, Definition of

Integrated assessment (IA) is a reflective and iterative participatory process that links knowledge (science) and action (policy) regarding complex global change issues such as acidification and climate change. IA can be defined as an interdisciplinary process of combining, interpreting and communicating knowledge from diverse scientific disciplines in such a way that the whole cause–effect chain of a problem can be evaluated from a synoptic perspective with two characteristics: (i) it should have added value compared to single disciplinary assessment; and (ii) it should provide useful information to decision makers (Rotmans and Dowlatabadi, 1997).

Assessment comprises the analysis and review of information derived from research for the purpose of helping someone in a position of responsibility to evaluate possible actions, or think about a problem. Assessment means assembling, summarizing, organizing, interpreting, and possibly reconciling pieces of existing knowledge, and communicating them so that they are relevant and helpful to an intelligent but inexpert decision-maker (Parson, 1995).

The cause effect chains that IA aims to evaluate start with socio-economic drivers, leading to economic activity and other practices, leading to emissions and other pressure on the environment, leading to environmental changes, leading to physical impacts on societies and ecosystems, leading to socioeconomic impacts, eventually returning to change the socioeconomic drivers. Therefore, IA needs to integrate insights from a multitude of disciplines to arrive at a synoptic view on the problem at hand.

See also: Integrated Assessment Models of Global Change, Volume 4.

JEROEN P VAN DER SLUIJS *The Netherlands*

Integrated Assessment

Jeroen P van der Sluijs
Utrecht University, Utrecht, The Netherlands

Integrated assessment (IA) can be de ned as an interdisciplinary process of combining, interpreting and communicating knowledge from diverse scienti c disciplines in such a way that the whole cause- effect chain of a problem can be evaluated from a synoptic perspective with two characteristics: (i) it should have added value compared to single disciplinary assessment; and (ii) it should provide useful information to decision makers (Rotmans and Dowlatabadi, 1997). Thus (IA) is an iterative participatory process that links knowledge (science) and action (policy) regarding complex global change issues such as acidi cation and climate change.

Assessment comprises the analysis and review of information derived from research, for the purpose of helping someone in a position of responsibility to evaluate possible actions or think about a problem. In this context, assessment thus means assembling, summarizing, organizing, interpreting, and possibly reconciling pieces of existing knowledge, and communicating them so that they are relevant and helpful to an intelligent but inexpert decision-maker (Parson, 1995).

Providing such a synoptic view required new analytical tools and procedures to integrate a wide range of disciplinary knowledge. As Parson (1995) phrased it: " to make rational, informed social decisions on such complex, long-term, uncertain issues as global climate change, the capacity to integrate, reconcile, organize, and communicate knowledge across domains - to do integrated assessment - is essential." IA has emerged as an approach that is suitable for accommodating the uncertainties, complexities and value diversities of issues such as climate change.

The cause–effect chains that IA aims to evaluate start with socioeconomic drivers leading to economic activity and other practices, leading to stresses on the environment, leading to environmental changes, leading to physical impacts on societies and ecosystems, leading to socioeconomic impacts, eventually returning to cause changes in the socioeconomic drivers. Therefore, IA needs to integrate insights from a multitude of disciplines and stakeholders to arrive at a synoptic view of the problem at hand.

One of the consequences of the novelty of the field of IA is that the literature does not yet show a uniformity in terminology. Even the appropriate term to indicate the research field is subject to debate. Some groups talk about *integrated environmental assessment* (IEA), whereas others use the term IA. The proponents of the term IA argue that adding environmental as the focus detracts from the integrated nature that IA should have. On the other hand, IA makes no reference to complex environmental policy problems, whereas until now, the assessment of complex environmental policy issues has been both the incentive for the development of, and the major concern of IA. There is, however, no *a priori* reason to restrict the application of IA to environmental policy problems. It is obvious that the IA research community has the aspiration that IA be applicable to the entire field of science for policy. IEA can then be seen as the subset of IAs concerned with environmental issues.

In the literature a large number of attempts to define IA can be found. Weyant *et al.* (1996); Van der Sluijs (1997) and Toth and Hizsnyik (1998), give reviews of IA definitions. This multitude of attempts to define and redefine IA re ects the novelty and dynamics of the field. For the purpose of this article we adopt the widely cited Rotmans and Dowlatabadi (1997) definition, describing IA as:

> an interdisciplinary process of combining, interpreting and communicating knowledge from diverse scientific disciplines, in such a way that the whole set of cause–effect interactions of a problem can be evaluated from a synoptic perspective with two characteristics: (i) it should have added value compared to single disciplinary assessment; and (ii) it should provide useful information to decision makers.

To understand the concept of IA, it is useful to distinguish *doing assessment* from *doing research*. Assessment comprises the analysis and review of information derived from research, for the purpose of helping someone in a position of responsibility to evaluate possible actions or think about a problem. Assessment usually does not mean doing new research. Assessment means assembling, summarizing, organizing, interpreting, and possibly reconciling pieces of existing knowledge, and communicating them so that they are relevant and helpful to an intelligent but inexpert policy-maker or other actor involved in the problem at hand (Parson, 1995).

IA addresses three goals (Weyant *et al.*, 1996):

- coordinated exploration of possible future trajectories of human and natural systems;

- development of insights into key questions of policy formulation;
- prioritization of research needs in order to enhance our ability to identify robust policy options.

The IA process overlaps with the policy development process, as is shown in Figure 1.

An important notion in the definition given above is that IA is understood as a process and not a method. In the early period of the development of the field (that is from the early 1980s till the mid 1990s), the label IA was often used to refer to the technical analytical methods used in the process, with integrated assessment models (IAMs) and scenario development as the dominant tools. Nowadays, it is widely recognized that IAM is not a complete IA methodology, it is one set of analytical tools for integration used in conjunction with other methods of integration in a broader participatory assessment process.

Historically, IA is rooted in scientific and public policy efforts to understand and control acid deposition in the 1970s in Europe and North America. Public policy organizations had asked the scientific community to prepare IAs of the acidification problem (Toth and Hizsnyik, 1998). In practice, traditional forms of knowledge integration, such as books, expert panels and advisory bodies combining monodisciplinary assessments were too slow and too in exible to fulfill all the needs of the dynamic and issue-driven policy process. Examples of policy needs where traditional means of integration were weak, are the *ex-ante* evaluation and comparison of the potential impacts of a wide range of policy scenarios, and estimates of the effectiveness of alternative (combinations of) conceivable policy measures. Facilitated by developments in computer technology and systems analysis, IA modeling emerged in the 1980s as a new methodology that was capable of addressing such questions in a fast, exible and consistent way.

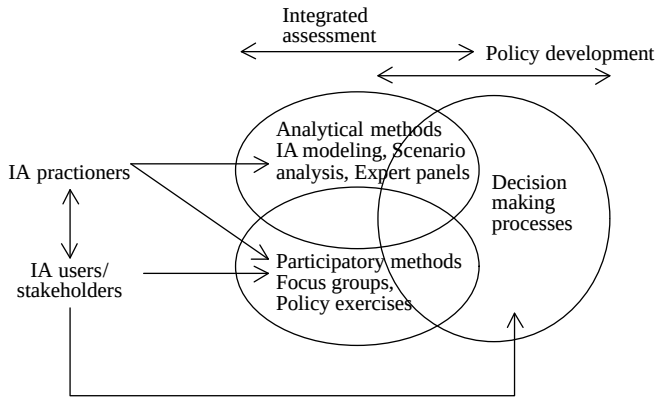

Figure 1 IA involves practitioners and users, uses technical analytical methods and participatory methods and overlaps with the policy development process

IAMs are computer simulation models in which knowledge from many different disciplines is combined in an analytical computational framework to analyze the problem at hand in an integrated fashion. IAMs are used for several purposes, such as scenario analysis, (*ex-ante*) evaluation of the environmental, economic and social consequences of different policy strategies, translation of environmental quality standards into acceptable emission trajectories (*safe landing corridors* or *tolerable windows*), and optimization of key policy variables such as rate of greenhouse gas emission reduction or level of carbon taxes.

Within IAMs, both the natural system and the socioeconomic system are simulated. A perfect policy evaluation IAM would model the complete so-called *causal chain*, including all the feedbacks within this chain. The major innovative characteristic of an IAM, which has made it an essential tool in IA, has been its capacity to dynamically include feedback loops between different stages of the causal chain. There is no other means of integration of insights into complex interlinked cause–effect relationships from multiple disciplines with that capacity.

The first generation of these integrated models focused on acid rain. The Regional Acidification INformation and Simulation (RAINS) is the most obvious example (Alcamo *et al.*, 1990). RAINS was developed in the 1980s at the International Institute for Applied Systems Analysis. The RAINS model played a major role in the international acid deposition negotiations in the framework of the United Nations (UN) Convention on Long-range Transboundary Air Pollution, and became an annex to the UN SO_2-protocol (*see* RAINS (Regional Air Pollution Information and Simulation), Volume 4).

In the second half of the 1980s, the success of the RAINS model led to the belief that integrated modeling would be the optimal way to interface science with policy, regarding environmental issues. Consequently it is not surprising that IAMs were developed all over the world. For the climate issue more than 50 IAMs coexist (Van der Sluijs, 1997). Looking back at the developments in the IA field over recent decades, the role of IAMs in the IA process has been closely linked to the policy development process. The climate change problem is a key example to illustrate this changing role and its consequences for evolution of IA and its toolbox.

The development of international climate policy can be roughly divided into five periods (Table 1). IA started to play a role in the agenda-setting phase. In this process of agenda setting, the 1985 Villach Conference on the Assessment of the role of Carbon Dioxide and other Greenhouse Gases in Climate Variations and Associated Impacts (*see* Villach Conferences, Volume 4) and the 1988 World Conference on the Changing Atmosphere: Implications for Global Security in Toronto were the milestones. These conferences were typical attempts to bring together experts

Table 1 The development of international climate policy

Period	Phase	Major characteristic
1895–1985	Foundational period	Scientific concern about global warming developed
1985–1988	Agenda-setting phase	Climate change was transformed from a scientific into a policy issue
1988–1990	Pre-negotiation period	Governments became heavily involved in the process
1990–1992	Formal intergovernmental negotiations phase	Led to the adoption of the FCCC[a] in May 1992
1992–present	Post-agreement phase	Focus on the elaboration and implementation of the FCCC and the initiation of negotiations on additional commitments; more and more stakeholders became involved in the climate policy debate

[a] UN Framework Convention on Climate Change.

from a multitude of scientific disciplines to arrive at an integrated view on the climate problem. These meetings were successful in putting the issue of climate change on the policy agenda, and were the first steps towards the creation of IPCC (*see* Intergovernmental Panel on Climate Change (IPCC): an Historical Review, Volume 4).

In the pre-negotiation phase, climate IAMs began to be developed. For instance, in 1986 the Netherlands National Institute of Public Health and Environmental Protection developed the Integrated Model to Assess the Greenhouse Effect (IMAGE)-1 model (Rotmans, 1990). IMAGE was a pioneer in the field: the (completely revised) IMAGE-2 model (Alcamo, 1994) is still one of the leading models, at the frontiers of IA modeling. IMAGE was developed at the time when the climate problem appeared on the policy agenda. In that phase, scenario analyses were needed to support the thinking about the question of how much greenhouse gas emission reduction was needed in order to manage the risk. IAMs were also used for scenario analysis in the successive assessments produced by the Intergovernmental Panel on Climate Change (*see* Intergovernmental Panel on Climate Change (IPCC): an Historical Review, Volume 4).

In response to developments in the post-agreement phase of the international climate policy debate, in which quantified emission limitation and reduction objectives were negotiated, IAM results from different modeling groups were fed into the negotiations. A typical IAM application in this phase has been the calculation of so-called safe landing zones and corresponding safe emission corridors (or tolerable windows). *Safe emission corridors* are defined as the allowable lower and higher bounds of greenhouse gas emission scenarios, relating to a set of criteria for climate policy whose purpose is to protect both the environment and the economy from disruption. Ecological constraints (maximum acceptable total temperature increase; maximum acceptable rate of temperature change; and maximum acceptable sea level rise) determine the upper limit and economic constraints (maximum acceptable rate of emission reduction) the lower limit of the corridor. Such calculations have played a role in selecting the emission reduction targets in the Kyoto agreement. Overall over the past decade, IAMs have played an increasingly important role in the legitimization and scientific underpinning of policy targets regarding global environmental risks.

With the Kyoto protocol, a new phase has started. Major changes of global economic structure are being envisaged, as implied by long-term reductions of greenhouse gas emissions. As the 1998 Buenos Aires Conference of the Parties (COP)-4 and the 1999 Bonn COP-5 meetings have shown, however, no such major changes are currently being implemented. Rather, a long-term effort has started to design possible institutions and mechanisms whose implications are gradually being explored by international environmental diplomacy.

This phase is essential to build up the know-how and the trust required to develop effective environmental policies at a global scale. However, it is clearly insufficient if the problem of climate change is to be effectively addressed. If effective policy is to emerge, actions taking place at the level of international environmental diplomacy must be combined with actions involving various stakeholders, who range from peasants to forest managers, from tourist operators to inhabitants of coastal zones, and from financial investors to ordinary citizens. Involving the latter will be necessary because climate mitigation measures will require consumer and worker cooperation, as well as citizen consent, to be successfully implemented.

For IA, this implies a growing need for the integration of social science research, and in particular of participatory techniques into research on global change. Social science is needed to provide knowledge about stakeholders and their ways of opinion forming, and also to provide opportunities for including the knowledge of stakeholders and their judgments about controversial issues in policy making.

An innovative development in the IA field has been the design of *Participatory IA* (PIA) methodologies. A key example and pioneer in PIA is the European Urban LifestYles, SuStainability and Integrated Environmental Assessment (ULYSSES) project (*see* ULYSSES (Urban Lifestyles, Sustainability, and Integrated Environmental Assessment), Volume 4). ULYSSES has developed procedures allowing interfaces between expert models of environmental change on the one hand, and lay participants in focus group discussions on the other hand. ULYSSES conducted IA *focus groups*, in which selected citizens debated climate change and mitigation options, and were supported in their deliberations by access to expert information. IA focus groups undertake group discussions conducted with citizens and guided by a moderator. The citizens are given access to computer models on complex environmental topics to support their debates. For this process, a model moderator supports them. At the end of the process, the citizens give their assessment of the problem and of policy options. The PIA methodology developed in the ULYSSES project is comprehensively described at http://www.zit.tu-darmstadt.de/ulysses/tutorial.htm.

ULYSSES has shown that IA focus groups can increase the possibilities for ordinary citizens to articulate their views on environmental issues in a thoughtful manner. This can help to bridge possible gaps between decisions by policy makers and citizens' views. Exploring alternative explanatory and moral frames in such processes can complement expert assessments on complex environmental issues. In particular, focus group procedures involving open-ended discussions are well suited for PIA. In PIA, the discussions can broaden into directions impossible for the researchers to imagine beforehand. This is vital if we are to learn more about how the diversity of everyday life and experience affects the understanding, values, and objectives that different social groups bring to complex environmental issues.

Analytical IA methods and PIA methods complement each other in the IA process, the one being strong where the other is weak and *vice versa*. The fruitful combination of the two approaches yields a powerful means to interface science and policy with the capacity to cope with the complexity, uncertainty and value diversity that characterize present-day environmental problems.

Integrated Assessment Models of Global Change

Pierre Matarasso

Centre International de Recherche sur l'Environnement et le Développement, CNRS-EHESS, Nogent-sur-Marne, France

Integrated assessment models (IAMs) of global change are computer models, which integrate sets of equations describing the interwoven evolution of the different sub-systems making up the Earth system:

- *human production systems and their economic counterparts, including exchanges, nancial and monetary issues;*
- *coupled atmospheric and oceanic systems; and*
- *terrestrial and marine ecological systems.*

IAMs are based on a detailed description of geodynamic and ecological phenomena involving general circulation models (GCM), atmospheric chemical models and ecological models. However, economic issues are central to the assessment, through the coupling of these natural science models with macroeconomic models.

The goal of an IAM is to produce a uni ed picture of climate change oriented towards the evaluation of the

consequences of this phenomenon (negative and positive impacts), taking into account the driving forces behind climate change (demography, economy, development •••), possible mitigation processes (nuclear and renewable energies, demand side management (DSM), carbon capture and sequestration) and adaptation processes (changes in production methods in agriculture, protective infrastructures, etc.). IAMs of very different sizes and levels of detail have been developed (Dowlatabadi, 1995; Rotmans, 1998; Janssen, 1998).

It should be stressed that the question raised by IAMs is in essence a problem of decision-making involving a common property resource at a global level in an uncertain context, where the measures against climate change and their consequences are spread over much of the Earth's surface in an extended time frame. The purpose of an IAM is to integrate all these measures to prevent climate change, and its positive or negative impacts in a global framework. The aim of this integration is to de ne an indicator of ef ciency for each possible strategy involving mitigation and adaptation measures, summing up costs and bene ts of these measures at a world level and over the entire time scale of climate change. In other words, IAMs are devoted to climate policy analysis and in particular, to the computation of optimal emission trajectories. This problem concerns the most complex object that science has ever had to cope with: Planet Earth. Therefore, IAMs raise an important philosophical question: what are the scienti c limits to the knowledge of our planet, considered as a complex system? Which parameters of our future action regarding climate change can be selected according to reason and reliable arguments? An IAM constitutes an attempt to transcend providence or intuition in the decision and negotiation processes concerning climate change.

More speci cally, an IAM constitutes an attempt to nd answers to the following questions: (1) what are the best economic compromises involving measures designed to limit climate change and adaptation to it?; (2) what is the optimum distribution of the burden of mitigation and adaptation measures over different parts of the world?; (3) how do we combine institutional measures, such as taxes, tradable permits and subsidies to technical innovation to stabilize greenhouse gases (GHG) emissions at a safe level? A typical problem addressed by an IAM is to analyze when, where, and how to react to climate change in order to satisfy ethical and economical principles such as the precautionary principle, cost bene t analysis or cost ef ciency analysis. More generally, the dynamic aspects of global change are studied in the framework of an IAM with the intention of assessing the relative importance of the various uncertainties pertaining to that phenomenon.

The research community presently gathering around IAMs has reached a broad consensus of opinion on the questions that IAMs should address. However, in contrast, the technical solutions to these problems are extremely diverse, due to the complexity of the system under study. Therefore, the range of problems addressed by IAMs will probably remain stable for some time while model-building techniques will rapidly evolve. We will attempt to sum up this consensus, before introducing some of the general technical aspects of IAMs.

THE PARADIGM OF DECISION-MAKING IN FACING GLOBAL CLIMATE CHANGE: WHEN, WHERE AND HOW TO ACT?

If we decide to combat climate change, we have to answer at least three classes of questions related to the nature of different institutional and technical measures. The questions are:

- when are measures against climate change required?
- where are measures required? and
- what kind of measures are needed? (Manne and Richels, 1995).

In addition, measures should be evaluated in proportion to their consequences in terms of impacts. Impacts are obviously linked to the atmospheric levels of GHGs, which result from each set of measures.

Each of the preceding questions can be subdivided into many subtle problem areas, not the least of which is the fact that measures, as well as their consequences, in terms of impacts must be analyzed at three separate levels: (1) the physical level; (2) the direct economic level; (3) the indirect macroeconomic level of effects induced by mitigation policies and climate change impacts.

When to Act, or the Timing Problem

The elaboration of a set of institutional measures (taxes, quotas, tradable permits, innovation incentives) and related technical measures over time (mitigation and adaptation processes) is determined by the speed and level of climate change, technical progress, research and development expenditure, demography, economic development, etc. For example, an IAM can be used to evaluate and compare a package of precautionary measures and a package of follow-up measures with various temporal horizons associated with different final states regarding GHG concentrations and different levels of climate change. The use of an IAM has shown that many different paths (with various emission and mitigation profiles) can produce the same results in terms of final atmospheric concentration of GHGs. Therefore, decision-makers have to elaborate and compare sets of measures, with contrasting time-scales, which can lead to different global social costs. The determination of an optimal level of action, representing a good mix of mitigation and adaptation measures is sought. This is an

area where the use of an IAM has, directly or indirectly, structured and informed the international debate concerning the timing of policy measures (Wigley *et al.*, 1996).

Where to Act and Spatial Flexibility

The possibilities of reducing the emissions of GHGs are distributed throughout the different geographical regions and nations of the world. If we assess the costs of these reductions, it might appear that some geographical areas present, for technical and economic reasons, potentially cheaper mitigation possibilities than others. In this context a strategy of mitigation can be viewed as a set of technical operations indexed by geographical location and time scale, where these operations are ordered by increasing costs. Determining such strategies is one of the main goals of an IAM.

How do We Act on a Technical Level with respect to Trade-offs in the Mitigation Process?

On a technical level, mitigation measures include a number of potential components:

- at the level of energy demand;
- at the level of energy production (renewable or nuclear energy, more efficient energy conversion, carbon dioxide (CO_2) capture devices, etc.);
- at the level of the creation of CO_2 sinks (tree planting, induced algae production •••);
- mitigation measures could be distributed amongst the different GHGs (CO_2, methane (CH_4), nitrous oxide (N_2O), sulfur hexa uoride (SF_6), per uorocarbons (PFCs), hydro uorocarbons (HFCs)), with possible trade-offs between these gases.

Many IAMs are formulated to suggest least-cost packages of technical mitigation measures integrating various possible trade-offs and compromises between the different technical options.

What Kind of Public Policy will Trigger an Appropriate Association of Technical Options?

In many past studies related to energy issues, energy options were considered on the basis of technical scenarios. The shift from technical scenarios to reality was accomplished through planning and national policy formulation. This view is no longer valid in the present context of competition on energy markets. In negotiations concerning climate change, the discussion has progressively shifted from an approach centered on technical scenarios to the definition of public policies in terms of economic procedures and legal agreements. One of the goals of many IAMs is to test different economic taxes and permit regimes (distribution of entitlement to emission rights, quotas and ceilings of emissions, effects of differing exibility mechanisms such as the *clean development mechanism* (CDM) (*see* Clean Development Mechanism, Volume 4). Simulation of permit trading or of progressive carbon taxes and their interaction with development, growth, economic processes, technical progress, world markets of goods and capital are central to many IAM concerns. Equity issues play a major part in the evaluation of simulation results.

Evaluation of the Climatic Impacts of Different Packages of Measures

New climate patterns can be very diversified and this may, in turn, have various consequences on economic activities. Categories of impacts can be divided into the negative and positive impacts that can affect different societies at different moments in time. Typical forms of climate events producing damages or negative impacts are:

- hurricanes and tornadoes and other types of extreme weather events;
- droughts or oods; and
- rises in sea level.

Possible positive impacts are

- Lengthening of growing seasons;
- CO_2 fertilization of plant growth; and
- improved rainfall in dry areas.

IAMs provide a quantified description of impacts and evaluations of regional consequences through climate patterns, calculated with GCMs fed with GHG concentrations resulting from sets of measures and actions. Particularly important is the study of the impacts of climate change on economic activities and possible adaptations (Tol, 1996).

Evaluation of the Cost and Macro Economic Consequences Induced by Mitigations or Adaptation Measures and Impacts

It should be noted that each pattern of measures and impacts of climate change has a profound in uence on economic issues. A few examples will illustrate this point:

- the reduction of individual car use through switching towards other transportation modes might have a knock-on effect in the entire economy (with, for example, reductions in car production and a slowing down of individual transportation-related activities in services such as garages, gasoline distribution, etc.);
- limiting energy consumption might depress energy prices, which could be detrimental to oil producing countries. On the contrary, measures based on CO_2 capture will not affect energy markets;

- promoting a new international market of permits can have a marked in uence on the mobility of capital; and
- a reduction in agricultural production may result in economic decline and migration.

IAM MATHEMATICAL STRUCTURE

In the absence of a general theory of modeling, only a very simplified description of the technicalities and issues concerning the working of IAMs can be given. An IAM is a computer model, but a model made up of many intricate phenomena belonging to the natural and human domain. It is an assemblage of very heterogeneous processes. In some IAMs, different sub-models are linked, in others equations representing the different phenomena are more truly integrated. Such models may be described from different viewpoints. The first viewpoint is thematic; it consists of an individual description of the rather independent sub-models or models at a lower level coupled in the global model (equations grouped in themes and linked by common variables). The second viewpoint concerns purely methodological considerations independent of the classes of the phenomena described by sets of equations and involves a more fundamental definition of types of equations. The third viewpoint is related to solving procedures. In order to be useful, a model should produce a solution; and yet, different solving procedures are available for a given model, depending on the questions put to the model. From this latter viewpoint, IAMs are very different from natural science models that do not raise the issue of decision-making and hence the study of many alternative scenarios that will never materialize in the real world. The problem of decision-making in a context of indeterminacy and uncertainty is at the core of IAM resolution and computing (Dowlatabadi, 1995; Rotmans, 1998; Janssen, 1998). In order to understand the way in which IAMs work and especially the procedures for solving them, the second viewpoint should be adopted.

General Structure of an IAM

An IAM is a set of equations describing the evolution over time of the Earth System as a whole. Basically an IAM is a dynamic model, which implies the following types of equations, illustrated by simplified examples:

- Equations concerning evolution, linking one period to the next period. For example, the equation which establishes that the level of concentration of CO_2 is dependant on emissions, mitigation and on the different natural processes of absorption of this gas. Other classic equations in the same category involve the evolution of capital goods through investment, obsolescence and dismantling, and descriptions of demographic change according to birth and death rates.
- Equations linking contemporaneous variables; equations linking GHG concentrations to global temperature; the relationships between damages and global temperature. In the economic domain, production expressed as a function of various factors such as available capital and available manpower; emissions calculated as a function of global production; constraints stipulating that consumption and investment should not exceed total production at a given time.

Concerning variables, it is usual, in the first instance, to distinguish between:

- ow variables (emissions, CO_2 captured by forests and biomass, final consumption, investment, death and birth.); and
- stock variables (atmospheric level of CO_2, levels of various capital stocks, population figures).

This is only a rough classification as some variables, which play a major role in quantification of ows, are neither stock variables, nor ow variables. Good examples of such variables are the temperatures in a GCM and the prices of goods in the economic section of an IAM. In a simplified interpretation of these classifications of equations and variables, it can be argued that the equations of evolution describe the evolution of stock variables as a function of the values of the relevant ows.

In the past, models were often expressed in continuous time (and treated as systems of differential equations), especially natural science models such as GCMs. Today many factors favor the expression of models in discrete time (with finite difference equations):

- the models are too complicated to be treated analytically and the calculation of results requires the use of computers that rely on discrete computations;
- at the level of the Earth System, natural discrete periods already exist, such as the seasons or the farming year and budgeting within industry and services;
- the treatment of discrete events implies the use of discrete time periods.

Many IAMs are therefore expressed in a discrete time framework. In some models, different time scales could be used since geodynamic phenomena often involve shorter time periods than economic processes.

Solving Procedures in IAMs

Basically two types of solving procedures are used in IAMs

- recursive solving through sequential simulation; and
- intertemporal solving through optimization.

The principle of recursive sequential simulation is fairly straightforward: with prescribed initial conditions, the state of the system at $t \bullet 1$ is computed from the state at t, by introducing values for ows in the evolution equations. Some of these ows are defined as control variables or policy variables. In simulations these control variables will be given through an exogenous control scenario (for example, a mitigation policy). It should be noted that all ows should be specified to arrive at a determinate evolution of the system represented. The calculation follows the temporal order of the real pattern of events and simulates change.

The principle of inter-temporal solving through optimization is different. A system of simultaneous equations is established by duplicating, for all periods, the group of equations valid for one period (equations of evolution and contemporaneous equations). Initial conditions and, eventually, final conditions are defined. This system of simultaneous equations expressed for n periods, with time indexes for each period, is then solved globally as a whole (and not sequentially as in ordinary simulation), generally through optimization algorithms.

The main difference between the two approaches lies in the treatment of decision-making. In simulation, in order to impose a determinate evolution, all the decision variables (usually ow variables, such as investment decisions in the energy field) have to be defined exogenously by a scenario. This is why simulation models are considered as models of policy evaluation. The evaluation centers on the scenario (mitigation and adaptation policies, emission permit policy) fed into the model and its consequences in terms of climate change impacts. In contrast, in inter-temporal solving procedures, some of the possible decision variables are left free and a determinate evolution is computed in which the algorithm selects an optimal control, that is a complete set of control variables covering the whole time scale. Optimization is achieved by selecting a temporal evolution by computation which maximizes an inter-temporal function, usually an economic welfare function expressed by a discounted sum, over all periods of the utility of consumption at each period. In this framework, running the model results in the selection of a coherent optimal set of decisions throughout the whole time scale (mitigation and adaptation measures, or least-cost mitigation for a given target of final GHG concentrations) including consequences in terms of damages, cost and benefits. This is why this procedure is termed *optimal policy de nition*.

It should be stressed that in the optimization framework, various constraints on the final period (stable final concentrations of GHGs for example) can be specified and computation produces solutions respecting these constraints (or the optimization algorithm yields the result that such a solution is impossible to find). In simulation, on the other hand, the scenario submitted to computation produces end conditions that could not be anticipated. This is why simulation might lead to overshoot and collapse not previously envisaged in the scenario submitted. In other words, simulation is blind or short sighted and optimization in some respects is forward looking and mimics behavior with expectations or perfect foresight, where decisions are taken with a knowledge of their consequences. This last peculiarity is especially important when trade-offs between decisions over a longer time scale are envisaged.

In theory, any dynamic model structure (if by model we mean the core structure of the equations) can be solved either way. In practice, our ability to compute inter-temporal optimization is limited to simplified models for a basic reason: an optimization algorithm explores an infinite number of alternative solutions whilst simulation computes only one solution at a time. Optimization therefore requires much greater computing power. Other model-solving procedures should also be mentioned, especially the inverse mode in which a solution is computed in a reverse temporal order, with a final state taken as initial conditions.

For an excellent example of policy optimization models see Nordhaus (1994) who introduced this paradigm in the field of climate change. An example of a leading simulation and policy evaluation model, IMAGE, can be found in Alcamo (1994).

CURRENT DEBATES CONCERNING IAM STRUCTURE AND USES

Cost Benefit Analysis Versus Cost Effectiveness Analysis

Evaluation of impacts is one of the weakest elements of an IAM. Impact evaluation raises very complex problems due to the many uncertainties of climate models for long-term forecasts.

Some IAMs try to integrate the cause (human activities), modification of the cause (mitigation of emissions), consequences (climate change impacts) and adaptation to consequences (adaptation to climate change) in the framework of cost-benefit analysis (CBA). Costs are related to mitigation, adaptation or damages and benefits to avoided damages or more favorable climate conditions. But due to the huge uncertainties concerning physical impacts, evaluation of adaptation costs, many models of a lower level of integration adopt a cost effectiveness analysis (CEA) framework. In such cases the aim is to reach a given stable final concentration target of each GHG or to satisfy mitigation objectives at least cost (Bruckner *et al.*, 1999).

The Top-Down Versus Bottom-Up Debate

The level of description of economic phenomena, especially energy systems, is a much debated question in IAMs. Traditionally there are two opposing approaches, top-down and

bottom-up modeling. Top-down models synthesize major tendencies in economic trends such as demography, economic growth, investment, consumption and a fairly crude indicator of trade. In a top-down IAM context, geodynamics are aggregated and damages are dealt with through damage functions in a global context.

Bottom-up models involve the detailed description of components of economic systems, usually energy systems, in terms of elementary process analysis. When IAMs are developed from a bottom-up perspective, damages are also usually more detailed and their evaluation takes into account the temporal and geographic peculiarities of climate change and their consequences on agriculture, industry and housing.

When insights regarding timing of action are sought or when a broad geographical distribution of the burden of mitigation is envisaged, order-of-magnitude analysis is often a prerequisite. In this case, top-down models are used. But if the question involves precise mitigation options with trade-offs between different energy technologies (nuclear, renewable), trade-offs between gases (CO_2, CH_4, N_2O, SF_6, PFCs, HFCs), and trade-offs between reductions of emissions and capture of CO_2 by tree plantation, bottom-up models are absolutely necessary. Only a bottom-up model can break down a global mitigation effort into a sequence of precise technical decisions with time and regional indexes. Increasingly, the frontiers between top-down and bottom-up models are vanishing; some models incorporate a bottom-up description of the energy or production sector (for example the MERGE model, and MARKAL family models) within a top-down framework for the whole economy. For the foreseeable future, bottom-up models will raise questions concerning data availability and computation. Even if they seem more satisfactory from many points of view, it will be a long time before they are fully effective (Dowlatabadi, 1995; Janssen, 1998).

Uncertainty

Uncertainty is the thorniest issue in the IAM field; and it does not appear that a consensus has yet been reached. However, some methodological trends can be identified. They range from a strict application of the precautionary principle to more classic applications of decision-making in the framework of uncertainty theory. The treatment of uncertainty causes difficult problems in computation, as uncertainty adds many dimensions to the search for sustainable development solutions. Also the question of whether a reduction of uncertainty through research and development is possible has to be raised. Usually two general categories of uncertainty are defined:

- parametric uncertainty that stems from imperfect knowledge; and
- stochasticity due to natural variability.

Significant uncertainties occur, for example, in demographic behavior, damage functions, energy efficiency trends and in endogenous technical progress. The discount rate (policy choices are very sensitive to the discount rate) and information costs (funds spent to reduce uncertainty) are important issues in the uncertainty debate. On the important subject of discounting, see Portney and Weyant (1999). It should also be noted that uncertainty is a major issue in the debate on the timing of mitigation; uncertainty acts in favor of precautionary action, especially in the case of the high inertia of energy systems (Ha-Duong *et al.*, 1997).

Various ways (with many intermediate levels) of treating uncertainty have been developed:

- a systematic treatment of uncertainty using rigorous mathematical techniques such as stochastic dynamic optimization (Kann and Weyant, 2000);
- application of the precautionary principle and the viability approach through inverse problem methodology, where sustainable approaches in an uncertain context are established through a reverse computation (the *Tolerable Window Approach*) (Bruckner *et al.*, 1999);
- exploring a large number of alternative problem formulations with different sets of risk events (cultural theory) (Rotmans, 1998).

The When and Where Flexibility Debate

In a cost-effectiveness framework, one of the hotter questions is the search for the best allocation of mitigation in space and time. Use of IAMs has shown that the answer to these questions can be far removed from a first guess, which is usually to begin action as soon as possible and in the countries with higher levels of energy consumption. In fact there are many arguments in favor of delayed action. For example, it seems justified to await the effect of technical progress, the end of life of current energy installations, a better understanding of the real effect of climate change and a better discounting effect. Delayed action appears to have some advantages in economic terms when tested through IAM. In space it is best to allow some degree of exibility (with emission permits or CDM) in order to take advantage of the lowest mitigation costs available at a world level. The idea of exibility in time has been called into question when dynamic effects such as the increased cost of mitigation are introduced into the scenario, where rapid mitigation is required (if impacts turn out to be worse than previously expected). The when and where controversy is a typical example of a debate, which has developed from insights introduced by IAMs. Such a debate stemmed from the use of inter-temporal IAMs that showed that the introduction of exibility in time and space favors lower global social costs in climate change (Wigley *et al.*, 1996; Ha-Duong *et al.*, 1997).

IAM IN THE CONTEXT OF THE HISTORY OF SCIENCE

World Dynamics

As previously stated, the idea of constructing models of what is, perhaps, the most complex object ever considered in science, planet Earth, raises many epistemological questions. For some scientists, this attempt is still illegitimate. The idea of comprehensively integrating global phenomena is not new and the first approach of this type was both highly praised and strongly denigrated (Forrester, 1971; Meadows *et al.*, 1972). These two books met with a very mixed response. Widely accepted by the public and the media, they were rejected by many earth scientists and economists. Many people misinterpreted the results as predictions rather than simply answers to what-if questions. Notwithstanding an inadequate appraisal of the Earth's complexity (through the concept of static limits, the use of differential equations and deterministic system dynamics, inadequate economic representation, etc.), these two books should receive due credit as the first attempt to think globally about the future of planet Earth. As such they in u-enced many of the contemporary model builders.

But the criticisms leveled were equally important in developing lines of argument that still apply to the new generation of models:

- the data are insufficient;
- knowledge of the differing phenomena is grossly approximate;
- in running models, many elements, ranging from the inadequate treatment of uncertainty to deterministic chaos and multiple equilibriums, alter the dynamics.

However, although they seem justified at first sight, these critiques do not suggest any alternative. The problem is complex and so are the methods devised to treat it. Therefore, we should make the effort to analyze both the limitations and the merits of IAMs. The models should not be considered as truth machines, but as the best (and only) means we have to elaborate complex arguments related to a complex problem. In this context, models should be viewed as arguments in form, integrated into the framework of provisional knowledge, with the intention of defining action, rather than as a faithful mirror of the essence of the phenomena. At best, IAMs should be seen as providing order-of-magnitude modeling, comparison of policy scenarios and forecasting of trends, but not prediction.

A New Dimension in Science

The attempt to construct a predictive or a decision-making model at the level of an object as complex as planet Earth opens an entirely new field in science. We should first underline the paradox produced by this attempt. Since the 16th century the study of the universe and the cosmos has been a miraculous success. The study of the terrestrial environment and complex ecologies is only just beginning. The *cosmos* is, in some ways, more familiar than the *oikos* (Greek term from which ecology and economy derive). The part seems more complex than the whole. Clearly planet Earth is almost unthinkable in its complexity, especially in the context of decision-making. However, unfortunately, the human impact on the terrestrial environment through climate change has obliged us to focus on this objective.

Such complexity defies the very element which underpins the success of modern science since Galileo: the reduction of the complex to simple components. The scientists of the 17th and 18th centuries provided a new understanding which led to the development of modern science through a straightforward metaphysical principle: the superior being who created the world founded this creation on reason and simplicity, and based it on mathematics. The way to understand this world was to apply a platonic principle: to look for what did not change in the change itself and express this in mathematical form as the laws of change. The quest for invariance, symmetries and conservation principles opened up a new avenue in the discovery of mathematical principles underlying phenomena at a cosmological level. This constituted the origin of differential calculus. Such an approach led to the successful unification of the earth and the heavens under the universal laws of physics. This replaced Aristotelian physics, which preceded modern science, in which the earth and the heavens were governed by different principles.

The approach of the new physics of the 17th and 18th century did not, however, provide an answer to some of the problems which have been raised since Aristotle's time and which are still relevant at a terrestrial level (in ecology and economy). From the 17th to the 20th century, the mathematization of reality borrowed most of its principles and style from a mechanical model, that is to say mathematical modeling of movement, or *kinesis* (and associated systems of differential equations). But at the level of global reality, there is a form of change other than the change of place. This other type of change is designated by Aristotle as *genesis*. In genesis, new beings differing from those preceding are created and the ways of changing constantly change, in part because of the introduction of these new beings. Modern IAMs are still confronted with the major difficulty of the temporal heterogeneity of dynamic phenomena.

Some scientists who paved the way for modern IAMs, such as Von Neumann, Georgescu Roegen or Casti, underlined the fact that models of reality at a

global level should depart from the classical platonic discourse concerning phenomena (search of invariance and mathematical realism) and return to a new form of Aristotelianism (formalization of reasoning through logic on reality with deep qualitative changes). Besides the question of genesis at a terrestrial level (as underlined by Casti), not everything can be explained by a single cause, an efficient cause (a cause entirely defined by ordinary state variables), as in the mathematization of movement. Other forms of cause such as the Aristotelian formal causes, i.e., phenomena guided by programs or internal representation, should be reconsidered. Therefore, some new principles should be introduced in models of the phenomena at the level of the Earth, notably:

- *discrete events*: events which cannot be submitted to an infinite division; a move in a game, the process of formation of an animal and the construction of a factory are examples of such events;
- *formal causes*: the evolution of living creatures implies a program such as a genetic code; the evolution of human societies implies intention, will, anticipation and programs of action founded on symbolic representations by economic actors;
- *indeterminism*: the evolution of social phenomena depends on decisions taken by economic actors or agents.

In this context, classical laws of evolution only partly determine the global phenomena integrating natural events and human activities. In this sense the evolution of the Earth System is indeterminate as it involves decision-making. This new context pervades the IAM attempt to represent global phenomena. More precisely, the problem is no longer to define a phenomenology of the Earth's evolution, which treats this phenomenon as something exterior to humankind, on which we have no action, akin to planetary motions. On the contrary, we have to study very diverse trajectories which will never materialize, apart from the one that will derive from our decisions or actions. In this sense, the main object of an IAM is to set up realistic fictions to facilitate decision-making. This self-contradictory expression raises many questions: what are the realistic criteria in representing a very complex and heterogeneous object and what is the optimum level of detail in the fiction? The prevailing belief in classical science of the quasi-perfect adherence of the mathematical model to the phenomena (such as in mechanics and electromagnetism) no longer applies, and this leads to many epistemological enigmas.

All these peculiarities are responsible for major difficulties in model building (in articulating a deterministic view with alternatives and uncertainty in decision-making), in model calibration (calibration of sequences of events far from known situations), in running models (protocols for running models devoted to policy definition).

Some scientific resources exist to treat these problems, occupying a position between logic and differential calculus. Important sources of inspiration may be provided by operational research and optimal control theory.

Integrated Pest Management (IPM) in an Era of Global Environmental Change

Richard A Fleming
Great Lakes Forest Research Centre, Sault Ste. Marie, Canada

Organisms considered as threats to human beings or to their interests are often classi ed as pests. The fact that many pretty garden plants (e.g., purple loosestrife, Lythrum salicaria*), once introduced to new locations around the world, became aggressive weeds emphasizes the subjectivity and context-dependence of the term pest. Besides weeds, organisms considered pests include disease-causing microorganisms (e.g., fungi, bacteria, and viruses), as well as invertebrate (e.g., protozoa, atworms, nematodes, snails, slugs, insects, and mites) and vertebrate (e.g., rabbits, elk, deer, birds, and rodents) animal species. As a group, these organisms threaten humans indirectly by causing losses to food and ber production systems in agriculture, aquaculture, and forestry, and directly by causing or transmitting disease (e.g., malaria, Lyme disease, yellow fever, West Nile virus, bubonic plague, and sleeping sickness).*

Generally, demands for pest management will almost certainly increase as global change progresses. The exact form of these demands is unknown. Global change can be expected to produce unpredictable changes in the nature of pest problems and in the effectiveness and perceived costs of control methods. These uncertainties have a number of important implications for future pest management. They make it important to have a full menu of methods available and to have the knowledge available to integrate these methods effectively. Generating the available knowledge will depend on research, sampling, and monitoring.

Integrated pest management (IPM) ful ls this role. IPM was conceived in the late 1950s as using ecological and economic knowledge to optimally blend biological and chemical methods for effective and sustainable pest control. Thus, IPM integrates different kinds of knowledge and different methods of control. Recently there has also been increasing emphasis on integrating pest management decisions into the context of total resource management. Advances in information technology are greatly facilitating this task. Thus, as global change progresses, one can expect that IPM approaches will increasingly dominate pest management, and that generating knowledge and integrating decision-making into total resource management will become ever more important aspects of IPM.

PEST CONTROL METHODS

Since their initial development in the 18th century, pest control programs have generally been aimed against either insects, pathogens (disease-causing organisms), or weeds. Pest control methods range from practices that reduce pest populations directly to methods that provide resistance and tolerance to pest attack. These methods have been categorized as cultivation, physical, chemical, and biological.

Cultivation Methods

Many cultivation methods involve reducing the suitability of the environment for pest populations. For instance, draining, ooding, or changing the soil's level of acidity or alkalinity are often used to combat soil-borne and sometimes other types of pests. Rotating a susceptible agricultural crop with non-host species or resistant varieties in time and space can reduce pest survival after emergence from resting or dormant stages of the life cycle and during dispersal. Other cultivation methods, such as the surgical removal of infectious parts of infected hosts (e.g., pruning diseased fruit or branches in orchards), directly decrease the size of the pest population. Other examples are sanitization, the elimination of shelters (e.g., crop litter, alternate host species) which pests rely on during critical stages of their life cycles, and roguing, the removal of diseased or infected plants or seeds. Tillage and cultivation (e.g., coverage with straw, leaves, or wood chips) often provide weed control.

Physical Methods

Physical methods generally aim to eliminate the pest entirely from all or parts of the resource. Physical methods can take the form of mechanical or sticky barriers such as netting, screens, or fences on small scales. On much larger scales, quarantine procedures and importation restrictions can support pre-existing geographical barriers. Heat treatments are often applied to crop seeds or greenhouse soil to kill seed-borne or soil-borne pests (e.g., insects, fungi, nematodes, and weed seeds).

Chemical Methods

Chemical methods are largely based on pesticides, materials poisonous to at least one stage of the pest's life cycle. The first recorded chemical pesticides were poisonous plant compounds. In the 1760s, ground tobacco was used to kill aphids in France. The 19th century saw the introduction of other natural products (e.g., creosote, rotenone, turpentine, kerosene, and petroleum) plus some inorganic compounds (e.g., lime sulfur, Paris green, lead arsenate, hydrogen cyanide, and Bordeaux mixture). The relative ineffectiveness of many of these pesticides prompted further development of pest control methods. During the late 19th

and early 20th centuries there was increasing confidence that pest populations could be successfully managed and manufacturing companies began to concentrate on improving pesticides and application technology.

The effectiveness of synthetic organic compounds such as the insecticide dichloro-diphenyl-trichloroethane (DDT) and the herbicide 2,4-dichlorophenoxyacetic acid developed during the first half of the 20th century beckoned in a new generation of chemical pesticides. These new pesticides were very effective at killing pests, but a variety of problems accumulated as their usage expanded. These problems included harm to non-target organisms and human health, poisoning of soil and water resources, and in some cases, a resistant pest population with its natural enemies depleted by pesticide exposure. Consequently, legislation restricting pesticide usage was enacted in many countries. For instance, Canada, Sweden, the United Kingdom, and the United States have each restricted or completely banned DDT applications because DDT accumulates in human body fat, harms certain wildlife species, and persists in the environment. This general situation motivated a search for selective pesticides (pesticides unlikely to harm exposed, non-target organisms) and for methods which accurately target applications on pests and reduce off-target effects.

Most pesticides (e.g., bactericide, fungicide, herbicide, insecticide, miticide, and nematicide) exhibit some selectivity and thus are typically categorized by the pests they kill. For instance, few insecticides kill weeds. The need for ever more selective pest control motivated the development of new pesticides such as mercaptosuccinate, trade named Malathion, which demonstrated reduced human toxicity and they revived interest in biological methods.

Research showed that careful timing of applications (to attack pest populations during vulnerable stages of their life cycle), adjustment of dosages, and advances in application technology could produce better targeted applications and reduce off-target effects. The need for better timing led to programs for monitoring pest activity, and with better timing the same effect on the pest population could be achieved with smaller dosages. Technological advances have been largely directed at reducing spray volumes. Most pesticides are sprayed as solutions or suspensions and this requires applying much inert material along with comparatively little active ingredient. Modern ultra-low volume spraying technologies apply less than 1 liter ha^{-1}, roughly 1% of the volumes applied in the 1950s. Systemic fungicides represent another recent advance in targeting. Crop plants absorb the applied fungicide and then distribute it throughout their tissues so whole plants become effectively resistant to the targeted fungal pathogen.

Biological Methods

Biological control has been practiced in one form or another for almost 10 000 years when farmers, probably unintentionally, began planting seed from resistant plants. Manipulation of natural enemies began to be seriously considered after the successful importation of the ladybird beetle (*Rodolia cardinalis*) from Australia in 1888 to control the cottony-cushion scale (*Icerya purchasi*) threatening California's citrus fruit industry. At about the same time, microorganisms were first used against insect pests. Interest in biological control waned as the effectiveness of synthetic organic pesticides became apparent, but in the early 1960s grave ecological concerns (e.g., pest resistance, risks to non-target organisms) about pesticides arose, and this propelled government research into biological methods and accelerated plant breeding programs for developing and patenting new pest-resistant plant varieties.

Biological methods encompass a broad range of strategies and approaches. The longest and most extensively employed method in agriculture is selection of crop varieties that are tolerant of, immune to, or resistant to pest attack. Many countries support large research programs devoted to incorporating genetic resistance against plant pathogens (and also some insects) into major crops. A difficulty with this approach is that as successful varieties get more widely planted, sometimes creating vast monocultures, selection pressure unavoidably mounts for pathogenic races able to overcome the resistance of these new varieties. Another genetically based method introduces lethal or weakening genes into an insect population so that mating produces what are virtually neutered insects, or an unbalanced sex ratio, in the next generation. The goal is to depress the reproductivity of that generation.

Sterile male release is another strategy aimed at depressing pest reproductivity. Males reared in captivity are sterilized by gamma radiation and then released to mate with wild females who consequently lay no viable eggs. This has been effective in Texas against the screwworm, a major cattle pest.

Some methods focus on the chemical substances which attract pests to food or to the opposite sex. Attractants for the opposite sex (pheromones) generally attract only a specific pest species and can be broadcast during the adult part of the lifecycle to disrupt mating. Traps baited with sex or food attractants can be used for monitoring or reducing pest population densities. In the latter case, traps might include a pesticide or pathogen as well as the attractant.

Natural enemies are the focus of many biological control strategies directed against insect pests. Conservation strategies attempt to maintain the effects of native predators and parasites by ensuring as favorable an environment for them as possible. Typically this is accomplished by habitat manipulation, often in conjunction with cultivation methods. Augmentation strategies generally involve rearing and then releasing native predators and parasites in order to increase the size, and hence the effect of, natural enemy populations. Introducing exotic natural enemies is often

attempted against imported pests. First, the pest's native habitat is searched for natural enemies. Appropriate species are then reared and introduced into the new area to attack the imported pest. Often the introduced natural enemy is unable to establish itself in the new environment. Occasionally the introduced natural enemy does establish but it attacks non-target organisms (as well as the target species) and may thus become a pest itself. Hall *et al.* (1980) estimate that less than 20% of introduction attempts have been economically successful; this demonstrates the complexities involved in manipulating population regulation.

Legislative Measures

Importation restrictions on goods which may harbor exotic pests are common aspects of international trade and travel. Legislative measures can also operate on a more local scale. For example, in some fruit-growing areas where pest control is the most expensive and time-consuming farming operation, quarantine regulations require removal of untended orchards acting as sources of pestilence for neighboring farms.

INTEGRATED PEST MANAGEMENT (IPM) AND GLOBAL CHANGE

In the late 1950s when problems with extensive use of chemical methods such as pesticide resistance and non-target impacts became apparent, and the relative ineffectiveness of available biological methods during pest outbreaks was a concern, the notion of IPM was conceived. Accordingly, chemical methods are used only when needed to supplement, and in ways minimally disturbing to, biological methods. Thus, IPM programs also require ecological and economic knowledge to decide when chemical use is justified and how chemicals should then be applied. Much of the ecological knowledge is gained from sampling programs designed to estimate pest population sizes and life cycle stages as the growing season progresses. Recent pest population sizes are typically used as a basis for predicting population sizes later in the growing season, and hence, future impacts on the resource. Life cycle stage typically affects pest vulnerability to particular control methods and is therefore important to consider in choosing methods. Economic factors such as expected market price and pesticide costs partially determine whether the expected benefits of considered pest control efforts justify the likely incurred costs. Ecological costs (e.g., non-target pesticide impacts) should also be considered; so benefits and costs do not necessarily have monetary measures. A further complication is that pest management is only one aspect of the total management of the resource, so pest management decisions need to be integrated into the broader context of total resource management. For instance, in forestry, the same forest areas are often used for recreation as well as timber and paper production and these multiple uses mean that pest management decisions can no longer always be based on just economic thresholds. The issue of carbon credits is a new climate change-driven use for forests which can be expected to have some effect on pest control decision making, and the ranking of different control techniques. Thus, modern IPM integrates biological, chemical, cultivation, legislative, and physical controls; it integrates economic, ecological, and other knowledge; and it integrates pest management decisions in the broader context of total resource management.

Global Change Impacts on Pests

Global change has long been in uencing the pest status of many species. Global change is occurring because the scale of human activities now exceeds that of all other species and affects biospheric uxes of matter and energy, and it is the ever-increasing human demand for resources which underlies most pest problems. At one extreme, some pest species have maintained the same general population behavior since long before human activity had any significant effect on their environment. Nonetheless, they are considered pests now because expanded human demands for resources have made the pests competitors. For example, the outbreak cycle of the spruce budworm, *Choristoneura fumiferana* has shown little change since long before Europeans had any significant impact on North America's spruce/fir forests, but now this insect is considered a major pest by the forest industry.

Generally, however, the behavior of pest populations has responded to global change. Global change encompasses the direct and indirect effects of changes in atmospheric composition, climate, biological diversity, and land use, and it is particularly through effects on biological diversity and land use that human-caused environmental modifications have inadvertently contributed to the development of many pest problems. For example, the large-scale displacement of natural vegetation with single-crop (monoculture) agriculture has substantially improved the survival rates of some pests by: (a) providing a uniform food source over vast areas which allows easy access to new host plants for pests during the critical dispersal stages of their life cycles (*see* Life Cycles, Volume 2); and (b) by destroying the habitat of, and consequently reducing the impacts of, many competing species and natural enemies (diseases, predators, parasites). Such increases in survival have been large enough to produce major pests from what were once relatively unimportant species (e.g., Colorado potato beetle, *Leptinotarsa decemlineata*) which attacked only scattered native plants. Modern cultivation practices including irrigation, fertilization, and harvesting methods which leave much residual plant litter, often improve pest (e.g., cereal

rust, *Puccinia* spp.) reproduction or survival during critical parts of the life cycle. Crop protection with pesticides (e.g., DDT) toxic to competing species and natural enemies of a pest (e.g., California red scale, *Aonidiella aurantii*) may seriously impede these regulating factors over the long term. The volume of modern transportation of people, merchandise, and organisms, both accidentally and purposefully, introduces many exotic organisms (e.g., potato late blight, *Phytophthora infestans*) into ecosystems where the introduced species lack effective competitors and natural enemies. In some cases, pest problems initiated by human activity have been serious and extensive enough to cause human responses on scales constituting acceleration of further global change. For instance, after the potato (*Solanum* spp.) became widely established as the major food crop in Northern Europe, particularly in Ireland, late blight was also brought back from the New World, presumably in some diseased potatoes. When late blight epidemics destroyed Northern European potato crops between 1830 and 1850, the resulting widespread famine prompted massive shifts in human populations and migrations to North America.

Global Change Impacts on Pest Management

Global change can be expected to affect the practice of pest management in many ways. First, in addition to persisting pest problems, new ones are expected to arise as a result of the ever increasing scope of human activities. As discussed above, these activities have historically included extensive changes in land use (e.g., monoculture), disruption of native biodiversity (e.g., through species introductions and ecosystem simplification), and steadily rising resource usage. The accelerating pace of global industrialization and human population growth give every reason to expect these trends towards increasing pest problems to persist.

Other aspects of global change, such as changes in atmospheric composition and climate, could also have profound in uences on future pest problems. Many pest species (and presently innocuous species which will become future pests) will likely benefit from better survival with warmer climates in their current range and may well be able to invade previously hostile territory once the climate there becomes more suitable for them (*see* Life Cycles, Volume 2). Longer growing seasons may allow some pests (e.g., aphids) to increase the number of generations they have each year. This may lead to increased genetic adaptability of these populations as well as larger population sizes. Some pest species (e.g., certain plant pathogens, slugs) which prefer cool, damp climates may become relatively harmless as their populations wilt in warmer climates. In agriculture and forestry, some crops and trees may grow larger and faster as CO_2 levels rise, but the duration of this benefit is uncertain. On the other hand, long-lived forest trees may become stressed and have difficulty completing their life cycles as the climate warms. Stressed trees are often more vulnerable to pest attack, and if a tree population is already having difficulty completing its life cycle, losses to a pest outbreak could extirpate the population from the area. The complexities of the interactions make it exceedingly difficult to predict how currently established pest problems will respond to global change, let alone forecast the future, presently unforeseen pest problems.

Besides altering the nature of pest problems, global change is also likely to affect approaches to pest management through shifts in the perceived benefits and costs of most control methods. For instance, with increasing pressure for environmentally benign pest control methods, pesticides must become ever more selective, short-lived, and accurately applied. Recent advances include the development of microbial insecticides, chemical formulations based on organisms (e.g., bacteria and viruses) pathogenic to the pest. The pathogenic components of these formulations are not self-sustaining in the environment so microbial insecticides, like chemical insecticides, must be resprayed as required. Biotechnology and genetic engineering promise tools for further developing the effectiveness and selectivity of microbial pesticides and plant resistance, but use of these tools has become hotly contested because of perceived threats to human health and biodiversity. Extensive testing will likely be required for both political and scientific reasons before many genetically engineered pest control products become operationally available. Climate change could have profound effects on biological and cultivation control methods. For instance, changes in the synchrony of seasonal development rates could disrupt predator–prey and host–parasite relationships and thus nullify attempts at manipulating natural enemy effects. In short, the optimal mix of pest control methods in an IPM program is likely to be continually shifting as global change progresses. Successful IPM programs will be those with the capacity to adapt to these shifts.

[1] *IPCC, Geneva, Switzerland*
[2] *IPCC, Geneva, Switzerland*
[3] *IPCC, Geneva, Switzerland*

The IPCC was established in 1988, under the joint sponsorship of the World Meteorological Organization (WMO) and the United Nations Environment Programme (UNEP), to provide assessments of scienti c and technical information on climate change, its impacts, and potential responses. Through its reports and methodologies, workshops, and expert meetings, the IPCC has become a primary source of current, independent scienti c information on climate change, its potential impacts, and options for response. This article describes the evolution of IPCC and of its working groups.

INTRODUCTION

It has been known for well over 100 years that the presence in the atmosphere of gases such as carbon dioxide (CO_2) leads to a warming of the Earth's surface. In 1896, Svante Arrhenius, a Swedish chemist, first computed the amount of warming that would occur should the amount of CO_2 in the atmosphere double. In the 1960s, observations made by Charles Keeling from the Mauna Loa Observatory on a mountaintop in Hawaii showed that background atmospheric CO_2 concentrations were indeed increasing significantly. However, it was not until the 1980s that it began to be generally recognized that increased human activities involving the burning of fossil fuels (coal, oil and gas) was resulting in a large increase in atmospheric CO_2 and a probable doubling of its pre-industrial concentration before the end of the 21st century. The possibility of serious consequences to the world's climate was increasingly raised. A comprehensive account of global warming and climate change can be found in Houghton (1997).

By the mid-1980s, the issue of climate change induced by human actions which augment greenhouse gases, especially CO_2, was moving on to the agendas of governments and the business community. An important scientific meeting in Villach, Austria in 1985 (*see* Villach Conferences, Volume 4) reviewed the evidence for global warming and concluded *inter alia* that concentrations of all the greenhouse gases including CO_2, methane and nitrous oxide were increasing and significantly changing the natural radiation balance at the earth's surface. The results of the Villach 1985 meeting did much to alert governments to the seriousness of the issue.

UNEP and the WMO, which had co-sponsored the Villach session jointly with the non-governmental International Council of Science (ICSU), then established (1986) a scientific advisory group on greenhouse gases (AGGG). Each of the sponsors named two representatives to the AGGG, all highly respected scientists in this field and Dr F Kenneth Hare of the University of Toronto was appointed as chair. The AGGG's work produced increasing evidence that without remedial action, significant damage might occur from climate change, and/or that costly adaptation measures might be needed. In addition, remedies to reduce greenhouse gas emissions would involve major changes in global energy and industrial systems.

Contributing to rising media attention in the late 1980s about the possibility of irreversible climate change occurring within the lifetimes of our children was the conclusion of an international conference held in Toronto in 1988, which, for the first time, pressed for specific international action to mitigate climate change. It was in that year too that world leaders began to speak out; for instance, Mrs Thatcher expressed her concern about climate change in a speech to the Royal Society of London that was widely publicized. However, many governments, led by that of the

US, became uneasy about a situation in which the main international advisory body on the subject was a group of academic and independent scientists, however eminent. Instead, governments wanted a science assessment process that would involve them, as well as industry and developing countries likely to be most affected by rising sea level. It was therefore timely that in 1988 a new scientific body to address the issue, the IPCC was set up jointly by the WMO and UNEP. Bert Bolin from Sweden, a scientist with a substantial record of contributions to the science of climate change, agreed to chair the IPCC, which established three working groups to facilitate its work.

- Working Group I: the science of anthropogenic climate change.
- Working Group II: the impacts of climate change.
- Working Group III: response strategies.

A secretariat was established at WMO Headquarters, Geneva, under the direction of N Sundararaman. Over the years, the terms of reference of Working Group I have remained unchanged, but those of Working Groups II and III gradually evolved, as shown by the titles of the published assessment reports:

Working Group II:

- 1990 assessment: climate change: impacts assessment
- 1995 assessment: impacts, adaptation and mitigation of climate change
- 2000 assessment: impacts, adaptation and vulnerability

Working Group III:

- 1990 assessment: climate change: response strategies
- 1995 assessment: economic and social dimensions of climate change
- 2001 assessment: mitigation

The First Assessment (1990)

A *First Assessment Report* (FAR) was published in 1990, the initial emphasis being on the natural sciences. The most successful parts of this report were those on the science of the climate system and on the physical impacts of a changing climate. This report was in uential in development of the United Nations (UN) Framework Convention on Climate Change (FCCC), signed at the UN Earth Summit in Rio de Janeiro in 1992 (*see* United Nations Framework Convention on Climate Change and Kyoto Protocol, Volume 4). the IPCC Impacts Assessment, brought together the then-emerging literature on effects of climate change on physical and economic systems worldwide. A third volume, on response strategies, was also prepared for the FAR. However, this part of the assessment became heavily politicized, and while the volume contains valuable insights on means of reducing greenhouse gas emissions and increasing sinks, it was unable to provide the sort of consensus achieved in the other parts of IPCC 1990.

The Relation between IPCC and FCCC

The UN/FCCC, signed by close to 160 countries at the Earth Summit in Rio de Janeiro in June 1992, sets the context in which international discussion regarding appropriate action can be pursued. The development of the Convention's agenda clearly requires continuous scientific and technical input. The Conference of the Parties (COP) to the FCCC set up a subsidiary body for science and technological advice (SUBSTA) to organize this input (*see* Conference of Parties, Volume 4). The IPCC works closely with SUBSTA through a joint working group to ensure that IPCC assessments are geared to provide the detailed scientific and technical input required.

The objective of the FCCC is contained in Article 2. It recognizes the need to prevent continued change of the climate. It reads as follows:

> the ultimate objective of this Convention and any related legal instruments that the COP may adopt is to achieve, in accordance with the relevant provisions of the Convention, stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system. Such a level should be achieved within a time frame sufficient to allow ecosystems to adapt naturally to climate change, to ensure that food production is not threatened and to enable economic development to proceed in a sustainable manner.

The Second Assessment (1995)

The IPCC restructured itself for its *Second Assessment Report* (SAR), which was completed in 1995. While Working Group I continued to focus on the climate system, Working Group II was asked to consider impacts and responses together (both adaptation and mitigation) because human adaptive responses could be expected to reduce the magnitude of the potential impacts. Working Group III focused on economic issues related to both impacts and mitigation.

The Third Assessment (2001)

Background preparations for the *Third Assessment Report* (TAR) started in September 1996 at a workshop for members of the research community convened at Imperial College, London (IPCC, 1996). This workshop developed several ideas for the structure of the report and how to improve coordination across the three working groups, particularly in the use of emissions and climate scenarios. The suggestions were incorporated into a white paper prepared by Robert Watson, IPCC chair, which was circulated for several rounds of review by both experts and government representatives (Watson, 1997). The government

representatives of the IPCC approved general plans and procedures for the TAR in September 1997 (IPCC, 1997). Members of the research community drafted detailed outlines for the chapters in a meeting in late June 1998, and governments approved these outlines and lists of lead authors to prepare them in October 1998 (IPCC, 1998). This represented more than two years of effort before the assessment even started.

The Third Assessment was tasked with covering the complete range of scientific, technical, economic, and social issues associated with the climate system and climate change deemed important by the expert or policy-making communities. Working Group I was again asked to focus on the scientific aspects of the climate system and climate change. Working Group II was given the charge of assessing the scientific, technical, environmental, economic, and social aspects of the vulnerability of ecological systems, socio-economic sectors, and human health to climate change. Working Group III was asked to review aspects of the mitigation of climate change, and a synthesis report was planned to provide a policy-relevant synthesis and integration of the three working group reports. The reorganization of the panel's Working Groups II and III was motivated by a desire to join scientific and technical aspects of impacts and mitigation assessment with economic analysis of these topics.

A series of crosscutting issues were also identified, including development, sustainability, and equity, costing methodologies, decision analysis frameworks, and uncertainties. Four papers were prepared by authors of the TAR on these issues to provide guidance on achieving more consistency across the working groups. For example, the guidance paper on uncertainties sought to develop common approaches for assessing and reporting on key uncertainties, so that users of the three working group reports would find similar terms used to describe the level of confidence associated with the TAR's findings. The papers were also intended to make the preparation of the synthesis report, which would need to draw on findings from all three groups, a process which would be facilitated if information was provided in a common format and based on agreed overall approaches. Working Group II played an important role in these papers, particularly the guidance on uncertainties. (Moss and Schneider, 2000).

THE ASSESSMENT PROCESS

Richard Moss and John Houghton

In its structure, the IPCC followed closely the structure of the assessment panels of the Montreal Protocol, which had been set up in 1987 by UNEP and WMO to address the problem of the depletion of stratospheric ozone by chloro uorocarbons (CFCs) and related chlorine-containing chemicals – another example of global pollution. Through the negotiation of the Protocol, with its arrangements for inputs from scientists and other experts, methods had begun to be developed in the international community through which global pollution problems could be assessed. Although the issue addressed by the Montreal Protocol was a more limited one than that of global climate change, especially in the range and size of the human activities that contribute to it, it was appropriate that the IPCC should build on this experience in addressing climate change issues. The development within the IPCC of ways to involve large numbers of scientists and of formal procedures for peer review in turn uenced the ongoing work of the assessment panels of the Montreal Protocol.

Recognizing the complexity and broad scope of the climate change issue as well as the potential for controversy, the IPCC process was developed around a set of principles meant to ensure accuracy and wide acceptance of its assessments of the state of knowledge. These principles include:

- openness and transparency: make draft reports freely and publicly available to experts and stakeholders for review and comment;
- comprehensiveness: provide information on all aspects of the climate change issue;
- inclusiveness: assess the full range of scientifically-grounded views, establishing consensus when possible, highlighting scientific disagreements when contradictory evidence cannot be reconciled, and characterizing uncertainties;
- policy relevance and neutrality: present information relevant to decision makers without making policy recommendations.

In practice, the IPCC works at two overlapping levels: as a formal intergovernmental body, and as a scientific and technical assessment body. At the intergovernmental level, approximately 120 governments participated in the IPCC process in the year 2000. In addition, several thousand scientists were involved in the drafting and reviewing the panel's reports. The assessment process includes five main steps:

- Commissioning of reports: intergovernmental sessions of government delegates approve the terms of reference of IPCC reports, workshops, and expert meetings, to ensure their relevance to decision-making needs. Scientific experts meet in Working Group sessions to approve detailed outlines and work plans.
- Drafting of technical materials: the chapters of the reports – highly technical in nature – are prepared by members of the research community based primarily on information in the open scientific literature. Contributions to the report are broadly solicited. Any expert can

contribute so long as the basis for his/her contribution is a peer-reviewed scientific article.
- Drafting of summary for policymakers: the summaries for policymakers present the most policy-relevant conclusions from the technical chapters. They are jointly drafted by the government representatives and expert lead authors – whose participation ensures consistency between the summaries and the underlying technical chapters.
- Review: drafts go through a two-stage review process. The first stage is an expert review, after which the drafts are revised and distributed for simultaneous government and expert review. Review editors ensure that all review comments are dealt with objectively by the authors in the review process.
- Acceptance and approval: each summary for policymakers is approved by governments on a line by line basis. The lead authors participate in the meetings to approve the summaries to ensure that any changes are consistent with the findings of the chapters and that the information is balanced. The panel accepts underlying technical chapters if they are judged to have been prepared according to IPCC procedures and represent a balanced assessment of the state of knowledge.

Structuring the process in this way results in the insulation of the evaluation of the scientific literature and drafting of the technical chapters of the report from the political processes of approving the final reports and the summaries for policymakers. Scientists are given freedom to prepare the reports on the basis of standard scientific peer-review principles. Political review and approval of the summaries involve interpretation and negotiation by government representatives, under the watchful eye of the scientific authors. This political review creates buy-in by governments, who are more likely to trust the conclusions and hence to use them in formulating government policies. As a result, the reports are more in uential than they might otherwise be. There are several points of interaction between the two levels, including the initial development of outlines, the preparation of the summary for policymakers, the government review process, and the intergovernmental meetings at which the reports are finally approved.

THE ACTIVITIES OF IPCC WORKING GROUP I

John Houghton
The IPCC Working Group I 1990 Scientific Assessment (IPCC, 1990)

It was agreed at the first meeting of the IPCC that a new scientific assessment of the whole issue of anthropogenic climate change should be prepared. There had, of course, been assessments before of the climate change issue, notably one published in 1986 organized under the auspices of SCOPE (the Scientific Committee on Problems of the Environment) (SCOPE, 1986) of ICSU again under the chairmanship of Bert Bolin. The IPCC saw its task as updating previous assessments but with a difference. Previous assessments had involved relatively few of the world's leading climate scientists. Because of the global nature of the issue that brought with it a large measure of international concern, the IPCC's ambition from the start was to involve as many representatives as possible from the world scientific community in the new assessment.

To assist in the preparation of the Working Group I report, a small technical support unit was set up within that part of the UK Meteorological Office at Bracknell, which was concerned with climate research. The report comprised eleven chapters totaling over 300 pages dealing with different components of the scientific issue together with a policymakers' summary and an executive summary. Twelve international workshops were held to address these different components. One hundred and seventy scientists from 25 countries contributed to the report either through participation in the workshops or through written contributions. A further 200 scientists were involved in the peer review of the draft report. The thorough peer review played an important part in ensuring the achievement of a high degree of consensus amongst the authors and reviewers regarding the report's conclusions.

A policymakers' summary (20 pages) together with its executive summary (2 pages) were prepared for those without a strong background in science, providing a clear statement of the status of scientific knowledge at the time and the associated uncertainties. In preparing the first draft of the policymakers' summary, the lead authors were first involved; it was then sent out for the same wide peer review as the main report. A revised draft of the summary was then discussed line by line at a plenary meeting of the working group attended by government delegates from 35 countries together with lead authors from the chapters. The final wording was agreed at that meeting. A avor of the style and content of the report is given by the first few paragraphs of the executive summary that read as follows:

> We are certain of the following:
>
> - there is a natural greenhouse effect which already keeps the Earth warmer than it would otherwise be;
> - emissions resulting from human activities are substantially increasing the atmospheric concentrations of the greenhouse gases: CO_2, methane, CFCs and nitrous oxide. These increases will enhance the greenhouse effect, resulting on average in an additional warming of the Earth's surface. The main greenhouse gas, water vapor, will increase in response to global warming and further enhance it.
>
> We calculate with confidence that:
>
> - some gases are potentially more effective than others at changing climate, and their relative effectiveness can be

estimated. CO_2 has been responsible for over half the enhanced greenhouse effect in the past, and is likely to remain so in the future;

- atmospheric concentrations of the long-lived gases (CO_2, nitrous oxide and the CFCs) adjust only slowly to changes in emissions. Continued emissions of these gases at present rates would commit us to increased concentrations for centuries ahead. The longer emissions continue to increase at present day rates, the greater reductions would have to be for concentrations to stabilize at a given level;
- the long-lived gases would require immediate reductions in emissions from human activities of over 60% to stabilize their concentrations at today's levels; methane would require a 15–20% reduction.

Based on current model results, we predict:

- under the IPCC business as usual (scenario A) emissions of greenhouse gases, a rate of increase of global mean temperature during the next century of about 0.3 °C decade^{-1} (with an uncertainty range of 0.2–0.5 °C decade^{-1}); this is greater than that seen over the past 10 000 years. This will result in a likely increase in global mean temperature of about 1 °C above the present value by 2025 and 3 °C before the end of the next century. The rise will not be steady because of the influence of other factors.

Later sections of the summary addressed the scientific uncertainties and the question of the degree to which anthropogenic climate change had been observed in the climate record.

Over the period of the preparation of the report, a significant change occurred in the attitudes of the scientists involved. To begin with, many scientists felt that the scientific uncertainty was too large for any useful statement to be made regarding future climate change. However, increasingly the scientists realized their responsibility to articulate carefully and honestly the available knowledge. This responsibility seemed all the more important because many individuals not possessing much expert scientific knowledge were making forecasts of future climate change – often of an extreme kind. Also, it was increasingly recognized that there was enough certainty in the science to provide meaningful information regarding the likely future provided that the uncertainty was also fully explained.

Many of the world's leading scientists in the field of climate and climate change contributed to the report. Inevitably they came mostly from developed countries although a significant number of contributors from developing countries were also involved. That so many of the world's scientists contributed or were involved in the review process meant that there was a genuine feeling of ownership of the report by the world scientific community.

The IPCC process led to a significant degree of consensus. It is sometimes pointed out that consensus amongst scientists is not necessarily a sign of scientific health; argument and disagreement are seen to be more usual building blocks of scientific advance. But the consensus achieved by the IPCC is not complete agreement about everything. It is agreement particularly about what we know and what we do not know – distinguishing clearly those matters about which there is reasonable certainty from those where there remains much uncertainty and where there continues to be lively debate and disagreement. It is this limited consensus that is reflected in the executive summary of the 1990 IPCC Report, which has been widely acclaimed for the clarity and crispness of its presentation.

It was clear from an early stage that not only was the scientific content of the assessment important but also the way in which it was presented. Scientists left to themselves do not always recognize what is relevant to policymakers, or present their material with maximum clarity. Further, the presentation of a scientific document can appear to a policymaker to convey a political message even though none was intended.

It has therefore been helpful in the formulation of summaries of IPCC Reports to involve policymakers or their representatives. For instance, they were full participants in the government review process and in the Working Group Plenary Meeting, which agreed the wording of the summary of the 1990 Working Group I scientific assessment. The report was greatly improved in its relevance and clarity through their participation. In addition because governments participated in the process, they felt a sense of ownership of the report.

The 1992, 1994 and 1995 IPCC Reports of Working Group I

As soon as the 1990 report was complete, the IPCC began work on further reports. In 1992, in time for the Earth Summit, Working Group I produced a report updating what was known about greenhouse gases (Houghton *et al.*, 1992), their sources and sinks, and about observations and modeling of climate change. In addition, the 1992 report developed various emission scenarios for the emissions of greenhouse gases over the 21st century, based on a variety of assumptions regarding factors such as world population, economic growth, availability of fossil fuels, etc.

The 1994 report updated the information and analysis regarding the radiative forcing of the various greenhouse gases (Houghton *et al.*, 1996a). Of particular importance was the new work carried out on the profiles of emissions of CO_2 and other greenhouse gases, which would lead to the stabilization of these gases in the atmosphere at different concentration levels.

By 1995, when the IPCC produced its second comprehensive assessment (Houghton *et al.*, 1996b; Watson *et al.*, 1996; Bruce *et al.*, 1996), 5 years after the first one in 1990, the community of scientists involved with the IPCC had become substantially greater. More scientists from more

countries participated both in the report's preparation (about 480 scientists from more than 25 countries) and in its review (over 500 from 40 countries). The participants at the plenary meeting of Working Group I that approved the summary for policymakers included 177 delegates from 96 countries, representatives from 14 non-governmental organizations and 28 lead authors.

Regarding climate change over the 21st century and its likely impacts, the messages of the 1995 report were essentially the same as those of the 1990 report. Some further detail had emerged during the five years in between, especially regarding the likely contribution to climate change from atmospheric aerosols. Also, there was more confidence amongst scientists that the historical increase in global average temperatures that had occurred since wide-scale industrialization might be the result of anthropogenic change. The Working Group I plenary meeting debated for a considerable length of time how to express this somewhat greater scientific confidence in the interpretation of the recent climate record – although still surrounded by much uncertainty. The delegates unanimously agreed a sentence carefully crafted by the meeting: the balance of evidence suggests a discernible human in uence on global climate.

The IPCC Working Group I 2000 Third Scientific Assessment

The IPCC 2001 Third Scientific Assessment has comprehensively updated the 1995 report. When work began, it had been envisaged that, being an update, it would be shorter than its predecessors. However, it soon became clear that during the five-year period, the amount of research had been rapidly growing as had the volume of published material. Despite efforts to keep it short, it was not possible to do justice to the scientific advances and the report was substantially longer than the 1995 one.

Despite the increasing demands on their time made by the IPCC, many scientists were again involved in the preparation of the report, including many of the world's leading experts: 122 scientists contributed as lead authors, 515 as contributing authors, 21 as review editors, 337 as reviewers in the expert review – other reviewers were involved in the subsequent government review. At the plenary meeting of the working group held in Shanghai in January 2001, delegates from 99 governments attended, as well as about 50 lead authors.

The Third Scientific Assessment of Working Group I contains three new and important conclusions.

1. New observational evidence is presented that the world is warming. In particular, the decade of the 1990s was probably the warmest decade globally since instrumental records began around 1860. In addition, new analyses of proxy data for the Northern Hemisphere indicate that the last decade of the 20th century was the warmest of the last millennium. Further evidence for warming comes from the recent melting of glaciers and of decreases in the extent of snow cover and ice.
2. A stronger statement regarding the detection of anthropogenic climate change in the observational record was agreed compared to that made in 1995. Careful observational and modeling studies of the climate of the 20th century carried out since 1995 have provided new and stronger evidence that most of the warming observed over the last 50 years is attributable to human activities.
3. Projections of the likely change in global average temperature during the 21st century were larger than in 1995, mainly because of the substantial reduction in the expected sulfur dioxide emissions because of the impact of air pollution controls. There would therefore be less cooling occurring by sulfate particles and less offset to the projected warming by greenhouse gases (*see* Climate Change, Detection and Attribution, Volume 1).

THE ACTIVITIES OF IPCC WORKING GROUP II

Richard Moss

The IPCC Working Group II 1990 FAR: Initial Assessment of Impacts

Preparation of the Working Group II contribution to the FAR (1990) involved over 150 specialists from 24 countries. Leading the effort were Yuri A Izrael (Union of the Soviet Socialist Republics) and W J McG Tegart (Australia). The report focused on several broad impacts categories: agriculture and forestry; natural terrestrial ecosystems; hydrology and water resources; human settlements, energy, transport, and industrial sectors, human health, and air quality; oceans and coastal zones; and seasonal snow cover, ice, and permafrost. Overall, the report showed that climate change would likely be of great importance for the future development of mankind and the economy, although it would not lead to any catastrophic socio-economic consequences on global scales. The report did not anticipate any adaptation, technological innovation, or any other measures to diminish the adverse effects of climate change because this was considered to be the responsibility of Working Group III.

Preparation of the report was made difficult by the fact that Working Group II received recommendations on climate scenarios from Working Group I only late in the preparation of the impacts report. The timing of provision of scenarios, coupled with the known shortcomings of models – the extent to which they incorporate water vapor feedbacks, effects of aerosols, sudden doubling rather than transient increase of greenhouse gas concentrations, and high variance across models at regional scales – led

the Soviet co-chair to champion the use of paleoclimate analogues. The paleoclimate analogue method assumes that past warm geologic intervals provide insight into possible future climate conditions. A controversy erupted within the working group on the validity of this approach, focusing on a number of shortcomings of the method (Agrawala, 1998a,b). In addition to the use of paleoclimate analogues, authors made use of some of the climate scenarios published in the literature (Izrael, 1991). For the most part, these scenarios posited a more extreme set of changes than those ultimately suggested by Working Group I's business-as-usual scenario. The impacts based on these more dire scenarios were seen by Working Group II as a warning of the consequences of continued uncontrolled emissions (Working Group II FAR, Scenarios chapter, p. 1).

The IPCC Working Group II 1995 SAR: Integration of Impacts and Responses

The IPCC restructured itself for its SAR, which was completed in 1995. Working Group II was asked to consider impacts and responses together (both adaptation and mitigation) because human adaptive responses could be expected to reduce the magnitude of the potential impacts. (Working Group III focused on economic issues related to both impacts and mitigation.) Working Group II's contribution to the SAR was co-chaired by RT Watson (USA) and MC Zinyowera (Zimbabwe). Over 500 scientists from 55 countries participated as authors – including a greatly expanded set of researchers from developing countries.

The purview of the group was massive: primers on ecological processes and the energy system; 18 impact chapters including several that were focused on predominantly natural ecosystems, several on human activities or systems such as agriculture and human population health, and several on environmental processes such as hydrology and desertification. In addition, the report also included seven chapters on technical options for reduction of emissions in broad sectors of the economy including energy, industry, transportation, human settlements, agriculture, forestry, and cross-cutting issues such as geo-engineering and land use. Finally, the nearly 900-page volume included technical appendices on methods for assessing impacts, mitigation options, and an inventory of technologies, methods, and practices. Responsibility for these efforts was distributed across four sub-groups, each with its own set of co-chairs.

Working Group II introduced several innovations to the IPCC assessment of impacts, drawing on a formal methodology for impact assessment prepared under the IPCC's auspices during 1993–1994 (Carter *et al.*, 1994). Considering adaptive responses as a part of the analysis of impacts was felt to provide a more realistic picture of potential adverse consequences of climate change. In addition, more attention was given to potential beneficial effects of climate change, for example increased water use efficiency in some types of crops as a result of increased atmospheric concentrations of CO_2. To the extent permitted by the literature, authors also attempted to integrate bio-physical changes such as increases or decreases in crop yields or water available with potential consequences for socio-economic systems and resources.

Confidence in regional projections of temperature, precipitation, soil moisture, extremes, and other parameters important to impact assessment remained low. In addition, Working Group II confronted two specific challenges in obtaining state-of-the-art climate scenarios for use in quantitative modeling of impacts. First, regional projections of climate would be affected by aerosols as well as greenhouse gas emissions, but aerosols were only beginning to be incorporated into climate change modeling. Second, models using gradual increases in greenhouse gas concentrations (transient scenarios) rather than a sudden doubling of concentration were just being prepared and it was considered important to use these new scenarios for understanding the effects of a gradual transition in climate. These issues shaped several aspects of the Working Group II SAR. Working Group II, in close collaboration with Working Group I, compiled a set of transient climate scenarios with aerosol forcing developed in conjunction with three modeling centers (Geophysical Fluid Dynamics Laboratory (US), Hadley Centre (UK), and Max Plank Institute (Germany)) and distributed these to authors for use in the report (Greco *et al.*, 1994). To distinguish between those uncertainties arising from unknowns related to responses of systems to climate change from those related to the regional-scale climate projections themselves, Working Group II focused on the vulnerability of different systems and sectors to the level of change posited in these scenarios. The analysis integrated information on the sensitivity of response of systems to climate change in a wide variety of functional forms ranging from quantitative relationships to more qualitative analysis and the adaptive capacity of the systems, i.e., the degree to which adjustments in practices, processes, or structures could reduce adverse effects or take advantage of opportunities. In addition to attempting to distinguish among the different sources of uncertainty, Working Group II also tried to apply a consistent set of confidence levels to re ect the amount of consistent information and the degree of author consensus that supported the main findings of the report.

The Working Group II contribution to the SAR reached several overarching conclusions, especially that human-induced climate change is an important added stress to many natural and human systems already threatened by pollution, increasing resource demands, and practices ill-suited to current climate conditions, including variability. Quantitative estimates were prepared for geographic shifts in ecosystems, for changes in food production, for shifts in incidence of vector-borne diseases, and numerous other

potential effects. General conclusions on adaptation and the conditions necessary to facilitate successful adjustment to changing climate were reached in the summary for policymakers, although the individual chapters did not include as much information on this issue as some expected. Finally, detailed options for reduction of greenhouse gas emissions were reviewed, with the overall conclusion that 10–30% efficiency gains above present levels are available in many parts of the world at little or no economic cost. Integrated energy demand and supply scenarios were also evaluated as part of the report to explore the contributions of different technologies to low emission energy futures.

The report was ultimately seen as an advance (Kates, 1997), particularly in areas such human population health impacts, but was still deficient in several important respects that affected plans for subsequent reports. Attempting to analyze the effects of climate change at a global scale provided important generic information about basic relationships and processes in different systems and sectors, but it did not take account of the regional differences in environmental, social, and economic circumstances around the globe. This was particularly a concern because the circumstances of different countries would lead to very different sensitivities, adaptive capacities, and vulnerabilities, all of which needed to be factored more explicitly into the assessment. In addition, there was insufficient information on adaptation options contained in both the literature and the SAR. While the report presented a vast amount of information on technical options, separating the socio-economic analysis of impacts and mitigation costs into a separate working group (Working Group III) resulted in policymakers receiving seemingly different messages on the magnitude of the social and economic costs of impacts and mitigation measures. Finally, integrating impacts and mitigation options across so many sectors and regions was also seen as overwhelming the analytic framework of the report. The chapter on cross-cutting issues attempted to deal with macro-scale questions such as whether, in the face of climate change, there would be sufficient land, soil, and freshwater resources to support a growing population with changing dietary preferences while simultaneously increasing land use for biomass energy production or sequestration of carbon in forests. But the framework for integrated assessment was insufficient to come to grips with this issue, even in the view of lead authors (Schneider, 1991).

Targeted IPCC Reports: Meeting the Information Needs of UN/FCCC Negotiators

In the period immediately following the completion of the SAR, the IPCC began to respond to the emerging needs of the UN/FCCC, which had entered into force in April 1994 with the first meeting of COP-I in Berlin. The primary point of interaction was the Convention's subsidiary body on scientific and technological advice, which was seen as the conduit through which the IPCC SAR would be provided to the full Convention, and through which subsequent requests for reports, methodologies, and other information would be directed to the IPCC. Additional reports were requested of the IPCC in early 1996 to support the Convention's consideration of whether existing commitments were adequate to meet the Convention's goal of avoiding dangerous anthropogenic interference in the climate system. A series of four technical papers – documents that synthesized information from previous IPCC reports and applied them to a particular question or decision context – resulted. In addition, special reports – assessments that reviewed new literature but had a more specific orientation than the panel's periodic comprehensive assessments – were also prepared on a number of topics, including the impacts of aviation, the regional impacts of climate change, emissions scenarios, and technology transfer.

Lead responsibility for a number of these requests fell primarily to Working Group II. One of the technical papers was an assessment of *Technologies, Policies, and Measures for Mitigating Climate Change* (IPCC, 1996) that married the technical studies of mitigation potential from the Working Group II SAR with the assessment of policies that would affect the economic and market feasibility under different circumstances from Working Group III. A second was a special report on the *Regional Impacts of Climate Change: an Assessment of Vulnerability* (Watson *et al.*, 1997) that explored the potential consequences of climate change and other environmental stresses for 10 continental or subcontinental scale regions. This report represented an important step in the evolution of the impact assessment process for the IPCC in that previous reports analyzed the effects of climate change by sector, rather than by looking at how change would affect all of the important sectors in a particular region in an integrated fashion. Working Group II, principally through its technical support unit, also played an important role in a number of the other technical papers and special reports of this period.

The IPCC Working Group II 2000 TAR: Integrating Sectors and Regions

The Working Group II contribution to the Third Assessment Report provided an update to the sectoral treatment of impacts contained in the SAR (IPCC, 1995), and to the regional focus of the Special Report on Regional Impacts of Climate Change (IPCC, 1998). The Working Group was co-chaired by Dr O Canziani (Argentina) and Dr J McCarthy (USA). The report was compiled by 183 lead authors and 243 contributing authors between July 1998 and February 2001. Comments were received from 440 reviewers, with guidance on assimilating these comments provided by 33 review editors. The revised report was accepted, and the accompanying summary for policymakers

approved in detail, at a session of the Working Group held in Geneva, Switzerland, from 13 to 16 February 2001 (IPCC, 2001).

The literature on impacts grew considerably in the years since publication of the SAR, resulting in a substantial increase in knowledge of vulnerabilities for a variety of ecological and human systems. One of the major advances in the TAR over previous reports was increasingly solid observational evidence of changes consistent with warmer temperatures in many physical and biological systems (e.g., continued glacial melting, earlier onset of leafing in plants, shifts in geographic ranges of both plant and animal species, etc.). There was also emerging evidence that some social and economic systems were affected by changes in climate, but confounding effects of changes in demographic and other conditions made these effects much more difficult to quantify. A number of unique systems were identified as especially vulnerable to climate change, including coral reefs and atolls, mangroves, boreal and tropical forests, polar and alpine ecosystems, wetlands, and remnants of native grasslands. Systems were identified as being especially sensitive to potential changes in climate extremes. Multiple interacting stresses from other environmental changes (e.g., acid deposition) or socio-economic conditions (e.g., increases in human population density) were also identified as crucial in determining how vulnerable systems would be to future changes in climate.

The report confirmed earlier findings that the vulnerability of human populations varies substantially by region due to differences in baseline climate, the potential magnitude of change, and the varied socio-economic characteristics and pressures that give rise to different degrees of sensitivity and adaptive capacity. The report included assessments of adaptive capacity, vulnerability, and key concerns for each of eight different regions or groups of countries. Increased emphasis on the components of adaptive capacity (e.g., access to capital, highly educated populations, adequate economic infrastructure), as well as technological options for adaptation (e.g., new drought-resistant crop varieties), confirmed that developing countries, particularly the least developed, are most vulnerable to climate change, due to their relatively reduced access to resources for adaptation.

A synthesis chapter focused on a set of reasons for concern that was intended to help readers in making their own determinations about what constitutes dangerous human interference in the climate system. The reasons for concern included the relationship between global mean temperature increase and (1) loss of unique systems, (2) distribution of impacts geographically, (3) aggregate economic damages, (4) the probability of extreme weather, and (5) the probability of large-scale singular events such as reduction in North Atlantic thermohaline circulation.

Overview of Working Group II Experience

Over its evolution, Working Group II has contributed to the development of assessment methods and products. As Working Group II adopted the rigorous drafting and review process used by Working Group I (with lead authors of technical chapters largely autonomous and responsible for the content of their chapters and several layers of technical and policy review), the quality of the products of the group improved. While some critics assailed the process as politically motivated or involving a biased group of scientists who were more inclined to see climate change as a serious problem, governments and the scientific community continued to find that the process and its products were useful in assessing the scientific literature and applying it to understanding the potential impacts of human activity on climate, the potential impacts of changes in climate on society and the environment, and of options for reducing emissions to reduce the risks of large-scale global environmental change.

THE ACTIVITIES OF IPCC WORKING GROUP III

J P Bruce

The First Assessment (1990)

The initial emphasis of the IPCC was on the natural sciences. There was a volume on response strategies prepared by Working Group III but as already mentioned herein, this part of the assessment became heavily politicized, and while the volume contains valuable insights on means of reducing greenhouse gas emissions and increasing sinks, the report was unable to provide the consensus achieved in the other parts of IPCC 1990.

The Second Assessment (1995)

For the SAR, it was recognized that there was a large and growing climate change literature in the social sciences, especially economics. Thus, Working Group III was reborn in 1992 to more closely parallel, in the social sciences, the literature assessment focus for the natural sciences conducted in Working Groups I and II. The Bureau for Working Group III was selected at an IPCC plenary session in Harare and consisted of co-chairs, Canada (James Bruce from 1993) and Korea (Hoesung Lee), with vice-chairs, Kenya (Richard Odingo) and Norway (Lorents Lorentsen from 1994). The Canadian government supported the formation of a small technical support unit, based in Toronto, under the leadership of Erik Haites.

At the first plenary session of Working Group III, Montreal, May 1993, with some 80 countries represented, an outline was agreed of the main topics that countries wished to see included in the report. This was approved by the full

IPCC Plenary in June 1993. The outline defined sufficiently the scope of the work, to permit requests to be made to countries for nomination of experts to serve as authors of the various chapters. The response to the call for nominations was very encouraging, but failed to include some of the leading economists and other social scientists that had published papers related to climate change. In these cases, countries were encouraged to consider adding to their nominations some of these prominent experts. In the event, a very impressive group of economists was nominated to the writing teams as well as a more limited number of social scientists, engineers and natural scientists. There was unfortunately an unavoidable dominance of US and other Western authors since at that time (1993) they had undertaken most of the modeling efforts.

While the work on the 11 chapters of the TAR proceeded, a further task was required of Working Group III. That was an evaluation of the IS92 emission scenarios. An IPCC team had developed these scenarios of future greenhouse gas emissions over the coming century in 1992, based on projections of population, economic conditions and technology. They were intended as an input to mathematical modeling of future climate conditions, without policy-driven emission limitations. A writing team led by Joseph Alcamo (The Netherlands), compared the IS92 scenarios to other scenarios in the published literature, many prepared after 1992. They concluded that the six IS92 scenarios covered much of the very wide range of likely future emissions and were suitable for climate modeling work. However, the authors noted the high degree of dependence on input assumptions that are not readily testable, and a number of gaps in knowledge. Thus, IPCC Working Group III decided to undertake construction of a new set of emission scenarios. Working Group III appointed a writing team led by N Nakicenovic, International Institute for Applied Systems Analysis, Austria, to undertake this work. The team developed a number of plausible, and internally consistent story lines about the future and derived emission scenarios from these. They became available in 1999.

In preparing the 11 chapters of the TAR, there were many legitimate controversies amongst the lead authors. Among the more lively debates was that between developing and industrialized country authors on decision-making frameworks (Chapter 2). A difference in view also arose between economists over the discount rate that should be applied in considering climate change actions – a social discount rate to take inter-generational aspects into account, or a market rate (Chapter 4). In addition, the different perspectives of top-down econometric modelers and bottom-up sectoral studies on costs of emission reductions resulted in divergent results (Chapters 8 and 9). Differences of views are re ected in the chapters.

However, the controversy that drew most attention, and spread to a more public debate, was in connection with Chapter 6 on the social costs of climate change: greenhouse damage and the benefits of control. In this chapter, the authors cited literature dealing with the statistical value of a human life since the projected number of deaths was part of the damage estimates for a significant climate change. The economics literature uses proxy values for how much society is prepared to pay for saving a life (e.g., building straighter roads to reduce accidents, vaccination programs). These proxy values are higher for wealthy countries than for poorer ones. While this was not a central matter in the chapter or report, it became a matter of lively debate since developing countries clearly could not accept that a life in their country is worth less than a life in industrialized countries.

A Plenary Session of Working Group III (Geneva, July 1995) was held to consider a draft summary for policy makers drawn from the chapters, to which national delegates had to agree. The debate became very heated over Chapter 6, and resulted in the need to hold a second plenary session in Montreal in October 1995. On that occasion, a special task group, chaired by Ambassador John Ashe (Antigua and Barbuda) was struck, which developed summary language that was acceptable to national delegates, but which left economist lead authors somewhat dissatisfied. The finally agreed text for the summary for policy makers read in part:

> There is no consensus on how to value statistical lives or aggregate statistical lives across countries. Monetary valuation should not obscure the human consequences of climate damages, because the value of life has meaning beyond monetary consideration. Some regard valuation of such impacts (human mortality) as essential to sound decision making, but others reject monetary valuation on ethical grounds.

At the plenary sessions of Working Group III in 1995, a number of important conclusions, based on the chapters, were adopted in the summary for policy makers. This summary and the underlying report were accepted by the full IPCC Plenary in Rome, December 1995. Many of the Working Group III findings were also included in the 1995 IPCC Synthesis Report. Some of the important conclusions in the summary for policy makers of Working Group III were the following.

- Estimates of (aggregate annual) damages from $2-3\,^{\circ}C$ global warming tend to be a few percent of world gross domestic product (GDP), with, in general, considerably higher estimates of damage to developing countries as a share of their GDP. Small islands and low-lying coastal areas are particularly vulnerable to projected sea level rise accompanying global warming.
- Climate change policies should not aggravate existing disparities or attempt to redress all equity issues. Climate policy also raises particular questions of equity among generations. Sustainable development is one approach to inter-generational equity, as is the selection

of a suitable discount rate for actions to limit climate change (see above re Chapter 4).

- The literature indicates that significant no-regrets opportunities for greenhouse gas mitigation are available in most countries. No-regrets measures are those whose benefits, such as reduced energy costs and reduced emissions of local/regional pollutants, equal or exceed their cost to society, excluding the benefits of climate change mitigation. They are sometimes known as measures worth doing anyway (*see* No Regrets Principle, Volume 4).
- The risk of aggregate net damage due to climate change, consideration of risk aversion and the precautionary principle, provide rationales for greenhouse gas mitigation actions beyond no regrets.
- Potential for energy efficiency gains of perhaps 10–30% below baseline trends over the next two to three decades can be realized with net economic benefits at zero net cost for society as a whole (an example of no-regrets measures).
- Two main types of models were used to analyze costs of greenhouse gas mitigation. These are referred to as top-down models of the large-scale economy, and bottom-up models, which incorporate more detailed studies by sector of engineering costs. However, it was recognized that these model structures are converging.
- In the specific case of stabilizing emissions at 1990 levels over the next several decades, most top-down studies estimate annual costs in the range of • 0.5% of GDP (equivalent to a gain of about $60 billion in total for Organization for Economic Co-operation and Development (OECD) countries at today's GDP levels) to 2% of GDP (equivalent to a loss of about $240 billion).
- Although it is difficult to generalize, top-down analyses also suggest that the costs of substantial reductions below 1990 levels in OECD countries could be as high as several percent of GDP. However, studies also show that appropriate timing of abatement measures and the availability of low-cost alternatives may substantially reduce the size of the overall bill. Realization of economic double dividends (through use of carbon taxes to reduce more distortionary taxes), and secondary environmental benefits through reduction of local and regional air pollution, can also significantly offset costs of mitigation in some countries.
- Bottom-up studies are more optimistic about the potential for low or negative cost emission reductions, and the capacity to implement that potential. Such studies show that the costs of reducing emissions by 20% in developed countries within two to three decades are negligible to negative (i.e., economically beneficial). Other such studies suggest that there exists a potential for absolute reductions in excess of 50% in the longer term, without increasing and perhaps even reducing total energy system costs to society.
- Studies indicate that global emission reductions of 4–18%, together with increases in real incomes are possible from phasing out fuel subsidies world-wide.
- Appropriate early warning signals are required to allow producers and consumers to adapt cost-effectively to constraints on greenhouse gas emissions and to encourage research and development. Failure to adopt policies as early as possible to encourage efficient replacement investments at the end of the economic life of plant and equipment (i.e., at the point of capital stock turnover) imposes an economic cost to society. Implementing emissions reductions at rates that can be absorbed in the course of normal turnover are likely to be cheaper than enforcing premature retirement now.
- The (economic) value of better information on predictions of, impacts of, and responses to climate change is likely to be great. Research and development on energy-efficient technologies and non-fossil energy options also offer high potential value.
- A prudent way to deal with climate change is through a portfolio of actions aimed at mitigation, adaptation and improving our knowledge. The appropriate portfolio will differ for each country. The challenge is not to find the best policy today for the next 100 years, but to select a prudent strategy and to adjust it over time in the light of new information.

In addition to the contribution to the SAR, summarized brie y above, IPCC Working Group III (1992–1997) also left a legacy of several important workshop reports (see section on Completed IPCC Reports and Projects, below).

A further legacy of the Working Group III contribution to the IPCC Second Assessment was the active involvement in the IPCC process for the first time, of a number of economists, and a lesser number of other social scientists. A criticism was that nearly all of the economists and other social scientists were in one working group and that they needed to be involved in the full range of impacts, adaptation and mitigation measures considered by IPCC. In the structure for the TAR, this was achieved to a greater extent. Another result of the Second Assessment is that the Working Group III findings and the full IPCC Report have clearly in uenced thinking in the economic and policy communities. Indeed, some 400 economists in North America in early 1997 signed petitions to governments on this issue. They said:

> as economists we believe that global climate change carries with it significant environmental, economic, social and geopolitical risks, and that preventive steps are justified. Economic studies have found that there are many potential policies to reduce greenhouse gas emissions for which total benefits outweigh the total costs.

The Third Assessment (2001)

For the Third IPCC Assessment Report, the division of effort was modified somewhat. Working Group II addressed impacts of and adaptation to climate change in physical, social and economic dimensions. Working Group III did the same for mitigation measures (i.e., reducing greenhouse gas emissions and increasing sinks).

The contribution of Working Group III to the TAR casts the climate change issue in the contexts of development, equity and sustainability. The report affirms that technologies now available could reduce global greenhouse gas emission levels close to, or even below those of year 2000 by 2010 and even lower by 2020. Furthermore, known technological options (energy efficiency, alternative fuels, process changes) when combined with socio-economic and institutional changes could in the long term achieve stabilization of CO_2 concentrations at double pre-industrial levels or lower. Many measures can be achieved at little or no net costs, especially when co-benefits of emission reductions or carbon sequestration are taken into account. These include reduction of local air pollution, and water quality benefits of better land and forest conservation. The range of estimates of the costs to OECD countries of implementation of the Kyoto Protocol are from 0.1–1.1% of GDP if a full range of emission trading is permitted (*see* Tradable Permits for Greenhouse Gases, Volume 4). Without trading mechanisms, costs could be considerably higher. However, the costs of inaction could be very much higher for many vulnerable countries. To address climate change, a transition away from conventional fossil fuels is necessary and will require substantial investment, replacing investment in further developing fossil fuel resources.

Working Group III continues to suggest that a portfolio of early actions in a country, including energy efficiency measures, alternative fuels, carbon sequestration and research support increases exibility for the future. Such exibility will be essential in moving towards appropriate contributions, at minimal costs, to the ultimate goal of stabilization of atmospheric concentrations of greenhouse gases.

CONCLUDING REMARKS

The elements that have been critical to the success of the IPCC have been those of:

1. ensuring the widest possible participation by experts from all relevant disciplines;
2. ensuring a clear separation between scientific assessment and policy determination;
3. through the close involvement of the expert community, of governments and, more recently, of relevant industry, ensuring wide ownership not only by the community of experts but also by those who have a stake in the policy process.

Although anthropogenic climate change is perhaps the largest and most complex problem concerned with the global environment that we face, it is not unique. Models similar to that of the IPCC with its essential elements could be applied elsewhere. The development of the work of the IPCC has demonstrated the enormous capacity of the international community to work together towards the common aims of care for humanity and care for the environment and provides encouragement in the belief that problems as complex as that of climate change are capable of resolution.

For complex environmental issues such as climate change, IPCC's experience demonstrates that an interdisciplinary approach is essential to assessing both natural sciences and social sciences, including economics.

Internalization

The phrase *internalization of costs* refers to an action or instrument for correcting a market failure. The underlying idea is one of the most fundamental in economics: that a perfect free competitive market will result in a Pareto-optimal allocation of resources. *Pareto-optimality* is an ideal state such that each actor in the market, consisting of all buyers and sellers, ends up as well off as possible without making another actor worse off. This ideal result depends on a number of conditions, which need not be discussed in detail here. However, one of those conditions is that the price at which an exchange takes place maximizes gains (and minimizes losses) to both buyers and sellers. This assumes that the exchange between a buyer and a seller does not affect any other party, either beneficially or adversely. Such effects, when they occur, are known as positive or negative spillovers or (more commonly) externalities. The important point is that, in the real world, most kinds of economic transactions do result in *externalities* of one sort or another. For example, production and consumption activities generate wastes and pollution, not to mention noise, congestion, and so forth. Externalities are pervasive, not rare.

It is a fundamental assumption of economics that external effects, as well as goods and services exchanged in the

marketplace, should have monetary value. An important result in economic theory is that a real (i.e., imperfect) market approaches Pareto-optimality if, and only if, the monetary value of externalities is re ected in the market prices of all goods and services that are exchanged. Thus, when a negative externality such as pollution, is generated by the production (or consumption) of a good, the quantity produced is Pareto-optimal only if the resulting damage cost to all affected parties is included in the price of that good or service. This is what is meant by internalization of damage costs. When damage costs are not internalized, the damage-producing good or service is over-produced. Similarly, if a positive externality is neglected (e.g., the contributions of Research and Design (R&D) to general scientific progress) the good or service (e.g., R&D) will be under-produced.

The responsibility for internalizing costs lies with government. Instruments available for the purpose are generally classified as regulation (e.g., by imposing emission standards) and/or taxation. A tax on the carbon content of fuels would be an example of the latter. However, a newer idea for internalizing costs is the creation of exchangeable permits or exchangeable consumption quotas. In this case the role of government is to decide on the allowable pollution burden and to regulate the market for permits, allowing the market itself to set the price.

International Environmental Prizes

Ian Burton

Meteorological Service of Canada, Downsview, Canada

The creation of a highly visible and prestigious prize is often regarded as an effective way of promoting a particular activity or cause. Perhaps the most famous are the Nobel Prizes offered for outstanding achievement in elds of scienti c research, as well as peace and economics. Such prizes not only reward achievement, but also are thought to challenge others to greater effort, and also perhaps to re ect some credit on the prize donor or sponsor.

In recent times, the rise of the environmental movement, and the recognition of the importance of scienti c understanding of the environment, has given rise to the idea that a prestigious Nobel-type prize for the environment would help to advance the protection of the global environment, and strengthen the reputation of interdisciplinary environmental science and scientists. Three leading environmental scientists have in fact been awarded a Nobel Prize. Paul Crutzen (Max-Planck-Institute for Chemistry in Mainz, Germany), Mario Molina (Massachusetts Institute of Technology in Massachusetts, United States) and Rowland Sherwood (University of California in California, United States) won the prize in 1995 for their work in atmospheric chemistry, particularly concerning the formation and decomposition of stratospheric ozone.

For the environment not one, but many prizes have been established. A few, brie y described in the following text, have attained outstanding international recognition. The list is by no means comprehensive and is necessarily somewhat arbitrary. The selection of prizes is illustrative rather than de nitive.

THE TYLER PRIZE

The World Prize for Environmental Achievement was established by the late John and Alice Tyler in 1973. Prizes are awarded for the protection, improvement or understanding of ecological and environmental conditions anywhere in the world or for the discovery, further development, improvement or understanding of known or new sources of energy.

Laureates receive a US$200 000 prize and are presented with a gold medallion at ceremonies in Los Angeles.

Contact: Dr. Jerome B. Walker, Executive Director, The Tyler Prize, Office of the Provost, University of Southern California, Los Angeles, CA 90089-4019, USA. Telephone: • 1-213-740-9760, fax: • 1-213-740-1313, e-mail: tylerprz@usc.edu.

THE GOLDMAN PRIZE

The prize was established in 1990 by the Goldman Environment Foundation and is given each year to six environmental heroes , one from each of six continental regions: Africa, Asia, Europe, Island Nations, North America, and Central/South America. The prizes are awarded for sustained and important efforts to preserve or enhance the environment, including, but not limited to: protecting endangered species, combating pollution, restoring damaged ecosystems, raising public awareness of environmental issues, or in uencing environmental policies.

Laureates receive a US$100 000 prize.

Contact: Goldman Environment Foundation, 1 Lombard, Suite 303, San Francisco, CA 94111, USA. Telephone: • 1-415-788-9090, fax: • 1-415-788-7890, e-mail: gef@igc.apc.org, URL: www.goldmanprize.org.

THE INTERNATIONAL SAINT FRANCIS PRIZE FOR THE ENVIRONMENT

The prize was established in 1990 by the Franciscan Center of Environmental Studies in Rome, and the General Custody of the Sacred Convent of Saint Francis in Assisi. The prize addresses the global and interdisciplinary character of environmental, spiritual, ethical, cultural and interreligious issues in the search for solutions to ecological problems. The prize is awarded in three categories: education and communications; scientific research; realized projects and effective action. The prize is awarded to persons or institutions that, in a spirit of humility and simplicity, exemplify or promote love of nature. Consideration is also given to conformity to the values and spirit of St. Francis as expressed in his *Canticle of All Creatures.*

In keeping with the vow of poverty taken by St. Francis there is no award of money. Laureates receive a sculpture created by Mario Ceroli and attend the prize award ceremony and symposium in Assisi.

Contact: Franciscan Center of Environmental Studies, via del Serafico, 1, 00142 Rome, Italy. Telephone: • 39-6-519-15-95, fax: • 39-6-504-33-53 or 519-20-67.

THE BLUE PLANET PRIZE

The prize was established in 1992 by the Asahi Glass Foundation of Japan. The prize is an international environmental award given to individuals and organizations who have made outstanding achievements in scientific research and its application and in doing so have helped provide solutions to global environmental problems.

Each year, two award recipients are chosen and each laureate receives 50 million Yen.

Contact: Nobuaki Kunii, Head of Secretariat, Asahi Glass Foundation, Science Plaza, 5-3 Yonbancho, Cliyodaku, Tokyo 102-0081, Japan. Telephone: • 81-3-5275-0620, fax: • 81-3-5275-0871, e-mail: post@af-info.or.jp, URL: www.af-info.or.jp.

THE VOLVO ENVIRONMENT PRIZE

The prize was established in 1988 by the Swedish automobile manufacturer with headquarters in Goteborg. The criteria for receiving the prize are that:

••• the candidate shall have made outstanding innovations or discoveries in the scientific, socio-economic, or technological area, which have had a direct or indirect significance in the environmental field and are of global or regional importance. If a person who meets these standards has also been active in in uencing the decision-making process and in the change of policies, this would be regarded as an additional merit.

Laureates receive SEK 1.5 million.

Contact: The Volvo Environment Prize Foundation, c/o Environmental Affairs, AB Volvo, S-405 08 Goteborg, Sweden. Telephone: • 46-31-59-66-77, fax: • 46-31-53-84-31, e-mail: vhk.1650kh@memo.volvo.se. (*See* Volvo Environment Prize, Volume 4).

THE GLOBAL 500 ROLL OF HONOR FOR ENVIRONMENTAL ACHIEVEMENT

This award was established in 1987 by the United Nations Environment Programme (UNEP). While not strictly a prize, the roll of honor serves a similar purpose. A place on the roll of honor is awarded to those who have demonstrated that environmental issues originate in the daily life, and that individual actions affect the larger community. It recognizes the achievements of individuals and

organizations in the front lines of global environmental action.

Contact: The Secretary, Global 500 Roll of Honour, United Nations Environment Programme, Communications and Public Information, P.O. Box 30552, Nairobi, Kenya. Telephone: • 254-2-62-3401 or 62-3128, fax: • 254-2-62-3927 or 62-3692, e-mail: elisabeth.guilbaud-cox@unep.org or ipainfo@unep.org.

UNEP SASAKAWA ENVIRONMENT PRIZE

The UNEP Sasakawa Environment Prize, sponsored by the Nippon Foundation, was established in 1982. It is awarded every November to individuals who have made outstanding contributions to the management and protection of the environment at the global level.

Laureates receive US$200 000, a crystal trophy and a certificate from the United Nations Secretary-General.

Contact: The Secretary, UNEP Sasakawa Environment Prize, United Nations Environment Program, Communications and Public Information, P.O. Box 30552, Nairobi, Kenya. Telephone: • 254-2-62-3401 or 62-3128, fax: • 254-2-62-3927 or 62-3692, e-mail: elisabeth.guilbaud-cox@unep.org or ipainfo@unep.org.

ZAYED INTERNATIONAL PRIZE FOR THE ENVIRONMENT

The Zayed International Prize for the Environment was founded by the Crown Prince of Dubai to promote sustainable development through various environmental protection initiatives. The Prize of US 1 000 000 dollars is presented every 2 years as follows: first prize, US$500 000; second prize, US$300 000; third prize, US$200 000.

Contact: General Secretariat, Zayed International Prize for the Environment. Fax: • 971-4-332-6777, e-mail: zayedprz@emirates.net.ae.

In addition to this short list of well known prizes there are many more prizes and awards offered on a national and community level far too numerous to identify.

The sponsorship of environmental prizes is not limited to any one type of organization. Private sector companies, government agencies, individual citizens, and religious orders have all become involved. Nor are the prizes limited to science. Both practical results and communication and education are also recognized. No one prize has yet emerged as the preeminent Nobel prize for the environment, and probably never will. The diversity of global environmental prizes re ects the multidimensional nature of global environmental change, and the eclectic and ecumenical character of the global environmental movement.

International Environmental Standards

Scott Vaughan
North American Commission for Environmental Cooperation, Montreal, Canada

A growing list of global, regional, transboundary and shared environmental problems, and state and non-state actors have increasingly turned to a broad range of international environmental standards. Such standards assume several forms, including standards of environmental conduct articulated in such core declarations as the Rio Principles of the United Nations Conference on Environment and Development (UNCED), quantitative emission reduction or threshold standards contained in binding environmental treaties requiring signatories to undertake speci ed domestic measures, the growing emphasis on harmonized environmental and human health assessment procedures, and an increased interest in and adoption of voluntary international environmental management standards. Despite the absence of a precise estimate of the scope and number of such standards, thousands continue to evolve, be reviewed, amended and strengthened. Altogether, they form the backbone of the international environmental agenda.

A number of de nitional issues arise when describing international environmental standards. The rst revolves around the very broad, and at times ill-de ned, parameters of the term environment itself. Experts point to the absence of a universal de nition of environmental policy, such that policies and standards which fall under the environment rubric include measures specifying maximum allowable pollution emission limits for speci c pollutants and chemicals, the speci cation of environmental performance standards for technologies or more general industrial production methods, standards covering the management of renewable and non-renewable natural resources (e.g., forestry or sheries), or standards related to wildlife management and the conservation of biodiversity.

It is worth noting that although standards and regulations often cover identical environmental policies, these two terms - standards and regulations - are not synonymous. Environmental regulations are developed, codi ed and enforced within domestic jurisdictions, at the federal, sub-federal (state/provincial and/or municipal) levels, or through executive or administrative procedures. Regulations developed through such domestic legislative or administrative frameworks tend to be mandatory, and are applied within domestic jurisdictions. By contrast, compliance with international and domestic environmental standards is generally non-mandatory, for several reasons. International organizations mandated to develop standards

are not similarly mandated to enforce the domestic implementation of such measures through supra-national or supra-jurisdictional mechanisms. (However, most environmental treaties contain measures by which other parties can review the extent of domestic compliance with international standards, as well as revert to various non-compliance and more formal dispute settlement provisions.) This absence of a supra-national authority partly stems from the emphasis of international environmental law itself to respect the sovereign right of individual nations to establish their own environmental regulations and standards.

The above distinction between international standards and domestic regulations is not intended to suggest that international environmental laws are not binding upon signatory governments. As illustrated below, many international environmental agreements contain speci c and quanti able targets to which signatory countries are obliged to adhere, primarily through various domestic measures affecting production or consumption of environmental resources.

However, international environmental standards also include a wide range of non-binding measures. As a group, such standards can be divided into four broad categories: (a) standards that are contained in binding international treaties, or non-binding standards that are developed internationally; (b) plurilateral, regional or bilateral standards to address transboundary or shared environmental and conservation problems or priorities; (c) standards setting out best practices in environmental assessment and risk assessment procedures; and (d) voluntary environmental management standards.

STANDARDS CONTAINED IN INTERNATIONAL ENVIRONMENTAL AGREEMENTS, OR DEVELOPED THROUGH NON-BINDING INTERNATIONAL CONSENSUS

Multilateral Environmental Agreements (MEAs)

Approximately 185 MEAs have been negotiated and signed by governments. Obligations and standards contained in international treaties cover a very broad range of both general obligations of environmental protection and the pursuit of sustainable development, as well as specific, quantitative measures that countries must implement through the codification of MEA standards at the national level, through a process of treaty ratification and introduction of national regulations in support of treaty commitments. During this process of national ratification, varying degrees of exibility exist, whereby states can adopt standards that are either higher than those articulated in the MEA itself, or that translate into slightly different national approaches than those suggested in the international standard itself. This exibility in the process of translating international standards into national regulations takes into account important differences, which exist, between countries in domestic regulatory approaches and partnerships in place to pursue environmental policies.

MEAs are often organized, by legal scholars, into environmental media, such as atmospheric protection, the protection of freshwater resources, the protection of oceans and the marine environment, the management of hazardous wastes and chemicals, the protection of wildlife and biodiversity, and the protection of habitats. Each of these broad groupings of MEAs contains different, and often complementary, approaches to environmental management, whereby different types of environmental standards are pursued. For example, under the rubric of the protection of the marine environment and its resources, international standards cover a wide range of activities and obligations contained in different legal instruments: standards related to controlling sources of marine pollution, pipelines and seabed operations are set in the United Nations Law of the Sea Convention (UNCLOS), while standards controlling the operational discharge of pollution from marine vessels, as well as the accidental release of pollutants from vessels, are set out in the International Convention for the Prevention of Pollution by Ships (MARPOL 73/78). UNCLOS also establishes an umbrella for several fisheries management approaches. These include the United Nations (UN) Conference on Straddling Stocks and Highly Migratory Fish Stocks, which establishes limits on commercial fishing in the high seas. To lower damages to fisheries from the use of driftnets in commercial operations, the UN General Assembly adopted a moratorium in 1990 on the use of driftnets. This non-binding resolution by the General Assembly complements standards set out in the Wellington Convention intended to prohibit member countries from using driftnets in their commercial operations.

Although there are important distinctions that exist among different MEAs, re ecting the media-specific, focused and increasingly sophisticated nature of environmental policy, there are numerous examples of common environmental standards that are germane to several international accords. One such example is the principle of international cooperation in support of the on-going exchange of scientific and technical cooperation, coupled with a commitment by signatory governments towards the on-going assessment of specified environmental problems. Another example is the principle of prior informed notification and prior informed consent, contained in several MEAs. These latter principles represent the operational foundation of several MEAs, including, for example, the Convention on International Trade in Endangered Species (CITES), the Basel Convention, and more recently the Montreal Protocol (in which parties are obliged to issue export and import licenses for specified, ozone-destroying substances identified under the Protocol).

Since MEAs represent perhaps the most important source of international environmental standards, examples of specific standards contained in three particularly prominent environmental accords are provided below.

The Montreal Protocol on the Control of Substances that Deplete the Ozone Layer

The Montreal Protocol, originally signed in 1987, establishes concrete provisions that parties to the Protocol are obliged to follow. Two broad types of standards are contained in the Protocol and its amendments: standards covering domestic production and consumption of a clearly defined group of ozone-depleting substances; and standards covering cooperation between parties to the Protocol, as well as standards specifying the treatment of non-parties to the Protocol.

The foundation of the Montreal Protocol rests on the obligations that parties must follow, setting out minimum standards relating to domestic targets and timetables to freeze, reduce and eliminate the domestic production and consumption of ozone-depleting substances. The original (September 1987) Protocol required parties to freeze the domestic consumption and production of chloro uorocarbons (CFCs) at 1986 levels by 1990, to reduce them by 20% by 1993, and to reduce them by 50% by the year 2000, as well as freezing four types of halons by the year 2005. Exceptions to these initial schedules were extended to developing (Article 5) countries for a period of 10 years.

Following scientific evidence that emerged after September 1987, which confirmed the accelerated rate of stratospheric ozone depletion, the Protocol has undergone several important amendments, each of which contains newly revised standards to which signatory governments must adhere. Such amendments began in the London meeting of the Protocol (held in 1990), in which the CFC reduction timetable was moved up to the year 2000. Other standards set out in London included a 50% reduction in halons by the year 2000, the reduction in carbon tetrachloride by 85% by 1995, with a complete phase-out by the year 2000; a freeze of methyl chloroform emissions by 1993, a 30% reduction by 1995, a 70% reduction by 2000, and a complete phase-out by 2005; and a reduction by 20% in all other fully halogenated CFCs by 1993, and a phase-out by 2000. Amendments adopted at the Conference of the Parties following London further strengthened the obligations of parties to protect the ozone layer. For example, in Copenhagen in 1992, the phase-out schedule for most controlled substances was further accelerated, to 1995; substitute chemicals, hydrochloro uorocarbons and hydrobromo uorocarbons, were included in new schedules, and methyl bromide was also included in the list of controlled measures (with exceptions for agricultural quarantine and other specified uses).

As the Montreal Protocol marked its first decade, developing (Article 5) countries have begun the process of implementing domestic controls on the production, consumption and international trade in substances controlled under the Protocol. By 1 July 1999, all Article 5 countries were obliged to implement a freeze on the consumption of five (Annex A) CFCs. A similar freeze on halons and methyl bromide will commence on the 1st January 2002, and other freezes and reduction schedules will begin slightly later. For example, by 2010, Article 5 countries will implement a 100% elimination of all CFCs and halons.

The second grouping of environmental standards set out in the Montreal Protocol comprises methods of cooperation among parties, both in financial and technical assistance extended to developing countries, as well as procedures governing international trade in controlled substances between parties. Such procedures include prior informed notification provisions. Standards also include the prohibition of all international trade in controlled substances between parties and non-parties to the Protocol (with certain exceptions). This latter area, that of international environmental standards specifying trade prohibitions, has been a source of discussion and concern in the World Trade Organization's Committee on Trade and Environment, and highlights the problem of inconsistent obligations and standards that can arise between different areas of public policy and treaties (*see* WTO (World Trade Organization), Volume 4).

CITES

The CITES (*see* CITES (Convention on International Trade in Endangered Species of Wild Fauna and Flora), Volume 4) agreement was completed in 1973, and entered into force in July 1975. Among the key objectives of CITES is to establish an international mechanism to address high exploitation levels and volumes of international trade in wild animals and plants, which present risks to their survival. Two key standards represent the foundation of CITES. The first is the sophisticated system of notification procedures governing all trade in a list of species, which are protected under the Convention. Under the notification system, CITES trade permits (covering both import and export permits) must be exchanged between parties to the Convention if trade in a certain species is permitted. Where all trade in specified species is prohibited, parties are obliged to ensure that domestic authorities enforce all trade in specimens of endangered species, through customs authorities and other measures. The second is the development of science-based procedures relating to species assessments: species classifications are based on consensus decisions taken by parties to the Convention concerning whether to include, remove or alter the status of species listed in one of three CITES appendices. Altogether, approximately 30 000 species are listed in CITES appendices. Taken together, the notification system and CITES

appendices represent important examples of international environmental standards.

Kyoto Protocol

In December 1997, the Kyoto Protocol was adopted under the auspices of the UN Framework Convention on Climate Change. The Kyoto Protocol (*see* United Nations Framework Convention on Climate Change and Kyoto Protocol, Volume 4) established quantified greenhouse gas (GHG) emission limitations for industrialized countries. In addition, the Protocol sets out the initial rules and allowable mechanisms with which governments can pursue domestic and international GHG emission reductions. Under the Kyoto Protocol, industrialized countries that ratify the accord are required to lower GHG emissions with a view to achieving a 6% reduction in total domestic emissions based on 1990 levels, based on average emissions in the years 2008 through to 2012. The Protocol covers six gases – carbon dioxide, methane, nitrous oxide, hydro uorocarbons, per uorocarbons, and sulfur hexa uoride. Those parties that have ratified the targets set out in the Kyoto Protocol can meet domestic GHG reductions either through domestic measures alone, or by including options based on international cooperation identified under the Protocol, and subsequently referred to as the *Kyoto Mechanisms*. Among the mechanisms identified under the Protocol is the clean development mechanism (CDM) (*see* Clean Development Mechanism, Volume 4), which allows industrialized countries to sponsor and share credit for emission offset projects undertaken in developing countries: under rules set out in the Protocol, all transactions involving industrialized and developing countries would be brokered through the CDM, with certified emission reductions achieved through the CDM undertaken between the year 2000 and the 2008–2012 period being used as credits to meet the domestic emission goals of industrialized countries. In addition, the Kyoto Protocol will consider international emission trading schemes as being supplemental to domestic actions for reducing GHG emissions (*see* Emissions Trading, Volume 4). Under the treaty, emission reductions that are achieved with international emissions trading would view the latter approach as being supplemental to any domestic actions taken.

International Environmental Standards Developed through Non-binding Negotiations

In addition to the international standards developed in binding international legal agreements, numerous environmental standards are developed, reviewed and revised through a process of non-binding international procedures. Such standards include, as noted, non-binding international environmental principles. Among the most prominent of these are such provisions as the Common Heritage of Humankind, the Obligation Not to Cause Environmental Harm, the Principle of Intergenerational Responsibility, the Precautionary Principle and the Polluter and User Pays Principle. Each of these principles and concepts articulates different types of minimum standards of acceptable actions that state and non-state actors are expected to pursue in support of environmental protection. These principles are contained both in their own right, such as in the UNCED Rio Principles, as well as in the UNCED Forest Principles commitment adopted by governments at the UNCED. It is important to note that while such environmental principles are non-binding (or are commonly referred to as soft law), they are increasingly important in guiding both national and international environmental laws and regulations. To illustrate, differing interpretations of the operational implications of the precautionary principle, in relation to burden of proof, in denying market access within countries for foods treated with different additives and drugs, was the source of at least one dispute in the World Trade Organization (between the US and the European Union (EU) around the use of growth hormones in beef).

This case illustrates an important area of international standards around the protection of human health and the environment. The International Program on Chemical Safety (IPCS) (*see* IPCS (International Program on Chemical Safety), Volume 4) jointly administered by UNEP, the World Health Organization (WHO) and the International Labor Organization, undertakes comprehensive assessments of the effects of individual chemicals on human health and environmental quality. Such assessments have been undertaken for over 150 chemicals, and conclusions of assessments, which comprise a summary of the type and severity of risks to humans from different exposures of the specific chemical, represent one type of non-binding, information-based international environmental standard. In many cases, results of IPCS assessments are adopted by national environmental or health authorities, and therefore represent one type of international environmental standard.

Other examples of international standards that combine scientific evidence with international consensus include international food standards developed under the Codex Alimentarius Commission (jointly administered by the Food and Agriculture Organization and the WHO). CODEX sets out procedures both to determine international food safety priorities, as well as procedures to be followed by countries and that international body relating to the adoption of draft standards. International food standards combine scientific evidence, gathered through different scientific committees, with other non-scientific policy goals (including, for example, commercial interests related to ensuring fair trade in international food markets). In mid-1999, the Codex Alimentarius Commission established three new task forces to review how international standards will be set for

foods produced with biotechnology, trade in fruit juices, and the production and use of animal feeds.

A third example of international standards that marry scientific consensus with other policy goals are predictions issued by the Intergovernmental Panel on Climate Change regarding probable increases in global mean temperatures.

REGIONAL AND BILATERAL ENVIRONMENTAL STANDARDS

In addition to standards set out in MEAs and through non-binding international negotiations, an estimated 700 bilateral or regional environmental agreements exist. Such agreements are similar to global or multilateral agreements in terms of scope, but are designed to address shared or transboundary environmental problems.

Examples of regional environmental standards include the over 200 binding Environmental Directives which have been adopted by the EU, and with which the 15 EU member countries are obliged to comply. EU Environmental Directives cover such activities as allowable emission levels for different specified pollutants, proposed standards related to environmental performance requirements in the road transportation sector, directives covering the treatment and management of individual hazardous wastes and toxic chemicals, and a wide range of other standards related to community-wide approaches to environmental protection. For example, in June 1998, the EU established a new water framework directive. Among the provisions in the framework include a listing of 30 hazardous chemicals slated for priority action, including eventual phase-out. Other examples of international standards included in EU law include voluntary environmental management systems (EMAS), which are viewed as complementing the ISO 14 000 series of environmental management standards (*see* ISO (International Organization for Standardization), Volume 4), and criteria setting out provisions related to environmental labeling schemes in the EU. The following provides more detailed examples of bilateral or regional environmental standards:

Canada–US Bilateral Air Quality Agreement

Adopted in 1991, the agreement sets out obligations to control sulfurdioxide (SO_2) and nitrogen oxide (NO_x) emissions, the principal sources of acid rain. Among the standards contained in the agreement are specific targets outlining emission reduction levels, as well as the establishment of procedures related to joint cooperation between the two countries. Among the quantitative emission reduction targets set out in the agreement covering the US were a required reduction in annual SO_2 emissions by 10 million tons *per annum* below 1980 levels, by the year 2000 (with limited exceptions); the achievement of a national cap of just under nine million tons of SO_2 emissions per year from electrical utilities by the year 2010; the introduction of additional national regulations if SO_2 emissions from industrial sources exceed 5.6 million tons *per annum*, and the specification of certain technology-based standards intended to lower stationary and mobile sources of NO_x. For Canada, for example, obligations under the agreement included a reduction in SO_2 emissions in the seven easternmost provinces to 2.3 million tons *per annum* by 1994; establishment of a cap at that level of SO_2 emissions until 1999; to achieve a permanent cap of 3.2 million tons by 2000, and other emission reductions. In addition, the Acid Rain Agreement sets out provisions for notification and consultation requirements covering a range of activities, including assessment, notification and mitigation obligations (Article V) covering proposed changes in domestic laws, regulations and policies that may affect SO_2 and NO_x emissions.

Northwest Atlantic Fisheries Organization (NAFO)

NAFO is a regional organization comprising 15 member countries of the Northwest Atlantic area, with the mandate of promoting the conservation and optimum utilization of the fishery resources of the Northwest Atlantic area within a framework appropriate to the regime of extended coastal State jurisdiction over fisheries . The centerpiece of NAFO's work is the annual setting of total allowable catch (TAC) limits for commercially significant species, and the allocation of quotas to NAFO members. The TACs and quotas, while adopted by consensus, are not binding: member countries have the exibility within NAFO to object to the quota allocated within a pre-determined time period, and subsequently declare its own quota.

The Bamako Convention on the Ban of Import into Africa and the Control of Transboundary Movement and Management of Hazardous Wastes within Africa

Fifty-one countries of the Organization of African Unity signed the Bamako Convention in early 1991. The Convention prohibits the import of all hazardous wastes from outside Africa, with no exceptions. The Convention notes that any imports originating outside the continent shall be deemed illegal and a criminal act, although specific legal recourse provisions are not fully articulated. The Convention also prohibits the dumping of hazardous wastes at sea or in the territorial waters of Parties. The Convention also requires Parties to establish national waste monitoring and enforcement mechanisms. Although the Bamako Convention prohibits waste imports from outside of Africa, it allows trade in wastes between African states that are party

to the Convention. However, the Convention requires all parties to pass domestic legislation requiring waste generators to notify all waste shipments prior to their movements. Moreover, the Convention stipulates that all generators will be subject to strict joint and several liability for the release of hazardous wastes. The Bamako Convention arose as a direct result of concern amongst African countries during the final phase of negotiations, which led to the adoption of the Basel Convention on the Transboundary Movement of Hazardous Wastes, in March 1989 (*see* Basel Convention, Volume 4). Specifically, many African countries voiced concern that the original Basel Convention did not ban waste shipments from developed to developing countries.

UN Economic Commission for Europe Protocols on Persistent Organic Pollutants and Heavy Metals

In 1998, environment ministers from Europe (including western, central and eastern European countries), the US, Canada and Mexico signed two protocols to eliminate or severely restrict all emissions of heavy metals and *persistent organic pollutants* (POPs). Standards covering heavy metals and POPs were included as Protocols under the umbrella UN Economic Commission for Europe (ECE) Convention on Long-Range Transboundary Air Pollution. The POPs protocol identifies 16 substances, which are subject to stricter regulations, including the listing of eight substances – aldrin, chlordane, chlordecone, diedrin, endrin, hexabromobiphenyl, mirex and toxaphene – that would be subject to an outright ban upon entry into force of the protocol. Provisions contained in the protocol on heavy metals include emission reduction levels covering cadmium, mercury and lead, setting new and binding emission limits for new as well as existing industrial and energy production sources, the requirement for the use of best available technologies for reducing emissions, and a commitment to phase out leaded gasoline. This regional accord complements work at the global level in the development of an international Convention on POPs, which is being negotiated under the auspices of UNEP.

STANDARDS THAT SET OUT BEST PRACTICES OR GUIDELINES IN ENVIRONMENTAL ASSESSMENT AND ENVIRONMENTAL RISK ASSESSMENT

At the UNCED, the world community committed itself towards the development of harmonized environmental and risk assessment procedures (Agenda 21, 19, 20a). In recent years, considerable attention has focused on developing common environmental assessment procedures, to help ensure that comparable environmental data, baselines and methodologies are used by individual countries. In order to help frame common environmental impact assessment (EIA) procedures, in 1991 the UN ECE facilitated negotiations towards the Convention on EIA in a Transboundary Context. The Convention identifies key sectors that should be subject to environmental assessments, and commits signatories to establish comparable technical and other procedures, including public participation and EIA documentation. Efforts by several international organizations, including the OECD Development Assistance Committee, UNEP, the World Bank and others continue to focus on developing common international procedures and standards for project and policy reviews.

International effort also focuses on developing common approaches to specific environmental issues. For example, the World Meteorological Organization (WMO) has been coordinating activities to harmonize assessment methodologies related to both weather forecasting and climate change. A standard assessment tool that continues to be developed by WMO and the Intergovernmental Panel on Climate Change is the General Circulation Model, which is applied to simulate the rate and impacts of climate change. Under the IPCS, as another example, common scientific concepts and principles related to assessing risks to human health associated with chemical exposure have been developed, and workshops have been held in support of the harmonization of procedures to assess risks from exposure to chemicals. In mid-1999, Canada and the US reached an agreement covering procedures for the sharing of information related to the environmental and health review of new industrial chemicals, including administrative procedures concerning the exchange of data covering new chemicals and polymers.

VOLUNTARY INTERNATIONAL ENVIRONMENTAL STANDARDS

In recent years, interest in voluntary international environmental standards has increased among both state and non-state sectors, including, in particular, the private sector. Examples of international voluntary standards include codes of conduct negotiated and adopted by international industry associations as well as private corporations and companies. It has been estimated that more than 50 such international environmental codes of conduct have been adopted by the private sector, covering a wide range of sectors. Such international codes complement initiatives undertaken at the national level. Examples include:

- the Business Charter on Sustainable Development (1990), adopted through the International Chamber of Commerce;
- the Responsible Care Program and its supporting Guiding Principles and Guidelines and management practice codes;

- the FAO Code of Conduct on the Distribution and Use of Pesticides which was adopted by the International Group of National Associations of Agrochemical Manufacturers International; and
- the Environmental Charter of the International Council on Metals and the Environment.

Another example of an international industry code of environmental conduct is UNEP's Statement by Commercial Banks on the Environment. The statement, which was negotiated by UNEP and an advisory group of banks, commits some 150 bank signatories to best practices in environmental management, undertaking business partnerships with suppliers that follow similarly stringent environmental standards, and obliges signatories to integrate environmental considerations into core credit risk decisions. (A similar UNEP initiative, launched in 1995, involves the insurance and pension fund sectors.)

Another important component of international standards related to the environment is the development of environmental management tools. Such tools are intended to help companies identify, prioritize and integrate environmental considerations into operational systems. The two most prominent tools are the EU's EMAS, and standards developed under the ISO 14 000 series of environmental management standards.

IOC (Intergovernmental Oceanographic Commission)

The IOC was created by the United Nations Educational, Scientific and Cultural Organization (UNESCO) General Conference in 1960, as a body with functional autonomy within UNESCO, following the recommendation of the First International Oceanographic Conference, convened by UNESCO in Copenhagen, Denmark in 1960. The

mandate of IOC is to develop, recommend and coordinate implementation of international cooperative marine research programs; to develop and provide ocean services to member states; and to develop and help implement training, education and mutual assistance programs for capacity building in marine science, technology, ocean observations and services.

The IOC has a governing body of its own member states in the form of: an assembly of all its member states (presently 126) meeting biannually; an Executive Council, meeting annually; and a secretariat, housed in the UNESCO headquarters in Paris, and headed by an executive secretary, with the rank of assistant director general of UNESCO. The membership is open to any one member state of anyone of the organizations of the United Nations (UN) system. A state becomes a member state of IOC through communicating its wish to the Director General of UNESCO.

The IOC cooperates closely with all bodies and programs of the UN system dealing with various aspects of ocean issues and with relevant non-governmental organizations, e.g., International Council for Science (ICSU), Scientific Committee on Oceanic Research (SCOR), the Scientific Committee on Problems of the Environment (SCOPE), IUCN and the International Ocean Institute (IOI).

The IOC cooperates with and provides advice to the parties of the UN Framework Convention on Climate Change and the Convention on Biological Diversity.

The IOC is recognized in the UN Convention on the Law of the Sea as the competent international organization in the context of scientific research and ocean observations.

The IOC assembly formulates and guides the implementation of the IOC programs. These currently focus on four major themes: international ocean research; establishment of the Global Ocean Observing System; capacity building; efficient and widespread sharing of ocean data and other ocean services. The major program areas are developed and guided by subject area intergovernmental committees. Some of these are joint with other organizations, e.g., the World Meteorological Organization (WMO), the UN Environment Programme, and the International Maritime Organization (IMO).

The implementation of the IOC programs relies on active participation of the member states and financial contributions for international programs from UNESCO, member states directly and donor institutions. In order to stimulate capacity building and promote participation, the IOC has created regional subsidiary bodies in developing regions. The IOC has currently seven such regional, intergovernmental subsidiary bodies governed by the members states from the region in question. The IOC has several series of publications, e.g., reports of its bodies; workshop and training course reports; books; ocean maps; manuals and guidelines.

The IOC co-sponsors all major global ocean programs and the joint Group of Experts on the Scientific Aspects of Marine Environmental Protection (GESAMP). It provides the secretarial services for the Intersecretariat Committee on Scientific Programs Relating to Oceanography, and the Administrative Committee on Coordination (ACC) Subcommittee on Oceans and Coastal Areas. The IOC assembly was the body that proposed the celebration of the 1998 International Year of the Ocean.

The address of the IOC secretariat is: Intergovernmental Oceanographic Commission, UNESCO, 1, Rue Miollis, 75732 Paris Cedex 15, France.

IPCS (International Program on Chemical Safety)

The IPCS was launched in 1980 as a joint undertaking of the World Health Organization (WHO), the United Nations Environment Programme (UNEP) and the International Labor Organization (ILO).

Its role is, on the one hand, to establish the scientific health and environmental risk assessment basis for the safe use of chemicals and, on the other, to strengthen national capabilities for chemical safety.

In this context, it is carrying the following main tasks:

- evaluation of the risk to human health and the environment from exposure to chemicals and establishment of guideline values for exposure: about 200 priority chemicals have thus far been assessed (environmental health criteria documents), and health and safety guides have been published for over 200 chemicals;
- to promote the development and use of methods for laboratory testing and epidemiological studies for the health and environmental assessment of chemicals: about 20 reports in this area, plus ten books by the Scientific Group on Methodologies for the Safety Evaluation of Chemicals (SGOMSEC), co-sponsored by

the IPCS and SCOPE (the Scientific Committee on Problems of the Environment) of ICSU (the International Council for Science);
- to promote cooperation, in particular with developing countries, for capacity building in the area of chemical safety: organization of courses, preparation of training modules, etc.;
- to promote international cooperation for emergencies and accidents involving chemicals;
- to support national programs for prevention and treatment of poisonings involving chemicals: handbooks, poison information database *INTOX*, etc.

IPCS is managed by the WHO in Geneva and works through a worldwide network of Participating Institutions and National Focal Points. It played a major role in the elaboration of Chapter 19 (Chemicals) of Agenda 21, defining an international strategy for action on chemical safety into the 21st century. This strategy calls for accelerating the international assessment of chemical risk, harmonizing the classification and labeling of chemicals, establishing risk reduction programs, preventing illegal international traffic in toxic and dangerous products and building capacities.

The implementation of Agenda 21, Chapter 19 led to the establishment in 1994 of the International Forum on Chemical Safety (IFCS), a non-institutional arrangement where government representatives and NGOs (non-governmental organizations) meet to integrate and consolidate efforts to promote chemical safety, as well as to the setting up of, the Inter-organization program for the Sound Management of Chemicals (IOMC), grouping relevant bodies in the UN family (including UNEP and its chemicals program, *see* IRPTC (International Register of Potentially Toxic Chemicals), Volume 4), plus the OECD (the Organization for Economic Co-operation and Development).

IPCS has made an invaluable contribution to the improvement of chemical risk assessment and the dissemination of good practices in this important area. One can only regret that WHO decided recently to downgrade the program.

PHILIPPE BOURDEAU *Belgium*

IPO

IRPTC (International Register of Potentially Toxic Chemicals)

The IRPTC was set up shortly after the United Nations Environment Program's (UNEP) creation, upon a suggestion of the Scientific Committee on Problems of the Environment (SCOPE), which had prepared proposals for the 1972 Stockholm United Nations (UN) conference on the human environment. It was realized that the large and ever-increasing number of manufactured chemical products, some of which were highly persistent, was generating global contamination (e.g., DDT residues in Antarctic fauna), with little knowledge of its health and environmental impacts.

The IRPTC was supposed to build a database on these chemicals and their production, uses, degradation patterns, environmental pathways, toxicity and ecotoxicity, regulatory controls if any, etc. This it undertook and achieved to a certain extent. Its databank with data profiles on chemical substances (over 8000) is available for consultation. It also helps developing countries to establish their own national registers and offers training on the control of hazards posed by chemicals. It operates a query response service and publishes a bulletin on information about hazardous chemicals.

IRPTC has now expanded to become UNEP Chemicals, the mission of which is (1) to catalyze actions to promote chemical safety by helping countries in building their capacity to produce, use, and dispose of chemicals safely, and (2) to facilitate global actions that may be needed to reduce or eliminate chemical risks. In all this it cooperates with the International Program on Chemical Safety (IPCS), a joint program between the World Health Organization (WHO), the UNEP and the International Labor Organization (ILO).

National capacity building is an important part of UNEP Chemicals' work, either through the promotion of access to the relevant information or by direct work with the countries in organizing training and workshops (about 20 per year) and providing hotline support to governments.

UNEP Chemicals has also been quite active recently in its second role by working toward two important global agreements. The first is a legally binding instrument for the application of the prior informed consent (PIC) procedure for the import of hazardous chemicals, which was initially applied on a voluntary basis but was eventually signed in 1998 by over 50 countries. The second deals with the persistent organic chemicals (POPs) 12 of which are targeted for priority action, which would include, among other things, reduction programs. The matter is handled under the auspices of the International Forum on Chemical Safety (IFCS) and it is hoped that an agreement will be adopted in the year 2000.

Further information is available from http://www.unep.org/unep/program/hhwb/chemical/irptc.

PHILIPPE BOURDEAU *Belgium*

ISO (International Organization for Standardization)

The ISO is comprised of national standardization bodies from approximately 130 countries. The mandate of the ISO, which is based in Geneva, Switzerland, is to promote the development of international standards and supporting activities, including the exchange of technical information, technical capacity building and training, the review and revision of standards, and the formulation and adoption of new ones. An underlying goal of ISO standards is to facilitate international trade in goods and services, as well as to support international cooperation in such areas as scientific, technological and economic activity.

Traditionally, ISO standards have been developed to cover merchandise products. Hundreds of technical committees meet regularly to review and update a wide range of product-related standards. A highly successful and visible departure from traditional ISO activities was the launching of the ISO 9000 series of quality management standards. Following the ISO 9000 series, in the early to mid-1990s, the ISO commenced work on the ISO 14000 series of international, voluntary environmental management standards. Established under the Technical Committee 207 of the ISO, the 14000 series are intended to address six broad areas of environmental management: environmental management systems; environmental auditing and related investigations; environmental labels and declarations; environmental performance evaluation; life cycle assessment; and terms and definitions. By mid-1999, more than 5500 organizations had obtained certification worldwide under the ISO 14000 series.

The goal of the ISO 14001 series, completed in late 1996, is to promote better internal management approaches in companies and organizations, by identifying priority areas, establishing internal systems and providing external benchmarks by which to measure progress in improving environmental management. Given differences among companies that can apply for the ISO 14000 series, it is by definition generic and exible, so as to meet differing operational needs of large and small scale enterprises in all sectors, in a way that is cost effective and subject to external verification by third-party certification agencies. Among the concerns of the series is that this exibility implies the absence of clearly defined and quantitative environmental management targets. More information on ISO can be obtained by contacting the ISO, 1, Rue Varembe, Case Postale, CH-1211 Geneve 20, Switzerland.

SCOTT VAUGHAN *Canada*

IUCN (The World Conservation Union)

Founded in 1948, with the original name of the International Union for Conservation of Nature and Natural Resources (IUCN) and now called The World Conservation Union, the IUCN brings states, government agencies and a diverse range of non-governmental organizations together in a unique world partnership. Its 955 members include 76 state members, 111 government agencies, 732 non-governmental organizations, and 36 affiliates. Its six technical, voluntary commissions, with nearly 10 000 members from over 180 countries, include: education and communication; environmental law; environmental, economic and social policy; protected areas; species survival; and ecosystem management. IUCN's mission is to in uence, encourage and assist societies throughout the world to conserve the integrity and diversity of nature and to ensure that any use of natural resources is equitable and ecologically sustainable . IUCN provides information and technical knowledge, based on the latest scientific research. It promotes a common approach to the world's environmental problems, ensuring that lessons learned in one area are available in others. And as a global advocate for the environment, it represents the views of its members on the world stage. IUCN's Environmental Law Centre has drafted or assisted in the drafting of the major international conservation conventions, including CITES, wetlands, world heritage, migratory species, and biodiversity. Its Species Survival Commission provides the authoritative view on threatened species through its Red Data List, its World Commission on Protected Areas produces the definitive UN List of Protected Areas, and its Biodiversity Policy Programme is a leading advisor on implementation of the Convention on Biological Diversity. IUCN has about 900 employees and an annual budget of about US$60 million. With headquarters in Switzerland, IUCN's operations are decentralized and are carried forward by a network of 42 regional and country offices, located principally in developing countries. IUCN's website is http://www.iucn.org.

JEFFREY A MCNEELY *Switzerland*

Izrael, Yuri A

(1930-)

Yuri A Izrael, Russian atmospheric scientist, graduated in 1953 from the Central Asian State University (Tashkent), and received his PhD in 1963, when he became director of the Institute of Applied Geophysics, State Committee for Atomic Energy. In 1970 he became deputy head of the USSR Hydrometeorological Service, and head in 1974. Despite the enormous management and administrative burden associated with these positions, Izrael continued his active research career over the next two decades, working (often on Saturdays) with a small group of scientists interested in the problems of environmental monitoring and assessment. During this period, Professor Izrael sponsored a number of international workshops on the subject, including publication of the proceedings. Izrael developed the concept of integrated monitoring systems, the idea being that the biosphere ought to be treated as a whole, involving coordination amongst meteorologists, hydrologists, oceanographers, limnologists and ecologists. These ideas had a considerable impact on the design of the global environmental monitoring systems that were being developed by the World Meteorological Organization (WMO) and the United Nations Environmental Programme (UNEP) in the 1970s and 1980s.

During these two decades, Dr Izrael was the Soviet representative to the WMO, where he became Second Vice-President, and then First Vice-President. He was also an active member of the Intergovernmental Panel on Climate Change (IPCC) in its early years.

In 1991 Yuri Izrael retired from government service and created his own research institute, the Institute of Global Climate and Ecology. In 1994, he became a full member of the Russian Academy of Sciences, and in 1996, he was chosen as Secretary of the Department of Oceanology, Atmospheric Physics and Geography of the Russian Academy of Sciences.

Academically Izrael has published frequently, in both English and Russian, including a number of books that he has written or edited. His latest work (1998) is an atlas of cesium deposition on Europe after the Chernobyl accident, published by the European Union in Luxembourg.

Joint Implementation

Joint implementation is the terminology used in the Framework Convention on Climate Change (FCCC) – whereby greenhouse gas reduction projects are implemented in one FCCC party and funded from another; the sponsoring party gains a credit against its own obligations under the convention to reduce its emissions of greenhouse gases (*see* United Nations Framework Convention on Climate Change and Kyoto Protocol, Volume 4).

Kassas, Mohamed

(1921-)

Mohamed Kassas, Egyptian, Emeritus Professor of Botany, University of Cairo, holds a PhD from the University of Cambridge (UK) (1950). He is married and has two children.

At home, in Egypt, he is a member of the Egyptian Academy of Science and the Institute d 'Egypte. Internationally, he is past President (1978–1984) of the World Conservation Union (IUCN), fellow of the Indian National Academy of Science, the World Academy of Art and Science, and the Club of Rome.

In the early 1960s, he wrote reports to the Egyptian authorities on the likely environmental consequences of the Aswan High Dam. These were among the earliest environmental impact assessment studies. Since the preparations for the Stockholm Conference on the Human Environment 1970, he has become the most in uential figure in Egyptian environmental circles.

His principal research interests during the last 55 years have been in plant ecology, especially in arid lands. He and his students (a score of them got their MSc and PhD under his supervision) surveyed plant life in the deserts and coastal lands of Egypt, Sudan, Saudi Arabia, and Iraq, and contributed to basic understanding of the ecology of desert vegetation. At the international level, he was among the pioneers who warned the world against hazards of desertification and contributed to the United Nations Educational, Scientific, and Cultural Organization (UNESCO) Arid Lands Research Program, and to the scientific preparation for the United Nations Conference on Desertification (1977). He was on the panel of senior advisors to the United Nations Environment Programme (UNEP) between 1973 and 1992. He is on the editorial boards of several international journals in the fields of ecology and environmental sciences. He has published profusely in major scientific journals, especially in Europe and US. He was part author and co-editor of the first of two major UNEP environment reports: The World Environment 1972–1982.

In the process of elaborating the World Conservation Strategy (launched 1980), he, as president of IUCN, assisted in drafting and he actively participated in consultations among partners: IUCN, UNEP and World Wildlife Fund and their associates. The final text bears his moderating in uence.

He was a very active member of the (*inter alia*) Egyptian delegation to the 1972 Stockholm Conference. He led

or actively participated in the development of The National Environmental Action Plan and The National Conservation Strategy and led the Egyptian delegation through most of the negotiations of the UN Convention on Desertification. During this period he became the *de facto* science advisor to the Intergovernmental Negotiating Committee for the Elaboration of an International Convention to Combat Desertification (1992–1994).

Professor Kassas has many of national and international honors. He has published more than 100 scientific papers in highly respectable journals, a representative sample of which are:

- *Habitat and Plant Communities in the Egyptian Deserts*, Part I–VII, Journal of Ecology, 1953–1970;
- *Deserti cation Versus Potential for Recovery in Circum-Saharan Territories; Arid Lands in Transition*, AAAS, US, 1970;
- *Ecology and Management of Deserti cation. Earth 88: Changing Geographic Perspective*, National Geographic, 1988;
- *Deserti cation: a General Review*, Journal of Arid Environments, 1995;
- *Fragile Ecosystems in Near East Countries. Ecology Today: an Anthology of Contemporary Ecological Research*, 1998.

Professor Kassas was the recent (2000) winner of the important Zayed International Prize for the Environment.

Lang, Winfred

(1941 - 1999)

The late Ambassador Lang played a very significant role in the negotiation and formulation of the Vienna Convention on the protection of the ozone layer and its Montreal Protocol on substances that deplete the ozone layer.

He studied law during the period 1959–1966 at Vienna University (Law School), Oslo University, The Hague Academy of International Law and the Vienna Diplomatic Academy. From 1966, until he died in 1999, he was member of the diplomatic service of Austria. He was posted in Belgium, Paris, Tokyo and Geneva. He was deputy permanent representative and then permanent representative to the United Nations (UN) Office of International Organizations in Geneva; observer to the Committee on Disarmament and head of Austrian delegation to many disarmament related conferences. In 1982, he became Professor of International Law and International Relations at the University of Vienna. He published profusely, books and articles on international law, then on international environmental law.

In 1985, he was elected president of the UN conference that adopted and opened for signature the Vienna Convention. Immediately after the adoption of the Vienna Convention he played an important role towards the formulation of the Montreal Protocol by chairing the Ad Hoc Working Group on the Development of the Montreal Protocol. In 1986, he was the president of the UN Conference on Biological and Bacteriological Weapons (Geneva).

In 1987 he was elected president of the UN conference that finalized and adopted the Montreal Protocol and opened it for signature. In 1993 he was chairman of the council of the European Free Trade Association (EFTA). He served in various capacities within and outside the UN system. He was also since 1993 member of the Board of Trustees of the United Nations Institute for Training and Research (UNITAR).

Ambassador Lang was married with three children. He passed away on 19 May 1999.

MOSTAFA K TOLBA *Egypt*

LEAD (Leadership for Environment and Development)

The Leadership for Environment and Development (LEAD), established in 1991 by the Rockefeller Foundation, is today an independent, non-governmental and non-profit international organization with the basic mission of capacity building for selected future leaders, whose actions will contribute to the decisions made about environment and development issues in most parts of the world.

LEAD associates are generally drawn from five sectors of society: academia, business, government, media, and non-governmental organizations. They are between the ages of 30 and 40 and are fully employed in their organizations and are expected to play key roles in their countries. Their employers contribute to the LEAD program by allowing the associates to be absent from their jobs to participate in the LEAD training which normally takes approximately 80 days (including week-ends) during the 2-year training program.

Once they complete the training phase of the program, the associates become LEAD fellows for whom there exists a special program designed to nurture this growing network of leaders. LEAD ensures that all of the members of the LEAD family (associates and fellows) are kept in close touch with each other and with other, relevant organizations, through LEAD's own electronic network, LEADnet.

LEAD presently has nearly 1000 fellows and associates from over 40 countries through its 13 national and regional member programs in Brazil, Canada, China, the Commonwealth of Independent States, Europe, Francophone Africa, India, Indonesia, Japan, Mexico, Nigeria, Pakistan, and six countries of southern Africa. Studies to expand the LEAD Program to the United States are presently underway.

More information about LEAD may be obtained from its web site: www.lead.org.

JULIA MARTON–LEFEVRE *USA*

Leapfrogging Technology

José Goldemberg
University of São Paulo, São Paulo, Brazil

Growth and development, which are the fundamental aspirations of 70% of the world's population, can lead to disastrous consequences from the environmental viewpoint. It is argued that this disastrous course of events can be avoided by leapfrogging the steps followed in the past by industrialized countries and by incorporating currently available modern and ef cient technologies early in their development process.

Presently, only one-fourth of the world's population has reached a standard of living that can be considered acceptable. In the low income economies of the developing world, gross domestic product (GDP) *per capita* is only one-tenth as high as in the Organization for Economic Cooperation Development (OECD) countries. *Per capita* consumption of raw materials and energy is also about 10 times smaller. Of the three-fourths of the world's population spread among more than a 140 non-OECD countries, only a small fraction has reached a reasonable standard of living. The rest live a little above, or below, the absolute poverty line.

Such disparities will not last forever. Growth and development are fundamental aspirations of the 70% of the world's people who live in the poor countries of Africa, Latin America, the Middle East and South Asia. Indeed, the economies of a number of very populous developing countries are growing rapidly. In some areas, GDP *per capita* is likely to soon approach the level of the developed countries.

Long-term studies of *intensity-of-use curves* (measuring mass of material used per unit of income) have shown that, in general, they rise and then fall with further development. (Mandelbaum, 1978). These curves indicate that:

1. the intensity of use of many materials follows a predictable pattern: as *per capita* GDP increases from 0, intensity-of-use increases, reaches a maximum at moderate levels of *per capita* GDP, and then declines;
2. peak intensities of use of a material by different societies tend to fall over time.

Such behavior is particularly striking for curves describing industrialized countries' intensity-of-use of energy (usually called *energy intensity*, or energy consumption per unit of GDP) (Figure 1).

As Figure 1 shows, energy intensity grows during the initial phase of industrial development as heavy infrastructure is put in place, peaks, and then declines (Martin, 1988). Countries that industrialize later go through the same pattern as their predecessors, but with less accentuated peaks: they do not have to reach such high energy intensities, because they benefit from modern methods of manufacturing and more efficient systems of transportation. This was

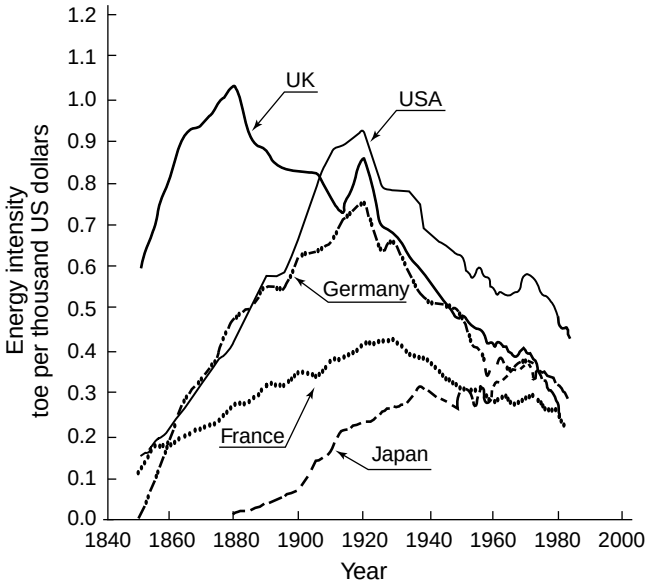

Figure 1 Long-term trends in energy intensity of industrialized countries. Only commercial energy is considered in this analysis. Commercial energy includes all energy that is the subject of monetary transactions (generally coal, oil, gas, nuclear, and hydro). *Source:* Martin (1988)

true even before the oil crisis of 1973, when rising oil prices accelerated the pace of energy efficiency improvements in industrialized countries.

The energy intensity of most industrializing countries is increasing although, in general, it is still lower than in industrialized countries (Goldemberg, 1996). Since most energy growth is in the developing countries, this trend portends a potential energy and environmental disaster.

The strategy of promoting energy efficiency – i.e., performing the same task with less energy – which has been successful in the OECD countries since 1973 is necessary but not sufficient for developing countries. As developing countries build modern economies with attendant industrial infrastructure, transportation systems, and urban development, growth in commercial energy consumption is inevitable.

But developing countries have an alternative: rather than mimicking the industrialized nations, going through an economic development phase that is dirty and wasteful, creating an enormous legacy of environmental pollution, they can leapfrog over some of the steps originally followed by industrialized countries, and incorporate currently available modern and efficient technologies into their development process. Less-developed countries are important theaters for innovation and leapfrogging, especially in energy-intensive, basic material industries such as steel, chemicals, and cement.

1. The adoption of cellular telephones can supplement and sometimes replace the traditional wired telephone systems, such as in Manila or certain regions in China. Although cellular telephones were originally developed for mobile uses or rural areas where wiring is expensive, technical developments have made them economically competitive for regular service.
2. The restructuring of the world steel industry opens new possibilities for developing countries to enhance their comparative advantages. In the past 5 years, since 1995, large conventional steel mills, requiring the use of large blast furnaces, coke ovens and sintering plants, have come under attack for their environmental impacts, including toxic and carcinogenic by-products. In many parts of Europe, licenses for new plant construction are almost impossible to obtain. One result has been an increase in the use of electric furnaces. These furnaces were used in 35% of the world steel production in 1995, compared to 10% in the 1960s. This technology depends on the availability of low-cost electric energy, which is abundant in many of the developing countries to which the modern steel industry is migrating. Another trend has been toward decentralized, small and medium size mills with a production capacity of less than 1 million tons per year.

The potential for leapfrogging is inherent in both process and products. Often, there is synergy between the two, as between the use of renewable energy sources and energy efficiency. Take, for example, lighting in isolated villages, typically supplied by kerosene lanterns, batteries, or candles. Switching to a compact uorescent light bulb, which is four times as efficient as a conventional incandescent bulb, makes it economical to supply power from a solar photovoltaic (PV) panel. Connecting to an electric grid – probably a requirement if inefficient conventional bulbs are used – is unnecessary, generating vast savings in capital equipment.

A second major dividend from leapfrog technologies derives from the avoided costs of long-term environmental clean-up. Most current environmental expenditures (approximately $100 billion per year in the US) go to mopping up old toxic sites, supplying power from a solar PV panel, installing scrubbers in coal-fired power plants, and so on. Connecting to an electric grid – probably a requirement if inefficient conventional bulbs are used – is unnecessary, generating vast savings in capital equipment. A significant fraction of health care costs are linked to environmental pollution and degradation. Using leapfrog energy technologies minimizes these future costs.

Market forces might not suffice to make transportation systems pollution-free, since the benefits are largely public but the costs are largely private. Government incentives and national and international regulations will be necessary to transform this sector. With some assistance, technological revolutions in batteries, fuel cells, and drive systems, as well as in the use of raw materials, could very significantly reduce energy use and accelerate the path to a pollution-free world (Goldemberg, 1998).

London Dumping Convention

Thomas A Mensah
London, UK

The London Dumping Convention is the short name for the 1972 Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter adopted by an International Conference held in London from the 30th of October to the 13th of November 1972.

The object of the convention is to promote international action to control the pollution of the sea by dumping. *Dumping* is defined as any deliberate disposal at sea of wastes or other matter from vessels, aircraft, platforms or other man-made structures.

The wastes and other matter covered by the convention are listed in three Annexes. Dumping of wastes and other matter listed in Annex I (black list) is prohibited absolutely. Those in Annex II (grey list) cannot be dumped at sea except with a prior special permit, and those in Annex III may only be dumped with a prior general permit. Special and general permits are issued by a contracting state if wastes or other matter to be dumped are to be loaded in its territory or by a vessel or aircraft registered in its territory or ying its ag. Each contracting party is required to take appropriate measures to prevent and punish violations of the convention.

A Protocol was adopted in 1996 to align the 1972 convention to the provisions of the 1982 United Nations Convention on the Law of the Sea. The Protocol amends the definition of dumping to include storage of wastes and other matter in the seabed from vessels, aircraft platforms and other man-made structures and abandonment or toppling at site of platforms and other structures for the sole purpose of disposal. The Protocol is more restrictive regarding the substances that can be dumped at sea. It prohibits dumping of all wastes and other matter except the seven categories expressly listed in Annex 1. It also prohibits the practice of incineration at sea. Other innovations are a new procedure for the settlement of disputes and provisions on compliance, including technical assistance to promote ratification and effective implementation by developing countries.

The original depositaries of the convention are the Governments of Mexico, Russia, the UK and the US. Pursuant to article XIV, paragraph 2, of the convention, the contracting parties designated the International Maritime Organization (IMO) to be responsible for secretariat duties in relation to the convention. IMO provides secretariat and other services to the consultative meetings of the states parties to the convention.

Further information may be obtained from the secretariat of IMO, 4 Albert Embankment, London SE1 7SR, England, UK.

LRTAP (Convention on Long Range Trans-boundary Air Pollution)

The convention on LRTAP was signed in Geneva (Switzerland) on 13th of November, 1979 and entered into force on 16th of March, 1983. By January 2001, 47 parties, including the European Community, had ratified the convention. The United Nations Economic Commission for Europe (ECE) is serving as secretariat for the convention. Fifty-five countries in Europe, North America and Central Asia and Israel are members of ECE.

The convention establishes a broad framework for cooperative action on air pollution and sets up a process for negotiating, adopting and implementing concrete measures to control specific pollutants through legally binding protocols. Eight protocols to the convention had been adopted by January 2001.

The protocol on Long-term Financing of the Cooperative Program for Monitoring and Evaluation of the Long-range Transmission of Air Pollutants in Europe (European Monitoring and Evaluation Program, EMEP) was adopted in 1984 and has been ratified by 38 parties. EMEP has three main components: collection of emissions data, measurement of air and precipitation quality and modeling of the movement of air pollutants.

The protocol on the Reduction of Sulfur Emissions of 1985 (the first sulfur protocol) has been ratified by 22 parties. It required parties to reduce annual emissions by at least 30% from 1980 levels as soon as possible and, at the latest, by 1993.

The protocol concerning the Control of Emissions of Nitrogen Oxides (NO_x) of 1988 has been ratified by 28 parties. It required parties, as a first step, to limit their nitrogen emissions to their 1987 levels by the end of 1994 and to apply best available technology to major new stationary and mobile sources.

The protocol concerning the Control of Emissions of Volatile Organic Compounds (VOCs) of 1991 has been ratified by 20 parties. In the protocol, parties committed themselves to reduce VOC emissions by at least 30% by

1999, using 1988 or any other year between 1994 and 1990 as the base year.

The protocol on Further Reduction of Sulfur Emissions (the second sulfur protocol) of 1994 has been ratified by 23 parties. The protocol was the first to use the *critical loads* concept, assigning to each country a reduction target based on the effects its sulfur emissions have on the region's ecosystems (*see* Critical Load, Volume 3).

The protocol on Heavy Metals of 1998 has been signed by 36 signatories. It aims at cutting emissions of cadmium, lead and mercury, including phasing out of leaded petrol.

The protocol on persistent organic pollutants (POPs) of 1998 was signed by 36 signatories. Its objective is to control, reduce or eliminate discharges, emissions and losses of certain POPs into the environment.

The protocol to Abate Acidification, Eutrophication and Ground level Ozone of 1999 has been signed by 31 signatories. The protocol sets emission ceilings for 2010 for four pollutants: sulfur, NO_x, VOCs and ammonia.

The three latest protocols do not yet have the needed 16 ratifications to enter into force.

According to the latest review of the implementation of the protocols in force (done in 1999) all parties to the first sulfur protocol met the required reductions in 1993. Some countries have reduced their emissions much more than required in the protocol.

Of the 28 parties to the nitrogen oxides protocol, 19 met the requirements in each of the years 1994–1996. Regarding the protocol on VOC seven parties have already achieved the target levels of the protocol. A further four have not yet met the target but appear to be on course to do so. The targets for 2000 in the second sulfur protocol have been met by 15 parties, whilst another four are on course to do so.

None of the protocols has been ratified by all parties to the convention. The reasons for non-ratification of the various protocols differ from case to case. Country replies to questionnaires point to problems of getting agreement through national procedures (ministries and parliament) or to difficulties in achieving the targets set in the protocols. In certain countries overall economic problems make some emission controls a lower priority. A considerable amount of effort is usually required by national civil servants before national procedures enable ratification.

MacNeill, Jim

(1928-)

Jim MacNeill was born on April 22 in 1928. He has enjoyed nearly four decades of experience as a policy advisor on environment, energy, natural resources management and sustainable development to leaders of international organizations, governments and industry. He is an author, speaker, member of several boards, and the recipient of many honors and distinctions, national and international. Currently, he is chairman of the World Bank's Independent Inspection Panel in Washington, DC. He is also chairman of the International Institute for Sustainable Development (IISD) in Winnipeg. He is a member of the board of the Woods Hole Research Center, Woods Hole, MA, the Wuppertal Institute on Climate and Energy Policy in Germany and the Environmental Education and Training Institute of North America (EETINA), Mexico City. He is also editorial chairman of the Earth Times, New York, and member of the jury for the Volvo Environment Prize, Gothenburg, Sweden. Recently, he served as a member of the High Level Advisory Group established by the secretary-general of the Organization for Economic Cooperation and Development (OECD) to advise on the future of that organization.

He began his career in Saskatchewan in 1952 as an economist and later as an engineer/manager with responsibility for coordinating development of the power, irrigation, and other benefits of the huge, multipurpose, South Saskatchewan River Dam Project. Moving to Canada's Department of Energy, Mines and Resources in 1965, he was responsible for policy and later for federal responsibilities for water and renewable resources, including marine resources.

In 1970, during a 2-year stint as an advisor to Prime Minister Pierre Trudeau, he authored the first major book published in Canada on *Environmental Management*. In 1971, the book played a major in uence in shaping the policies of Canada's new Department of Environment. In addition, he played a key role in the establishment of that department, one of the firsts in the western world. He led Canada's preparations for the 1972 Stockholm Conference on the Human Environment, while acting as a senior advisor to the United Nations (UN) Secretary-General of that Conference. Later, as deputy minister of the federal Ministry of Urban Affairs, he played a major role in shaping Canada's urban policy. This led to his appointment as Canada's Ambassador and Commissioner General for the 1976 United Nations Conference on Human Settlements (Habitat), held in Vancouver.

Moving to the international arena, Dr MacNeill served for 7 years in Paris as Director of Environment for the OECD. While at OECD, he negotiated several international agreements on policies and programs to enhance environmental quality.

In the same year, Norway's Prime Minister, Gro Harlem Brundtland, invited him to become a member and Secretary-General of the World Commission on Environment and Development (the Brundtland Commission). He was the principal architect and major author of the Commission's world-acclaimed report *Our Common Future*. From 1989 to 1992, he acted as a special advisor to the Secretary-General of the Earth Summit. He also established and chaired the EcoFund, which provided over $5 million in special funding for the Rio Conference.

MacNeill is the author of a number of articles, publications and books. He is also the recipient of a number of awards including the Order of Canada, his country's highest honor, the highest achievement award of his native Province of Saskatchewan, the City of Paris' Silver Medal, the Merit Award of the Climate Institute, and the Lifetime Achievement Award of Environment Canada.

Born on Earth Day, Jim MacNeill was an ecological refugee at the age of one, when his family moved from the Southern Dust Bowl to the Central Park Belt of the Province of Saskatchewan. He is married with two children and has four grandchildren.

Materials Flow Accounting

William M Stigliani
Center for Energy and Environmental Education, University of Northern Iowa, Cedar Falls, IA, USA

Materials flow accounting (MFA) is an invaluable tool for solving problems of chemical pollution. In essence, MFA provides a tracking system for the flow of a pollutant as it progresses through different stages of its lifetime in the industrial economy, and identifies points along the flow where the pollutant is released to the environment. The important stages include: (1) extraction of raw materials, (2) production (manufacturing), (3) storage and transport, (4) consumption, and (5) waste disposal. Recycling can have an important influence on the mass flow because it reduces the quantities of materials in the extraction, production, and transport stages, as well as pollution generated within these stages.

The guiding principle of MFA is the law of mass balance. Materials cannot disappear. When their useful lifetime in the economy is over they are returned to the environment, usually in a degraded form called pollution. The physical laws of nature determine whether the pollutant is stored or mobilized, persistent or decomposed, dissipated or bioaccumulated. Estimations of mass flows in the industrial economy help to insure consistency with estimates

of mass flows in the environment. In fact, MFA can provide invaluable information, often lacking in environmental assessments, in identifying sources of pollutants, quantifying their loads to the environment, and insuring that estimates of such loads are neither too high nor too low.

The MFA technique is flexible with regard to its scale of application. At the factory level, MFA can account for major waste streams and help to discern how they can be reduced via recycling or reuse. Often, a waste from one process is a feedstock for another, either in-house or in a different industry. So called waste exchange networks are already in place in many nations that serve to broker the transfer of one industry's waste to another's feedstock.

On the other end of the spectrum, MFA can be applied at the regional to continental scales, where it can be an instrument for analyzing and quantifying cross-boundary pollution. MFA has an important role to play as cooperating nations devise policies for reducing air, water, and solid waste pollution between and among states, provinces, and nations.

METHODOLOGY

As shown in Figure 1, emissions of pollutants to the environment can occur at all stages of its pathway through the industrial economy. The quantity of an emission released can be calculated as the product of two indices: (1) the quantity of pollutant in a given stage (represented here as Q_i); and (2) an emission factor that is a fraction of the quantity that goes to air, water, or soil (represented as EM_{ic}). The index i is keyed to the five stages indicated in the figure; $i = 1$ for the extraction of raw materials stage, $i = 2$ for the production stage, etc. The index c in EM_{ic} represents the three compartments of the environment. As defined here, $c = 1$ for atmosphere, $c = 2$ for water, and $c = 3$ for soil. For example, the emission of pollutant to the atmosphere during stage 2 (production) can be calculated (Equation 1):

$$\text{emission to air} = Q_2 \times EM_{21} \qquad \bullet 1 \bullet$$

By similar calculations total emissions to air, water, and soil over all stages in the flow can be summed in Equations (2), (3) and (4):

$$\text{total emissions to air} = \sum Q_i \times EM_{i1} \qquad \bullet 2 \bullet$$

$$\text{total emissions to water} = \sum Q_i \times EM_{i2} \qquad \bullet 3 \bullet$$

$$\text{total emissions to soil} = \sum Q_i \times EM_{i3} \qquad \bullet 4 \bullet$$

Typically, the MFA analysis is broken down into three steps:

1. identifying the sources of the chemical being assessed for each of its stages in the industrial economy;
2. assigning values to Q_i and EM_{ic} and quantifying chemical emissions to air, water, and soil;
3. assessing current chemical flows and their pathways into the environment, and estimating how proposed environmental policies would shift mass balances and affect environmental impacts.

Despite the power of the MFA methodology, assigning quantitative values to Q_i and EM_{ic} is often not entirely straightforward. Rather, the data must be pieced together from a variety of sources, making the task extremely labor intensive. Some important references include: reports of various industries and trade associations; state, provincial, and national accounts providing statistics on economic, environmental, and production data; publications of international organizations such as those of the United Nations Environment Programme and the United Nations Industrial Development Organization; articles in the environmental and economic literature; direct environmental monitoring data; and model estimates based on engineering principles.

A system of national accounting that harmonizes economic, environmental, and production/consumption data would be a vast improvement over the current availability of data, and would allow MFA much broader application than it now enjoys. Data availability has slowly improved, however, over the last 10–20 years. One example is the vast database, which began in 1987, of the US Environmental Protection Agency's Toxic Release Inventory.

EXAMPLE OF THE RHINE RIVER BASIN

In contrast to regions defined by political boundaries such as states, provinces, or nations, river basins are perhaps the ideal spatial scale for MFA studies. By definition, a river basin encompasses the land area that drains into the river or its tributaries. Thus, after accounting for pollutant losses to the sea via river transport, and atmospheric transport into and out of the basin (both of which can be monitored and modeled), it can be assumed that emissions of pollutants within the basin remain in the basin. This allows the economic space where the sources of pollution reside to correspond to the environmental space over which the pollutants are discharged and accumulated. Such overlapping of spatial domains greatly facilitates the calibration of economic and environmental data.

The Rhine Basin offers a particularly fertile area of investigation of material flows and environmental impacts because historically it has been one of the most heavily industrialized regions of the world. Although the stream flow of the Rhine comprises only about 0.2% of the flow of all rivers in the world, about 10–20% of the total Western chemical industry (Organization for Economic Cooperation

and Development (OECD) countries) is located in its basin. The area extends over five European nations: most of Switzerland, the northeastern region of France, Luxembourg, most of the Southwestern Lander (provinces) of Germany, and most of the Netherlands. The population of the basin is about 50 million and the area is about 220 000 km^2. About half of the land is devoted to agriculture, one third is forest, and the remainder is urban and suburban land.

The following discussion illustrates the usefulness of MFA as applied to cadmium flows in the Rhine Basin over the period 1970 to 1988. A more detailed discussion can be found in Stigliani and Anderberg (1994).

Step 1: Identification of Sources of Cadmium in the Industrial Economy of the Rhine Basin

Cadmium provides an interesting example because there are two distinct modes by which it enters the industrial economy. One is cadmium's inadvertent interjection into the economy piggy-backed on high volume raw materials that, when finished into consumer products, carry the cadmium as a trace impurity. Phosphate fertilizer is one important example. The ores from which it is made contain concentrations of cadmium in the range of 0.25–80 parts per million. Much of the cadmium is retained in the fertilizer, and is spread on agricultural land.

Table 1 Sources and emissions of cadmium in the Rhine Basin in 1970 and 1988 (tons year^{-1})

Source	Air (1970/1988)	Water (1970/1988)	Land (1970/1988)
Inadvertent sources of cadmium present as impurity			
Natural sources		3.2/3.2	
Coal combustion	45.0/16.2		9.9/19.2
Iron and steel production	48.8/6.8	32.1/3.0	68.3/14.0
Non-ferrous metal refining[a]	29.3/1.5	3.7/0.0	
Zinc product use[b]		4.5/1.1	
Phosphate fertilizer manufacture		27.9/9.8	
Phosphate fertilizer use			47.7/35.9
Cement manufacture	7.8/0.8		
Subtotal	130.9/25.3	71.4/17.1	125.9/69.1
Sources of cadmium related to products containing cadmium			
Zinc/cadmium refining	31.6/3.5	77.0/0.1	60.8/54.6
Products containing cadmium, manufacture	1.7/0.5	30.0/0.5	50.4/11.5
Products containing cadmium, use		2.9/1.5	
Products containing cadmium, disposal	8.4/4.6		675.0/659.0
Subtotal	41.7/8.6	109.9/2.1	786.2/725.1
Grand total	172.6/33.9	181.3/19.2	912.1/794.2

[a] Does not include zinc refining since cadmium is refined as a by-product, and thus is not an inadvertent waste at the zinc refinery.
[b] Refers to zinc products that contain cadmium as an impurity.

As shown in the upper part of Table 1, other important commodities containing trace amounts of cadmium are coal, iron and steel, zinc products, and other non-ferrous metals.

The category, cement manufacture, illustrates the complexity of proper source identification, and highlights the importance of constructing a comprehensive inventory with particular attention paid to sources that at first glance appear to be unrelated to the pollutant in question. There is no intrinsic step in cement manufacturing that depends on the use of cadmium-containing materials. Factories in the Rhine Basin, however, have used old automobile tires as a fuel. In the manufacture of tires, zinc is incorporated as an additive to enhance performance. Trace amounts of cadmium piggybacked on the zinc are thus inadvertently added to the tire. When combusted as a fuel, a tire releases cadmium to the atmosphere.

The lower part of the table indicates the second way cadmium enters the economy. The listed sources are products containing cadmium, where cadmium is added intentionally. The four major products are pigments, nickel–cadmium batteries, cadmium plated steel, and cadmium stabilizer in polyvinyl chloride (PVC) plastic. Cadmium is linked to zinc refining because it is present in trace amounts in zinc ore, typically 1–2%. These concentrations are generally sufficiently high to make separation and refining of the cadmium economically feasible. In fact, it is by this route that all primary cadmium is produced.

Step 2: Estimation of Cadmium Emissions and Deposition to Air, Water, and Soil

Each source indicated in Table 1 was assigned a set of values for Q_i and EM_{ic}. They were multiplied and summed to obtain cumulative emissions to air, water, and land. Changes in emissions are dictated by changes in Q_i and/or EM_{ic}. In general, values of EM_{ic} decline over time in response to increasingly more stringent environmental emission standards, or the adoption of newer and cleaner technologies. Values of Q_i depend on the intensity of production and consumption of materials containing cadmium within the basin. In some cases the materials have increased (e.g., coal), and in others they have decreased (e.g., cadmium plated steel).

The grand total in the table shows that large reductions in air (80%) and water (90%) emissions occurred between 1970 and 1988. These were due to several factors, among the most important being the enforcement of more stringent environmental standards, the shut-down of old factories or the introduction of modern cleaner technologies, and reduction in overall use of cadmium in the Basin.

In contrast, the reduction in deposition to land was only about 13% between 1970 and 1988. One reason for this is that reducing emissions to air and water created an increase in solid wastes. For example, reducing cadmium emissions to the atmosphere from coal burning facilities was attained by collecting more of the y ash that contained cadmium in the smokestack. Thus, reducing emissions to air led

to an increase in fly ash that was sent to landfill. This can be observed in Table 1, which shows coal combustion generated 9.9 tons of emissions to land in 1970, compared to 19.2 tons in 1988. A more important factor is that among the sources of land deposition, disposal of products containing cadmium to municipal landfill (nickel–cadmium batteries, etc.) is by far the largest input, comprising 74% of all landfilled cadmium in 1970, and 83% in 1988. The use of some products containing cadmium increased and others decreased in the 1970s and 1980s, but overall products delivered to landfills declined only slightly over this period.

The entry marked zinc/cadmium refining shows exceedingly large emissions to air and water in 1970, and drastic reductions by 1988. This trend appears surprising given that zinc refineries, even in 1970, were in the business of producing refined cadmium as a lucrative by-product of zinc. In this case, however, there was one antiquated zinc refinery that did not refine cadmium, but rather, viewed it as a waste product. Emission control measures were primitive, and the cheapest option was to unload the cadmium to the air and water. Needless to say, such practices could not survive as clean up of point sources in the basin began in earnest by the late 1970s.

The final point of note is that solid wastes (i.e., emissions to land) dwarf the emissions to air and water. In 1970 when total emissions were around 1264 tons, 14% went to the air and water each, and 72% to the land. Percentage of solid waste to land was even higher in 1988 with a 94% share, compared to 4% and 2%, for air and water, respectively. This is not surprising since products containing cadmium dominate most of the gross cadmium solid flow in the basin.

Step 3: Applying MFA for Assessment of Risk Reduction Policies for Cadmium Pollution in the Rhine Basin: a Hypothetical Example

In comparing the reduced cadmium emissions in 1988 relative to 1970, one might surmise that environmental risks of cadmium pollution in the Rhine Basin are declining. Our MFA model, however, allows us to probe beyond superficial assessments based upon limited information. As an illustration, let us test the effectiveness of a proposed policy that would ban by 2010 all products containing cadmium except for nickel–cadmium batteries, with a target that 50% of the batteries would be recycled, thus averting their disposal in municipal landfills.

Figure 2 shows the flow of products containing cadmium in the Rhine Basin in the mid-1980s, as determined by the MFA model. One may notice that because there was a shortage of cadmium metal needed for the manufacture of the products, 570 tons of refined cadmium was imported. Also, with the exception of industrial batteries, there was very little recycling. As a result of this flow, most of the cadmium (almost 700 tons) ended up as solid consumer waste, of which over 80% went to municipal landfill and the balance to incineration.

Figure 3 shows how the flows would change if the proposed policy were fully enacted. One consequence of the policy would be creation at the zinc/cadmium refineries of a surplus of cadmium in contrast to the scarcity that existed in the mid-1980s, when 570 tons had to be imported.

The problem arises because the supply of cadmium into the Rhine Basin is essentially inelastic. It enters the basin as a by-product of zinc refining, which still maintains a high degree of productivity. The fact that 50% of the batteries would be recycled increases the surplus even further. Thus, the amount of cadmium ending up in municipal landfills would indeed be sharply reduced to around 100 tons. However, cadmium-laden solid waste would increase at refineries from about 30 tons in the mid-1980s to more than 450 tons if the policy came into in force. This analysis suggests that the result of the policy is merely to transfer the solid waste load from the municipal landfill to the landfill into which the zinc refinery wastes are deposited. Thus, the policy would most likely have little positive benefit with respect to cadmium's impact on the environment.

With respect to human health, the major exposure pathway is:

$$\text{cadmium in agricultural soil} \longrightarrow \text{cadmium in vegetables} \longrightarrow \text{cadmium ingested in human diet}$$

Any policy targeted at lowering risks to human health should pay close attention to input of cadmium to agricultural land. Cadmium in safely engineered and maintained landfills, whether municipal or industrial depositories, is less likely to constitute a serious hazard to human health. We can see from the last column of Table 1 that cadmium deposition to land from phosphate fertilizer use differs significantly from other sources. It is the only one that is not delivered to an industrial or municipal landfill. Rather, it is inadvertently applied directly to agricultural land as a trace impurity of phosphate fertilizer. Even though in 1988 its total on agricultural land constituted only about 9% of all cadmium deposited on land, its risk to human health is magnified many times because of its direct linkage to human exposure via crop uptake.

Having identified this key exposure pathway, MFA can carry the assessment to the next level of complexity. It is possible to construct a mass balance for cadmium in agricultural soils by estimating its inputs and outputs. The results are shown in Table 2, which identifies three inputs and three outputs.

Atmospheric deposition is related to the sources identified in the air column in Table 1. Some of these air emissions are eventually deposited on agricultural land, either in wet form with rain or in dry deposition. Sewage

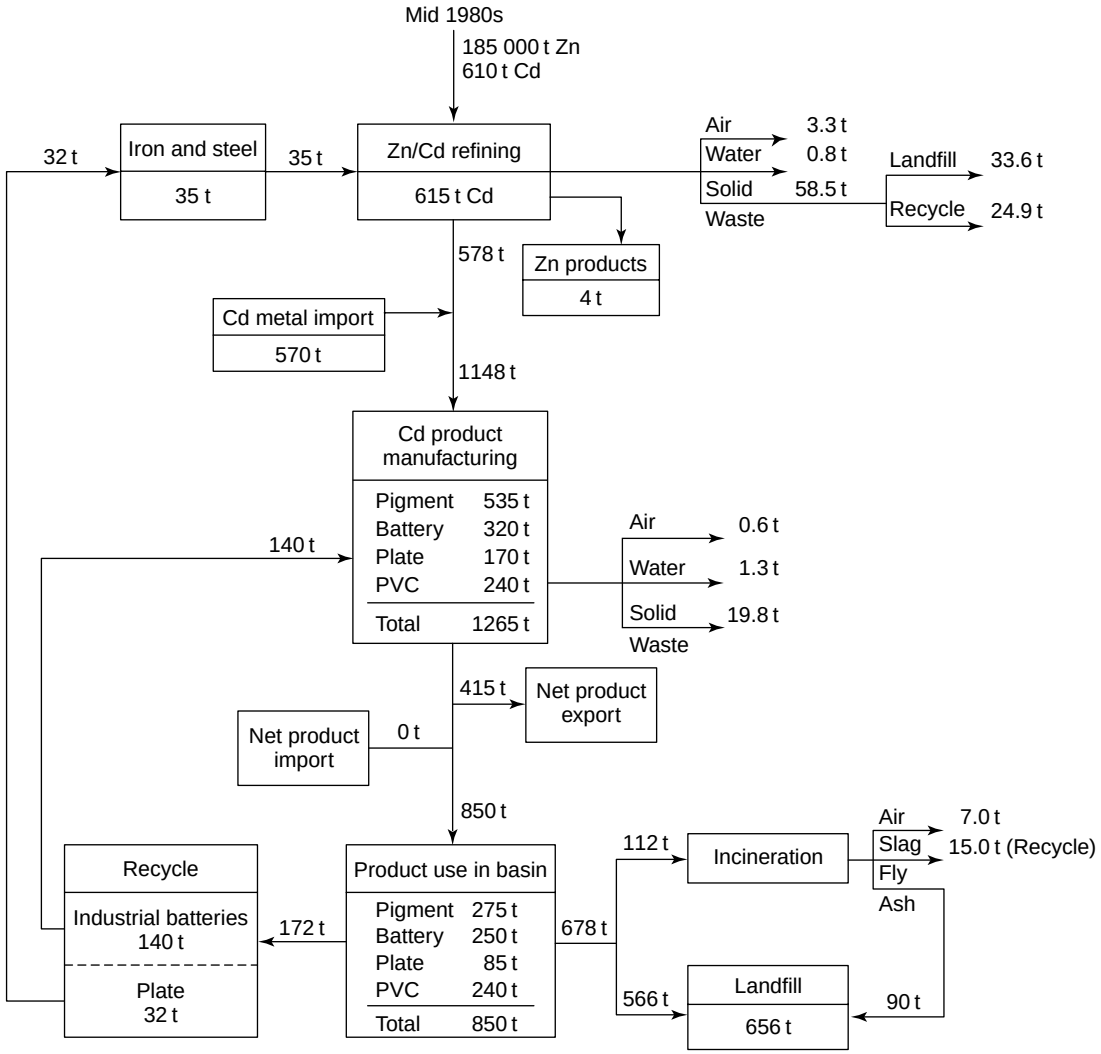

Figure 2 Balance of cadmium product use and disposal in the Rhine River Basin in the mid-1980s

sludge containing cadmium is applied as a fertilizer in some areas, although its overall use basin-wide is rather limited. We can see that 30 years earlier, total inputs of cadmium were almost double what they were in 1988. Also, atmospheric deposition was the major source to croplands in 1970, but by 1988 it was surpassed by phosphate fertilizer.

The three outputs of cadmium from agricultural land are plant uptake, runoff, and erosion. One important observation is that while all cadmium input to the land declined between the years 1970 and 1988, the uptake by crops increased (i.e., compare 2.2 tons in 1970 to 4.1 tons in 1988). The reason for this is that over the entire time period, inputs continued to exceed outputs, even though by 1988 the net positive balance was less than half what it was in 1970. A positive balance indicates that the soils were still accumulating cadmium, and its soil concentration was increasing as well. Since plant uptake of cadmium depends on soil concentration, it is not surprising that uptake would continue to increase.

The above analysis suggests that to reduce the public health risk of cadmium toxification, the most effective step would be removal of cadmium from phosphate fertilizer rather than banning cadmium products. It is curious that to date this has not been accomplished. One reason is that current regulations work against this measure. Removing cadmium from the final product is neither difficult nor too expensive. The expensive and laborious step is managing the cadmium waste after it is removed from the phosphate. Cadmium solid waste, like other toxic materials, is tightly regulated. Environmental enforcement agencies impose stringent engineering standards and a demanding maintenance protocol. To avoid the difficulty of landfilling and safely maintaining a non-leaking depository, it is cheaper and far less bothersome to keep the cadmium in the fertilizer and spread it in diluted

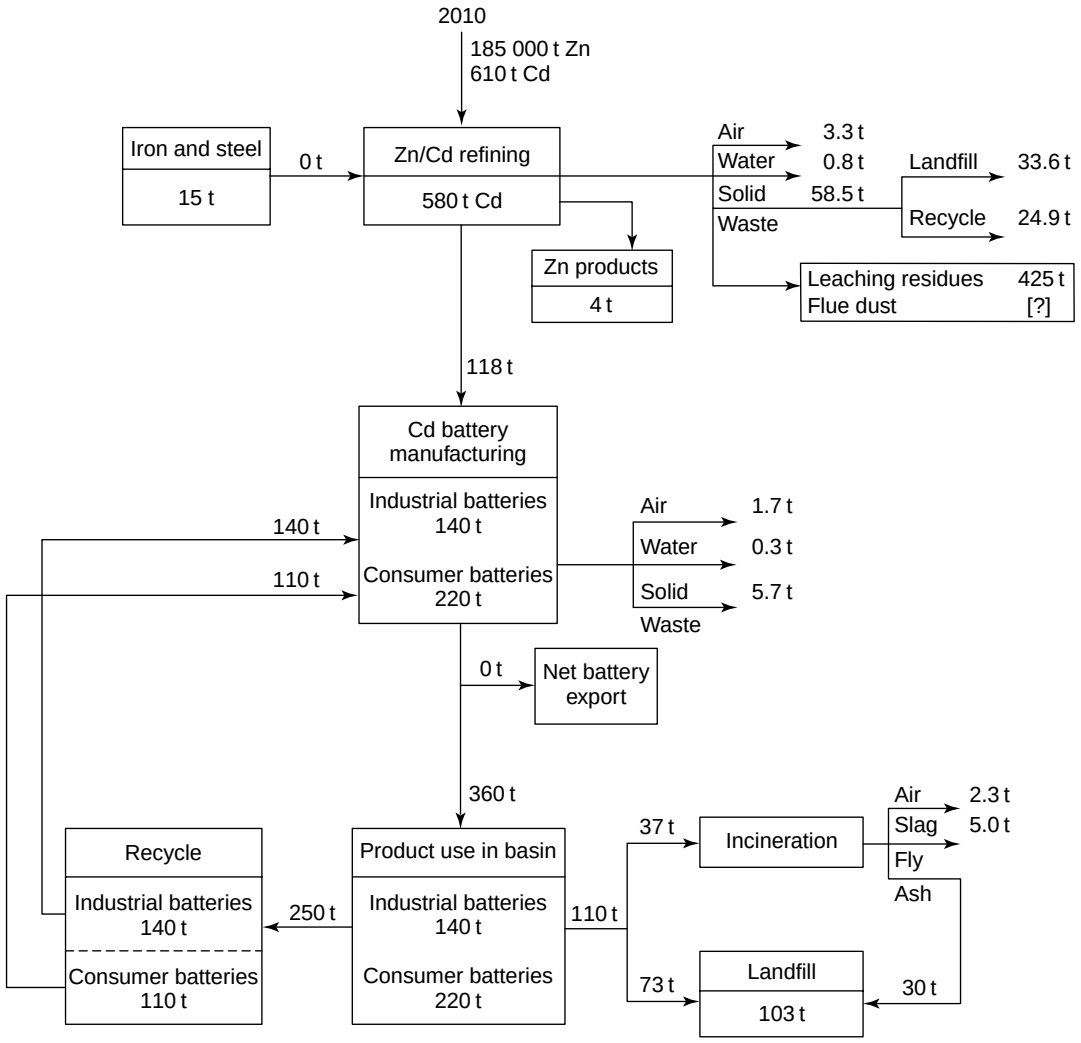

Figure 3 Balance of cadmium product use and disposal in the Rhine River Basin: 2010 Scenario for Cd product ban except for nickel–cadmium batteries

Table 2 Inputs and outputs of cadmium to agricultural soils in the Rhine Basin (tons year^{-1} and percentage of total)

Process	1970 (%)	1988 (%)
Inputs		
Atmospheric deposition	+61.6 (55.2)	+13.2 (26.3)
Phosphate fertilizer	+47.7 (42.8)	+35.9 (71.7)
Sewage sludge	+2.2 (2.0)	+1.0 (2.0)
Subtotal	+111.5 (100)	+50.1 (100)
Outputs		
Plant uptake	−2.2 (20.0)	−4.1 (51.9)
Runoff	−6.8 (61.8)	−1.4 (17.7)
Erosion	−2.0 (18.2)	−2.4 (30.4)
Subtotal	−11.0 (100)	−7.9 (100)
Inputs minus outputs[a]	+100.5	+42.2

[a] Because inputs are larger than outputs, there is net accumulation of cadmium in agricultural soils in both 1970 and 1988.

amounts over agricultural land. It seems that more prudent policies could be enacted to encourage the removal of cadmium during the phosphate production process while at the same time easing the regulatory burden on the manufacturers.

CONCLUSION

MFA can be an invaluable tool in the management of chemical pollution. Identifying sources and quantifying ows of pollutant-laden materials through the industrial economy provides a basis for a comprehensive understanding of the most serious threats to the environment and human heath. It is especially useful for exposing pollutant sources and pathways that might otherwise be hidden from the assessor.

MFA provides a benchmark against which environmental managers can test prospective policies. It sheds light on how

a proposed policy might change a pollutant's mass balance as well as its flows and exposures in the environment. As provided in the above example of cadmium in phosphate fertilizer, we have seen how a relatively minor flow can have a disproportionately high impact when it is unregulated and feeds directly into important exposure pathways.

Holistic solutions to environmental pollution should include MFA as a complement to traditional environmental analysis. Both kinds of studies are needed for comprehensive understanding of societal causes of trends in pollutant emissions and their environmental effects. A great step forward would be the establishment of a national accounting system that harmonizes economic and environmental data with data on production and consumption.

Stigliani, W M and Anderberg, S (1994) Industrial Metabolism at the Regional Level: The Rhine Basin, in *Industrial Metabolism - Restructuring for Sustainable Development*, Chapter 7, eds R U Ayres and U E Simonis, United Nations University Press, Tokyo, 119–162.

Maximum Sustainable Yield (MSY)

Starting late in the 19th century, governmental managers with formal responsibilities for regulating the harvests of natural resources that were not privately owned (forests, birds, mammals, fish, shellfish, etc.) came to interpret success in that role as depending on achievement of MSY of the most valued population in the relevant lands and waters. Maximization was as important as sustainability, in that each resource sector was expected to do its best for a nation's economic progress.

In retrospect we note that such an early version of MSY is based implicitly on an ecological concept of an ecosystem's carrying capacity for the valued population. Also, there is a presumption that the target population and its host ecosystem will maintain their integrity by adapting systemically to the external harvesting of that population at the MSY level. Finally, it is to be noted that this is implicitly a high-grading approach, in that the harvester selects only the most valued population available at the time, but may do so carelessly and destructively of other features of the ecosystem (*see* Carrying Capacity, Volume 4; Ecosystem Integrity, Volume 4).

By the 1950s, the MSY goal was being applied to all lands and waters of North America that were not zoned as protected natural parks or private property. By about 1970 the goal had been extended to all the world's oceans. And by 1970 it was becoming apparent to many researchers that this goal was grossly simplistic, at best. For example, various other human uses of these ecosystems were affecting the valued resource populations ever more intensely, and almost always adversely. Also, fisheries were increasingly targeting a mix of several interacting populations of fish and shellfish in an ecosystem. Hence a resource population could not be managed as though it were isolated ecologically, as presumed a century earlier with a simple MSY approach.

MSY was initially interpreted as relating to the harvest in terms of biomass or total mass of an individual population or set of interacting populations of a particular valued species. If the harvested biomass was then sold, a price could be observed and a comparable goal of maximum sustainable economic yield (MSEY) could perhaps be specified, at least if the costs of harvesting could also be included in the calculations. It was quickly learned that MSEY implied that the harvesting goal in terms of biomass was less than MSY and the term *optimum sustainable yield* (OSY), came to be the practical goal, at least in some locales where the political process permitted some rationality.

Simplistically MSY, as the amount of biomass of a population harvested per year, can be equated to the amount of mass that the population can add through reproduction and growth in that year, with the population at a size at which such an addition is maximized. Slowly growing populations of whales, large fish and tree species in cold habitats may add only a few percent of biomass per year under those conditions, so the annual MSY amounts to only a few percent of the biomass of that population. Fast growing populations of small fish and shellfish may double their biomass under MSY conditions, so that the total harvest over one year, if appropriately distributed seasonally, may equal the amount of biomass of the population at the beginning of the year.

An accountant who takes into consideration the opportunity cost of capital invested in a resource might find that earnings attract a higher rate of return elsewhere in an economy than the rate of growth in biomass of some natural resources. Under such circumstances the financial returns to the entrepreneurial harvester of a slowly growing population could be maximized if that population were rapidly over-exploited to the point of mining the resource,

and investing the quick profits at higher rates of return elsewhere. In these circumstances a broadened version of MSEY, which focused on the productivity of economic capital, could justify the unsustainable over-exploitation of a slowly growing resource. This kind of economic development has often occurred with respect to forests, whales and large fish species.

By the end of the 20th century, a simplistic linear approach to management of natural resources, as exemplified by the use of MSY or OSY for a few of an area's most valued species, had fallen into disrepute. The macroeconomic considerations of economic development, simply over-rode any ecological considerations on many occasions. Even where there was still a commitment to ecological sustainability, it had become evident through much bitter experience that the population dynamics models used for estimating the annual or periodic total allowable harvests of valued populations could not be made sufficiently accurate, for annual adjustments to harvest regulations, with any reasonable level of funding available for such information services. An alternative, more systemic regime seems to be emerging, with an ecosystem approach (*see* Ecosystem Approach, Volume 2) to an understanding of the natural resources in their habitats, together with a pluralistic decision-making regime along the lines that had evolved over centuries in many locales the world over with respect to common property resources.

Assimilative capacity is a similar concept to MSY both practically and politically, but relates to loadings of wastes rather than removals of resources. It denotes the maximum amount of a particular pollutant that can be assimilated by a particular ecosystem in a year. Assimilation, in turn, may mean simple dilution, or transport and burial by natural processes, or gradual degassing to the atmosphere, or biological inactivation, or other processes. It too is in disrepute, and new alternative approaches are coming into place, one of which resembles that for natural resources sketched above.

Sometimes the term MSY is also applied to intensive culture of farms of many kinds. Some of a farm's limiting factors (*see* Carrying Capacity, Volume 4) may be progressively relaxed to increase the maximum yield. A question then arises as to which if any of the farm's original natural features are to be maintained in such an altered ecosystem, and how that would then constrain further maximization.

MEPC (Marine Environment Protection Committee)

An organ of the International Maritime Organization (IMO), the MEPC was established in November 1973 by resolution A.297 (VIII) of the IMO Assembly as a permanent subsidiary body of the Assembly with the mandate to coordinate and administer ••• the activities of the organization concerning the prevention and control of marine pollution by ships . It was also to perform such functions as are or may be conferred upon the organization under international conventions for the prevention and control of pollution from ships.

By resolution A. 296 (VIII) MEPC was designated as the appropriate body to perform functions concerning the amendment of the International Convention for the Prevention of Pollution from Ships, 1973 (MARPOL/73) and the 1973 Protocol Relating to Intervention in the High Seas in Cases of Marine Pollution by Substances other than Oil, both of which had just been adopted.

Following the amendment of the IMO Convention by resolution A.317 (Es.V) of 1974, MEPC became a principal organ of IMO in 1982 with the mandate to consider any matter within the scope of the organization concerned with the prevention and control of marine pollution from ships. It may also

> consider appropriate measures to facilitate the enforcement of conventions, provide for the acquisition of scientific and technical information on the prevention and control of marine pollution from ships for dissemination to States ••• and consider and take appropriate action with respect to any other matters falling within the scope of the organization which would contribute to the prevention and control of marine pollution from ships •••.

MEPC is responsible for implementation of MARPOL/73 as modified by the Protocol of 1978 relating to the International Convention for the Prevention of Pollution from Ships (MARPOL 73/78), the 1990 International Convention on Oil Pollution Preparedness, Response and Cooperation and major aspects of the activities of IMO on the protection of the marine environment.

Montreal Protocol, Multilateral Fund for the Implementation of

Omar E El-Arini
Multilateral Fund Secretariat, Montreal, Canada

While the original Montreal Protocol on substances that deplete the ozone layer (UNEP, 1987), adopted in 1987, provided for technical assistance to promote participation and implementation, it did not include any arrangement for nancial assistance to developing countries to meet the control measures applicable to them. Such an arrangement - the nancial mechanism - was put in place through the London amendment to the Protocol adopted in 1990 (UNEP, 1990). According to Article 10 of the amended Protocol, the parties are to establish a mechanism to provide nancial and technical cooperation, including the transfer of technologies to parties operating under paragraph 1 of Article 5 of the Protocol to enable their compliance with the control measures and to meet all agreed incremental costs of achieving such compliance. (Developing countries that are party to the Montreal Protocol and whose annual per capita consumption of controlled substances is less than 0.3 kg for Annex A substances are generally referred to as simply Article 5 parties. Other Parties (from developed countries) are referred to as non-Article 5 parties.) This mechanism would include a multilateral fund. Pending the entry into force of the London Amendment, the parties decided in decision 2/8, to set up an interim mechanism, including an interim multilateral fund, which began operation in 1991 (UNEP, 1990).

The London Amendment entered into force in August 1992 and, accordingly, the fourth meeting of the parties, held later that year, formally established the nancial mechanism, including the multilateral fund and transferred to the latter the resources remaining in the interim fund (UNEP, 1992c). The multilateral fund became operative in January 1993. Over the years the protocol was amended four times and adjusted ve times, and 130 developing countries have become parties to the Protocol, 110 of which have received nancial assistance from the multilateral fund amounting to US$1.13 billion to phase out 135 000 ODP (ozone depletion potential, one ODP tonne of a controlled substance equals one metric tonne of the substance multiplied by its ODP; the latter ranges from 0.001 to 10) tonnes in consumption and 37 000 ODP tonnes in production.

Likewise, the business plans for 2001 are to be compliance-driven, with priority given to countries most in need of funding to meet their targets. The implementing agencies involved in institutional strengthening in those Article 5 countries unable to comply with the chloro uorocarbon (CFC) freeze and the 2002 freeze with respect to halons and methyl bromide, have been requested to contact the national ozone units in those countries to assess the activities that might be needed to ensure compliance. Nevertheless, when the fund was replenished in 1999 for the period 2000- 2002, it was accepted that it was important to continue to undertake activities even in those countries that did not strictly require immediate assistance to meet their initial targets, in order to maintain momentum for the phase-out and to ensure that they would be in a strong position to complete

the nal phase-out steps to be achieved in the second half of the present decade.

STRUCTURE

The fund operates under the authority of the parties, who decide on its overall policies and the level of funding, while responsibility for overseeing the operations of the fund rests with an executive committee, supported by the fund secretariat. The projects supported by the fund are implemented by four implementing agencies – the United Nations Development Programme (UNDP), the United Nations Environment Programme (UNEP), the United Nations Industrial Development Programme (UNIDO) and the World Bank; and by a number of developed countries.

Executive Committee

The executive committee was established to develop and monitor the implementation of specific operational policies, guidelines and administrative arrangements, including the disbursement of resources, for the purpose of achieving the objectives of the multilateral fund (UNEP, 1990; UNEP, 1992c). It consists of 14 members, seven from Article 5 parties (from developing countries) and seven from non-Article 5 parties (from developed countries). The members are selected by each group of parties and formally endorsed by the meeting of the parties. The office of chair of the committee is subject to rotation, on an annual basis, between Article 5 and non-Article 5 parties, while the group not providing the chair selects the vice-chair from among its committee members.

The executive committee meets three times a year, each meeting lasting 3 days. The meetings are preceded by two-day meetings of the two standing sub-committees – the sub-committee on project review and the sub-committee on monitoring and evaluation. A small sub-group on the production sector has also been established and meets periodically.

Fund Secretariat

The role of the fund secretariat is to assist the executive committee in the discharge of its functions. The secretariat is based in Montreal, Canada, and consists of a small number of internationally recruited professional staff and local support staff. The secretariat is headed by the chief officer, who is nominated by the executive committee for appointment by the executive director of UNEP and reports directly to the committee.

The terms of reference of the secretariat (UNEP, 1991a) as approved by the executive committee at its third meeting include 23 specific responsibilities, which essentially include: development of the three-year plan and budget and a system of funds disbursement; management of the business planning cycle of the fund; monitoring the expenditures and activities of the implementing agencies; preparation of policy papers and other documents; review and assessment of project-related submissions of the implementing agencies; liaison between the committee, governments and the implementing agencies; and servicing the meetings of the executive committee. Since 1997, the secretariat has also included a monitoring and evaluation function, established expressly by the executive committee.

Implementing Agencies

The roles of the implementing agencies for projects approved under the multilateral fund were outlined broadly in decision 2/8 of the second meeting of the parties to the protocol (UNEP, 1990). More detailed arrangements are set out in the individual agreements concluded between the executive committee and UNDP, UNEP, UNIDO and the World Bank, which cover such matters as management of funds and reporting requirements.

Broadly speaking, UNDP, UNIDO and the World Bank are responsible for the preparations and implementation of investment projects, while the main thrust of UNEP's activities is on information dissemination, capacity-building, institutional-strengthening, networking, and assistance to low-volume consuming Article 5 countries.

The agencies' activities are based on their annual business plans, which contain specific targets for the year and must be approved by the executive committee. The shares of total funding to be received by each agency for investment projects are also decided upon in advance by the committee.

Projects submitted by the agencies for approval of the executive committee are reviewed by the fund secretariat for conformity with the eligibility criteria and are then forwarded to the executive committee.

Treasurer

The UNEP acts as treasurer of the fund, at the invitation of the executive committee. As such, it is responsible for receiving and administering contributions, including bilateral contributions, and disbursing funds to the fund secretariat and the implementing agencies, as agreed by the executive committee. It also reports to the executive committee on the status of the fund, including the availability of resources.

CONTRIBUTION AND REPLENISHMENT

The multilateral fund has been replenished four times for three-year cycles. The interim multilateral fund that was

Table 1 Replenishments of the multilateral fund

Replenishment period	Amount of replenishment (US$ million)
1994–1996	455
1997–1999	466
2000–2002	440

set up by the second meeting of the parties wound up with a total capitalization of US$240 million for the period 1991–1993. Since that time, the parties have undertaken technical studies in 1993 (UNEP, 1993), 1996 (UNEP, 1996c), and in 1999 (UNEP, 1999c), to support their decisions to replenish the fund three more times in the amounts indicated in Table 1.

The level of contributions required from each party is determined by the meeting of the parties in accordance with the UN scale of assessments. The budget is prepared and the assessments made in US dollars.

Bilateral cooperation by a party may be credited as a contribution to the multilateral fund up to a total of 20% of the total contribution due from that party (UNEP, 1990). Requests to offset such cooperation against assessed contributions to the fund must be approved by the executive committee. By the end of 1999, a total of US$39 million had been approved for bilateral cooperation, representing about 4% the total funds approved through the multilateral fund. The range of bilateral projects approved includes demonstration projects, training workshops, project preparation, investment projects and technical assistance.

The terms of reference of the multilateral fund (UNEP, 1990; UNEP, 1992c) state that contributions shall be in convertible currency or, in certain circumstances in kind and/or in national currency. Payment may be made either in cash or through the use of promissory notes, issued with a fixed schedule of encashment with the option of an accelerated schedule in the light of needs. In 1999, the 11th meeting of the parties (UNEP, 1999c) agreed to the use of a fixed-exchange rate mechanism on a trial basis for the 2000–2002 replenishment, in order to ease some of the administrative difficulties caused to parties by having to make commitments in foreign currencies. The implementation of the new mechanism will be reviewed at the end of 2001 to determine its impact on the operations of the multilateral fund and on the funding of efforts to phase out ozone-depleting substances in Article 5 countries.

As of November 2000, the total income to the multilateral fund, including interest and miscellaneous income stood at some US$1.2 billion, while disbursements amounted to US$1.13 billion. Arrears stood at some US$141 million for the period 1991–1999.

OPERATION

Phase One: From Start-Up to the Review of the Financial Mechanism (1991–1995)

The multilateral fund started very much from scratch. Not only was it the first funding mechanism of its kind, but the practicalities of the task ahead were ill defined: even though the use of ozone-depleting substances was virtually ubiquitous, the records of the amounts consumed and the sectoral distribution within Article 5 countries were in general rudimentary.

Much of the early work of the executive committee was devoted to operationalizing the general guidance on incremental costs and project eligibility handed down by the second and fourth meetings of the parties. The start-up period of the multilateral fund saw the establishment of the basic operational procedures for the fund, including the approval of eligibility criteria for project approval and guidelines for setting priorities. Importantly, the eligibility criteria covered projects other than capital investment projects, for example, technical assistance and clearing-house functions.

The period also saw the initiation of the process of preparing country program, which were aimed at, *inter alia*:

- Assessing the consumption of controlled substances and their sectoral distribution within countries.
- Setting out the strategy and an action plan for the implementation of the Protocol.
- Presenting a timetable for each activity and for action plan review, as well as a budget and financing program.

The country program is intended to be flexible, setting out the framework for the country's actions to meet the requirements of the Montreal Protocol. It serves as the basis for project preparation, although, initially, in the interests of expediting the start-up process, the executive committee did allow the funding of individual projects prepared prior to the completion of country programs.

Although institutional strengthening is not explicitly mentioned in the indicative list of categories of incremental costs approved by the second and fourth meetings of the parties to the Protocol, the executive committee did recognize at its fifth meeting, in November 1991 (UNEP, 1991b) that it might, in exceptional cases, be an essential element in achieving the objectives of the fund. The exceptional cases rapidly became the rule and, at its seventh meeting, in June 1992 (UNEP, 1991a), the committee decided that the main objective of institutional strengthening was to provide the necessary resources to an eligible country to enable it to strengthen a mechanism within the country for the speedy implementation of projects and for ensuring effective liaison with the executive committee, the fund secretariat and the implementing agencies.

Once a review is completed, the project is submitted to the executive committee with a recommendation from the secretariat. This stage has frequently seen significant adjustments made to project proposals, particularly in terms of costs and technology choices, to take account of previous policy decisions by the executive committee. Should the issues arising from project proposals not result in a positive recommendation by the secretariat, they are forwarded to the executive committee, together with the project proposal for individual consideration. At meetings of the executive committee, project proposals, together with any related policy issues, are initially considered in the sub-committee on project review, which makes recommendations to the committee as a whole. The sub-committee was originally composed of six members, three from Article 5 and three from non-Article 5 members of the committee. As of the year 2000, a seventh member has been added, with the incumbency alternating between Article 5 and non-Article 5 members on an annual basis. To save time within the sub-committee, the practice was adopted of submitting project proposals under two headings:

- Projects for blanket approval, which, in the view of the Secretariat, meet all the eligibility requirements and may be approved en bloc, without discussion.
- Projects for individual consideration, i.e., proposals that give rise to policy issues that require consideration and resolution by the sub-committee and the executive committee itself.

Once the project proposal has been approved by the executive committee, with whatever modifications or conditions that might be decided upon, the necessary funding may be released by the treasurer to the implementing agency concerned. Each implementing agency is responsible for the implementation and supervision of its projects and is required to report to the executive committee annually on the progress of work, and to submit a final report on completion of the project.

Throughout the first phase in the fund's development, the communication of progress in project implementation was a constant preoccupation of the committee, possibly as a result of frustration at the perceived lack of immediate tangible results of fund activities in terms of actual phase-out of controlled substances. A similar concern was re ected in repeated requests to the implementing agencies to expedite project delivery. At its eighth meeting (UNEP, 1992b), the committee decided that implementing agencies should submit progress reports on project implementation and identify and describe any problem areas. At the same time, the secretariat should assess project implementation status, ascertain problem areas, and offer assistance in their resolution between committee meetings. A uniform format for reporting was adopted in 1995, re ecting the need for closer monitoring by the executive committee and greater uniformity and clarity in reporting by the agencies. By the end of the period, the executive committee had committed itself to a more formal and exhaustive monitoring and evaluation system, as part of the more structured approach toward planning and follow-up that was put in place after 1995 (UNEP, 1997).

Indeed, although much commendable work was completed during the first four years of the fund's existence in terms of the development of policies, guidelines and the processes of project preparation and approval, the whole period was marked by a lack of true strategic planning. Project proposals were submitted and approved on a first come, first served basis, and were submitted from countries without a country program. There was no emphasis on the sectoral distribution of projects or the mix of countries for which projects were prepared. Nor were there any established cost-effectiveness criteria for project eligibility. In addition, most industrial plant conversion was based on total replacement of equipment, and, importantly, the projects were not explicitly linked to the achievement of the compliance targets by Article 5 parties.

Phase Two: From the Review of the Financial Mechanism to the First Control Measure (1995–1999)

The year 1995 was a pivotal one in the evolution of the multilateral fund. It saw four major developments:

- the introduction of a rigorous system of business planning;
- the establishment of cost-effectiveness thresholds for project funding;
- the completion of the review of the effectiveness of the financial mechanism, called for in decision 4/18 of the fourth meeting of the parties (UNEP, 1992c), and the review of the situation of the parties operating under paragraph 1 of Article 5, including the effective implementation of financial cooperation and transfer of technology to them, required by Article 5, paragraph 8, of the amended Montreal Protocol (UNEP, 1990);
- The establishment of the basis for a monitoring and evaluation system for the Fund.

With the second replenishment of the multilateral fund, for the period 1994–1996, there was a significant increase in the number of project proposals being submitted to the executive committee. By late 1994, it became clear that there was a need to address the situation where the total value of proposals would exceed the amount available to the fund. This was initially done through the addition of a procedure known as *cleared for approval* pending availability of funds, which meant that the funding necessary to finance approved projects would be released by the treasurer as and when it became available after the executive committee meeting at which the project was cleared. This departure

from the previous practice of approving projects only up to the limit of resources available at the meeting concerned could not however solve the emerging structural problem of an excess of project proposals over resources allocated to the Fund. At its 16th meeting, in March 1995 (UNEP, 1995a), the executive committee approved a framework for resource allocation, under which resources would be divided into distinct slices for various categories of projects. It also set cost-effectiveness thresholds for the various sectors and sub-sectors, with the proviso that projects from low-volume consuming countries would not be subject to these thresholds.

The experience of the period 1994–1995 highlighted the need for stricter business planning that would link proposed activities to the funding available and to the sectoral priorities. The first such plans were submitted by the agencies in 1996. They were to include all projected activities for the year in question, as well as performance indicators, thus providing a basis for monitoring and evaluation as well as strategic planning. In order to avoid project delays resulting from the emergence of policy issues at the project review stage, agencies were also encouraged to include any policy issues likely to arise so that they could be addressed in a proactive manner by the executive committee. A consolidated business plan would then be prepared by the secretariat of the multilateral fund, together with targets for controlled substances phase-out for each agency. The consolidated plan also sets out the resources to be allocated to each agency in the course of the year. Non-Article 5 Parties also submit business plans for bilateral cooperation activities.

The year 1995 also saw the completion and review of the meeting of the parties of two major studies of relevance to the operations of the fund. The first, on the operation of the financial mechanism, had been called for at the fourth meeting of the parties (UNEP, 1992c), when the fund was established on a permanent basis. As a result of the study, the seventh meeting of the parties (UNEP, 1995b) approved a series of 21 actions to be taken to improve the mechanism, including the development of a systematic approach to policy development, the establishment of a monitoring and evaluation system, the improvement of policy dissemination procedures, and the establishment of firm compensation policies for phase-out in the production sector. The implementation of these actions underlay much of the work of the executive committee in the years to come.

The second study had been provided for in Article 5, paragraph 8, of the Montreal Protocol as amended at London in 1990, which stipulated that a meeting of the parties;

> shall review, not later than 1995, the situation of [Article 5 Parties], including the effective implementation of financial cooperation and transfer of technology to them, and adopt such revisions that may be deemed necessary regarding the schedule of control measures applicable to those parties.
>
> (UNEP, 1990)

At Copenhagen, in 1992, the parties had agreed that any further amendments to the adjustment and amendment of the protocol adopted at London would be applicable to Article 5 parties only after this review had taken place and would be based upon its conclusions. The study itself, as presented to the seventh meeting of the parties, presented a number of possible phase-out scenarios and the related costs to the multilateral fund. As a result of the review, the parties decided (UNEP, 1995b) to retain the London schedule for Article 5 Party phase-out of annex A and B substances and introduced control measures for hydrochloro uorocarbons (HCFCs) and methyl bromide for those countries.

Although a presumption against the use of HCFCs as substitutes and a requirement to fully justify such use had been in place since the 15th meeting of the executive committee in 1994, the decision to make them controlled substances for Article 5 opened the way for a protracted and often acrimonious debate within the committee. Immediately after the meeting of the parties (1995) (UNEP, 1995b), the executive committee decided to request more complete justification for the use of HCFCs as transitional substances and to make it clear that the industrial enterprise concerned would have to bear the full costs of subsequent conversion to non-HCFC substitutes. Subsequent decisions called for even more stringent requirements for the submission and review of information to support the choice of HCFCs, including a letter from the government concerned in which it would verify that it had reviewed the specific situations involved in the project, as well as its relevant commitments under the protocol and that it would state that it had determined that HCFCs were required at the present time and that it understood that no funding would be available for future conversions from HCFCs for the company or companies concerned. The whole question of policy on HCFC use as an interim technology is still being considered by the executive committee.

The inclusion of methyl bromide (used in the agricultural sector for soil fumigations) as a controlled substance for Article 5 countries led to an acceleration of work on the subject in the executive committee, which had already approved three regional methyl-bromide data-collection and demonstration projects in 1995. Methyl-bromide projects are perhaps the most challenging area in which the fund has operated, as there is no one-size-fits-all alternative for every application or crop. In addition, while industrial conversion through the replacement and destruction of existing equipment is a one-off event, there are few technical impediments to a farm reverting to methyl bromide in the years after the completion of a phase-out project. Interim guidelines on methyl-bromide demonstration projects were adopted at the 20th meeting of the committee, in October 1996 (UNEP,

1996), and $10 million for such projects were allocated for the period 1997–1999. A strategy and guidelines for the whole sector, including a priority list of crops for soil fumigation, was approved in 1998, and the first investment projects aimed at phase-out began with the approval of a project in the tobacco sector in Cuba in November 1998. As of July 2000, a total of $35 million had been allocated to demonstration and investment projects on methyl bromide and the total amount of methyl bromide to be phased out stood at 937 ODP tonnes.

As already mentioned, the follow-up of project implementation was a general cause for concern in the first few years of the fund's operation. The period 1995–1999 saw the establishment and refining of a monitoring and evaluation system, as called for in the study on the effectiveness of the financial mechanism. In 1997, a monitoring and evaluation sub-committee was established and a monitoring and evaluation post created within the secretariat. The sub-committee, like its counterpart for project review, meets immediately prior to meetings of the executive committee and also has seven members, drawn from the membership of the committee. An evaluation guide was also prepared, intended to be a dynamic document subject to revision in the light of experience. Henceforth, all project proposals were to include a standardized component on monitoring and evaluation, including milestones for the completion of the various stages of the project that should be able to provide sufficient information to enable a comparison between the approved proposal and the project completion report. The purpose of the process is to ascertain whether the project objectives have been met in terms of the disbursement of funds, the amount of controlled substances phased out, and various other performance indicators. Agencies are to submit progress reports by May each year for all activities approved by the end of the previous year.

The period 1995–1999 saw a greater consciousness of the need to anchor fund activities more tightly to the commitments of parties under the protocol. At its 19th meeting, in May 1996 (UNEP, 1996a), the executive committee decided that all project proposals should contain a brief description of how the project would help the country achieve the 1999 freeze, and this decision was reiterated in one form or another at a number of subsequent meetings.

The period also saw attention turn to the question of production sector phase-out. Although only a handful of Article 5 countries produce ozone-depleting substances, the question of funding phase-out in the production sector has been one of the most complex faced by the executive committee. Work on establishing guidelines began in 1994, and was largely carried out by two small bodies established by the committee – the expert group on the production of ozone-depleting substances and the executive committee's subgroup on the production sector. Agreement was reached that the basis for compensation should be loss of future profits rather than the incremental costs of constructing new facilities. The main difficulty lay in devising a methodology for calculating these losses, as the total arrived at could vary widely depending on the baselines used and the assumption made for elements such as market trends. Donors, in particular, were reluctant to agree to any methodology without having an idea of the possible financial implications once data from actual factories were factored in.

Very little progress was made in 1996 and 1997, pending the submission of data on production facilities from Article 5 countries. In 1998, the executive committee agreed that technical audits of production facilities should be conducted to verify the data submitted and to calculate a possible reasonable level of compensation on the basis of a number of criteria. The following year, the first production phase-out project was agreed after lengthy negotiations with the government of China. A total sum of $150 million was allocated for the closure of the entire CFC production capacity in the country over a period of 12 years (UNEP, 1999a). An annual payment and phase-out schedule was included in the agreement reached with the country, with the release of each installation being made contingent upon the completion and independent verification of the reductions indicated in the schedule. Later in the same year, a similar agreement (UNEP, 1999b) was reached for the production sector in India, and a draft agreement with Argentina is currently under preparation.

Phase Three: Meeting the Control Measures (1999–2015)

As noted above, the first control measure for Article 5 countries – the freeze on consumption of CFCs at the average of the 1995–1997 level – came into effect on 1st July 1999. The focus of work of the executive committee since that time has been on the interim measures between freeze and final phase-out, which include a 50% reduction in CFC and halons consumption by 2005, and 20 and 85% reductions in the consumption of methyl bromide and carbon tetrachloride, respectively, by the same year. An analysis of controlled substances phase-out in Article 5 countries produced by the secretariat in 2000 indicated that the majority of countries were in a position to comply with the freeze control measures and that several already had sufficient phase-out activities approved to enable them to meet the 2005 target.

This period has seen a growing number of investment projects for the phase-out of methyl bromide, particularly in light of the freeze scheduled for 2002. It has also seen the commencement on work in new areas, e.g., on projects to limit controlled substances emissions from process agent applications, which became eligible for funding following a decision adopted by the 10th Meeting of the Parties (UNEP, 1998), at the end of 1998, and on the new subsector covering the assembly, installation and servicing of

refrigeration equipment. The current phase also includes the committee's decision on the refrigerants management plan for low-volume consuming countries (UNEP, 2000).

Strategic planning is becoming increasingly geared toward making the Article 5 countries the main motors for the fulfillment of their compliance obligations. In that respect, the executive committee has instructed all implementing agencies to ensure that project proposals are based on the current strategic planning of the Article 5 country concerned to ensure that the national ozone unit is fully involved in the planning and preparation of projects. The units are regularly provided with information on the progress of project implementation to assist them in improving their capacity to monitor and evaluate projects implemented including their impact at the country level.

Analysis of the most recent data reported by 101 developing countries indicates that 94 of them have been able, or will soon be able, to achieve the mandatory freeze in their consumption and/or production of chloro uorocarbons (CFCs). In addition, several of these countries are well on their way to achieving the mandatory 50% reduction in CFC consumption ahead of the protocol schedule of 2005.

ACHIEVEMENTS

While the most obvious achievement of the multilateral fund is the accelerated phase-out of ozone-depleting substances in developing countries, a less prominent – but in the long term possibly equally important – achievement lies in the successful transfer of technology to developing countries. Through the investment projects, all the new technology for ozone-friendly substitutes has been successfully transferred. The multilateral fund has paid for the costs of patents and technology licensing fees and the design, testing and demonstration of new technologies. This has allowed some developing countries to leap over interim options. For example, there are now more plants using liquid carbon dioxide (CO_2) technology in developing countries in the production of exible foams than in the US and Europe combined. Equally, the fund has been responsible for the increased penetration of hydrocarbon technologies, including adoption by small consumers in developing countries.

The institutional arrangements for project screening have allowed the fund to operate in a highly cost-effective way: many of the projects completed have shown savings over the approved amounts, which themselves were in many cases significantly lower than the original cost estimates submitted by the implementing agencies.

Capacity-building and institutional strengthening are two other areas in which marked progress has been made as a result of the fund. More than 105 countries have institutional strengthening projects financed from the fund. These projects generally involve the establishment and maintenance of a national ozone unit within the country. The fund provides resources for various networking activities, including regional workshops. As a result of the capacity-building activities undertaken with fund support, most medium-size and large countries now implement their own projects using national experts and drawing on the clearing-house facilities maintained by UNEP.

Demonstration projects for the introduction of integrated pest management techniques as an alternative to the use of methyl bromide may also be applicable for the replacement of other agricultural chemicals with more environmentally friendly pest-control technologies (*see* Integrated Pest Management (IPM) in an Era of Global Environmental Change, Volume 4).

Projects for the development of refrigerant management plans all contain such elements as the training of technicians and of customs officers, implementation of recovery and recycling projects and additional institutional support for the development of legislation. Again, this general enhancement of the capacities of the developing countries – in terms of both human resources and institutions – will surely have an impact that goes beyond the immediate objectives of the Fund.

THE ROAD AHEAD

The ultimate test of the effectiveness of the multilateral fund will be whether all Article 5 countries meet their commitments under the Montreal Protocol without disruption in the various sectors that have hitherto been dependent on a supply of the controlled substances. In the near term, up to 2005, there are grounds for optimism that the compliance targets for Article 5 countries will be met, at least by the majority of countries. There are, however, challenges remaining, particularly in achieving phase-out in the production sector in all Article 5 countries, ensuring the successful implementation of refrigerant management plans, handling the residual requirements for servicing existing equipment, combating illegal trade in controlled substances, and dumping of CFC-based appliances in developing countries. The central issue will be to ensure the sustainability of the achievements to date and to prevent backsliding and reversion to the use of controlled substances. On the latter point, there is some evidence that the prevailing lower price of CFCs is encouraging their use in servicing equipment initially designed for use with ozone-friendly substances. This situation may, however, only be a transitional phenomenon that will change as prices of controlled substances increase and that of substitutes decrease. In any event, much will depend not only on the collective resolve of the parties to the Protocol to maintain the momentum toward phase-out but also on the level of vigilance, commitment and capacity at the national level (For other entries on the Montreal Protocol *see* Ozone Layer: Vienna Convention and the Montreal Protocol, Volume 4).

ACKNOWLEDGMENTS

I wish to express my gratitude to Mr John Fry, Editor in the Secretariat of the Convention of Biological Diversity, for his invaluable assistance.

Multi-issue Assessments

R E Munn
University of Toronto, Toronto, Canada

Methods for undertaking single-issue environmental assessments are well established. But sometimes a suite of interrelated issues must be considered. A policy designed to resolve one issue may create or worsen another. In order of increasing complexity, multi-issue assessments may relate to:

1. *Potential impacts of a single environmental stressor (and appropriate policy responses) with respect to a variety of responders, e.g., the impacts of acid deposition on forests, agricultural crops, human health, lakes and groundwater.*
2. *Potential impacts of several environmental stressors, e.g., acid deposition, smog episodes and climate change, on a single type of responder, e.g., forests or lakes.*
3. *Potential impacts of several environmental stressors, e.g., acid deposition, smog episodes and climate change, on a variety of responders, e.g., on both agricultural crop yields and human health.*
4. *Potential impacts of several stressors, some of which are not environmental, on one or a variety of types of responders, e.g., the effects of climate change and human population growth on acid deposition and renewable resource depletion.*

The methodological uncertainties involved in dealing with multi-issue assessments are enormous, and it cannot be claimed that a handbook of solutions to the problems raised is available. Some stressors operate intermittently over decades or longer, and the responses are cumulative. During such long time periods, socioeconomic, cultural and technological conditions may change greatly, sometimes abruptly. These are real-world situations, which are very dif cult to model. Furthermore, the costs involved in undertaking additional scienti c research to resolve uncertainties, in establishing early warning monitoring systems, and in changing the human lifestyle patterns responsible for causing the issues, will vary greatly from issue to issue. It will be dif cult to develop common economic yardsticks that can be used across a range of issues.

SOME EXAMPLES OF MULTI-ISSUES

Taking action to reduce a trend towards some undesired environmental state, or to eliminate the long-term risk of such a state, may have either positive or negative effects

on other environmental components, and on socioeconomic conditions.

Positive bene cial effects: of course, positive effects of a particular policy on other biospheric or socioeconomic compartments would be desirable. For example, planting trees reduces soil erosion, increases the biospheric sink strength of carbon dioxide (CO_2), and provides jobs for students and the unemployed. Policies that foster these benefits are called no-regrets policies (*see* No Regrets Principle, Volume 4). Generally speaking, environmental assessments should try to identify the opportunities that such policies might provide.

Negative and potentially harmful effects: on the other hand, action taken to reduce some environmental threats may cause potentially harmful effects on other environmental components, or on the socioeconomic well-being of society. Here are some examples that fall into this category:

1. Replacing chloro uorocarbons in the manufacturing sector with other gases may reduce stratospheric ozone depletion but the replacement gases may contribute to climate warming.
2. Automobile catalytic converters reduce emissions of tropospheric ozone precursors (NO_x and volatile organic compound (VOC)) but release nitrous oxide (N_2O), a greenhouse gas.
3. Sulphate aerosols cause acidic deposition while at the same time absorbing and scattering solar radiation, thus cooling the surface of the earth. Reducing sulfate emissions will therefore partially compensate for greenhouse gas warming.
4. Electric cars reduce emissions at the point of use, but they operate on lead batteries which must be recharged, increasing emissions from coal-fired and oil-fired power stations; also, increased emissions from lead smelters and from re-processing of lead batteries will cause local pollution. Lave *et al.* (1995) estimate that an electric car will cause the indirect release of 60 times more lead per km^{-1} of use than a car using leaded gasoline.
5. The cumulative deposition of sulfates and nitrates into lakes, the increasing penetration of UV-B radiation into lakes, and the potential drop in lake levels due to a drier climate all contribute to a decline in the health of freshwater ecosystems (Schindler *et al.*, 1996).

GUIDELINES ON HOW TO FORMULATE A MULTI-ISSUE ASSESSMENT

The following guidelines are not prescriptive but may be helpful to practitioners of multi-issue assessments:

General Guidelines

- The ecosystem approach (EA) should be used as the arching framework for multi-issue assessments (*see* Ecosystem Approach, Volume 2; Monitoring in Support of Policy: an Adaptive Ecosystem Approach, Volume 4).
- A common policy framework should be used, i.e., the process of policy formulation should be the same for each issue.
- Winners and losers should be identified with respect to each issue.

Global Multi-issues

Some issues may be well recognized and of immediate concern. Other issues may involve great uncertainty and may be long-term. How should a balance be struck between current threats and long-term sustainability of the human race? Only some general suggestions can be given, as follows:

- The assessment should cover very long time periods – several decades at least, even though the uncertainty is great. One way of designing such an assessment is to develop several internally consistent socioeconomic scenarios, then testing the effects of each on the environmental issues being studied, the objective being to select adaptive robust policies that minimize future environmental risks. Every effort should be made not to foreclose future options.
- The concept of biogeochemical cycling provides a good framework for assessing global multi-issues. Most of the major issues are coupled through these cycles, e.g., climate change, stratospheric ozone depletion, acidic depletion, and nitrogen over-fertilization of the biosphere.
- Relevant results coming from the emerging field of ecological economics should be applied wherever possible (*see* Ecological Economics, Volume 5).
- The precautionary principle should be adopted (*see* Precautionary Principle, Volume 4).
- The possibility of feedbacks, overshoots and ip- ops should be assessed.
- People's perceptions of the differing risks associated with different environmental issues will require identification; a common understanding amongst all stakeholders, of the risks involved will need to be achieved. In some cases, this process will lead to disagreement rather than agreement amongst the parties concerned. However, information of this nature will be useful in the subsequent negotiating process, for which the multi-issue assessment will be a valuable decision-support tool.

Regional Multi-issues

In some cases, a region (e.g., Los Angeles County) is the main cause of its environmental problems. Sometimes, however, regional issues may be amplified by global change, e.g., by the potential damage that would be caused by sea level rise. Nevertheless, regional issues are more likely to be more immediate, and to involve large concentrations of people and industry than are global ones. In this context, the following suggestions are made:

- Regional multi-issues should be assessed within the framework of global change.
- An appropriate spatial boundary for a regional multi-issue assessment is often a watershed or river basin. This may sometimes extend the proposed outer boundary of a conventional environmental assessment, but it may often provide long-term insights into the nature of interactions amongst two or more environmental issues.

CONCLUSION

As a general rule, practitioners ought to look farther afield and further ahead than they normally do whenever they prepare environmental assessments. This is particularly true with regional and global assessments.

As a final example of this broader outlook, Chamiedes *et al.* (1994) have used a simulation model to project that by the year 2025, due to the increasing numbers of motor vehicles, there will be more frequent and more intense surface oxidant episodes in mid-latitudes, placing 10–35% of the world's grain production at risk. The simulation model assumes that all other environmental factors will remain unchanged, but global projections of climate warming suggest that drought may become more prevalent and that the frequency of stagnant anticyclonic conditions may increase. The risk factor for decreased crop yields is therefore greater than that obtained from an analysis of the effect of increasing automobile emissions alone.

N

National and Local Responses to Desertification

Harold E Dregne
Texas Tech University, Lubbock, TX, USA

Deserti cation is the widely used term for land degradation in the world's drylands. Those drylands represent about 40% of the earth's land surface, lying in what climatologists refer to as the arid, semi-arid, and dry subhumid climatic zones. Deserti cation was the subject of the 1977 United Nations Conference on Deserti cation. That conference focused attention on the effect that land degradation in the drylands has on land condition and human welfare.

There are six deserti cation processes of major concern worldwide. They are vegetation degradation of grazing lands, water erosion, wind erosion, salinization, soil compaction, and soil fertility decline. All of these processes are human-induced and are, accordingly, preventable. Drought frequently is associated with deserti cation but it is only a contributing factor, not a cause. Drought is an inevitable climatic condition, which is not caused by humans and cannot yet be predicted. Its impact on livestock and humans can, however, be eased by good land management before the drought strikes and by preparing for drought-induced water shortages.

Most countries, both developed and developing, have government agencies charged with conserving land resources, such as grazing and croplands. Additionally, there are numerous non-governmental organizations (NGOs) that have for their objective the conservation of natural resources and the improvement of human welfare. 'Landcare', for example, is an in uential Australian NGO which is a grassroots coalition of urban and rural people. Its purpose is to generate political, public, and private support for land conservation throughout Australia. Its efforts complement and strengthen the activities of government agencies.

Desertification is an old problem, despite the greatly increased attention focused upon it since the United Nations Conference on Desertification in 1977. Historical evidence demonstrates that serious and extensive land degradation occurred many centuries ago in the drylands, principally in three regions: around the Mediterranean Sea, in the Mesopotamian Plain of Iraq, and on the Loess Plateau of central China.

Water erosion was widespread in the eastern Mediterranean hills and mountains more than 2000 years ago. Deforestation provided wood for fuel, timber for ships and temples, and space for cropland. Cutting the stately cedars of Lebanon is the classical example of how tree removal leads to land degradation. With the loss of the protective cover of trees and leaf litter, soil erosion was greatly accelerated and landscapes altered, giving the false impression that the climate had become more arid. As long ago as 2600 BC Egyptians were known to have imported timber from Phoenicia for the resins used in mummification. Today, only a few sacred groves remain in Lebanon to show how the magnificent cedars looked. Even though the climate is the same as it was when the cedars ourished, the possibility of reforestation now is slight. Bare rocks, continued reliance of people on wood for fuel, and wandering goats free to eat every green plant that manages to germinate are formidable obstacles to the survival of trees.

In a pattern that has been repeated across the world, destruction of forests was followed by expansion of cultivated land ever higher on the slopes. Early settlers learned to hold the soil in place by constructing terraces. In later years, as wars, civil strife and pestilence devastated the countryside, maintenance of terraces and other soil-saving structures often was neglected. The inevitable result was accelerated water erosion, leading to the barren landscapes that now mark many of the hills of the eastern Mediterranean countries. Occasionally, well-maintained terraces demonstrate that the land is capable of sustained use for thousands of years if properly cared for.

The most significant instance of desertification resulting from soil salinization in olden times is found in the lower valleys of the Tigris and Euphrates rivers. Present-day Iraq is still trying to recover from a salt build up that began more than 4000 years ago in the plains of ancient Mesopotamia. Salinity problems in irrigated lands became serious for the first time in about 2400 BC in southern Iraq. Additionally,

irrigation systems were plagued with siltation of canals. The heavy load of sediment coming from eroded uplands made it mandatory that canals be cleaned frequently. That burden and the increasing salt problem eventually led to the abandonment of irrigation over much of Mesopotamia in the 13th century AD when Mongol armies conquered the area.

Wind-deposited soils of the Loess Plateau in China are naturally highly erodible. That susceptibility to water erosion is responsible for the occurrence in the Loess Plateau of probably the most severe land degradation anywhere in the world. The degradation began at least 3000 years ago when forests were turned into cropland as the population grew. The loss of productive cropland to erosion was bad enough but the eroded soil, when it enters the Yellow River, causes serious problems of sedimentation in reservoirs and raises the bed of the river above the surrounding plains. The latter problem threatens the lives of untold numbers of Chinese in the North China Plain if a major flood were to break the dikes that now confine the river to its main channel.

Deterioration of rangelands due to overgrazing and wood cutting seems to have become significant only in the last few centuries. Large numbers of cattle, sheep, and goats are responsible for most of the vegetation degradation. Now, few rangelands anywhere in the drylands are in excellent or good condition. The exceptions are the rare places where the native vegetation is unpalatable to livestock, as in northwestern Australia.

DISTRIBUTION OF DRYLANDS

Drylands are defined by the United Nations as lands in the arid, semi-arid and dry subhumid climatic zones. Extremely dry (hyperarid) regions are excluded from the dryland definition because they are too dry for any agricultural activity, including grazing. The largest climatic desert in the world is the Sahara in Africa. Crop production in the Sahara is possible only in irrigated oases such as the Nile Valley. Within the drylands, there are three dominant land uses: grazing, rainfed cropland, and irrigated agriculture. About 88% of the drylands are used for grazing (rangelands), 9% for rainfed cropping, and 3% for irrigated agriculture.

The United Nations Educational, Scientific, and Cultural Organization (UNESCO) published a map in 1977 showing the world distribution of arid lands. That map is based on the ratio of precipitation to potential evapotranspiration ($P \bullet ET_p$) and is a measure of the degree of water deficiency. A $P \bullet ET_p$ of less than 0.03 means that the climate is extremely dry. A ratio of 0.50–0.75 indicates that the climate is dry subhumid. Arid and semi-arid zones have intermediate $P \bullet ET_p$ ratios.

Among the continents other than Antarctica, Australia has the highest percentage of drylands (84%) and Europe the least (3%). Asia has the largest dryland area (20 100 000 km^2), followed by Africa with 14 000 000 km^2. Europe has 150 000 km^2 of drylands, nearly all around the Mediterranean Sea.

GLOBAL SIGNIFICANCE OF DESERTIFICATION

There is limited reliable information available on the global extent and severity of land degradation in the drylands. Many countries have experimental data on the magnitude of water erosion, salinization of irrigated lands, and soil fertility decline. Fewer have data on rangeland deterioration, wind erosion, and soil compaction. A 1992 Global Assessment of Soil Degradation, funded by the United Nations Environment Programme, produced the first worldwide map of soil degradation in both humid regions and the drylands. No similar map showing the distribution of vegetation degradation in the drylands has yet been published.

Dominant land degradation processes differ among the three major land uses in the drylands. In rangelands, the principal desertification process is vegetation degradation, followed by water and wind erosion. Salinization, usually accompanied by waterlogging of soils, is by far the most economically damaging process in irrigated lands but soil compaction is common also (*see* Salinity and Agriculture, Volume 3; Waterlogging, Volume 3). Water erosion, wind erosion, soil fertility decline and soil compaction constitute the major degradation processes in rainfed croplands. In a few countries, mainly Australia, Canada and the United States, salinization affects local non-irrigated land in certain semi-arid climatic zones. Soil compaction is a widespread and important problem in cultivated lands, especially where field operations are done with heavy machinery. It attracts little attention, usually, because the compaction occurs out of sight in the subsoil. Fortunately, its effects are easily reversed, once it is recognized.

In 1991, the United Nations Environment Programme commissioned a country by country analysis of global desertification. The study was a part of the background material prepared for the United Nations Conference on Environment and Development (UNCED) held in Brazil in 1992. Table 1 summarizes the estimated extent of land degradation in the drylands at that time, by land use.

Since the database upon which the desertification estimates were made was weak, the numbers in the table are only general approximations. The desertified rangeland

Table 1 Global desertification in drylands (1992)

Land use	Area (ha)	Desertified (%)
Irrigated land	145 500 000	30
Rainfed cropland	457 700 000	40
Rangeland	5 160 000 000	70

figure, particularly, could be much too low. It could well be 80% or more, given the increases in livestock populations in the past 50–100 years.

REVERSIBILITY OF DESERTIFICATION

Of the six principal processes of desertification, all except water and wind erosion are reversible using well-known practices. However, the reversibility may not be economic to carry out. The best example of that limitation is reversibility of rangeland deterioration. Restoration of the original vegetative conditions in overgrazed pastures can frequently be done if the rainfall is relatively high. This means that reversing vegetation degradation in dry subhumid climates probably will require 10–20 years, depending upon how badly degraded the land is. In the arid climatic zone, however, restoration may well take 40 or more years. If vegetation degradation has caused severe water or wind erosion, restoration may not be possible at all unless the landscape is drastically altered, at a high cost.

Soil fertility decline and soil compaction are relatively easy to reverse. Salinization usually is costly to reverse but the benefits of doing so usually are also high. Soil loss due to water and wind erosion is not reversible in a human lifetime because soil formation is slow. Erosion damages to soil productivity are a function of soil depth: greater damage on shallow soils, lesser damage on deep soils.

COST OF DESERTIFICATION DAMAGE

Land degradation causes two kinds of damage, on-site and off-site. On-site damage is the impact the degradation process has directly on the place where it happens. Off-site damage is that which occurs elsewhere. For example, on-site water erosion damage refers to soil and crop damage in the field where erosion occurred. Off-site damage refers to the harm that water erosion does elsewhere, such as sediment accumulation in reservoirs, deterioration in river water quality, increases in flooding, and other problems.

Water and wind erosion are the degradation processes that cause most off-site damage. In fact, off-site wind erosion damage is much worse than on-site damage, principally due to air pollution, reduction in visibility, and abrasion of structures and machinery by air-borne soil particles. Asthma problems in the Canary Islands have been attributed, in part, to dust carried on winds from the Sahara. The cost of on-site and off-site water erosion damage is believed to be about equal. In the Loess Plateau of China, however, off-site water erosion damage costs are much higher than on-site costs.

The most comprehensive study of on-site soil degradation costs was conducted in eastern Australia by the state of New South Wales. That survey showed that deterioration of soil structure, principally increased soil compaction, was by far the most important degradation process in terms of loss of income from lower crop yields. Salinization of irrigated land was next in importance. The annual cost of income foregone due to all forms of soil degradation was US$160 000 000 per year. A more generalized analysis in Canada concluded that the annual on-site cost of soil degradation in the entire country was about US$900 000 000.

CAUSES OF DESERTIFICATION

The direct cause of land degradation is improper management of land resources. The indirect cause is far more complex. High on the latter list is poverty and land tenure problems. Contributing factors include lack of incentives to conserve land, absence of credit arrangements for purchasing fertilizers and pesticides, extension of rainfed cropping into climatically marginal lands where droughts become more frequent and more severe, weak research and training programs and poor transportation facilities.

While droughts do not cause desertification, they do magnify the effects of previous overuse of the land. Rangeland vegetation weakened by overgrazing when the weather is good becomes especially susceptible to further degradation when drought strikes. With the reduced vegetative cover, water and wind erosion is more likely to occur. Rainfed croplands also become more susceptible to erosion during droughts because crop cover is reduced. Drought effects become much more pronounced when droughts continue for two or more consecutive years.

COMBATTING DESERTIFICATION

Preventing desertification is more effective and cheaper than reclamation of degraded land. Unfortunately, it is easier to get support for coping with a crisis than for avoiding future crises. Land degradation in the drylands now is so widespread that stopping further degradation is a major challenge to governments, non-governmental agencies, and land operators. Combating desertification cannot be done successfully as an isolated effort directed solely toward that objective. Anti-desertification programs must be part of a broader development policy to bring about improvement of rural conditions of health, education, communication, the economy and human welfare. A technical program of land conservation has little chance of success if it attacks only the symptoms of the problem.

Basic principles of good land management are well known. Their use does, however, require knowledge of the local environment and the adaptations that must be made for the practices to be introduced successfully. Windbreaks, for example, have been shown to reduce wind erosion worldwide. The tree and shrub species to be planted,

however, must be adapted to the local soils and climate. There is no one universal solution that fits all environmental conditions.

Adoption of improved technology appears to be essential if desertification is to be controlled, given the inability of the technology in current use to prevent continued land degradation. The technology needed is what is appropriate for the educational and financial level of the land users. By and large, the technology that is the most simple, cheap, easy to use, and effective is the most appropriate technology. It may be high level or low level technology, depending upon what is needed to fit the circumstances.

Optimally, the use of advanced systems of technology in agriculture would increase crop production on the better lands. That could allow the poorer lands to be returned to less intensive grazing, forestry, wildlife, and recreational uses, as has been done in the humid regions of Europe. The current need to eke out as much as possible from every piece of available land, no matter what its condition, is a severe restraint on land improvement efforts.

Reliance on advanced technology to solve desertification problems may be essential but it has drawbacks. There are certain to be negative as well as positive effects. Constant vigilance is necessary to keep the negative effects under control. Fertilizer use is a prime example. A little may be good but a lot can pollute surface and groundwater supplies.

ORGANIZATIONAL FRAMEWORK FOR COMBATTING DESERTIFICATION

Desertification programs almost always are administered by governmental and non-governmental units of agriculture, the environment, or soil and water conservation. Every country in the world has a national agency dealing with agriculture. Most nations also have a ministry, department or independent agency responsible for environmental affairs. Soil and water conservation commonly is carried out in ministries of agriculture. Desertification, with its central emphasis on the conservation of natural resources, fits easily within already established government agencies, for the most part. Soil and vegetation degradation, the cornerstone of desertification, is the subject of teaching and research in agronomy and range science departments of universities. There is nothing significantly different about desertification that would ordinarily require establishment of a new administrative unit. The absence of special desertification departments or agencies does have the disadvantage of not publicizing the issue or not giving it legitimacy within governments and teaching and research institutions.

The same organizational framework noted earlier applies to hundreds of NGOs. Those environmental organizations have contributed greatly to local, national, and international efforts to combat desertification. They have been particularly effective in Africa, India, and Australia. A coordinating agency, the *Environment Liaison Center International* in Nairobi, Kenya, has a membership of 850 organizations in 107 countries. It is a global communications network for NGOs and community groups working on environmental and development affairs, with desertification a major issue. Funding for the Center comes from United Nations agencies and international donor organizations in developed countries. In 1994, a new international network for NGOs called the International NGO Network on Desertification and Drought (RIOD) was organized. It is operated out of the Environment Liaison Center International.

The United Nations Environment Programme, headquartered in Nairobi, has been the international leader in assisting governments in developing countries to plan national action programs and establish desertification control projects. Funding for projects comes mainly from donor agencies, the United Nations Development Program, and the World Bank. NGOs frequently are especially effective at the local level in generating community support for forestry and soil and water conservation projects. The United Nations Food and Agriculture Organization (FAO) carries out many projects dealing with desertification processes, particularly projects on soil erosion control.

In 1996, an international United Nations convention (agreement) on combating desertification and drought became operative. The official name of the convention is The United Nations Convention to Combat Desertification in Those Countries Experiencing Serious Drought and/or Desertification, Particularly in Africa. It usually is referred to as the Convention to Combat Desertification (CCD). The objective of the convention is to combat desertification and mitigate drought effects by an integrated approach that will contribute to sustainable development in affected areas. The secretariat for the CCD is in Bonn, Germany.

National Self-interest: a Major Factor in International Environmental Policy Formulation

Detlef F Sprinz[1] and Tapani Vaahtoranta[2]

[1] *Potsdam Institute for Climate Impact Research, Potsdam, Germany*

[2] *Geneva Centre for Security Policy, Geneva, Switzerland*

The second half of the 20th century witnessed substantial growth in the number and magnitude of international environmental problems, both transboundary and global in scope. In response, a multitude of actors - from local to global - have responded to the challenge of international environmental problems. Egoistic (systematic self-interest) states, represented by governments, are still the major institutions attending to such challenges, both as entities of international law by (not) taking over legally binding obligations and in terms of (not) providing the resources needed to pursue environmental policies. Which incentives lead these countries to negotiate international environmental agreements that mitigate or adapt countries to international environmental problems? The interest-based explanation of international environmental policy (Sprinz and Vaahtoranta, 1994) provides a parsimonious answer by focusing on two crucial factors, namely ecological vulnerability and abatement costs. By classifying countries according to their values of both variables, it can be explained why some countries act as pushers for reducing international environmental problems while other countries act as draggers. Furthermore, it is suggested that technological advances may allow more countries to pursue strict international environmental policies as a result of declining abatement costs.

THE INTEREST-BASED EXPLANATION

The interest-based explanation suggests a benefit–cost approach as the central calculus driving a state's decision to strive for strict international environmental agreements. The degree to which countries are ecologically vulnerable provides incentives to remedy the situation by undertaking beneficial mitigation (e.g., reducing emissions) or adaptation measures (e.g., enhancing ground water supplies in arid areas). Thus, the interest-based explanation suggests that countries which experience high ecological vulnerability (i.e., damages to the environment) will favor strict international environmental regulations as compared to countries which have a resilient environment. However, countries are not solely driven by considerations of the environmental damages avoided by way of international environmental policies. Instead, they also take the abatement costs of such measures into account. Other aspects held constant, the interest-based explanation expects that countries with low abatement costs will be more inclined to strive for stringent international rules as opposed to countries with high abatement costs. Once countries are classified along both dimensions, namely ecological vulnerability and abatement costs, as high or low, four groups of countries can be distinguished (see Table 1).

In particular, we expect countries with high ecological vulnerability and low abatement costs to act as *pushers* in international environmental negotiations, whereas countries with the opposite characteristics are expected to act as *draggers* (see Table 1). Countries with low ecological vulnerability and low abatement costs are expected to act as *bystanders* since they have little ecological incentive to strive for strict regulations, but enjoy low abatement costs. Countries with high ecological vulnerability and high abatement costs are expected to act as intermediates since their pursuit of strict international environmental regulations will be demanding in terms of resource mobilization (see Table 1).

This four-fold typology generates expectations about the behavior of countries. Since the benefit–cost ratio is the most favorable for pushers and the least favorable for draggers – with bystanders and intermediates falling in between – the interest-based explanation also generates expectations about the stringency of the international rules favored: pushers will lead with high demands and draggers will be the least enthusiastic, whereas both bystanders and intermediates will fall in between.

The interest-based explanation of international environmental policy is not static. Technological progress often reduces abatement costs. Should this be the case, formerly less enthusiastic countries (draggers and intermediates) are likely to be able to strive for international environmental regulations that are more strict than those originally favored.

The original explanation (Sprinz and Vaahtoranta, 1994) was tested in two case studies, namely the Montreal Protocol on Substances that Deplete the Ozone Layer (see, e.g., Benedick, 1998) and the Protocol to the 1979 Convention on Long-range Transboundary Air Pollution on

the Reduction of Sulfur Emissions or Their Transboundary Fluxes by at Least 30% (see, e.g., Jackson, 1990; Levy, 1993; Sprinz and Helm, 1999). By using quantitative data and either thresholds or averages for allocating countries to groups according to ecological vulnerability and abatement costs, it could be shown that the predictions were largely borne out in the case of stratospheric ozone. In the case of acid rain, only the group of pushers was well explained, whereas the countries in the remaining three groups mostly behaved passively in regulating sulfur emissions in the 1980s and early 1990s. Furthermore, it could be shown that reductions in abatement costs made countries more inclined to agree to more demanding environmental policies (stratospheric ozone); and economic interests to sell abatement technologies led countries to favor stricter international rules (stratospheric ozone and acid rain).

In the following section, we will summarize how the interest-based explanation was received in the literature (see the section on discussion in the literature) and outline a strategy to extend the explanation towards compliance with international environmental agreements (see the section on re ections and extensions).

DISCUSSION IN THE LITERATURE

The academic debate on the interest-based explanation focused on two aspects: the underlying assumptions about the role of the state, and the variables included in the explanation.

Role of the State

The interest-based explanation assumes that the nation–state plays a central role in international environmental policy. It explains in a parsimonious way how countries reacted to international environmental problems in the latter part of the 20th century (the explanation has been critized for not attending to the causes of international environmental action, but this was never the goal of the explanation, see Frank, 1997) by focusing on the interests of countries (Keohane, 1997). In discussing the interest-based explanation, the literature emphasizes four aspects as being central for international environmental action: (i) public pressure on decision makers resulting from (ii) dramatic instances of environmental degradation and (iii) scientific understanding of the environmental problem; furthermore, (iv) it has been suggested that international institutions have been responsible for the current environmental agreements (see Frank, 1997; Meyer *et al.*, 1997; Ungar, 1995). While providing useful insights into international environmental action, these factors offer an insufficient explanation of international environmental policy since they omit the role of the state and its interests.

If countries were not ecologically vulnerable, there would be no need for environmental protection. Vulnerability by itself may not be able to spur a response. Rather, the scientifically informed perception of an ecological risk can make decision makers act on environmental degradation. (We are grateful to Matthew Auer for drawing our attention to this point (private correspondance, 8th May 1999)). Incorporating ecological risk perception makes the interest-based explanation more dynamic since the perception of ecological vulnerability may change even in the absence of changes in the state of the environment. The same observation applies to abatement costs. Public pressure may also contribute to international environmental action, although it is suggested in the literature that those political leaders having played a key role in pushing for environmental protection have not been driven by public concern but by their personal beliefs about the severity of environmental problems (see Kawashima, 1997).

However, the observable reality shows that states' preferences and policies differ from each other. The divisions cut across more familiar ways of categorizing states. For instance, one cannot necessarily predict states' preferences with reference to Western and developing countries (this categorization is used in Meyer *et al.*, 1997). For example, though western industrialized countries have been the main pushers in the international negotiations to curb the emissions of greenhouse gases, they have not acted as a unified group. The United States has referred to scientific uncertainties as well as high abatement costs and has tended to act as a dragger. Most developing countries have been sceptical about the need to act on climate change, but the judgment has not been shared by the small island nations that are particularly vulnerable to the potential rise in sea level and to greater incidences of tropical storms (for an introduction to the international politics of climate change, see Soroos (1997), 176–207, as well as Luterbacher and Sprinz, 2001). Neither does it seem useful to regard international institutions as the dominant cause of international environmental policy. For a measurement concept of the effect of international environmental institutions and a review of the literature, see Sprinz and Helm (1999), as well as Helm and Sprinz (2000). The emphasis on international institutions fails, in particular, to account for variance in states' reactions to environmental degradation. A more fundamental reason for not regarding the United Nations or other international institutions as the main actors is the fact that states have established international institutions to facilitate environmental cooperation among themselves (Bernauer, 1995).

In short, the assumption of the interest-based explanation is that the main actor responsible for international environmental policy is the state, whose preferences may be shaped by factors such as scientific understanding and public concern. Even though the state is regarded as the main actor in international environmental policy,

international cooperation to protect the environment should not necessarily be perceived as being impossible. The success of international environmental policy depends to a great extent on whether states perceive shared interests or not. Whereas in the case of stratospheric ozone depletion, there has been a sufficient degree of shared interests to enable states to agree on the protection of the ozone layer, we witness a greater diversity of state interests in the case of climate change.

Explanatory Variables

The second major reaction concerns the explanatory variables used in the interest-based explanation. Some authors suggest that the explanation could be even more parsimonious by focusing only on abatement costs (for a strong focus on the economic cost of environment protection as a factor in uencing states' policies, see Biermann (1997), Montes and Magno (1997), as well as Vogel, 1997) whereas others would like to add more explanatory variables. We find it difficult to exclude environmental vulnerability from the explanation without seriously weakening its ability to account for international environmental policy. In particular, it would be difficult to explain why a country would ever accept costly environmental remedies in the absence of ecological vulnerability. There are several examples of how environmental vulnerability or the perception of it shapes the preferences of states. For instance, the policy of the Federal Republic of Germany on acid rain changed in the early 1980s when the Germans learned about the large extent of damage to their own forests; and Finland has been particularly concerned about the environmental problems in the bordering Russian regions and has been willing to pay for controlling and solving these problems which are adverserly affecting the environment of Finland.

A first lesson to be drawn from the interest-based explanation is that economic side payments can be used to change the preferences of states and to in uence their policies on environmental protection. As David Vogel concludes, one way of promoting effective international environmental action is for the more af uent countries not only to change their own policies but also to provide less af uent countries with sufficient incentives to modify theirs as well (Vogel, 1997). The question is how much is required and feasible. From an economic perspective, it would be most effective to protect the international environment if transfers are kept sufficiently small in relation to the donor country's wealth and sufficiently large in relation to the recipient country's wealth.

A second lesson highlights the role of changing the ecological risk perception of laggards and bystanders. China's policy on curbing the emissions of greenhouse gases, for example, should favor relative emission reductions in a pronounced way if China were to change its evalution of the vulnerability of its low-lying coastal areas to the threat posed by the rise of sea level.

Two studies tested the interest-based explanation or used a similar explanatory approach, and deserve more detailed attention. Rowlands (1995) uses the explanation to find out how well it accounts for national climate change policies. He calculates environmental vulnerability and abatement costs indices for 24 countries. To determine the ecological vulnerability of countries, Rowlands uses variables which measure the impacts caused by sea-level rise and measures of the impacts on agriculture. For the abatement costs he relies on three previous studies and uses the projected energy needs as well as the potential for fuel substitution to estimate the abatement costs for countries not included in the studies. After having incorporated secondary benefits, he predicts that there should be three kinds of responses to the limiting of climate change: pushers should be proactive in the efforts to reach an agreement, draggers should resist such efforts, and intermediates should be passive. Rowlands' findings show that 11 out of 24 countries were acting as predicted by the interest-based explanation and concludes that the interest-based explanation may be helpful in understanding states' environmental foreign policies. We concur with Rowlands that our explanation may be linked to a more extensive domestic policy model, and that the explicit operationalization of the two dimensions of the explanation is crucial.

In her interview-based study, Kawashima (1997) explains how five industrialized countries adopted their policies to reduce carbon dioxide (CO_2) emissions. While she does not apply the interest-based explanation, she uses similar explanatory factors to account for the behavior of states. Based on the policies pursued, countries are divided into three groups. The Netherlands and Germany are leaders, the UK and Japan act as followers, and the US is the only laggard in her sample. Kawashima's research suggests that six factors might have affected the preferences of states, namely harm caused by climate change (ecological vulnerability), economic cost of reducing emissions (abatement costs), domestic factors, international politics, the degree to which an international agreement is binding, and the experience of past negotiations on other environmental issues. According to the answers from expert interviews, four factors affected the national policies in particular. Interviewees from all countries except the US were concerned about the ecological impact of climate change, whereas US interviewees stressed the importance of high CO_2 abatement costs. These results are in accordance with the interest-based explanation. Kawashima also found that two additional factors had played a role in shaping the states' preferences. First, the role of political leaders was regarded as one of the most decisive factors in the Netherlands, Germany and Japan. These leaders pushed for emission reductions regardless of the scientific evidence of

the adverse ecological impact or of the abatement costs involved. Second, international politics played a decisive role for the UK and Japan. International pressure within the European Union in uenced British policy, and Japan's policy was affected by its concern for an active international role. Kawashima agrees with Rowlands that domestic policy and international politics may shape states' policies on environmental issues.

In general, we suggest that the present form of the interest-based explanation permits a first order assessment of the likely positioning of countries in negotations on international environmental agreements (for an affirmative assessment of the method used in the interest-based explanation, see Zurn, 1997). Subsequent detailed studies may allow for the incorporation of additional variables which permit detailed explanation of the behavior of a more limited set of countries. However, the purpose of the interest-based explanation is to simplify reality in order to draw attention to major causal relationships in international environmental policy. A more elaborate explanation will have to demonstrate that the inclusion of additional factors leads to substantive increases in explanatory power.

REFLECTIONS AND EXTENSIONS

Re ecting on the interest-based explanation, we will discuss two aspects which merit attention: a variance argument and an intercomparison (or locking) argument. In addition, we will outline how the original explanation can be extended from the stage of negotiating international environmental agreements to the stage of compliance.

First, the usefulness of the classification scheme seems to vary with the magnitude of the variance found across the two variables, namely ecological vulnerability and abatement costs. If there is very little variation in the values of both variables across countries, the classification becomes less robust. Thus, the higher the variance, the less arbitrary the thresholds, and the stronger the classificatory power of the explanation.

Second, the operationalization of the interest-based explanation rests on the relative ecological vulnerability and abatement costs, i.e., it relies on the relative positioning of countries within the same pollution domain. However, the explanatory power of the explanation could be enhanced by pooling the abatement costs and ecological vulnerability scores from a large set of pollution domains across countries – using a common metric which makes such data intercomparable. In such a pooled analysis, an (absolute) average threshold for ecological vulnerability and abatement costs could be determined for the set of countries (locking of the thresholds) and the particular pollution case could now be nested within the larger pooled analysis. This would allow us to assess whether we should expect more pushers in these negotiations as compared to the pooled average, and, subsequently, more stringent regulations. Similar propositions can be made with respect to other quadrants of the classification found in Table 1.

In general, each party to an international treaty is expected to comply with its rules. Some treaties also have specific articles on non-compliance, but still some states do not always comply with treaties. The original interest-based explanation derived hypotheses about the expected negotiation behavior of states. In the remainder of this section, we outline an extension of the explanation so as to capture expected compliance behavior while keeping the basic logic of the original explanation. For reasons of convenience, we do not assume that countries change their classificatory label between both phases (e.g., because of changes in the abatement costs or their ecological vulnerability). Furthermore, we assume that at the end of the negotiations countries are forced to take the decision of whether to sign or not sign the international environmental agreement (signing an international agreement may take various forms such as accession, signature, ratification without signature, etc.). This may lead to the expectation that the signatories will be bound by the legal provisions of the international environmental agreement whereas the non-signatories remain free to pursue any policy they wish. Contrary to this depiction spurred by the tradition of international law, this extension of the interest-based explanation to the stage of compliance provides a much richer explanation.

First, the basic provisions of international environmental agreements may lead to positive abatement costs and therefore divert resources from the pursuit of other public policies. Thus, it is hypothesized that the higher the compliance costs for a country, the lower the degree of compliance.

Second, ecological vulnerability provides countries with positive incentives to actually implement and enforce international environmental agreements domestically. Thus, it is hypothesized that the higher the degree of ecological vulnerability for a country, the higher the degree of compliance with the basic rules of an international environmental agreement.

Pursuant to the classification introduced earlier, we suggest that one should dichotomize countries into those with low versus high compliance costs and those with low versus high ecological vulnerability, and derive expected behavior accordingly. Countries which are signatories of an international environmental agreement will carry the attribute committed', whereas non-signatories will be labeled uncommitted' (see Tables 2 and 3).

Even if a country does not sign an international environmental agreement, high ecological vulnerability provides it with some incentives to undertake actions in line with the provisions of the international environmental agreement (e.g., uncommitted pushers), especially if self-help is possible and efficient. This is also supposed to hold for countries

Table 2 Expected compliance of signatory countries[a]

		Ecological vulnerability	
		Low	High
Relative national Compliance costs	Low	Committed bystander medium compliance	Committed pusher full to (voluntary) over-compliance
	High	Committed dragger no to low compliance	Committed intermediate medium compliance

[a] Upper entries depict classificatory labels, lower entries refer to the degree of compliance. Scale for degree of compliance: none, low, medium, full, over-compliance. Scale for ecological vulnerability and compliance costs: low, high.

Table 3 Expected compliance of non-signatory countries[a]

		Ecological vulnerability	
		Low	High
Relative national Compliance costs	Low	Uncommitted bystander low compliance (voluntary)	Uncommitted pusher medium to full compliance (voluntary)
	High	Uncommitted dragger no compliance	Uncommitted intermediate low compliance (voluntary)

[a] Upper entries depict classificatory labels, lower entries refer to the degree of compliance. Scale for degree of compliance: none, low, medium, full, over-compliance. Scale for ecological vulnerability and compliance costs: low, high.

with low compliance costs. Thus, we suggest that the same rationale holds for signatories as well as non-signatories. However, non-signatories are expected to achieve a lower level of (voluntary) compliance with the provisions of an international environmental agreement (compare Tables 2 and 3). Nevertheless, for most groups we should expect actual steps towards partial compliance rather than inaction. We will highlight this by way of paired comparisons of each group across signatory status.

Five levels of compliance are used (in ascending order): none, low, medium, full, and over-compliance. The lowest rating (none) refers to no compliance behavior or even actions which are directed against reducing ecological vulnerability (e.g., increased emission); low compliance relates to very minor steps taken in the direction of compliance; medium refers to steps short of full compliance; full compliance refers to 100% congruence of the rules in the international environmental agreement and compliance-related behaviors; and over-compliance refers to any substantial exceedance of full compliance. This 5-step scale should not be confused with the two-point scale (low vs. high) for ecological vulnerability and compliance costs.

First, push countries in international negotiations seem to have the greatest incentives to actually sign and comply with international environmental agreements because of the attractive benefit–cost ratio. Thus, we should expect full compliance, at a minimum, and possibly (voluntary) over-compliance. If a push country does not succeed in upgrading international rules sufficiently, it may decide not to sign the international agreement, e.g., for domestic political reasons which would not support weak international rules. However, given their interest configuration, we should expect uncommitted pushers to voluntarily implement the international environmental agreements to a medium or full extent.

Second, draggers are likely to show the reverse behavior because of the low benefit–cost ratio. For committed draggers, signing international environmental agreements only fulfills the useful functions of creating leverage at extracting resources from other countries in order to enhance compliance, or the opportunity to in uence the negotiations of subsequent international environmental agreements. For uncommitted draggers, there are even fewer incentives to undertake any actions towards compliance. In fact, we should expect no compliance at all.

Third, intermediate countries are challenged by the high costs of compliance. Therefore, we should expect committed intermediates to show medium levels of compliance, whereas uncommitted intermediates will only endeavor to show low levels of (voluntary) compliance. Thus, the vigor of compliance behavior falls in between those of pushers and draggers because of the intermediate benefit–cost ratio. A similar calculus applies to bystanders.

In general, this approach to compliance predicts a substantial range of compliance levels – even among signatory countries. While signatory countries are likely to show uniformly higher levels of compliance as opposed to non-signatory countries, even some non-signatory countries are likely to contribute to the alleviation of international environmental problems due to their enduring ecological and economic incentives.

CONCLUSIONS

The interest-based explanation of international environmental policy provides predictions of the likely behavior of countries in international environmental negotiations, by utilizing a combination of ecological vulnerability and abatement costs. Given its parsimonious and operational nature, the interest-based explanation can be empirically tested and extended from the stage of negotiating international agreements to the stage of expected compliance with international environmental agreements. While the critique of the explanation has focused on the role of states in international environmental action, as well as the number of variables to be included in research, we remain confident that the interest-based explanation provides a successful approach to derive initial expectations of the behavior of countries.

Natural Hazards: Social and Policy Responses

Dennis S Mileti and Mary Fran Myers
University of Colorado, Boulder, CO, USA

Natural hazards and disasters are not isolated phenomena that can be divorced from the societies they affect: a disaster is a symptom of broader and more basic problems. Hazard losses, and the fact that there seems to be an inability in most if not all societies to reduce those losses, are the consequences of narrow and short-sighted development patterns, cultural premises, and attitudes toward the natural environment, science, and technology. A proposal is put

forward to assist people and societies in taking responsibility for reducing hazard losses.

DISASTER LOSSES ARE GROWING

Natural hazards have caused a steady increase in property losses in the past century as the world's population has grown and increasingly occupies hazard-prone areas of the planet.

For example, the dollar losses associated with most types of natural hazards in the United States are rising. A conservative estimate of total dollar losses from 1975 to 1994 is $500 billion (in 1994 dollars). More than 80% of these costs stemmed from climatological events. More revealing is that in that 20-year time frame, the ten most costly disasters (based on dollar losses) in the US occurred between 1989 and 1994, suggesting bigger and more catastrophic losses are on the rise.

While the United States has succeeded in saving lives and reducing injuries from some natural hazards such as hurricanes over the last half-century, recent events such as Hurricane Mitch in Central America, the Venezuelan oods and landslides, and the earthquake in Turkey which claimed thousands of lives indicate that deaths and injuries from natural hazards have not declined substantially world-wide.

WHY DISASTER LOSSES ARE GROWING

Many disaster losses are the predictable results of interactions among three major systems: the global physical environment, which includes climate change and the occurrence of hazardous events; the social and demographic characteristics of the communities and societies that experience disasters; and the buildings, roads, bridges, and other components of the built environment. Growing losses result partly from the fact that the world's capital stock is expanding, but they also stem from the fact that all these systems and their interactions are becoming more complex. Three main in uences are at work.

Global Change

First, the Earth's physical systems are constantly changing. For example, a warming climate is expected to produce more dramatic meteorological events such as storms, oods, drought, and heat waves. Indeed, the greatest impact of climate change on human beings probably will be an increase or decrease in the frequency of different types of extreme events that initiate natural disasters.

Socio-demographic Change

Second, recent and projected changes in the demographic composition and distribution of the world's population mean greater exposure to many hazards. The number of people residing in earthquake-prone mega cities and coastal areas subject to cyclones, for example, is growing rapidly. The immigration of poor people into these mega cities invariably results in their occupying the most vulnerable ood- or landslide-prone areas of these communities. Worsening inequality of wealth also makes many people more vulnerable to hazards and less able to recover from them.

Changes in the Built Environment

Third, the built environment – public utilities, transportation and communication systems, and homes and office buildings – is growing in density, making the potential losses from natural forces larger. The ability of the built environment to withstand the impacts of extreme natural forces plays a direct role in determining the number of lives lost, the number and severity of injuries, and the financial impact of disasters.

Other Issues

Another major problem has become clear over the past 20 years: some efforts to head off damages from natural hazards only postpone them. For example, communities below dams or behind levees may avoid losses from the oods that those structures were designed to prevent. But such communities often have more property to lose when those structures fail. This is due to the fact more development occurred as a result of the structure because people thought they would be safe from the ood risk. Such a situation contributed to catastrophic damage from the 1993 oods in the Mississippi basin. And many of the world's dams, bridges, and other structures are approaching the end of their designed life revealing how little thought their builders gave to events 50 years hence. The availability of insurance in some cases induces people to occupy hazard-prone areas. Similarly, by providing advance warnings of severe storms, it is possible that more people have been encouraged to build on fragile coast lines. Such development, in turn, makes the areas more vulnerable by destroying dunes and other protective natural features.

THE CYCLICAL NATURE OF COPING WITH NATURAL HAZARDS

Societal adjustments to natural hazards have typically been viewed in a cyclical framework comprised of four stages: preparedness, response, recovery, and mitigation. Preparedness involves building an emergency response and management capability in advance of a disaster to facilitate an effective societal response if a disaster occurs. Response refers to the actions taken immediately before, during, and after a disaster in order to save lives, minimize property

damage, and enhance the effectiveness of recovery. Disaster recovery involves short-term activities to restore vital life-support systems to minimum operating standards and long-term activities to return life to normal or improved quality. Mitigation refers to the policies and activities that will reduce an area's vulnerability to damage from natural disasters. It is important to note that the word *mitigation* as used here is equivalent to the word *adaptation*. In this context, mitigation is much broader in scope than it is when referred to in the global climate change literature. Mitigation generally includes those adjustments described below (*see* Adaptation Strategies, Volume 4).

TRADITIONAL APPROACHES TO DEALING WITH HAZARDS

Over past decades an array of techniques and practices has evolved to reduce and cope with losses from disasters.

Land Use

Wise land use planning that limits expansion into sensitive areas can keep people and property out of the way of hazards and can also contribute to promoting environmental quality.

Warnings

Significant improvements in short-term forecasts and warnings (hours to days ahead of a hazardous event) have dramatically reduced loss of life and injury in North America and other parts of the developed and developing world. It is important to remember, however, that warning systems do not significantly limit damage to property, nor do they mitigate economic disruption from disasters.

Engineering and Building Codes

Disaster-resistant construction of buildings and infrastructure is an essential component of any mitigation program. Engineering codes, standards, and practices have been promulgated for natural hazards; now they must be incorporated into local building codes and practices world-wide, with special attention paid to the enforcement of those codes.

Insurance

Insurance does help minimize some disruption caused by disasters by ensuring that people with coverage receive compensation for their losses. However, most property owners do not buy coverage against special perils, notably earthquakes, hurricanes, and oods. For example, in the US only about 20 percent of the homes exposed to oods are insured for them. Further, the industry has problems providing insurance in areas subject to catastrophic losses because many insurers do not have the resources to pay for a worst-case disaster.

New Technology

Computer-mediated communication systems, geographic information systems (GIS), remote sensing, electronic decision-support systems, and risk-analysis techniques have developed substantially during the last two decades and can support hazard mitigation programs. For example, GIS models enable managers to consolidate information from a range of disciplines, including the natural and social sciences and engineering, and to formulate plans for mitigation accordingly (*see* Geographic(al) Information Systems (GIS), Volume 4).

Emergency Preparedness and Recovery

Good mitigation programs will never eliminate the need for plans to address the destruction and human suffering imposed by disasters. As such, creating policies for disaster preparedness and response are needed to save lives and injuries, limit property damage, and minimize disruptions, when extreme environmental events do occur. In addition, such policies that are extended to include plans that focus on recovery and reconstruction for rebuilding in safer ways and in safer places can be effective in reducing future vulnerability to disasters.

A CENTRAL PROBLEM WITH TRADITIONAL APPROACHES

One central problem with the accepted methods described above for coping with hazards is that they have been based on the idea that people can use technology to control nature to make themselves safe. Further, most strategies for managing hazards have followed a traditional planning model: study the problem, implement one solution, and move on to the next problem. This approach suggests that hazards are static and mitigation is an upward, positive, linear process.

But natural disasters are not linear problems that can be solved in isolation. Rather, they are symptoms of broader and more basic problems. Losses from hazards, and the fact that most societies cannot seem to reduce them, result from shortsighted and narrow conceptions of the human relationship to the natural environment.

To redress those shortcomings, a shift is needed to a concept that links wise management of natural resources with local economic and social resiliency and that views hazard mitigation as an integral part of overall sustainable development.

A NEW APPROACH TO HAZARDS

The main guidelines for achieving this shift and improving society's ability to mitigate hazards are described below.

Adopt a Global Systems Perspective

Rather than resulting from surprise environmental events, disasters arise from the interactions among the Earth's physical systems, its human systems, and its built infrastructure. A broad view that encompasses all three of these dynamic systems and interactions among them can enable us to find better solutions.

Accept Responsibility for Hazards and Disasters

Human beings and not nature are the cause of disaster losses, which stem from choices about where and how human development will proceed. There is no final solution to natural hazards, since technology cannot make the world safe from all the forces of nature, and in some cases (e.g., climate change) can even be seen to be increasing these forces. As such, humans must accept responsibility for their decisions that result in future risks.

Anticipate Ambiguity and Change

The view that hazards are relatively static has led to the false conclusion that any mitigation effort is desirable and will in some way reduce future losses. In reality, change can occur quickly and nonlinearly. Human adaptation to hazards must become as dynamic as the problems presented by hazards themselves.

Reject Short-term Thinking

Mitigation as frequently conceived is too short-sighted. In general, people have a cultural and economic predisposition to think primarily in the short term. Sustainable mitigation will require a longer-term view that takes into account the overall effect of mitigation efforts on this and future generations.

Account for Social Forces

Societal factors, such as how people view hazards and mitigation efforts or how the free market operates, play a critical role in determining the extent of future disaster losses. Because such social forces are so in uential, growing understanding of physical systems and improved technology alone cannot suffice. To effectively address natural hazards, mitigation must become a basic social value.

Embrace Sustainable Development Principles

Disasters are more likely where unsustainable development occurs, and the converse is also true: disasters hinder movement toward sustainability because, for example, they degrade the environment and undercut the quality of life. Sustainable mitigation activities should strengthen a community's social, economic, and environmental resiliency, and *vice versa*. By incorporating disaster resistance into community planning and economic development, growth can be managed and can result in lessening the impact that disasters have on communities, businesses, and citizens.

ESSENTIAL GOALS FOR A NEW APPROACH

Sustainability means that a locality can tolerate and overcome damage, diminished productivity, and reduced quality of life from an extreme event without significant outside assistance. To achieve sustainability, communities must take responsibility for choosing where and how development proceeds. Each locality must evaluate its environmental resources and hazards, choose future losses that it is willing to bear, and ensure that development and other community actions and policies adhere to those goals.

Six objectives must simultaneously be reached to mitigate hazards in a sustainable way and stop the trend toward increasing catastrophic losses from natural disasters.

Maintain and Enhance Environmental Quality

Human activities to mitigate hazards should not reduce the carrying capacity of the ecosystem, for doing so increases losses from hazards in the longer term.

Maintain and Enhance People's Quality of Life

A population's quality of life includes, among other factors, access to income, education, health care, housing, and employment, as well as protection from disaster. To become sustainable, local communities must consciously define the quality of life they want and select only those mitigation strategies that do not impede any aspect of that vision.

Foster Local Resiliency and Responsibility

Resiliency to disasters means that a locale can withstand an extreme natural event with a tolerable level of losses. Mitigation actions should be consistent with achieving that level of protection.

Recognize that Vibrant Local Economies are Essential

Communities should take mitigation actions that foster a strong local economy rather than detract from one.

Ensure Inter- and Intra-generational Equity

A sustainable community selects mitigation activities that reduce hazards across all ethnic, racial, and income groups, and between genders equally, now and in the future. The costs of today's advances should not be shifted onto later generations or less powerful groups.

Adopt Local Consensus Building

A sustainable community selects mitigation strategies that evolve from full participation among all public and private stakeholders. The participatory process itself may be as important as the outcome.

RECOMMENDED ACTIONS AND INITIAL STEPS BEING TAKEN

The shift to a sustainable approach to hazard mitigation will require extraordinary actions. Here are several essential steps; many initial efforts that are underway are described.

Building Local Networks, Capability, and Consensus

Today, hazard specialists, emergency planners, resource managers, community planners, and other local stakeholders seek to solve problems on their own. An approach is needed to forge local consensus on disaster resiliency and nurture it through the complex challenges of planning and implementation.

One potential approach is a network of stakeholders in every community that would engage in collaborative problem solving. Each network would produce an integrated, comprehensive plan linking land use, environmental, social, and economic goals, as well as disaster resiliency. The stakeholder network especially needs to determine the amount of damage that those who experience disasters can bear. These plans would enable policymakers, businesses, and residents to understand the limitations of their region and work together to address them. Full consensus may never be reached, but the process is key because it can foster the sense of community required to mitigate hazards.

This kind of holistic approach situates mitigation in the context of other community goals that, historically, have worked against action to reduce hazards. Also, the process ensures that each locality controls the character of its disasters, forcing stakeholders to take responsibility for natural hazards and realize that the decisions they make today will determine future losses.

A problem with this approach is the challenge of generating sufficient interest to create a stakeholder network. However, efforts to overcome this problem are being funded by the US Federal Emergency Management Agency (FEMA) through its Project Impact program. Project Impact is a community based initiative designed to bring key partners together, including the private and non-governmental sectors, to work in concert with local government officials to develop and implement hazard mitigation projects which not only support disaster loss reduction but meet other community goals such as increased economic vitality and environmental quality as well.

Establish a Holistic Government Framework

To facilitate sustainable mitigation, all government policies and programs related to hazards and sustainability should be integrated and consistent. Statutes and regulations should be reexamined in light of the principles of sustainable mitigation. Changes needed might include limiting the subsidization of risk, making better use of incentives, and setting national policies for land use.

New Zealand commenced major reform of its emergency management framework in the mid-1990s. The modifications are designed to transfer the nation's response-focused counter-disaster approach into a system grounded in a sustainable hazard management framework. The reform calls for refocusing action onto the management of risk and the natural environment.

Conduct Nationwide Hazard and Risk Assessments

Not enough is known about the changes in or interactions among the physical, social, and built environments that are reshaping each nation's hazardous future. National risk assessments should meld information from those three environments so hazards can be estimated interactively and comprehensively, to support local efforts on sustainable mitigation. Once completed, these assessments need to be provided to communities at a scale that is sufficient for local decision-making.

Build National Databases

Countries should collect standardized data on losses from past and current disasters, to establish a baseline for comparison with future losses. The information should include the type, location, and cause of losses, taking into account problems of double-counting, comparisons with gross domestic product, and the distinction between regional and national impacts. A database is also needed on mitigation efforts: what they were, where they occurred, and how much they cost in order to provide a baseline for local cost-benefit analysis. These archives are fundamental to informed decision making and should be accessible to the public.

The US FEMA recently funded two panels of national experts at the US National Academy of Science's National

Research Council and the Heinz Center (a nonprofit environmental research organization located in Washington, DC) to address how the US might move forward to accurately count disaster losses. Although not yet implemented, FEMA and other agencies are working toward standardizing how loss data are measured and collected that might soon be brought together into a national data base.

Provide Comprehensive Education and Training

Today hazard managers are asked to deal with problems they have never before confronted, such as understanding complex physical and social systems, conducting sophisticated cost-benefit analyses, and offering long-term solutions. Education in hazard mitigation and preparedness should therefore expand to include interdisciplinary degree programs. University-based holistic programs that move away from traditional disciplines toward education designed to solve the real-world problems entailed in linking hazards and sustainability must be created.

Efforts to move away from traditional educational programs are underway in the United States. FEMA's Emergency Management Institute has established a Higher Education Initiative with a goal of establishing at least one program in a college or university in each of the 50 states that offers a bachelors degree in emergency management. Further, in cooperation with the US Army Corps of Engineers and FEMA, the Natural Hazards Research and Applications Information Center at the University of Colorado is working to create a vision for the higher education needs of the nation's hazards and emergency managers.

Measure Progress

Baselines for measuring sustainability should be established so future progress can be gauged. Interim goals for mitigation and other aspects of managing hazards should be set, and progress in reaching those goals regularly evaluated. This effort requires determining how to apply criteria such as disaster resiliency, environmental quality, intra- and inter-generational equity, quality of life, and economic vitality to the plans and programs of local communities.

Also important is evaluating hazard-mitigation efforts already in place before taking further steps in the same direction. For example, the US National Flood Insurance Program (NFIP), which combines insurance incentives and land use and building standards, has existed for more than 30 years, yet its effectiveness has never been thoroughly appraised. This is about to change as the FEMA has begun to conduct a detailed assessment of the NFIP. Six areas will be examined in detail: the occupancy and use of oodplains, costs and consequences of ooding, insurance rating, oodplain management and enforcement, hazard identification and risk assessment, and communication.

Another way to measure progress is to collect the new knowledge relevant to hazard mitigation and disaster response and recovery that results from every disaster that occurs. This information should be systematically collected and evaluated to assess progress in putting knowledge into practice.

Share Knowledge Internationally

Countries must share knowledge and technology related to sustainable hazard mitigation with one another and be willing to learn from each other as well. Disaster experts worldwide need to collaborate with development experts to address the root causes of hazard vulnerability, including overgrazing, poverty, deforestation, and unplanned development. Disaster reduction should be a part of everyday development processes, and international development projects must consider vulnerability to disaster.

There is progress being made in this arena. The United Nations' International Decade for Natural Disaster Reduction (*see* IDNDR (The International Decade for Natural Disaster Reduction), Volume 4) and the World Meteorological Organization's work in forecasting, preparedness, and mitigation have done much to promote efforts that reduce vulnerability to hazards around the globe. In addition, many of the world's financial organizations such as the International Development Bank, the Inter American Development Bank, and the World Bank now recognize the importance of incorporating mitigation into their lending and relief policies. An example is the launching of the World Bank's ProVention Consortium in February 2000. This Consortium is dedicated to reducing disaster risk in developing countries by making disaster prevention and mitigation an integral part of development initiatives.

A FEW FINAL WORDS

A good deal of progress has been made in the last few decades about understanding the relationship between society and its natural environment. Much of what societies have done in their recent past has been to adapt to environmental change and forces as they occurred. Global climate change, however, demands a shift in perspective, especially in regard to natural hazards. It illustrates the importance of adopting a future-oriented perspective and longer-term approach when dealing with the relationship between society and the natural environment: *See also* Natural Hazards, Volume 3; Adaptation Strategies, Volume 4; Risk Management in an Era of Global Environmental Change, Volume 4; Hazards in Global Environmental Change, Volume 5.

No Regrets Principle

The *no-regrets principle:* because of public apathy, uncertainties in possible outcomes, and/or the costs involved, it is sometimes difficult for a government or industry to do all that it should to prevent a long-term environmental situation (like climate warming) from developing. Thus, it is often urged that at least a start should be made through the promotion of a no-regrets policy, i.e., a policy which can be justified because it is likely to be beneficial, not only with respect to the issue under consideration, but also with respect to other environmental and/or socio-economic issues. Examples with respect to greenhouse gases include the following (Munn *et al.*, 1996):

1. Promotion of increased energy efficiency to reduce carbon dioxide emissions, thus reducing emissions of oxides of sulfur and nitrogen while conserving fossil fuel supplies for future generations.
2. The extension of industrial product cycles by reusing and recycling wastes.
3. Innovations in energy conversion, reducing environmental impacts without affecting the benefits currently enjoyed by high-energy users.
4. Tree planting not only to absorb carbon dioxide from the atmosphere, but also to provide shade during hot weather, to increase the available habitat for wildlife, and to reduce soil erosion.

However, the no-regrets principle should not be invoked as an excuse for not taking drastic action if there is evidence that a dangerous trend may otherwise become irreversible.

O

Obasi, G O P

(1933-)

Godwin Olu Patrick Obasi, a Nigerian citizen, has been the Secretary-General of the World Meteorological Organization (WMO) since 1 January 1984. He holds a Doctor of Science degree (1963) in Meteorology from the Massachusetts Institute of Technology, USA. He won the Carl Rossby Award for the best doctoral degree thesis.

He served as Dean of the Faculty of Science, Professor and Chairman of the Department of Meteorology at the University of Nairobi, Kenya and Visiting Research Associate at the Florida State University, Tallahassee, FL. He has published over 100 scientific and technical papers. He is a Consulting Editor to many international journals in meteorology.

Professor Obasi was instrumental in the initial planning of the Global Atmospheric Research Program (GARP) Atlantic Tropical Experiment. He also served as Vice-President of the WMO Commission for Atmospheric Sciences.

As Secretary-General of WMO, Professor Obasi raised the profile of WMO and the National Meteorological and Hydrological Services (NMHSs) worldwide in their role as major contributors to the sustainable development of nations in climate-related areas including climate change, improved weather forecasts and seasonal prediction, mitigation of natural disasters, e.g., combating desertification, increasing support to food security, water resources assessment and management, and the monitoring and prediction of the state of the stratospheric ozone layer.

In support of the NMHSs, he meets regularly with Heads of State and Governments, Ministers and senior Government officials worldwide. He has also fostered active collaboration between WMO and the organizations of the United Nations (UN) as well as with other international and regional governmental and non-governmental organizations in areas of interest to the NMHSs. Professor Obasi has initiated a number of reforms within the secretariat to enhance its efficiency and cost-effectiveness. His vision is to continue to develop a respected, forward-looking and effective organization that will meet the challenge of present and future generations.

In recognition of the outstanding achievements of the WMO under his able leadership as Secretary-General, the initiatives he has launched for the development of NMHSs in support of the sustainable development of nations, as well as for this continuing active involvement and achievements in the fields of meteorology, operational hydrology and general environmental matters, Professor Obasi has been honored by the governments of several member countries, universities, academic institutions and meteorological scientists worldwide, including Romania, Philippines, Nigeria, Russian Federation, Paraguay, Kenya and Czechoslovakia.

MOSTAFA K TOLBA *Egypt*

OECD (Organization for Economic Co-operation and Development)

The OECD, founded in 1961, is an intergovernmental organization of 29 of the world's most industrialized countries. As of early 1999, the OECD member countries are: Australia, Austria, Belgium, Canada, the Czech Republic, Denmark, Finland, France, Germany, Greece, Hungary, Iceland, Ireland, Italy, Japan, Luxembourg, Mexico, the Netherlands, New Zealand, Norway, Poland, Portugal, the Republic of Korea, Spain, Sweden, Switzerland, Turkey, the UK and the US. The European Commission also takes part in the work of the OECD. It addresses economic, social and environmental policy concerns in

an interdisciplinary way, and has sustainable development as one of its strategic priorities. The OECD Environment Policy Committee (EPOC), supported by the Environment Directorate, has been working on environmental policy issues, especially those at the interface of the economy and the environment, for nearly three decades. It cooperates extensively with other parts of the organization and with outside partners.

Two recent developments have provided a new impetus and direction to the Environment Program of work for which EPOC is responsible. First, the OECD Environment Ministers' Shared Goals for Action, which OECD Environment Ministers agreed on at their meeting in April 1998, promotes strong national policies and effective regulatory structures on the protection of the natural environment and human health. The goals are to:

- promote an integrated policy approach which encourages coherence among economic, environmental and social policies;
- strengthen international cooperation in meeting global and regional environmental commitments;
- strongly support participation, transparency, information and accountability in environmental policy-making by public authorities at all levels;

The second development is the implementation of a major horizontal program on sustainable development throughout the organization, which will culminate in a report to the OECD Ministers in 2001. Issues which will be addressed in this include climate change, the environmental impact of reforming subsidies and taxes, technology, the management of natural resources, governance for sustainable development, and indicators.

The integration of environment and economic policies, central to achieving sustainable development in OECD member countries and non-member countries alike, remains at the center of the Environment Program. It will promote compatibility and mutual reinforcement between economic and environmental policies, by: identifying market and intervention failures and how to remove them; analyzing policy instruments for achieving environmental objectives at least cost; and developing tools and strategies for integration in such sectors as agriculture, energy or transport. Key issues include the use of economic instruments, especially environmental taxes and charges, and the impact of subsidies on the environment.

The Environmental Outlook and Strategy is a major new activity. The outlook will provide an economy-based vision of environmental conditions in 2020 in key sectors and in relation to major environmental problems. It will be the basis for a new OECD Environment Strategy to be discussed when OECD Environment Ministers next meet in 2001.

Two new crosscutting activities in the program deal with *resource ef ciency* and *sustainable consumption*. Each is of growing importance for both OECD and non-OECD countries attempting to manage renewable and non-renewable resources more sustainably, and to in uence the ever rising demands for goods and services in such areas as transport, food, housing and tourism.

The Environment Program also examines the links between the globalization of trade and investment, and the environment. There is active engagement of non-member countries in policy analysis and dialogue on this and many other parts of the program. The Environment Directorate is also the secretariat for the Environmental Action Program Task Force, which is part of the Environment for Europe process.

On climate change, the Environment Program is contributing substantially through wide-ranging analysis in support of the development of domestic and international policy by Annex I parties to the United Nations (UN) Framework Convention on Climate Change. Work on environmentally sustainable transport, to explore the policies needed to achieve sustainability in this sector by 2020, is another element of the program.

Chemicals and biotechnology are also addressed, as is the management of the transfrontier movement of waste. The prevention and reduction of risks to health and the environment from chemicals, the harmonization of policies and regulations, and the promotion of integrated approaches to chemical testing, data and management are the main focus. Several OECD instruments, or Council Acts, deal with chemicals and waste management – as well as other environmental subjects – and member countries are committed to implement these.

Environmental data and indicators are essential to underpin the other work, and the OECD regularly publishes a core set of environmental indicators. It also measures countries' environmental performance with a program of Environmental Performance Reviews of all the OECD countries; this is nearing the completion of its first cycle. These peer reviews, in which other OECD member countries as well as the Secretariat are actively involved, have also been undertaken for several non-member countries in central and Eastern Europe, and most recently for Russia.

Ozone Layer: Vienna Convention and the Montreal Protocol

Mostafa K Tolba
International Center for Environment and Development, Cairo, Egypt

The atmosphere has evolved over geological time into a mixture of some 80% nitrogen and 20% oxygen. It also contains many trace gases, in concentrations ranging from a few points of a percent down to a few parts per trillion. Their biochemical, geochemical and geophysical importance is much greater than their relatively low concentrations might suggest. This is particularly true of ozone, which is produced and destroyed at a wide range of altitudes in the atmosphere. Near the ground, ozone is a potentially harmful pollutant, formed when emissions from cars and industry react with sunlight. But between 25 and 40 km up in the stratosphere, ozone is formed naturally from molecular oxygen and is a blessing. Although its concentration is only about 10 parts per million by volume, it acts as a natural filter which absorbs and blocks the dangerous short-wave ultraviolet (UV) radiation (UV-B) of the sun.

Ozone exists in equilibrium in the natural stratosphere, being formed from molecular oxygen and being destroyed by UV radiation. Reactive chemicals, such as the oxides of hydrogen, nitrogen and chlorine, can accelerate the process of ozone destruction and thus upset the natural balance, leading to a net reduction in the amount of ozone. Each molecule of these chemicals acts as a catalyst, destroying many (even thousands) of molecules of ozone before being removed from the stratosphere through interaction with other free radicals, and sinking down into the troposphere.

Concern that human activities were destroying stratospheric ozone began in the late 1960s and concentrated on high flying supersonic aircraft. Their engines become so hot that they convert atmospheric nitrogen and oxygen into nitrogen oxides (NO_x) and deposit these 17 to 20 km up in the stratosphere. The NO_x then destroys ozone. But when plans to build fleets of commercial supersonic aircraft were abandoned, this concern faltered.

In 1974, two scientists working at the University of California, Professors Sherwood Rowland and Mario Molina, advanced the hypothesis that chlorofluorocarbons (CFCs) which are inert gases near the ground, gradually rise into the stratosphere, where they cause a catalytic reaction which destroys ozone (Molina and Rowland, 1974). As CFCs were used in homes and industry, for example, the suggestion set alarm bells ringing. Rowland and Molina subsquently became Nobel Laureates as a result of their 1974 paper.

Early in 1977, United Nations Environment Programme (UNEP) convened a meeting of experts, which adopted a 21 point World Plan of Action on the Ozone Layer and gave UNEP the responsibility for collating, disseminating and encouraging research. The UNEP and the World Meteorological Organization (WMO) established a Co-ordination Committee on the Ozone Layer (CCOL) made up of representatives of specialized agencies, national, intergovernmental and non-governmental organizations, and scientific institutions. This committee was to produce semiannual assessments of ozone layer depletion and its impact.

At this stage there was no prima facie case against CFCs. But some governments were already anxious. In 1976, Canada had announced that it would order the progressive elimination of the most common CFCs (11 and 12) and prohibit their use in non-essential spray cans. In 1978, the USA banned the use of CFCs as aerosol propellants. Some large chemical companies began to look into developing safe substitutes.

OZONE OBSERVATIONS 1970–1987

Statistical analyses of ground-based total-column ozone measurements show that between 1970 and 1980 there was no statistically significant decrease in the annual global average content of ozone (i.e., the decrease was less than 1%). Model calculations, taking into account increases in nitrous oxide and halocarbons, predicted that total-column ozone should have decreased by less than 0.5% at all latitudes in the summer, and between 0.5 and 1% in the winter, with the largest depletions predicted at high latitudes. Thus the model results were not inconsistent with the observations.

By 1986 three mechanisms (two involving changes in natural processes (1 and 2) and one involving human activities (3) had been proposed to explain the observations of ozone loss:

1. *Solar cycle mechanism*: periodic increases in the abundance of nitrogen oxides in the lower Antarctic stratosphere due to variations in solar output.

2. *Dynamic mechanism*: a change in the circulation pattern from downwelling of ozone-rich air from the upper stratosphere to upwelling of ozone-poor air from the troposphere.
3. *Halogen mechanism*: several different theories invoking the catalytic destruction of ozone due to CFCs and halons.

A ground-based study based at McMurdo, Antarctica, in 1986 showed that:

1. The abundances of nitrogen oxides were exceptionally low, which largely disproved the solar cycle mechanism.
2. The levels of long-lived tracers were such that a dynamical mechanism was unlikely.
3. The elevated levels of active chlorine species suggested that chlorine catalysis was the most probable mechanism.

In 1981, accumulating scientific information led the UNEP Governing Council to establish an *ad hoc* working group of legal and technical experts to work out a framework convention on the protection of the ozone layer; the group met four times between January 1982 and March 1985. At the first meeting (January 1982) it was recognized that although the threat was still distant and the issue shrouded in scientific uncertainties, there was an urgent need for an international effort to deal with it. Excerpts from the opening statement by Mostafa Tolba, then executive director of UNEP, provide an overview of the situation.

> We are meeting to lay the groundwork for a convention that some argue may not be needed, for we cannot say with certainty that the ozone layer is being depleted. However, all the most reliable scientific evidence points to the fact that the earth's protective ozone layer has been, is being, and, more importantly, will continue to be depleted by CFCs and other chemicals unless the international community takes preventive action. The urgent task of this meeting is to create a framework that will make that action effective.
>
> Less than a decade ago, the problem of ozone depletion caused by chlorine atoms penetrating the stratosphere was hardly known. Now, following substantial research and monitoring, we are aware of a potential pollution problem of a scale and consequence never before faced.
>
> The costs of continued CFC pollution are not primarily ours to bear. If scientific observations over the next few years turn the theory of ozone depletion into unchallengeable fact, then the hazard of increased UV light exposure due to ozone depletion is a legacy we will pass on to future generations. Not only Man but also most other living things are susceptible to UV-B exposure. Nor is the problem one of limited area. Atmospheric transport ensures that the risk is distributed to all parts of the globe.
>
> If ozone depletion does reach levels where it becomes measurable and at the same time CFC emissions remain at their present levels, then, because of the stability of these chemicals in the troposphere, their imperviousness to degradation, their ability to remain in the atmosphere for long periods, the absence of any significant sink, there exists a certainty of a major accumulation of CFCs in the stratosphere. There, by catalytic action of chlorine atoms, photochemical dissociation of ozone molecules is predicted to occur. Such is the life time of these chemicals in the stratosphere that even if future releases of CFCs were stopped or severely limited today, ozone depletion would probably still continue well into the next century.
>
> We are dealing then with a problem that has yet to be proven conclusively. It is one that is out of sight, and one that could so easily be out of mind. The problem of ozone is not qualitative but quantitative. Uncontrolled release of CFCs other than CFCs 11 and 12 and of chemicals such as methyl chloroform and carbon tetrachloride, which may also affect the ozone layer, obscure the issue and limit our ability to predict with any confidence the future of the ozone layer. And our imperfect understanding of latitudinal, seasonal and other natural variations compounds this problem.
>
> Although the possible consequences of ozone depletion will not be experienced until well into the future, perhaps beyond our own lifetimes, time is not on our side. We have to act now if we are to ensure that the more severe penalties from upsetting the ozone balance are never incurred. These may include consequences for agricultural production, fisheries and human health. Recent research shows that many terrestrial plants, including important crops such as wheat and rice, and aquatic organisms such as fish eggs and larvae, undergo damage when exposed to increased levels of UV-B. The link between exposure to solar UV-B and skin cancer is well established and there are indications that sunlight may also be a causative factor of malignant melanoma.

In retrospect it is impressive how many of the above speculations would be proven to be true. Chemicals causing ozone depletion did indeed include carbon tetrachloride and methyl chloroform, which would be included in the controlled substances list in 1990, and in the same year the suspected effects of UV-B were confirmed by the assessment panels.

THE VIENNA CONVENTION, MARCH 1985

The negotiations that began in 1982 brought together representatives of the governments of both industrialized and developing nations, spokesmen for the scientific community, and industry representatives, notably those of the Chemical Manufacturers Association (CMA); although non-governmental organizations (NGOs) and the media were also present, they did not initially play an important role.

From the beginning, nations formed groups advocating very different approaches. Western nations fell into two factions: The Toronto Group, comprising Canada, the United States, Finland, Norway, Sweden, and Australia, who favored a worldwide ban on the use of CFCs as aerosol propellants but opposed other CFC restrictions; and the European Community (EC) nations, who advocated eventual limits on total production but opposed cuts from current production levels. Developing countries were concerned about the potential of the convention to impose stipulations that might inhibit their own development. Some

nations were anxious to address the problem by any means necessary, whereas others, such as the United Kingdom, France and Japan, were reluctant to agree to any regulatory measures. Among the industrial representatives, the European Council of Chemical Manufacturers' Federations (CEFFIC) took the position that even with significant CFC usage the threat was only a distant possibility and could be met with some future action; in short, they opposed cuts in the production and use of CFCs.

In spite of these disagreements, there was a general acknowledgment that although scientific uncertainties would exist for some time; it was necessary to consider the consequences of awaiting complete certainty, whereas action taken now might prevent irreversible damage to the ozone layer (*see* Precautionary Principle, Volume 4).

Major differences among Western countries remained unresolved, and only a draft General Framework Convention stressing the need for more research was ready for adoption by the Vienna plenipotentiary conference in March 1985.

However, before the Vienna meeting could take place, news from the scientific community electrified the delegates. Joe Farman of the British Antarctic Survey announced that in comparing measurements taken in the Antarctic spring (September and October) of 1984 with records compiled since the 1950s, he had found that the stratospheric ozone layer over the continent had been in sharp decline since the late 1970s (Farman *et al.*, 1985). Since 1957 the austral spring ozone layer had thinned by about 40%; in effect, a hole had developed in the ozone layer over the Antarctic as big as the United States and as deep as Mt. Everest, spreading north over Argentina and New Zealand. After Joe Farman's paper had been published, National Aeronautics and Space Administration (NASA) reviewed its long-term data banks and discovered that they too showed a downward trend in stratospheric ozone over Antarctica: the analysis technique had been programmed to discard outliers.

The plenipotentiary conference convened in Vienna in March 1985, under the auspices of the UNEP and the WMO, adopted a treaty to protect the ozone layer. It committed its signatories to take appropriate measures to protect human health and the environment from human activities that potentially could have adverse effects on the ozone layer. The community of nations had decided not to wait for incontrovertible proof of cause and effect, which could come too late to avert irreparable harm, but to take action against a future threat, in what is the first global application of anticipatory and precautionary principles.

The conference also requested that the UNEP continue work on a protocol on ozone-depleting substances, and the UNEP Governing Council delegated this task to its executive director, at the same time authorizing him to convene a diplomatic conference, if possible in 1987, for the purpose of adopting such a protocol, clear evidence of the sense of urgency that prevailed.

THE MONTREAL PROTOCOL, SEPTEMBER 1987

Negotiation began in 1986 in a changed perspective on the issues involved. Scientific information continued to pour in that strengthened the case for an effective protocol, but economic factors had taken on additional importance.

In 1986 NASA, whose satellites had produced the spectacular infrared maps of the Antarctic ozone hole, estimated that a 3% increase in CFC emissions could deplete the ozone layer by about 10% by the year 2050. The US Environmental Protection Agency (EPA) said that if CFC emissions continued at recent rates, the resulting extra UV-b radiation could cause 40 million more skin cancer cases and 12 million more eye cataracts over the next century in the United States alone. At about the same time, Swiss scientists reported evidence of an Arctic hole over Spitzbergen, with the ozone layer thinning as far south as Switzerland. The distant threat was clearly coming nearer. Pressure for global regulations and limits on CFC emissions was growing.

Some governments, thinking action premature, resisted, but most governments, most scientists, and some manufacturers, unwilling to gamble with the composition of the atmosphere and the future of the planet, advocated action. Scientists were firmly in favor of controls, without which, they said, changes to the ozone layer would certainly increase skin cancer and would probably affect agricultural production, atmospheric pollution, and the climate. Before the political and legal negotiations began in Geneva in April 1987, the Toronto Group, led by the United States, changed its position and supported a global freeze on CFC production followed by a series of reductions that would lead to a complete ban. The EC countries wanted a cap on production but no cuts; the Soviet Union and Japan were reluctant to accept any control measures; the developing countries feared that the new protocol would hamper their industrial development.

Trade factors dictated much of the differences between the Toronto Group and the EC: European chemical industries saw US industries as being a step ahead of them in developing substitutes for the CFCs, which could endanger their markets. Because the United States had already banned the use of CFCs in aerosol containers, it was concerned that further controls would affect their use in refrigeration and foam production unless the measures were carefully drafted. Negotiations went on almost non-stop between April and September 1987.

When the final text was presented to the Plenipotentiary Conference in Montreal, the feeling of triumph was general. This was the first truly global environmental treaty;

moreover it dealt with an issue that posed a threat, not immediately, but far into the future, one that potentially affected everyone on earth today. It was a monument of collective action, a masterpiece of compromise. It had the advantages of ease of implementation, exibility due to its mechanism permitting adjustments to meet scientific, technological, and socioeconomic changes, and the clearly applied principle of common but differentiated responsibility (*see* Common but Differentiated Responsibility Principle (Stockholm/Rio), Volume 4). It was also the first treaty to set for itself, subject to conditions, a date for its own entry into force: January 1, 1989, barely fifteen months after the treaty had been signed. There would follow a number of meetings to fine-tune its details, but the date (September 16, 1987) went down as a landmark in the history of international negotiation.

Advances in Scientific Understanding after Montreal

There has been tremendous advance in scientific understanding of the ozone layer since Montreal. These advances, based on laboratory studies, special field campaigns, theoretical studies and re-assessment of trends in stratospheric ozone, were reviewed during the 1989 and 1991 international scientific assessments which were required by the Montreal Protocol. The key conclusions of these two international assessments are summarized in Boxes 1 and 2.

London, Helsinki, Copenhagen and Beyond

Six months after the Protocol was signed, a major report was released by the NASA-National Oceanic and Atmospheric Administration (NOAA) Ozone Trends Panel, demonstrating conclusively that human activities were causing atmospheric concentrations of chlorine to increase around the world. Even more disturbing was the finding that from 1969 to 1986, a small but significant depletion of the ozone layer, amounting to 1.7 to 3.0% depending on latitude, had already occurred over heavily populated regions of the Northern Hemisphere including North America, Europe, the Soviet Union, China, and Japan. The announcement made headlines around the world.

London, 1989

Media pressure for more concrete action was intense. Two months after the entry into force of the Protocol, and only a month before its contracting parties were to meet in Helsinki, British Prime Minister Margaret Thatcher convened an international ozone conference in London, in March 1989.

More than 120 governments participated in the London meeting, more than two-thirds of them at the ministerial level, a far cry from the meager two dozen governments represented at the start of negotiations in 1982 and the sixty in Montreal in 1987. More than 90 environmental organizations, as well as media from all over the world were there, all calling for a stern approach to the problem. Several countries announced in London that they would ratify the Protocol; developing countries reiterated their demand for assurance that financial resources and technology transfer would be forthcoming.

Helsinki, 1989

The deluge of scientific information that had preceded the opening of the Helsinki 1989 First Meeting of the Parties to the Montreal Protocol assured that stronger control measures would be enacted. The difficult areas were finance and technology transfer. China, supported by India and other developing countries, had proposed establishment of a special fund for the Protocol. Neither China nor India was a party to the Protocol, in fact only 31 of the contracting parties were in Helsinki, but they were accompanied by 51 non-parties, which showed the global importance attached to this issue.

Box 1 Key findings of the Scientific Assessment of Stratospheric Ozone: 1989

- *Antarctic ozone hole*: the weight of scientific evidence strongly indicates that chlorinated (largely Man-made) and brominated chemicals are primarily responsible for the recently discovered substantial decreases in stratospheric ozone over Antarctica in the Southern Hemisphere springtime.
- *Perturbed arctic chemistry*: while at present there is no measurable ozone loss over the Arctic comparable to that over the Antarctic, the same potentially ozone-destroying processes have been identified in the Arctic stratosphere. The degree of any future ozone depletion will probably depend on the particular meteorology of each Arctic winter and future atmospheric levels of chlorine and bromine.
- *Long-term ozone decreases*: the analysis of the total-column data from ground-based Dobson instruments shows measurable downward trends from 1969 to 1988 in the Northern Hemisphere (30 °N to 64 °N) in the winter months which cannot be attributed to known natural processes.
- *Model limitations*: these findings have led to the recognition of major gaps in theoretical models used for assessment studies. Assessment models do not simulate adequately Polar Stratospheric Cloud (PSC) chemistry or polar meteorology. The impact of these shortcomings for the prediction of ozone-layer depletion at lower latitudes is uncertain.

Box 2 Advances in the Understanding of Stratospheric Ozone: 1991

- *Antarctic ozone losses continue*: strong Antarctic ozone holes have continued to occur. Large increases in surface UV radiation have been observed in Antarctica during periods of low ozone. While no extensive ozone losses have occurred in the Arctic comparable to those observed over Antarctica, localized Arctic ozone losses have been observed in winter concurrent with observations of elevated levels of reactive chlorine.
- *Larger global ozone decreases observed*: ground-based and satellite observations continue to show decreases of total-column ozone in winter in the Northern Hemisphere. For the first time, there is evidence of significant decreases in spring and summer in both the Northern and Southern Hemispheres at middle and high latitudes (about 3.5% at 45°N in summer for the period 1979–1991) as well as in the southern winter. No trends in ozone have been observed in the tropics. The downward trends were larger during the 1980s than in the 1970s by about 2% loss per decade. The observed ozone decreases have occurred predominantly in the lower stratosphere.
- *Observed ozone losses due to industrial halocarbons*: recent laboratory research and an extended interpretation of field measurements have strengthened the evidence that the Antarctic ozone hole is primarily due to chlorine-(and bromine-) containing chemicals. In addition, the weight of evidence suggests that observed middle (and high) latitude ozone losses are largely due to chlorine and bromine. Therefore, as the atmospheric abundances of chlorine and bromine increase in the future, significant additional losses of ozone are expected at middle latitudes and in the Arctic.
- *Future levels of ozone depletion*: even if the control measures of the amended Montreal Protocol (London, 1990, were to be implemented by all nations, the current abundance of stratospheric chlorine (3.3–3.5) parts per billion volume (ppbv) is estimated to increase during the next several years, reaching a peak of about 4.1 pphv around the turn of the century. Since the mid-latitude ozone losses are apparently due in large part to chlorine and bromine, the increased level of chlorine and bromine that are estimated by the year 2000 are expected to result in additional ozone losses during the 1990s comparable to those already observed in the 1980s. There is also the possibility of incurring widespread losses in the Arctic. Reducing these expected and possible ozone losses requires further limitations on the emissions of chlorine (and bromine) containing compounds.

London, 1990

The Second Conference of the Parties in London in 1990 was attended, mostly at the ministerial level. Against all odds, the London meeting succeeded. Governments agreed to phase out CFCs by the end of the century and to include a series of other chemicals in the list of controlled substances. They agreed to establish a special fund to help developing countries comply with the Protocol and devised rules for contributions by industrialized countries as well as a management plan. Language was found to provide developing countries with alternative chemicals and technologies.

These amendments to the Montreal Protocol required ratification, and ratification requires time. So that valuable time would not be lost, the parties agreed by a simple decision to establish an interim fund of $240 million for 1991–1993, with allocations to be determined by size of country: $5 million to a small country, $20 million to a medium sized country, and $40 million to a big country, such as China or India. These financial incentives led China to join in 1991 and India to follow soon after.

Montreal was offered and accepted as the seat for the new fund. It is still there.

Copenhagen, 1992

At Copenhagen the Contracting Parties agreed to reach the 100% phase-out of the substances that deplete the ozone layer by 1996 and established the fund to replace the interim one.

Since then, the process is continuing to control other substances that deplete the ozone and to replenish the Multilateral Fund.

Lessons from the Montreal Protocol

The sense of urgency shared by the negotiators of the Montreal Protocol not only led to the conclusion of an international treaty through an innovative process, but also resulted in the establishment of a number of precedents. One was that once a two-thirds majority of the delegates had approved the adjusted control measures, they became binding on its signatories without the lengthy process of formal ratification. Another was the establishment of the Interim Multilateral Fund by a simple decision of the Conference of the Parties, although there was no legal basis for this step in either the Vienna Convention or the Protocol; the fund's establishment under such circumstances was considered by some legal experts to be an unprecedented step. The non-compliance provisions were similarly unprecedented. Other decisions that were made by consensus, which would have under normal legislative rules required years of formal negotiation, included the requirement that any production increase of controlled substances be on the condition that it was not for export. The data-reporting provisions were similarly streamlined to permit swift action.

An important principle was developed and crystallized in the Montreal Protocol and its amendments, that of *common but differentiated responsibility* (*see* Common but Differentiated Responsibility Principle (Stockholm/Rio), Volume 4). Although it had existed since the 1972 Stockholm Conference, it had not previously been incorporated into regulatory framework. This was a strong encouragement to the developing countries to remain whole-heartedly in the negotiating process.

Probably the most important lesson of the ozone treaty negotiations was the value of informal consultation, away from the negotiating table (*see* Industrial Responses to Stratospheric Ozone Depletion and Lessons for Global Climate Change, Volume 4). Although the negotiators' goal remains the same as in the formal sessions, because they are not committing their governments in these off-the-record conversations, they can be more relaxed and more open to recognizing the merits of other points of view in reaching common solutions and to making compromises. They become friends working for a common cause.

None of these factors, however, would have been enough to bring about these international environmental agreements had it not been for the basic change in national attitudes away from the primacy of national sovereignty and toward international cooperation. During the years of negotiations, the issue of sovereignty was never raised: each country was in a sense interfering in the internal affairs of all the others for safeguarding the environment of all.

There is still at this writing some work remaining to achieve the goal of protecting the ozone layer. Governments until now have been unwilling to strengthen the non-compliance procedures and to carry them out vigorously. Yet, it can safely be said that the legal obligations established under the Ozone Convention and Protocol are preventive rather than remedial. There is also cause for optimism: The two instruments were designed to be flexible and adaptable to changing conditions, and the mandated periodic assessments will assure their relevance and usefulness well into the future.

Policies for Sustainable and Responsible Fisheries

John Caddy[1] and Henry Regier[2]

[1] *Imperial College, London, and CINVESTAV, Merida, Mexico*

[2] *University of Toronto, Toronto, Canada*

For millennia, human populations have changed planetary ecosystems; and hydrological basins and adjacent coastal seas have accumulated the consequences of human upstream alterations to terrestrial and aquatic ecosystems within these watershed or marine catchment basins. In addition to direct and indirect effects of shing, communities or assemblages of sh species must adapt to the aquatic effects on sh habitats of ecologically stressful human practices on land and along shore. Some sh species cannot tolerate these habitat changes. Climax assemblages of native species, or even the persistence of species components locally, cannot be sustained under intense stress to them and their habitat.

Some efforts to limit ecologically harmful practices date back many centuries. They are re ected in religious taboos, cultural mores, traditional knowledge and legal regimes. But as humans have became more numerous, and especially with industrialization, urbanization and impoverishment of shers, most attempts to limit adverse ecological effects have eventually failed. Contemporaneously, the stress regime on ecosystems generated by humans has grown inexorably. Degradation of aquatic ecosystems may not be apparent to the casual observer but can be inferred from sheries and other ecosystemic data.

Over recent millennia, humans have harvested sh, mostly for food for humans and their domestic animals, and to a much lesser extent for recreational and ceremonial purposes. When the demand for sh was less intense, shers selectively removed taxa that were highly valued locally and in trade, i.e., premium sh or target species. Taxa that were not valued for human food, i.e., coarse sh, were often discarded where they were caught, or transformed into animal feed. A main conclusion is that a major challenge in governance of sheries is managing the shers and not just the sh stocks.

CURRENT ISSUES IN THE GROWING DEPLETION OF WORLD FISH STOCKS

In recent decades, a progressively broader spectrum of fish species has been harvested by commercial fishers. New technologies in preserving and processing fish for human consumption, animal feed and pet food have resulted in increases in the value of incidentally captured species in the by-catch that were once discarded. Anglers have diversified to target a broader array of sport fish. Poor people, with access to fish near human settlements where diets are short of protein, may harvest all species almost unselectively.

The destructiveness to fish habitat of some fishing methods, such as trawling, has become increasingly evident. Ecosystem stresses from fishing have generally increased in phase with impacts on fish habitat from other human activities. Empirical study has shown that some fish species populations are suppressed and even extirpated by such a combination of stresses while other populations may react positively and increase. Both types of anthropogenic stresses, fishing and indirect impacts of human activities on fish habitat, may act synergistically, and there is often confusion as to proximate causes in any given situation. Qualitative and quantitative characteristics of a fish association or community are altered further by human-induced changes to the association of higher vertebrate populations (reptiles, birds and mammals) which depend on fish for their diet. Thus, humans have long acted in ways that

were unsustainable from both a fisheries and an ecosystem perspective.

From scattered evidence we infer tentatively that fish population extirpations occur more frequently through habitat destruction than through direct over-fishing, although extreme vulnerability, longevity and/or low fecundity exacerbate the risks of extinction by capture. The occurrences of fish population or stock extirpation, and much less frequently of species extinction, apparently increased progressively during the 19th and 20th centuries. The emphasis in management now seems less on the actual extinction of fish species than on the more immediate loss of genetic diversity through elimination of local stocks or races, especially for freshwater, estuarine and anadromous species, and those occupying specialized and restricted habitats such as estuaries, coral reefs or sea mounts. Nonetheless, currently few of the world's ecological associations of fish populations are not affected adversely by habitat abuses and/or improper fishing. Fishers can now take fish anywhere in the world's waters; for example, the recent ability to exploit economically extremely slow-growing, long-lived deep water species of oceanic slopes, ridges or sea mounts such as the orange roughy, is a deep concern. Given the few restraints that exist on overharvesting in international waters, many deep water stocks may be effectively eliminated before they can be studied.

Technological progress in industrial fishing of ocean resources has outstripped the ability of international regulatory bodies, hampered by inadequate powers allocated to them by coastal states, to counter the negative effects of overfishing in an environment where fishing power has grown continuously over recent decades. New technologies such as synthetic fibers for netting, echo location of schools, satellite navigation, and improved processing, transportation and marketing of fish, have all contributed to a frightening efficiency of harvesting and a greater range, versatility and speed of redeployment of fishing eets.

Atmospheric, hydrological and ecological processes carry hazardous chemicals everywhere, and especially to higher latitudes. Climate change is altering the current patterns and temperatures of water bodies. Stratospheric ozone depletion is changing the spectrum of the sun's irradiation at the water surface, particularly off the Antarctic coast. Exotic species are transported widely in the ballast water of ships and through the fish culture and aquarium trades. The genie of genetically modified organisms is also now out of the bottle as far as fish culture is concerned, with likely effects of escaped cage-reared salmon strains on reproduction of native stocks. In developed countries, local and regional ecosystemic stresses may be abating while global stresses are intensifying. In less developed countries all stresses may be expanding and intensifying.

PROSPECTS

So what might a new global commitment to sustainable and responsible fisheries mean in practice? Pessimists may fear that the sustainability concept relates to an historic ideal that has become progressively less realistic over the centuries. Late in the 18th century, Condorcet and Malthus initiated a debate that has continued since then between technological optimists and ecological pessimists. Two centuries later, the optimists may appear to be winning this debate; with each passing decade, natural features of ecosystems are less capable of satisfying the growing human wants and needs, and we are relying on increasingly artificial ecosystems using increasingly artificial techniques. Pessimists question if these artificial systems, with expanding loss of natural features, can exist independently of a healthy biosphere with the integrity of its natural life-support capabilities persisting unchallenged.

In the 1880s European fisheries experts debated whether or not serious over-fishing of oceanic fish populations did, or even could, occur. That debate was not resolved finally until the 1990s, when the collapse of several well-studied and supposedly well-managed groundfish stocks in the north Atlantic cast doubt on the efficacy of current risk-adverse type of science-based management regimes.

We note in retrospect that during the intervening 20th Century, much of the science and politics of fishing was captured by this debate about the reality of overfishing. Rational resolution may have been hindered because commercial interests and their client nations sought to maintain the freedom of the sea in order to exploit commercial opportunities. At the same time, scientific advisors working for governments placed too much emphasis on the concept of equilibrium conditions' and the mistaken idea that fisheries were sustainable' at levels at or around *maximum sustainable yield* (MSY) (*see* Maximum Sustainable Yield (MSY), Volume 4).

The politically weaker conservationists or ecological pessimists bore the onus of proof, in a case-by-case basis. Most management measures tended to be short-term, palliative, and fraught with problems due to unresolved differences about allocating catches between eets and states. In consequence, management was not sufficiently rigorous or sustained to lead to stock rebuilding. Powerful interests, i.e., exploitive technological optimists, dictated that fishing practices should not be constrained unless and until clear evidence of over-fishing was presented to, and accepted by the fishing industry. Exploiters often resisted reporting data that could prove useful to the conservationists, or reported false data on landings or their provenance.

In the 1990s a different debate was joined at a global level, with a revaluation of the proposition that commercial fisheries or other forms of exploitation of wild natural resource can be managed sustainably, and if so with what constraints? This debate has led to the extension of

the precautionary principle (*see* Precautionary Principle, Volume 5) from its original application in pollution science, to fisheries management. An attempt is now beginning to reverse the burden of proof to rest on exploiters rather than on conservationists, and require an assessment of fisheries impacts before authorizing new technological applications or increases in exploitation rate.

New interrelated global initiatives in ethics, law and science, applied to the shared use of fish and other ecosystem goods and services, began in the 1990s. There is as yet only scant empirical evidence that these noble commitments, which the two of us helped to foster, are being successfully put into practice. Optimists may argue that organisms that resemble wild fish, from a commercial perspective, can be reared economically in fish culture facilities. They admit that there will be adverse effects on the natural habitat, on the wild fish genome, etc. But it is better, they may say, to rear standardized, genetically-modified fish in abundance than to rely on stocks of variable wild fish that will likely fade away in any case. While the issues of fish culture, restocking and sea ranching are not addressed further in this essay, we have noted the dangers of genetic modifications to the fitness of wild stocks that they may pose. Among currently unresolved dangers of intensive and semi-intensive fish culture are: importation of diseases; local pollution of inshore environments and lagoons; and dependence on a limited supply of foodstuffs derived from harvesting wild stocks.

EARLIER SCIENTIFIC AND TECHNICAL APPROACHES

In this essay we mainly consider fisheries on fish (family Pisces) as such, but the aquatic realm provides somewhat similar opportunities and constraints to the ecological production, harvesting and relevant policies for other kinds of aquatic animals. Thus, much of our text is directly relevant to policies on harvesting of invertebrates and marine mammals.

During the 20th century a number of different approaches to population dynamics were employed for understanding, modeling and managing of fisheries. From roughly the 1950s onwards, these approaches were being applied in a rather widespread fashion to the management of commercial fisheries by industrialized nations. The primary focus was on the maximization of physical yield, using MSY as a target reference point sanctioned eventually by the Law of the Sea. Much later, and still inadequately, the focus shifted to the optimization of economic returns.

A problem with setting targets for catch or fishing rate is that fisheries data are rarely adequate to ensure a precision of greater than • 30% in optimal yield estimates, hence overshoots were frequent with subsequent recovery difficult. As a result, fishing effort tends to continuously increase, following the ratchet principle', aided by hidden effects of technological improvements not contemplated during the formulation of fisheries regulations. Much more recently, the specification and avoidance of the risk of overfishing has begun to be given priority in some fisheries, associated with the concept of precaution. As an example, the use of MSY as a limit reference point, rather than as a target, requires that managers take into account the variance in the data when seeking to avoid exceeding MSY, and prenegotiate an immediate effort reduction, should such an overshoot occur.

Within a particular ecosystem – river, lake, coastal sea, ocean – attention was focussed mostly on populations of the fish species favored by the fishers, with little concern for the inevitably high discards and other impacts on species caught incidentally by relatively unselective fishing gear. With commercial fisheries, such target species brought increasingly higher prices on an international market. Since the 1960s that market, in turn, has been increasingly efficient at linking hard-currency consumers anywhere, with fish resources harvested anywhere else in the world. Valued target species have shown an apparently unconstrained upward mobility in price, in turn increasing incentives for overharvesting. With ease of harvest and rudimentary regulatory systems, target species tended to be the first depleted in the local fish community. A bioeconomic model for a particular fish species might even have been fitted to data on catch and cost of fishing, but rarely was the concept of *economically optimal yield* used as a benchmark for determining harvest rate.

The abstractions from reality provided by simple single species models, that are often the best possible, given the limited information available, offer an illusion of certainty to fisheries managers. However, there is a growing awareness that aspects of the complex ecosystems in which the fish live, and of the societal and market complexities within which fishers operate, may better be described by chaos theory. Through time, a single species model's drift from realism is difficult to spot, and the inadequacies of information often means that decisions are made on yesteryear's information.

Numerous empirical generalizations or rules of thumb have been inferred from meta-analyses of population dynamics analyses over the years. Some examples are:

- The MSY of target species occurs when the total mass of the exploited fish population in the ecosystem is of the order of 50% of the biomass of that population in its historic pristine or virgin' state; unlike a virgin stock dominated by slow-growing older fish, an exploited population is dominated by more productive younger fish, posing a danger that excessive exploitation will cut into the population's spawning potential.
- The mean age in a population drops as fishing rate in a conventional fishery increases, so that the main

possibilities for regulating fishing are either postponing age at first capture by gear regulations (e.g., using larger meshes in the net), by avoiding fishing on juvenile nursery or adult spawning aggregations, and/or by reducing the fishing intensity, eet size and the individual fishing power of boats.

- As fishing intensity increases, longer-lived species (e.g., cods, halibuts, sturgeons) are replaced by shorter lived species (such as low-value forage fish and invertebrates), with consequent impacts on ecosystem balance.
- Species show an innate preferred temperature range; populations near the latitudinal mode of that temperature range are most productive while those at either the cold, high latitude or warm, low latitude extremes are smaller and produce less surplus for fisheries harvest perhaps due to irregular recruitment.
- In monetary units, net economic returns from commercial fisheries are usually maximized when harvests of individual populations are some 10–20% less than the MSY in mass units; this level of exploitation often corresponds roughly to the *optimal sustainable yield* or the *Maximum Economic Yield* in particular.

Current regulatory approaches often assume that the resource can be exploited throughout the year and throughout its range. Evidence is accumulating however, that such simplicity involves dangers because of the high seasonal vulnerability of some stocks due to a lack of effort control engendered by unresolved allocation issues. A more precautionary approach would be to start from the perspective that exploitation is prohibited, except for those time–area windows when established access holders are authorized to take a safe proportion of the stock, using selective, and tested harvesting methodologies with minimal discarding.

Because of the intractable unpredictability of nature and human activities that in uence exploited fish populations, in practice the population dynamics approach can mainly be used to construct accountancy models for fish currently in the waters, as a basis for allocation. Such models have little explanatory or predictive power with respect to what yield can reliably be expected some years in the future.

The population dynamics approach alone has seldom provided appropriate information directly relevant to the management of recreational fisheries. Generally anglers appreciate a natural setting and enjoy the prospect of capturing a large fish, at least occasionally. This implies that a low overall rate of harvest must apply in order to allow survival of that statistically improbable phenomenon, the large, older or record' fish. The gustatory pleasure and dietary benefit of actually consuming the fish may not now rank as highly as in Isaac Walton's day, and catch-and-release angling has gradually become more popular than angling for food. Aesthetic more than utilitarian considerations come into play with respect to considerations of sustainable angling pressure.

Artisanal or domestic fishers, who are often the poorer people of a region, tend to be opportunistic with respect to fish to which they have access. In North America, old treaties with some Native Peoples recognized usufructuary rights to harvest fish and other natural features in large areas beyond their immediate core reserves. Some of these treaties have been interpreted recently to imply that a Tribe is entitled to half the optimal sustainable yield of valued target species within its Treaty area. Often an artisanal fishery does not specialize just on a few valued species in its locale. Instead, fishers may remove fish of any size of numerous species. In many parts of the world a concept like sustainable fishing has seldom been applied to such artisanal fisheries. The poorest of the poor capture what they can where, when and however they can do so. Commercial and angling fishers may complain that artisanal fisheries are unsustainable, perhaps because some immature fish may be taken, but in general, artisanal fisheries provide more employment per ton of harvest, low wastage, and much of the catch goes for human food in local communities where fishers play an important economic role, as opposed to industrial eets which may not employ local labor, and where the owners are not necessarily vessel operators.

Aboriginal peoples who live in ecosystems that retain some features of wilderness may capture fish in ritualized ways for ceremonial purposes. In North America, for example, Aboriginal peoples who were not assimilated fully in Western culture have been re-instituting ancient ceremonial practices that relate to the spiritual interrelationships of humans with nature. Relatively few fish may be taken, so that there is no direct threat to sustainability. But ceremonial fishing may be deemed to exacerbate harm done by commercial fishers who are, or may be fishing such populations intensely. Or anglers may resent the removal of the scarce large fish valued both for recreational and ceremonial purposes.

Within an interdisciplinary ecosystem approach, there may often be a role for a population dynamics approach within a broader ecosystem perspective, but a scientist should take care to relate the more limited assessments to a more comprehensive ecosystem-based approach (*see* Ecosystem Approach, Volume 2). Sustainability of fisheries then becomes a facet of the joint sustainability of a mix of uses, both direct and indirect, of an aquatic ecosystem.

Integrated Coastal Area Management and watershed management are becoming more relevant, linking fisheries with other users of the aquatic environment through concepts such as zonation by priority use of subareas, and the employment of tools such as Geographical Information Systems now being widely used for planning user interactions and access rights (*see* Geographic(al) Information Systems (GIS), Volume 4).

A multi-stakeholder commitment to sustainability relates, in turn, to some politically agreed vision of selected features

of an ecosystem which are to be sustained. Any such vision will be tentative and subject to periodic revision as an ecosystem evolves in ways that are not fully predictable. Heretofore, few such shared visions have been negotiated and thus few are available to serve as case studies to guide further efforts to achieve joint sustainability. Any fishery of more than low intensity causes the ecosystem and the fish association to adapt irreversibly to some extent; thus a pristine state cannot provide a practical vision for a sustainable fishery. A debate between biodiversity preservationists and those favoring sustainable use in all waters continues, with the former slowly gaining in some countries through the adoption of marine parks or conservation areas in which commercial fishing may be banned.

OWNERSHIP REGIMES AND SUSTAINABLE FISHING

In many contexts, the management and transaction costs that come with private ownership of wild fish and their habitat may exceed the benefits to the owner of such ownership. In such cases, effective exercise of such ownership may not be worth the effort. Quasi-ownership regimes, involving a less formal balance of privileges and obligations, may be less expensive to administer. Common property resources may be formally owned in common by groups of people. The term may also be used loosely where access by fishers is open because no person or group holds formal ownership rights to the fish. The recent history of fishery policies is full of accounts of unsustainable exploitation of valued fish, in such open-access situations where no specific allocation of user access rights seems to mean that no duty of care for the resource is exercised.

A kind of Gordian knot is perceived by some fisheries analysts. It involves: both habitat and fish that are a commons; open access situations for fishers; fishing anywhere at any time of the year; unrestricted use of any kind of capture gear; rent-free harvesting; and willing consent of all harvesters prior to imposition of any constraints on extant fishing conventions and practices. This policy syndrome may seldom occur in full bloom in the real world, but is an interesting abstraction of what could happen where people have no commitment to intelligent joint action or to civic ethics.

Poorly-managed fisheries, with some features of the common property syndrome, may be complicated further by subsidies from governments to some fishers to help them to compete more effectively in such free enterprise. These subsidies, often rooted in political patronage, may be justified as efforts to assist poor fishers by supplying new technology to make their fishing more effective, or to reduce the costs of fishing. In fact, this may lead to further reduction of the level of fish abundance at which an economic breakeven point for fishing is realized, thus further increasing stock depletion. When external subsidies are not accompanied by compensatory constraints on fishery practices, they may well result in the intensification of existing unsustainable fishery practices, and promote further impoverishment.

Historically, many kinds of policy arrangements have emerged to guide the harvest of fish populations in situations where legal ownership, with a broad roster of enforceable rights, is not in place. In fact, in marine and some freshwater fisheries, ownership of a fish does not precede capture, and even where rights-based systems such as Individual Transferable Quota systems apply, it is more usual to speak of stewardship by the stakeholders over the resource, than ownership of a portion of the stock. As such, there may be few if any fish populations in the wild – other than in ponds, lakes and rivers on private estates – for which legal ownership of wild fish stocks can be invoked and enjoyed in practice. Ecosystems are by nature open systems, thus local, regional and global cultural stresses cannot be prevented from impacting at the local level. Thus, indirect effects of distant interests cannot be excluded from local ecosystems, however clear local legislation on exclusive ownership may appear to be.

Locally, some form of negotiation may lead to a balanced combination of privileges and obligations for each legitimate fisher and other users of the ecosystem. All stakeholders who enjoy some privilege of access are then constrained by some shared view of a preferred state of particular ecosystemic features, including those of the fish community or assemblage to be sustained. All local stakeholders' interests are also constrained by an ecosystem's subsequent responses to continuing regional and global stresses acting on it.

As is also the case with some mammals and birds, some fish species have populations that are strongly migratory with an annual cycle or space–time path. Policy issues, such as those concerning sustainable use, as related to highly migratory animals, are usually more difficult than those related to sedentary populations, since there are many points of harvest along the migration route. These are often in different jurisdictions or in international waters where legal constraints to overharvest are minimal. To limit harm to the habitat of highly migratory fish (as tunas and other large migrators are termed in the Law of the Sea), and to limit harvests to sustainable levels requires prior agreement among all those political entities scattered along the migratory path or with access to it.

Many inter-jurisdictional agreements have been negotiated over the decades to share sustainable yields of designated migratory stocks and to limit the harm done through abuse of habitats and bad fishing practices. Few of these agreements have served to protect the relevant stocks for long. In particular, enforcement of regulations in a multi-jurisdictional species range is a major weak point:

the negotiation of a sustainable *Total Allowable Catch*, and fair allocations from it are other obstacles where agreement is not easily reached.

In ocean waters outside of national extended economic zones (EEZs), neither the fish nor their habitats are owned by any group or nation. Currently the global regime of governance is not developed to a stage at which such ownership in the open ocean has been legitimized through fisheries commissions, special (e.g., bilateral) arrangements, or by the United Nations and its specialized agencies. A 1995 agreement on how the Law of the Sea provisions will apply to Straddling Fish Stocks (i.e., those lying across boundaries between EEZs and the High Seas), and Highly Migratory Fish Stocks, was not yet ratified at the turn of the century. Some measure of law and order with respect to hopes for sustainability may however be exercised jointly in specific areas through multinational or bilateral treaty arrangements among powerful fishing nations, expressed in the form of fishery commissions set up to provide for a discussion between member nations. Common provisions for monitoring, control and surveillance (MCS) and enforcement capabilities are rarely ceded by states to these commissions. Responsibilities for MCS and prosecution of fishers who offend outside the EEZs remain largely with the ag states of an offender's vessel. Non-tariff barriers with respect to trade are beginning to be used, but are not especially effective given the magnitude of unsatisfied demand for fish internationally. More recently, ecocertification with labeling of fish products from properly managed fisheries has begun, and is aimed at giving the consumer a role in choosing products from areas where healthy fish stocks are maintained by proper management.

SUSTAINABLE FISHERY REGIMES FROM AN ECOSYSTEM PERSPECTIVE

Every natural aquatic ecosystem together with its cultural system of human users is unique in some important ways. A universal analysis that ignores such uniqueness would not likely suffice for practical and political purposes within a particular ecosystem.

With ecosystems generally, intensification of some mix of ecological stresses has proceeded more rapidly than the creation of appropriate science to understand what then happens in particular ecosystems. Current efforts to innovate scientifically, with an ecosystem approach that takes account of all stresses, have mostly focussed separately on rivers, large lakes, enclosed coastal seas and shelf seas. Comparative studies or ecosystemic meta-analyses have been initiated within all four, with beginnings of studies interrelating all four types. The new science relies more on narrative and contextual case studies that have testable features, rather than on time-independent universalistic analyses also with testable features.

A favorite place for human settlements has always been along a river, near its mouth with a lake or sea. The waters near such settlements are often a particularly important habitat, at least seasonally, for valued fish species. With many exceptions, fishers have generally preferred to exploit large individuals of near-shore sedentary populations or of populations that performed predictable migrations through waters near settlements where they could be accessed easily during known seasons. Unless careful environmental stewardship was practiced, human settlements as onshore centers of cultural organization induced disorganization of ecosystems in adjacent nearshore waters. In terms of economic accounting, the environmental costs and consequences of settlements were externalized to the natural aquatic system and its human users. Such degraded waters have often been zoned tacitly as being closed to fishers, in part because of the high concentration of hazardous chemicals and pathogenic organisms in the fish esh. Increasingly strong programs to rehabilitate such locales are being initiated, with some successes.

One feature of the generally high fecundity of exploitable marine species is that a high level of attrition of juveniles naturally occurs due to predation, before the mortality of individuals drops to a much lower steady rate for adults. This means that a fish becoming large and mature even in a virgin population is a statistically rare occurrence, with probability of survival from egg to spawner of the order of one in a million in some cases. Thus, fisheries managers must make difficult decisions between: (a) harvesting juvenile fish (for which there is a good market in many countries) and conserving the few adult survivors; or (b) conserving the juveniles through closures of nursery areas and large mesh size and limiting harvesting of adults such that an adequate spawning stock survives. A fishing strategy which harvests all age groups intensively is rarely sustainable.

Centuries ago, fishing did not need to become very intense before some adverse effects of highgrading by discarding juveniles (which were dead in most cases) and by-catch became apparent, even in the absence of any noticeable habitat degradation. Fewer large fish were caught; annual recruitment of young fish failed in many years, more effort was needed to take the usual harvest, etc. If the fishing method involved barring the way to spawning habitat, then the population waned over the years due to inadequate recruitment.

Aristocrats or wealthy angler naturalists have traditionally acted to regulate commercial fishing locally and to protect the aquatic habitat in order to preserve near-pristine sports fishing opportunities. A common method was to have such habitat and riparian lands declared a preserve and to make capture of the preferred fish illegal other than in small numbers by the owners. Anadromous salmonids are prime examples of such conserved sports fish resources.

Nevertheless, of the uncounted thousands of anadromous salmonid stocks that existed three centuries ago, only a few percent have retained optimal sustainability.

Unintended habitat changes due to moderately intensive human activities in the ecosystem's hydrological basin or in the aquatic habitat itself may lead to increases in populations of small pelagic fish and other low-value forage fish, and thus to increases in their MSYs. The opposite may occur with large fish of demersal/benthic populations. With poorly managed or inappropriately regulated fisheries, fishing down the food web often occurs. Populations of apical predators – the large fish at the peak of the food chain such as groupers, pike, lake trout and halibut – were over-fished, with a reduction in annual catches leading to a reduction of predatory pressure and expansion of populations of smaller prey species, which in turn attracted fishing pressure.

The effects on an aquatic ecosystem of habitat degradation, together with overexploitation, interact in a common direction to produce a system dominated by lower trophic levels and small fish. This has often been labeled loosely with the code word *cultural eutrophication*, since the combined effects show some similarities to those caused by true eutrophication as with excessive nutrient runoff from land to aquatic systems. In turn, the combined effect of remediating a suite of cultural abuses has been termed *cultural oligotrophication*: an ecosystem is rehabilitated to a state showing some similarities to that which applied in pristine water bodies with low in ows of nutrients. Pristine oligotrophic systems contained clean water, low plankton density and dominance by apical or climax species in the food web (*see* Oligotrophic/Heterotrophic/Eutrophic, Volume 2). For both cultural eutrophication and cultural oligotrophication, a strongly artificial ecosystem may result, as for example in large lakes. Ecosystems have their ways of self-organizing beyond our full control. Thus the distinction between a culturally-stressed aquatic system and extensive aquaculture is blurred, now that some 30% or more of the products of photosynthesis in marine coastal waters eventually reach the human table.

An ecosystem adapts to an externally-applied stress regime, always. It may however be capable of self-organizing into more than one phase. Thus, the ecosystem may appear in an oligotrophic or eutrophic state, depending on the external regime of natural factors and cultural stresses. In such cases – in the past confined mostly to fresh waters, but now increasingly evident in coastal lagoons and semi-enclosed seas – the human community in the region may then take terrestrial and aquatic subsystems into account and opt politically for one of these states of nature. The stakeholders or managers might then formulate a qualitative/quantitative vision with benchmarks including preferred features of a past state of nature which are to be sustained in the face of the mix of legitimated human activities, that are themselves always evolving. They may use selected features of a fish association typical of the preferred state, e.g., oligotrophic or eutrophic, as an integrative indicator appropriate for assessing the state of sustainability.

During the 19th and 20th centuries, a common approach to mitigating the effects of habitat and fishery abuses has been to introduce selected exotic species that may have some innate tolerance of the ecological effects of extant ecological abuses. Or it may have been inferred that the reproductive capabilities of diminished native or introduced species have been severely harmed, which might justify the use of fish hatcheries to counteract such inferred effects. These may be perceived as examples of artificially upgrading a currently degraded fish association. This approach has sometimes been spectacularly successful, at least from a perspective of some anglers. Mostly it doesn't work very well, or has unexpected side effects.

The use of exotics and hatcheries has usually brought with it a new set of difficulties, some of which may be perceived to be disastrous. Some jurisdictions are now interpreting sustainability, in the context of rehabilitation from past abuses, as relating mostly to natural reproduction of valued native fish species, and are discontinuing reliance on exotics and hatcheries.

If the stress regime is extremely intense, the adaptation may involve systemic disintegration into a near-chaotic state of a few tolerant species, and ultimately death of all. The concept of sustainability as commonly applied in practice seems to presuppose that the ecosystem under consideration has not been forced to sacrifice many of its desirable features in adapting to the extant stress regime.

Current use of the sustainability concept also presupposes that the living part of an aquatic ecosystem can and does self-organize to a state of health or integrity, and contributes some degree of homeostatic capability with respect to the incessant uctuations characteristic of a stressed regime (*see* Monitoring in Support of Policy: an Adaptive Ecosystem Approach, Volume 4). In other words, sustainability implies that an ecosystem and fish association can take care of itself, to an important degree. Management costs can be constrained as a result of healthy ecosystem processes.

The shared vision of a preferred ecosystemic state, with its fish association, usually implies discontinuation of the more egregious ecological abuses and some rehabilitation to correct unacceptable effects of past abuses. In such cases it is this vision of a rehabilitated state to which a sustainability policy must relate and move towards through a long-term integrated-use policy. It may seldom be a matter of restoring a previous state, or preserving a current state which is already unacceptably degraded. The latter condition is still manifest in many parts of large lakes and coastal seas near industrialized cities.

Early in the 21st century there may be no fish population in the world that is not stressed by humans in one or more ways. Hence the concept of sustainability must always relate to a complex of natural and cultural processes. Relevant policies to foster sustainability must in turn exhibit an appropriate or requisite measure of complexity.

REFORMS OF THE 1990s

A global movement to reform human practices in our biosphere and be more responsible has been growing since the late 1960s. It was then that Sweden put in motion activities that led to the 1972 United Nations Conference on the Human Environment convened in Stockholm. Grossly unsustainable practices that degraded aquatic habitats and overfished valued stocks, though discussed at Stockholm, were generally neglected in the oceans until two or three decades after that.

In the 1990s, several initiatives by the United Nations or its specialized agencies have created a formal set of inter-related documents that is providing the conceptual framework for the emergence of the new global regime on fish and fishing. These include:

- the United Nations Conference on Environment and Development in Rio de Janeiro in 1992 from which came Agenda 21 with chapters on Aboriginal rights, biodiversity and its sustainability, the oceans and climate change;
- the United Nations Conference on Straddling and Highly Migratory Fish Stocks of 1995 which closed a major gap in the 1982 United Nations Law of the Sea Convention;
- the United Nations Food and Agriculture Organisation's Code of Conduct for Responsible Fisheries of 1995 with some six specialized appendices.

A strong theme in these initiatives was on the ocean but the agreements, suitably interpreted, are also relevant to closed seas, lakes and rivers.

For a particular ecosystem, although the transition has only begun, these reforms imply a change in emphasis from:

- maximal sustainable and independent use of each resource in the ecosystem by its own set of opportunistic stakeholders, to
- optimal responsible and shared use of the whole ecological web and aquatic habitat by an interacting network of sets of legitimate stakeholders.

Note that one aspect of this change is the shift in emphasis from *sustainability of use* to *responsibility of use*.

Responsibility by an ecosystem's users, including fishers, implies that each user and group of users bears an onus to take a precautionary approach to that use. A fisher's rights/privileges are balanced by a set of responsibilities/obligations to provide evidence *a priori* that the fisher's use will not induce ecosystemic changes that are impermissible with respect to the ecosystemic vision shared by all the ecosystem's users. During use, the fisher dutifully reports correct data relevant to accountability commitments and submits to sanctions for improper practices. This may be because the fisher is driven by considerations of intergenerational equity', and the wish to leave his children's generation an ecosystem that will provide the same livelihood, food potential and aesthetic pleasure as he has enjoyed. Or the fisher may be driven by deeper ethical commitments. From this it is evident that the search for sustainability inevitably takes us into the field of civics and ethics in a search for responsible behavior on the part of users, emphasizing the importance of this subject in future educational curricula from the earliest ages.

As a governance paradigm, the reform process is generating compatible information services and implementation features at all the levels in the nested hierarchy from individual users within groups of similar users, to the relevant level of formal governance within a nation, to a regional international commission.

Experts in international law were much involved in the 1990s' negotiations, together with experts in large-scale economic, ecological and technological systems. An emphasis is emerging on the methods of transdisciplinary discourse appropriate for negotiating and accountability processes, with respect to this new interactive set of international commitments. Versions of such appropriate discourse include: natural justice; communicative action; ethical discourse; post-normal participatory science (*see* Post-normal Science, Volume 5); and action research. A broadened scientific approach may still have a place for the reductionist population dynamics approach that dominated the earlier regime as it has for bioeconomic modeling, but that role is clearly subservient now. In fact, the application of games theory, developed by the military, to modeling competing fisheries makes it clear that the major challenge in governance of fisheries is managing the fishers and not just the fish stocks. Games theory also outlines the formidable obstacles in the face of reaching a sustainable harvest regime in situations where competition for resources occurs and allocations are not agreed to early on in the process.

Nonetheless, in recent decades, numerous innovators in the science and management of fisheries and other uses of aquatic ecosystems in various parts of the world have already begun local and regional reforms that have some of the features of the those mandated by the 1990s United Nations reforms. These include developing tools and concepts such as integrated coastal area management, large marine ecosystem approaches, appropriate scaling of human actions through marine catchment basins, and

ecosystem approaches in large freshwater basins. Some innovators are now meshing their own regional efforts within global initiatives to foster feedback mechanisms that might expedite implementation of the reforms.

Once proper management policies are developed, inefficiencies in traditional governance institutions are a serious impediment to the successful implementation of the policies. One fundamental weakness is that such institutions and their old mandates rarely encompass fully the real problem in all its dimensions. Fishery-induced and other anthropogenic causes are often intertwined in such a way that Ministries of Agriculture, Environment, Rural Affairs and others would have to cooperate in arriving at solutions which would then have repercussions for other Ministries, not least of which would be the Ministry of Finance.

People practicing governance in obsolescent ways may be offered few if any incentives to effect change. If an interdepartmental committee is struck to deal with fisheries, in the context of the health of aquatic environments, it may: be dominated by non-innovative persons; be given inadequate resources; be allowed an extended time frame that may invite postponement of urgent problems; and may eventually provide advice that is weakened with compromises. Another approach is to allocate rights to the private sector or to devolve responsibility to lower governmental entities such as provinces, municipalities and co-operatives. Here the incentive of ownership, and ready recourse to the courts that this implies, may provide a more prompt means of correcting imbalances. By following this latter course, the number of jurisdictional disputes may in turn become more frequent and intense.

In the international arena, the problem of shared stocks and their management has been assigned by the Law of the Sea to Fisheries Commissions and Arrangements. To date, states have rarely turned over to these bodies enough of their jealously guarded rights to allow them to conduct surveillance and exercise control effectively, especially with respect to allocations of catch. Multinational entities at the government–industry interface could be established with full powers to jointly manage shared stocks and national fleets, providing, for example, joint marketing services and dividends to the countries whose fleets are participating in the fishery.

The challenges to governance with respect to responsible fisheries – in freshwaters, in EEZs, in coastal marine waters, and in international oceanic waters – are daunting. Deliberate efforts directed toward quick learning would seem to be in order. Attractive incentives to innovate might speed such learning.

We fear that it may be decades before these 1990s responsibility reforms will be well in place in much of the world. Sustainability of some desirable ecosystemic features that will be extant at those times may then be more certain. Perhaps our responsible successors will then have transcended the centuries-long conflict between ecological pessimists and technological optimists.

Regretfully, the nature of fisheries for wild resources that will be conducted sustainably a few decades hence cannot now be predicted. Without a dramatic paradigm shift towards a revaluation of renewable resources through precautionary thinking, the prospect is for further ecosystem degradation and loss of biodiversity through human impacts. A necessary, but not necessarily adequate, precondition for avoiding further declines is that the fine words, principles and agreements developed laboriously in the 1990s be implemented swiftly.

Policies for Sustainable Forests: Examples from Canada

Peter N Duinker
Dalhousie University, Halifax, Canada

In some parts of the world, forests were at one time the dominant land cover, but agricultural and urban land uses have

reduced forest area dramatically. Examples would include Ireland, and some countries in the Mediterranean area. Forest policies in such countries need to focus on maintaining what little forest remains, and on ways to increase forest area. In other parts of the world, forests still dominate the landscape. Examples include Canada and Russia. In these countries, forest policies are concerned perhaps less about the forest area and more about forest condition. Forest ecosystems have become degraded in many countries due to exploitive practices, and restoration strategies should dominate forest policies in these countries.

Forests are important to people in many ways. Humans value forests for a wide range of ecological functions that pertain to conservation of biodiversity, soil, water and air. We also value forests for their economic functions, many of which are associated with wood products like lumber, panels and paper, but also for other goods such as fuel, foods, furs, medicines and craft materials. In addition, we value forests for their social functions, including recreation, solitude, study, aesthetic satisfaction, existence, and others. In a word, forests are extremely important to humans around the globe. Forest policies need to address all these values.

The main theme in all forest debates and discussions today is sustainability; how can we manage and use forests so that their myriad bene ts are available for future generations just like they are today, or better? We speak of sustainable forestry, forest sustainability, and sustainable forest management (SFM). In this article we shall examine how forest policies embrace the concept of sustainability. First we shall explore the meanings of forests and policies, and then we shall look at some forest policies to discover their sustainability content. Most of the policy examples are taken from Canada, where about 10% of the world's forests (by area) exist.

POLICIES

Policies are written statements that purvey the intent of the authoring organization and guide the behavior of persons and groups under the authority of that organization. Thus, the natural resources department of a national government may issue a policy that describes its goals, objectives, principles and strategies for forests. That policy would guide the behavior of the government itself as well as the persons and organizations over which the government has authority (e.g., recreationists, wood-using industries, loggers and silvicultural contractors). Policies basically try to convey what the authors are trying to accomplish, and how the aims are to be accomplished.

Policy documents range from vision statements to detailed operational guidelines. For governments, policy documents may include high-level policy statements, legislation, and regulations and guidelines under the laws. Policy-oriented documents related to forests are of three types. One is a policy declaration, where the organization issues a policy that dictates its own intent and behavior regarding forests. Another is a policy proposal, where the authors suggest what the policies should be for other persons or organizations. Finally, there are policy analyses, where the authors lay out the costs and benefits of implementing alternative policies on the same theme or issue. In this article, the emphasis is on policy declarations.

FORESTS

Let us define forests as tree-dominated ecosystems. Ecosystems have no predetermined scales or boundary definitions; people define them in a way that is appropriate to their own needs. Where then do forests stop, and other ecosystems start? In 1993, Ontario's Forest Policy Panel wrestled with this question, and offered the following insights. We said that a forest is:

- a great expanse of trees as far as the eye can see; or, in more technical terms, a landscape of stands;
- a group of trees in part of the agricultural landscape: a woodlot, a windbreak and a soil stabilizer;
- trees in the urban environment, lining residential streets, in parks and as fragments of original forests in valleys, ravines and naturalized areas;
- the tree cover found in (northern) barrens ••• where the trees may be sparse and small but they are old, intrinsic parts of the ecosystem;
- all ages and types of trees: young seedlings to mature trees, natural and artificial regeneration; and
- more than just trees: shrubs, plants, animals, insects, microscopic creatures and soil are all part of a forest ecosystem.

Thus, forests are wherever trees are, and span the range from urban to rural, young to old, sparse to dense, fragmented to unbroken, degraded to pristine, very small to very large. It is important to develop policies for all conditions and kinds of forests (*see* Forest: the FAO Definition, Volume 2).

EXAMPLES OF POLICIES PROMOTING SUSTAINABLE FORESTS

Government Policies

Intergovernmental Examples

In 1992 in Rio de Janeiro, at the Earth Summit (or, the UN Conference on Environment and Development (UNCED)), several international cooperation agreements

relating to forests were signed. These include the UNCED Statement of Forest Principles, the UN Convention on Biological Diversity, the UN Framework Convention on Climate Change, and Agenda 21. Each one of these has a strong forest component. The Statement of Forest Principles, a non-binding document endorsed by many nations, strongly encourages countries to conserve forests by adhering to a broad set of guidelines on how sustainable forest use and management should be carried out. Recent international forest policy initiatives (e.g., the World Commission on Forests and Sustainable Development) have discussed whether to pursue a fully- edged international convention on forests.

The UN Convention on Biological Diversity makes little specific mention of forests, but we know that forest ecosystems around the world are critical in the overall theme of conserving biodiversity. This underscores the point that forest management can be significantly affected by policies on other topics. We also know that, were it not for steady and increasing pressures from the expanding human population, forests would cover a much greater proportion of the Earth's land surface. Therefore, we can be sure that, while the convention is equally applicable to ocean, grassland and desert ecosystems too, much of the stimulus behind its creation came from concerns about the incessant erosion of forest biodiversity. If the convention is actually implemented around the world in the way it is intended to be, great strides will be made to reverse the decline of forest biodiversity globally.

The UN Framework Convention on Climate Change is mainly focussed on ways to slow down the build up of greenhouse gases in the atmosphere. This, in turn, should slow down the rate at which the world's climate is expected to change as a result. Carbon dioxide, an inevitable waste product from combustion of fossil fuels, is the main target for reduction. Forests take up carbon from the atmosphere through photosynthesis, and release it to the atmosphere through respiration. Many people hope that changes in the way we manage forests will make them, on the whole, net sinks of carbon, which means that forests would take up more carbon from the atmosphere than they give back. Parties to the Convention are supposed to develop and implement national policies that address mitigation of climate change. Countries with substantial forest areas are now examining ways to manage forests specifically to sequester more carbon from the atmosphere.

Agenda 21 emerged also from UNCED as a major action agenda on worldwide sustainable development. It calls on governments to become aggressive about sustainable development and adopt appropriate policies. One of Agenda 21's many chapters addresses the problem of deforestation. The Agenda paints a broad picture of how to improve forest management, and calls on all governments to create national action programs for sustainable forest development.

The efforts discussed above were all initiated during the early 1990s. Significant additional efforts have been made since that time to advance global forest policies. Two are particularly notable. For one, after a series of hearings on various continents, the World Commission on Forests and Sustainable Development released a report in 1999 entitled *Our Forests, Our Future*. The report calls on all forest stakeholders immediately to implement SFM, and to take bold political decisions and develop new civil society institutions to improve governance and accountability regarding forest use. The other initiative is that of the Intergovernmental Forum on Forests (IFF), set up by the UN Commission on Sustainable Development to succeed the Intergovernmental Panel on Forests (IPF). Both groups have been working toward comprehensive new understandings on how to achieve forest conservation worldwide, and have advanced global thinking tremendously on the need and prospects for an international, legally binding instrument (e.g., convention) on SFM.

National-level Examples

Each country has its own unique way of creating and implementing national forest policies. In some countries, forest policy is a main preoccupation of the national government (e.g., Sweden, Finland), but in other countries, many forests are under the control of sub-national governments such as states or provinces (e.g., Canada, US, Germany). Thus, forest policies vary widely among nations. We shall focus on Canada as an example.

Canada is a federation of ten provinces and three territories. The constitution puts publicly owned forests, which comprise about 94% of the forest area in the country, mostly under the control of the provincial governments. However, Canada has a national forest service (the Canadian Forest Service, or CFS), and implements policy for matters in which the national government has a clear role (e.g., information systems, international affairs, foreign trade, national forest land, and so on). Perhaps more visible, though, is the federal government's role in assisting forest stakeholders pursue SFM. The Canadian Council of Forest Ministers (CCFM), comprising ministers responsible for forests from the federal, provincial and territorial governments, is particularly active in this regard.

The CCFM recently facilitated renewal of both the Canada Forest Accord and the National Forest Strategy. The Accord is a high-level statement containing a vision, a goal, and some principles and commitments to action, which must be adhered to by all its signatories. To give a avor of the Accord's content, here is the goal statement:

> Our goal is to maintain and enhance the long-term health of our forest ecosystems, for the benefit of all living things

both nationally and globally, while providing environmental, economic, social and cultural opportunities for the benefit of present and future generations.

The Accord commits its signatories to prepare public and measurable action plans . These plans are guided by the Accord's sister document, the National Forest Strategy. There have been four such strategies in Canada, the latest produced in 1998 through a stakeholder consultation process. The Strategy calls on the forest sector stakeholders to make substantial progress in improving conditions related to nine strategic directions:

- forest ecosystems;
- forest management;
- public participation;
- the forest industry (meaning mainly the wood-using industry);
- forest science and technology;
- communities and the workforce;
- Aboriginal peoples;
- private woodlots; and
- global commitments.

Accord signatories, which include governments and a wide range of NGOs, have produced action plans that address each of these nine themes, according to their respective jurisdictions and interests.

Sub-national Level

We shall focus here on Ontario, a large province in central Canada, which is home to some 11.5 million people. Ontario has some 58 million ha of forest, 88% of which is owned by the provincial government.

Substantial changes were made to Ontario's forest policies during the 1990s. All these policy changes have focussed on making the forests and the forest sector more sustainable. In 1994, the Ontario Ministry of Natural Resources adopted a policy framework for sustainable forests. The framework includes a goal for the province's forests, much like the national goal in the Canada Forest Accord. It also provides guiding principles and strategic objectives for sustaining: (a) forest ecosystems (focussing on biodiversity, protected areas, and conservation of soil, water and air); (b) forest uses (focussing on employment, wood supplies, non-timber products, forest investments and revenues, and tourism); and (c) forest social values (focussing on cultural and spiritual values, recreation, and knowledge and understanding). In addition, the framework provides principles for forest decision-making, and promotes ecosystem management as the dominant management approach.

Hot on the heels of the framework came new legislation to govern the management of Ontario's public forests. The Crown Forest Sustainability Act of 1994 replaced the old Crown Timber Act. The new Act repeated some key principles from the Framework, as follows:

1. Large, healthy, diverse and productive Crown forests and their associated ecological processes and biological diversity should be conserved.
2. The long-term health and vigour of Crown forests should be provided for by using forest practices that, with the limits of silvicultural requirements, emulate natural disturbances and landscape patterns, while minimizing adverse effects on plant life, animal life, water, soil, air and social and economic values, including recreational and heritage values.

Major changes embodied in the Act included establishment of trust funds to ensure adequate funding for regeneration silviculture for each forest management unit. Previously, money for regeneration activities was granted annually from the provincial legislature, and forest management was usually a poor cousin in negotiations where health care, education and roads to compete for money. The Act also established a number of regulations, themselves to be considered as policy documents. Four key manuals are regulated under the Act: (a) forest management planning manual; (b) forest information manual; (c) forest operations and silviculture manual; and (d) scaling manual. The forest management planning manual was issued in 1996, and compared to its predecessor of 1986, requires extensive stakeholder consultations and rigorous technical analyses of forest sustainability.

Non-government Policies

International Level

Various international NGOs have their own forest policies. A well-known example today is the Forest Stewardship Council (FSC). The FSC was founded in Toronto in 1993, and has headquarters in Mexico. Environmental NGOs, aboriginal groups, consumer organizations and independent professional foresters are prominent among the members. The mission of the FSC is to support environmentally appropriate, socially beneficial, and economically viable management of the world's forests. The FSC, operating as a kind of certifier of certifiers, has created an eco-label that can be applied only on products made of wood coming from forests certified by an FSC certified auditor. The criteria applied by the auditor must be consistent with the FSC Principles and Criteria for Forest Stewardship. There are ten principles, each of which is amplified by some 4 to 10 criteria. The 10 principles cover the following topics:

1. compliance with laws and FSC principles;
2. tenure and use rights and responsibilities;
3. indigenous peoples' rights;
4. community relations and worker's rights;

5. benefits from the forest;
6. environmental impact;
7. management plan;
8. monitoring and assessment;
9. maintenance of natural forests;
10. plantations.

In essence, the FSC is trying to improve forest management throughout the world using a market-driven mechanism. The hope is that consumers will prefer to buy goods stamped with the FSC eco-label, even if it means higher prices. At the moment, the FSC is the only operational eco-labeling scheme for forest products available around the world. Regional international schemes are also developing, such as the Pan-European Forest Certification initiative.

National Level

In most countries there are national forest-related NGOs which develop and declare forest policies of their own. For example, there is a forest certification scheme operating nationally in Canada. Late in 1993, representatives of the Canadian forest products industry requested the Canadian Standards Association (CSA) to undertake development of a system standard for SFM. Using a consultative, consensus-seeking process, the CSA developed the required standard to be consistent with the ISO 14 000 standard series on environmental management systems.

The standard is voluntary, and focuses on the following four components: commitment; public participation; management system; and continuous improvement. The management system has five elements: preparation, planning, implementation, measurement/assessment, and review/improvement. The CSA standard requires forest managers to forecast and monitor all indicators chosen locally to represent the status of 21 themes associated with the six nationally accepted criteria published in 1995 by the CCFM:

1. conservation of biological diversity;
2. maintenance and enhancement of forest ecosystem condition and productivity;
3. conservation of soil and water resources;
4. forest ecosystem contributions to global ecological cycles;
5. multiple benefits to society;
6. accepting society's responsibility for sustainable development.

Any forest management agency or company wishing to become registered as compliant with the CSA standard adopts the standard as its operating policy, and is required to develop specific and detailed policies of its own for SFM.

Sub-national Level

Examples of sub-national forest NGOs in Canada include the Ontario Forest Industries Association (OFIA), the Council of Forest Industries of British Columbia, and the Nova Scotia Forest Products Association. As an example partly in response to the stimulus of the 1992 National Forest Strategy, the OFIA created its Guiding Principles and Code of Forest Practices. The document is binding upon all members of the organization, which represents about 20 firms which, collectively, account for most of the industrial wood processing in Ontario. Each year, member companies undertake an audit of their performance against the principles and the code, and report confidentially to the OFIA. Summary reports are made public. While some companies may find the principles and code redundant with their own internal policies, others have made significant improvements in their management practices because of their required compliance with the document.

WHAT TO LOOK FOR IN POLICIES FOR SUSTAINABLE FORESTS

With continued improvements in public participation in forest decision-making, more and more people are becoming involved in looking at forest policies and discussing ways to improve them. When people get involved like this, what should they seek in a good policy for sustainable forests? Here is a generic list, drawn from a combination of forest policy textbooks and examples of up-to-date strong policies:

- a firm grasp of the main forces driving change in forest ecosystems and the forest sector; these forces either constrain or give opportunity to the fulfillment of forest values; examples are demographic changes, climate change, globalization of trade;
- a comprehensive goal or vision statement, consistent with modern thinking and putting priority on forest sustainability;
- a broad array of forest values with a balance among social, economic and ecological themes, and each with its own strategic objective;
- a broad definition of forests to include most or all situations where trees are a dominating feature of the ecosystem;
- a small but strong set of broad principles to guide people's thinking about and behaviors toward forests;
- a firm recognition of how forest policies in uence policies on other topics (e.g., agriculture, water, wildlife), and how other policies affect forests;
- a package of regulations and incentives that promote forest sustainability on private lands;

- innovative arrangements for private use and management of public forest resources that ensure conservation of ecosystems and resources;
- a firm commitment to the use of protected areas as a key element of biodiversity conservation; and
- requirements for effective and efficient public participation in forest decision-making at all levels.

CONCLUSIONS

Forests have faced tremendous pressures down through the ages as humans have exploited them and, in so many instances, degraded them. The prospects for forests in the 21st century may be grim, with ever-increasing pressures to be faced. One main pressure is the continuing rise in the global human population. Each new person born will place demands on all the things that forests can offer to support a good quality of life. Another pressure is our constantly expanding expectation on forests; the more we know about them and interact with them, the more we want forests to do for us. Finally, global atmospheric change may put tremendous stresses and strains on forests as pollutants continue to be pumped into the air and as the climate continues to change.

We should realize, though, that these undesirable trends could be reversed. However, this depends on whether nations, international governing institutions, companies, NGOs and citizens will mobilize their collective wills to implement forest policies that can help forests survive the continuing pressures they face. We certainly have the know-how and technical capacity, not to mention the rhetoric; do we have the political will too?

Policies that Promote Sustainable Energy Futures

José Goldemberg
University of São Paulo, São Paulo, Brazil

Fossil fuels account for approximately 80% of human consumption of energy. Such dependence is unsustainable due to: (1) expected ultimate exhaustion of resources; (2) the impurities they contain; (3) emissions of CO_2. The Framework Convention on Climate Change (FCCC) might be an important driver in reducing fossil fuel use and thus open the way to a more sustainable energy future.

Energy policies to reduce local and regional environmental impacts have been in effect for a long time. Local pollution has to do with local governments, since it deals with clean air, fresh supplies of clean water, the removal and disposal of solid wastes and liquid ef u-ents, street cleaning, etc. However, in many developing countries, a large fraction of the population still lives among the rubble and residues that it produces, due to the lack of resources to remove waste and to build sewers and engineering works needed for the supply of water.

Regional pollution is caused mainly by automobiles, energy production and heavy industry which are inherent to more prosperous societies. Large cities and adjoining areas, such as Los Angeles, Mexico City and Sao Paulo, have long been suffocating under the pollution caused by the emissions and smog resulting from the burning of fossil fuels. Sometimes the amount of pollution produced is large enough to cause regional and even transborder problems, such as acid rain, some of which originates in the US but is responsible for the destruction of life in Canadian lakes. The same has happened to lakes in Scandinavia, due to industrial activities in surrounding countries. Regional pollution has to be dealt with at the state or national level and eventually among a number of countries.

Global environmental problems and concerns are more recent, the most conspicuous of them being the destruction of the stratospheric ozone layer by chloro uorocarbons (CFCs) and the greenhouse effect.

These problems result from changes in the composition of the atmosphere and have little to do with national borders. The causes of such global problems are gases originating anywhere in the world and the problem can only be tackled at the international level.

The ozone layer problem was successfully resolved by a concerted effort of a few countries which led to the Montreal Protocol. Subsequent decisions are effectively leading to the phase-out of CFCs from the face of the Earth. Other substances have been developed to replace them.

The outstanding current environmental issue is the greenhouse effect, which is proving to be much harder to solve since the most important greenhouse gas is carbon dioxide (CO_2), the unavoidable result of the combustion of fossil fuels, which is responsible for 80% of all energy consumed in the world today.

The basic policy in this case is to reduce CO_2 production through improved efficiency in energy use and to search for proper replacements such as renewable energy sources.

Appreciable success has been achieved in industrialized countries to reduce CO_2 emission mainly through rationalization in the use of energy. CO_2 emissions in those countries have leveled off since 1980 or are growing very slowly. In developing countries, however, emissions are growing at a fast rate.

The main policy instrument to solve this problem is the FCCC signed in 1992 during the Rio Summit and the Kyoto Protocol (1997), which adopted a binding resolution according to which industrialized countries, as a whole, would reduce their CO_2 emissions by 5.2% below the 1990 level in the period 2008–2012.

The US accepted a reduction of 7% to their 1990 level. Since emissions have been growing by approximately 1% since 1990, the reductions required would be much higher. Some estimates indicate that the reduction required will be approximately 25%.

In order to make it easier for industrialized countries to reduce their emissions, the Kyoto Protocol, in addition to setting caps on emission for the industrialized countries, has introduced features that could induce industrialized and developing countries to cooperate in reducing CO_2 emissions.

These proposals are the exibility mechanisms by which emission reductions in developing countries (or economies in transition, i.e., the former Soviet Union and countries of East Europe) can be counted as reductions in industrialized countries. In this category are emissions trading (ET), Joint Implementation (JI) and The Clean Development Mechanism (CDM).

ET is the more general, market-based instrument. It enables achievement of limits at least cost by taking advantage of marginal cost differentials in emissions abatement among countries. Since greenhouse gases are uniformly mixed at the global scale, both the damages from emissions and the benefit from emission reductions are independent of their origin. In order to minimize the cost of given global emission reductions, abatement should take place where the costs are lowest. This instrument is restricted to trading among the Annex I (industrialized) countries.

JI limits emissions trading to developed countries that have accepted emission reduction commitments under the Kyoto Protocol, as listed in its Annex I. Countries that are certified to be below their national limits are allowed to sell greenhouse gas offsets to other Annex I countries who are above their own limits. The latter's motivation is the opportunity to meet their commitments at lower cost than through purely domestic actions.

CDM is an instrument for joint action on emissions reduction (and therefore trading) between the developed countries listed in Annex I of the Kyoto Protocol and developing countries, which are not listed in Annex I. Article 12 of the Kyoto Protocol was the result of a political compromise. It conciliated two sharply opposing views that almost wrecked the Kyoto Conference in 1997. For some countries, an essential element of the Kyoto Protocol was emission trading based on adoption of mandatory reduction commitments by all countries. This feature was contained in a United States Senate Resolution, but was unacceptable to the developing countries. The creation of the CDM emerged as the solution.

In Annex I countries, there will be competition among the several mechanisms defined in the Kyoto Protocol to meet emission reduction requirements. The portion of resources allotted to each of them will prove to be an important internal problem to be resolved. The Kyoto Protocol left undefined what part of the emission reduction commitments could be met outside national borders through use of the exibility mechanisms. A small percentage would encourage domestic action in Annex I countries, reducing the financial ow to developing countries. A larger one would discourage domestic actions and eventually tend to lead to an inordinate increase of emissions in Annex I countries. In all likelihood, the market will determine the share for the CDM compared with other mechanisms.

The key industrial countries have not yet ratified the Kyoto Protocol, but – if and when they do – it might prove to be as effective as the Montreal Protocol in solving one of the most difficult global environmental problems of our time.

Policies to Achieve Sustainable Agriculture

John Lingard
University of Newcastle upon Tyne, Newcastle upon Tyne, UK

Sustainable agricultural development has the goal of ensuring adequate levels of current farm production, whilst preserving the land and natural resource base over time in order not to compromise or reduce development opportunities for future generations. It conserves land, water, plant and animal genetic resources, is environmentally non-degrading, technically appropriate, economically viable and socially acceptable. Agenda 21 of the Earth Summit in Rio in 1992 called for the development of sustainable agriculture and land management and the establishment of the systems necessary to monitor its achievement. Since then, this has led to a wide range of activities to de ne sustainable agriculture, land management and forestry and to develop monitoring methodologies, sustainability indicators and thresholds (Pretty, 1995).

The linkages between sustainable agricultural production and the natural resource base are strong, complex and, as yet, poorly understood. Economic constraints and government policies are important impediments to the adoption of sustainable agricultural practices, particularly in LDCs where the pressure to meet population-induced, food supply demands is likely to hinder the development of sustainable agriculture. Better methods must be found to measure and monitor the natural resource base in order to avoid counterproductive policies and then to design policy packages which are sustainable in the face of ever-increasing population and food demand pressures. Policies for sustainable agriculture must ensure the efficient use of available resources, develop sound and far-reaching investment strategies, and address the technical problems of natural resource degradation within a framework of appropriate national and international institutions. It won't be easy!

Non-sustainable agricultural practices, brought about by short-term mismanagement and policies, can result in a dramatic deterioration in the potential productivity of soils with a resulting decrease in the technical efficiency of inputs applied to the soil to make it more productive. As a consequence, there will be a decrease in the exibility of farming practices, a limit on innovative cropping and farming systems, and an inevitable increase in the costs of food production. Non-sustainability and natural resource degradation result from the interactions between economic and biophysical systems and are largely brought about by human behavior, directly by farmers and land users, and indirectly by policy makers and traders who partly determine prices in domestic and international markets.

Changing land use and agricultural practices worldwide are shaped by economic forces and demographic pressures, and often, non-sustainable systems may result. As populations and food demands grow, many farmers in the Third World are often forced to cultivate smaller and smaller plots, where the soil eventually becomes depleted, or they expand onto marginal lands: fragile hillsides, semi-arid areas and cleared forest land. India, with a recent annual population growth rate of 2.1%, a *per capita* income growth rate of 1.8% per annum and an income elasticity of demand for wheat of 0.5, must increase its wheat production by 3%, each and every year, if wheat prices are not to rise and threaten food security.

Biophysical land degradation and non-sustainable practices have their roots in household and social behavior. Access to the capital resources of human, natural, physical and financial capital by individual households acts as a constraint on their behavior as they seek to maximize incomes or defend their livelihoods. Cropping patterns, livestock enterprises, agro-forestry, aquaculture and other livelihood activities, and the associated soil, water and natural resource-using practices are the outcomes of decision-making of farm households attempting to earn an income and living. Often, these are made in response to market prices of agricultural inputs and outputs. In fragile environments in many resource-poor, less developed countries (LDCs) throughout the world, the economic pressures on households for merely short-term family survival are paramount. There, farmers degrade resources, not out of greed and ignorance, but out of short-term necessity. Peasant producers are often only loosely connected to poorly functioning, distorted and incomplete markets. There are few immediate rewards to such farm households for enhancing soil resilience, ecological sustainability and biodiversity. The interests of global society and individual households may thus diverge due to short-termism and market failure (Syers and Lingard, 1996).

AGRICULTURAL POLICY

Agricultural policy is concerned with the methods used by governments to change the decision-making environment within which agricultural production takes place; e.g., by altering farm input and output prices, introducing new institutions and regulations (e.g., food safety, animal welfare or environmental standards) or by promoting novel technologies. Sometimes policies are further sub-classified as price, marketing, input, credit, mechanization, irrigation, land reform and research policies (Ellis,

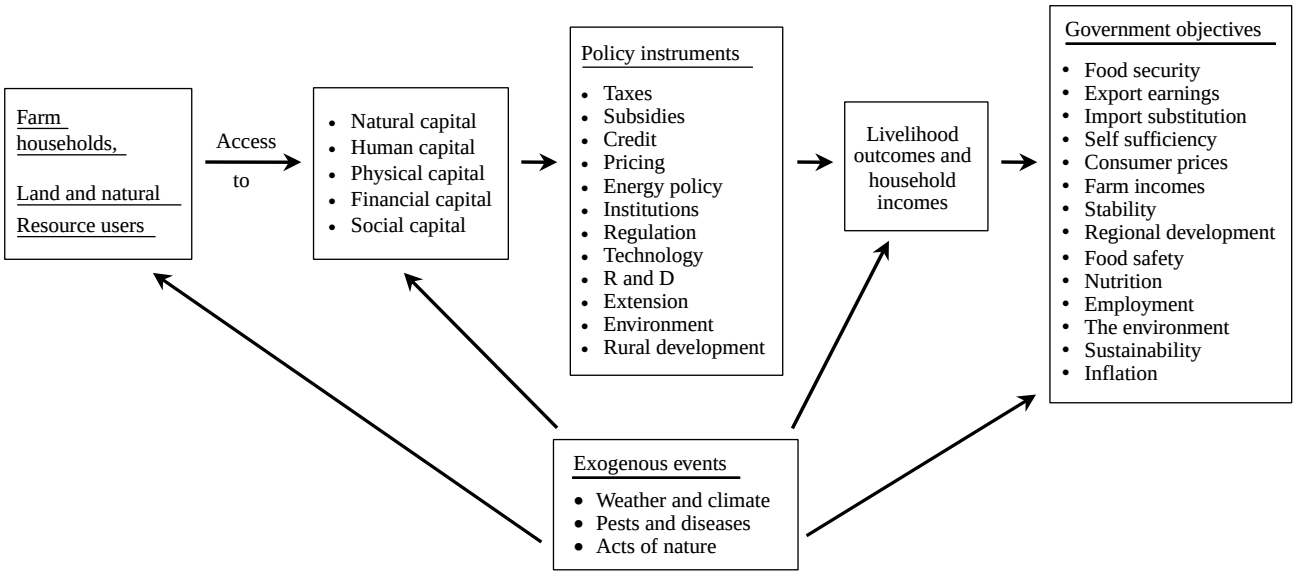

Figure 1 A schematic representation of agricultural policy

1992). Recently, a range of agri-environmental policies has been introduced in many, more af uent developed countries.

Figure 1 illustrates one form of the agricultural policy process whereby stated government goals, targets or objectives are achieved via the selection of the best or most appropriate policy instruments which cause farm households to modify their behavior subject to the available resource constraints and exogenous events over which the policy process has no control (e.g., climate and natural events). If high government or state priority is given to sustainable agricultural production, and agriculture is recognized as an important contributor to, and source of, pollution, then appropriate policy instruments could be identified and enforced to increase the sustainability of the agro-ecological system and to reduce agriculturally produced pollution. The chosen instruments (e.g., taxes, subsidies or regulations) should guide and steer farm producers and natural resource users to change their practices in such ways that society achieves a higher level of sustainability and welfare from within the farming system. It may, however, be necessary to trade off some loss in another policy objective, say foreign exchange from agricultural export earnings from e.g., cotton, to achieve this higher level of sustainability.

Economic incentives, therefore, have a key role to play in establishing agricultural development which is both economic and sustainable (Schuh and Archibald, 1996). Getting the prices right is critical to obtaining an efficient allocation of resources over both time and space. Given the importance of agricultural policy in transmitting society's wants and needs back to farmers, we need open-minded, intelligent and informed policy makers and governments who are not easily swayed by self-interest and narrow political pressure groups.

With the increasing globalization and integration of international agricultural and food markets, a macro-economic approach should be adopted to establish the price incentives for sustainability, with domestic prices of outputs and inputs being firmly based on prevailing trade parity prices (*see* Agricultural Subsidies and Environmental Change, Volume 3). That is, agricultural prices should be near to their corresponding international market prices with little explicit subsidization or taxation of domestic producers. International trade policies and managed exchange rates are often a major cause of the lack of agricultural sustainability. In other words, distorted prices create unsustainable development. In developed countries, agricultural subsidization leads to the excessive use of fertilizers, pesticides, irrigation water and modern inputs, whilst in LDCs, discriminating against agriculture and artificially depressing agricultural prices causes land to be undervalued, thereby reducing incentives to careful soil husbandry. Land managers and users there have neither the means nor the incentive to invest in terracing or contour cultivation to arrest soil erosion on steep slopes. A top-down, macro-economic approach should provide the initial framework for agricultural price policy before the more common, bottom-up microeconomic instruments are used.

PRICING-POLICY EXAMPLES

In many parts of the world, current pricing-policies for farm output, natural resources and inputs unfortunately discourage sustainable agriculture.

Water Policy

Salinization and waterlogging problems in irrigation systems which are associated with overuse would improve significantly if water pricing mechanisms, which currently greatly undervalue water, were reformed (*see* Salinity and Agriculture, Volume 3; Waterlogging, Volume 3). Farmers should be expected to meet the recurrent, full operation and maintenance costs of water provision, although metering and charging by the actual volumes taken is probably still not feasible on both technical and cost grounds in LDCs, but is in California. Over 90% of India's water use is for agriculture, mostly for irrigation, yet the revenues from irrigating farmers cover less than 10% of the total costs of operating and maintaining the irrigation systems. Subsidies cost Indian taxpayers dearly and there is not enough money to repair and desilt canals, so the whole irrigation network deteriorates. Such systems encourage misuse and over-use of irrigation water at the head of the system and under-use at the tail, and have led to much water-logging and salinization.

Fertilizer Policy

Subsidies on chemical fertilizers should be carefully evaluated. Fertilizers can run off into water courses, contaminating aquifers and groundwater and polluting public water supplies, thus causing health and environmental hazards. The challenge is to develop fertilizer technologies and farming methods to reduce or mitigate these deleterious effects, whilst at the same time, reaping the considerable yield-enhancing and productivity benefits from balanced fertilizer use. New ways must be found to create more efficient use of fertilizers, so that smaller applications are needed.

Subsidies often divert supplies away from smallholders and are a disincentive to other soil nutrient management techniques. In any case, they are often fiscally unsustainable for the limited government budgets in LDCs. Subsidized fertilizer exports from developed countries discourage the start-up of local fertilizer industries and build up long-term trade dependencies. Fertilizer subsidies should be part of, and tied to, an overall land improvement investment program, and where fertilizer costs are unacceptably high for farmers due to transport constraints, the subsidies should be removed once the transport infrastructure improves. As an aid to accelerate farmer education and the adoption of inorganic fertilizers, subsidies have a limited and initial role to play, but should be rapidly phased out once farmer learning and widespread adoption have taken place.

Pesticides Policy

Pesticides, another chemical additive to agricultural production, often produce environmental and human health externalities; that is, unwanted and unpriced interactions on other parties. Many governments subsidize pesticide use despite these externalities and the capacity of insect pests to evolve and develop resistance to pesticides. Pesticides can affect groundwater, fisheries and wildlife, and pesticide deaths worldwide may be as high as 250 000. Integrated pest management strategies (IPM), allowing a limited use of pesticides as part of an overall strategy involving mixed crops bred for disease resistance, staged planting and the biological control of insects using natural predators, have proven successful in both reducing rice pests and the damaging externality effects in rice production in Indonesia. The use of pesticides by farmers has declined and rice yields have been maintained following a drastic reduction in input subsidies and outright bans on some of the more dangerous pesticides. Sustainable IPM strategies have since been adopted elsewhere in world agriculture. New taxes should be considered for the most polluting and dangerous pesticides to discourage their use and to fully re ect their environmental and human health externalities. *See* Integrated Pest Management (IPM) in an Era of Global Environmental Change, Volume 4.

Other Pricing-Policies

In Latin America and South-east Asia, logging concession prices should re ect their true economic values to reduce deforestation on lands which are inherently unsuitable for intensive agriculture. In Latin America, land tax systems which currently encourage extensive, low input farming should be changed and enforced. Governments worldwide should reconsider agricultural taxes, duties, price subsidies, overvalued exchange rates and other mechanisms which reduce farmers' incomes.

RESEARCH AND TECHNOLOGY POLICY

A high priority to promote sustainable agriculture is well funded research aimed at the holistic understanding of natural resource degradation and the development of new resource-conserving and yield-enhancing technologies. The key to sustainable increases in food production from a static and fixed natural resource base is knowledge. Research is needed to better understand the socio-economic and policy conditions that support investment in land and water management and to design the appropriate policy instruments that promote such conditions. Priorities might be soil nutrient improvement through green manuring and the use of locally available products, control of soil erosion, water harvesting and recycling techniques, and the use of salt-tolerant plant varieties in saline conditions, etc. Yield losses and the financial costs of natural resource degradation must be calculated and the private and public returns to investment in land improvement established. Low-cost strategies

for technology development with local experimental input, indigenous knowledge and participative approaches need funding to develop appropriate new technologies for hillside, dryland and other semi-arid farming environments. There is an urgent need for a wider range of site-specific, on-farm research with greatly improved knowledge inputs and feedback from farmers.

There are some reassuring developments in the way in which technologies for promoting sustainable agriculture are conceived, evaluated and implemented. The use of participatory techniques, a wider recognition of indigenous knowledge and a closer collaboration amongst researchers, extension workers and small rural households potentially lead to enhanced adoption and improved livelihoods, primarily because they recognize the on-farm and near market constraints involved. This work provides an important interface between social scientists and science and technology, and a interdisciplinary research agenda for the future.

Funding for agricultural research could come from a mixture of private and public sources, including non-governmental organizations (NGOs). The development and use of new technology is a key policy instrument in attaining sustainable economic growth and development. However, policies must also foster and finance agricultural research if the world is to feed itself; the omens here are not promising. For example, the budget of The Consultative Group on International Agricultural Research (CGIAR) fell during the 1990s, seriously jeopardizing the ability of its network of 14 International Research Centers to maintain their research, development and testing activities. There is now a great need to urgently bolster national and international agricultural research funding in the quest for sustainability.

CREDIT POLICY

Many sustainable farming systems will entail substantial investment in land improvement and soil remediation to support more intensive input use. These include the planting of trees and hedges on steep slopes, terracing, intercropping and mulching to build up soil organic matter. Credit may be needed to support interventions; this requires, large, upfront, initial lump sums. However, repayment capacities need to be established at the outset and only activities which are inherently profitable should be supported. In this way, governments, NGOs and land user associations can promote land investments via local farmer experimentation to develop and test new land management systems.

One should not, however, underestimate the shortfalls in funding capacities for credit schemes, particularly at the required local government and regional levels. In any case, government credit provision which supplies credit to farmers at subsidized rates of interest is not without its critics. Frequently, such schemes are themselves a source of bureaucratic and market failure: the funds provided are often diverted away from their intended agricultural investment use; institutions fail to stimulate savings, and as well as the lending behavior, are expensive on limited government budgets and do not create lasting and sustainable rural financial markets.

PROPERTY-RIGHTS POLICY

Secure and assured property rights and rights of access to natural resources are essential for long-term investment by land users in land conservation and improvement, and the development of private and community management strategies. A lack of secure tenure is a major constraint on investment in natural resources; improvement and open access to common property resources results in overgrazing, over-fishing, etc. Property rights for women farmers is a significant problem in many parts of the world, despite the fact that women are often the principal land managers and farmers. Tenure and rental arrangements in many regions often militate against sustainable agricultural management and discourage investment. Property rights reform can bring long-term benefits, but governments are often reluctant to resolve the inevitable con icts and dislocation associated with such redistribution issues.

AGRI-ENVIRONMENTAL POLICIES

A more recent development of policies, particularly in developed countries, is a range of policy measures to provide incentives to farmers to safeguard and conserve the environment and produce environmental goods and services rather than crop and animal products. These services include non-traded public goods, such as landscape, amenity, open space, habitats for ora and fauna, wetlands, etc. In the US, set-aside programs have been used to divert erodible farmland from crop production in order to protect the topsoil. Set-aside programs have been widely used in recent years in the US, European Union and Japan to control the over-production of subsidized cereal production, although sometimes an environmental component has been added to the supply reduction objective.

Since the mid 1980s, European Union farmers have been compensated to reduce the intensity of their (subsidized) farming methods to encourage conservation compatible with sound farming practice. The *environmentally sensitive area* (ESA) scheme operating throughout the EU uses voluntary agreements and compensation payments to encourage farmers to adopt environmentally friendly practices in designated areas. In the UK, farmers are offered a 5-year agreement with annual compensation payments in exchange for following a contract of prescribed farming practices which include restrictions on fertilizer use and stocking densities, prohibitions on the use of herbicides,

pesticides and lime and on the installation of new drainage. Farmers also agree to maintain landscape features, such as hedges, ditches, ponds, woodlands, dry-stone walls and field barns. Adherence to the ESA prescriptions increases the supply of public environmental goods at the expense of a fall in agricultural output and profits, and farmers may end up being over-compensated for the income losses incurred (Lingard, 1999).

Policies to Achieve Sustainable Tourism

Eugenio Yunis
World Tourism Organization, Madrid, Spain

Tourism has been one of the fastest growing industries in recent decades, the importance of which is likely to increase even more in the 21st century, with signi cant impacts, positive and negative, upon the environment.

Tourism refers to all movements of people, irrespective of their motivation, but involving at least one overnight stay and not more than twelve consecutive months in a location that is not their usual place of residence. Tourist movements can be domestic or international.

The World Tourism Organization (WTO OMT) conducted a detailed study (Tourism Vision 2020, WTO OMT, Madrid, 1999) to examine how the tourism industry, and particularly tourism demand, is likely to evolve in the next 20 years. The results indicate that international tourist arrivals are likely to increase at an annual average rate of 4.1%, to reach nearly 1.6 billion by the year 2020; that is almost three times the number of arrivals recorded in 1998.

The impacts that these hundreds of millions of tourists moving around the globe may cause upon the environment need to be anticipated, prevented if possible and continuously monitored, if tourism is to contribute to sustainable development. This is so because of the complex and close relationships existing between tourism and the environment.

THE GROWTH OF TOURISM: PAST PERFORMANCE AND FUTURE TRENDS

Tourism has undoubtedly been one of the outstanding social and economic phenomena during the second half of the 20th century. International tourism movements in the world at large increased from 25 000 000 in 1950, to an estimated 650 000 000 in 1999, that is, an average growth rate of 7.3% per annum. This is perhaps the strongest and most steady growth rate observed after World War II among all indicators used to measure progress in social and economic development.

Since tourism became accessible to most consumers in the developed world, by the mid-1960s, world tourism receipts have been growing even faster than tourist arrivals, indicating that consumers are devoting a higher percentage of their income to tourism. Thus, in the period 1975–1980, while arrivals grew at an average annual growth rate of 5.2%, the corresponding income generated increased by an annual average of 20.9%. Similarly, during the 1985–1990 period, arrivals grew at 7.0% annually, while tourism income grew at 17.9% per annum.

The above figures refer only to international tourism. Yet it is equally important to consider domestic tourist movements, since the impacts of both types of tourist ows on the physical environment are basically the same. Detailed accurate figures for domestic tourism are, however, difficult to obtain. Some countries, such as France, Spain and the United States, have estimated that hotel occupancy by nationals is between 8 and 10 times higher than by foreigners.

All signs indicate that tourism will continue to grow, as a result of a number of factors affecting both demand and supply. Demographic trends, increased disposable incomes and free time, better and faster communications, better access to information by consumers, and an increased interest in nature and culture, seem to be the main elements pushing tourism demand. On the supply side, the openness and globalization of national economies, competition among large hotel groups, airlines and tour operators, cheaper transport, the creation of new generations of tourism products (e.g., thematic parks, sports tourism, etc.), are some of the main factors that contribute to the growth of tourism.

THE RELATIONSHIP BETWEEN TOURISM AND THE ENVIRONMENT

Unlike most other economic activities, tourism has a complex, many-sided relationship with the natural and man-made environment. First and foremost, tourism needs a clean, well-preserved, healthy environment to ourish. Indeed, the environment is fundamental to most forms of tourism: natural beauties and landscapes attract holiday visitors, as do pristine areas with rich biodiversity, well-preserved archaeological sites, architecturally rich urban areas, historic routes and the like. Clean, orderly cities are preferred by those attending conferences or trade fairs, while business and other tourists will generally avoid polluted cities or contaminated natural areas.

The elements that make up the environment are, in fact, the raw materials for the tourism industry. But unlike other industries, the tourists should not deplete these inputs, since such depletion would reduce their capacity to attract tourists.

Environmental disasters or substantial changes to the natural environment, such as intensive and indiscriminate felling of forests, shipwrecks of oil tankers, industrial pollution of rivers, etc., can drastically affect the possibility of developing tourism in areas endowed with natural or cultural assets.

Climate change, caused by many human activities including tourism-related air transport, is proving to be a major threat to many tourist destinations. Sea level rise resulting from global warming in coming decades will jeopardize not only the tourist industry of many small islands and small island states, but also their entire existence, since tourism is in most cases their main, and frequently their sole economic activity. Similarly, global warming and the resulting reduced snowfall are already affecting ski resorts in several mountain areas.

Secondly, tourism can significantly contribute to the preservation and improvement of natural areas, places of historic and cultural interest, and even urban environments. By giving economic value to the landscape and to archaeological sites, tourism generates income for their conservation and appreciation by people. Similarly, tourism can serve to improve people's environmental awareness. Adequately conducted eco-tourism and other forms of nature-based tourism are powerful tools for educating the general public about the fragility of ecosystems, endangered species and their conservation, and environmental matters in general.

However, for these benefits to occur, tourism must be developed and managed in a manner that does not exhaust the resource, while provisions need to be made for ensuring that part of the income generated is actually spent for conservation. This can be done through one or a combination of several instruments, such as taxing revenues of tourism operators, entrance fees, accommodation and food charges, direct sales to tourists, etc.

A third aspect that needs to be considered is that inadequately planned or improperly managed tourism can result in very negative environmental impacts. Uncontrolled growth of tourism facilities, be it hotel, transport or catering infrastructure, particularly in coastal zones, has already destroyed the resource base of many destinations around the world. Furthermore, the excessive number of summer tourists in certain beaches, that are scarcely populated during the off-season, has resulted in the contamination of marine or lake environments, due to inappropriate, or even the total absence of sewage systems, or of garbage collection and related treatment infrastructure.

Similarly, the use of national parks and protected natural areas by tourists, if uncontrolled, may degrade the plant and animal life of the areas, instead of contributing to their conservation.

In summary, the environmental impacts of the tourism industry can be numerous. This means that a careful, balanced analysis of such impacts – actual or potential – is normally required before reaching any conclusions regarding the development of tourism at any particular site, area, town or country. Such analysis is specially recommended prior to the implementation of tourism investment projects, particularly when these are of a large size, or when a whole area or community will be transformed as a result of such investments.

THE REACTION OF THE INTERNATIONAL COMMUNITY

It is not surprising, therefore, that several international organizations – intergovernmental, non-governmental and from the tourism and travel sectors – have addressed the subject of environmental sustainability in tourism.

The WTO OMT, as the largest intergovernmental agency in this sector, has been promoting an environmentally conscious approach to tourism planning since the early 1980s, with a number of technical publications and assistance missions to developing countries. The more recent publications of WTO OMT in this field are detailed in the bibliography at the end of this article.

The WTO OMT, jointly with the World Travel and Tourism Council, acting on behalf of the private sector, and the Earth Council, together formulated an Agenda 21 follow-up for the travel and tourism industry in 1995, being the only economic sector to have used the global Agenda 21 – emanating from the Rio Earth Summit in 1992 – to develop its own agenda for action.

Agenda 21 for the travel and tourism industry is necessarily general in nature, since it has been prepared by organizations which have a global coverage and a universal responsibility. Yet, the fact that it is global and general does

not diminish the validity of its recommendations. Indeed, in its part two, there is a very detailed framework for action, describing the responsibilities of government departments, national tourism authorities and travel trade organizations on the one hand, and of individual travel and tourism companies on the other. Of course not all these guidelines are equally applicable to all countries and destinations, but most can be easily adapted and applied, if there is the political will to do so.

Joint actions by the WTO OMT with the United Nations Environment Program, the World Conservation Union and other institutions, as well as independent actions carried out by WTO OMT and the United Nations Environment Program, have resulted in a number of guidelines for the development and management of specific types of tourism destinations, such as national parks, historic cities, archaeological sites, coastlines, small islands and others.

The United Nations Commission on Sustainable Development also took an interest in the tourism sector and the need for it to be developed in a sustainable manner. At its 7th session (April, 1999), it focussed on tourism, made a number of recommendations to governments and to the private tourism sector, and took a number of decisions in this respect (UN-CSD7 report on Tourism and Sustainable Development, UN, New York, 1999).

MAKING TOURISM MORE SUSTAINABLE: POLICIES AND GUIDELINES

There is often confusion about the concept of sustainable development when applied to tourism. Some authors and commercial organizations tend to equate sustainable tourism with green tourism or eco-tourism, that is, with some particular forms of tourism related to nature. It should be clearly stated, however, that this is not correct; all tourism activities, whatever their motivation (beach holidays, cultural circuits, business trips, conferences, congresses or fairs, health-related trips, adventure travel or eco-tourism, etc.) must be sustainable.

This means that the planning and development of tourism infrastructure, its subsequent management and also its marketing should be based on environmental, social, cultural and economic sustainability criteria; these criteria are meant to ensure that neither the natural environment nor the socio-cultural fabric of the host communities will be impaired by the arrival of tourists; on the contrary, local communities should benefit from tourism, both economically and culturally, while increased resources should be given for conservation and enhancement of the surrounding natural environment. Sustainability implies that not only tourism enterprises, but also the communities in which they operate, have something to gain from tourism. Sustainability implies, to paraphrase a recommendation of the Rio Summit of 1992, that tourism resources and attractions are utilized in such a way that their subsequent use by future generations is not compromised.

The sustainability of tourism should not be viewed as a static concept, referring only to the planning and development phases. Ensuring sustainability requires a continuous process of adaptive management and monitoring, since as destinations develop, grow in size and become more popular among tourists, new problems will arise and new solutions will have to be found to maintain or even improve their sustainability level.

A number of policy and planning approaches for achieving a sustainable tourism development have been proposed by the WTO OMT and other international agencies and academic institutions. The key elements of such approaches can be summarized as follows:

- A tourism policy is required at the national, regional and local levels. Tourism can no longer grow as a result of spontaneous, individual and uncoordinated actions by isolated actors; governments at all levels are required to formulate policies for its orderly development.
- The tourism policy should be the result of a participatory process, in which all interested parties, and particularly the local community, are involved.
- A comprehensive approach should be adopted, whereby all aspects of tourism development are considered in the planning process, including the tourist attractions, the basic infrastructure and services, accommodation and catering facilities, transportation, management aspects, human resource development, as well as the institutional elements.
- Similarly, an integrated approach is required. Tourism cannot be planned in isolation; instead, it must be part of the overall development efforts of a country or area, while local tourism plans must be integrated into national tourism strategies.
- Environmental impact assessment techniques must be applied from the very beginning of any tourism development plan or project. Efforts should be made to ensure that the cost of avoiding any potential damages to the environment as a result of such development has been taken into account in the economic and financial calculations.
- Tourism companies and destinations must be managed with the environment in mind. This needs appropriate environmental training of tourism managers and employees at all levels, to enable industry-wide application of environmental management systems in all tourism companies.
- The management of tourism at both the company and the destination levels requires continuous monitoring, particularly with respect to environmental variables. Monitoring allows managers and public authorities

to take corrective actions when needed and before negative impacts become irreversible.
- As an indispensable element for the above monitoring process, indicators for sustainable tourism (WTO, 1995) must be developed and introduced as a normal practice at all tourism destinations. Indicators also serve to guide consumers about the environmental and social quality of the destination, and are good benchmarks to stimulate destinations to compete on sustainability grounds rather than on price.

An effective tool for promoting conservation of natural areas and their biodiversity, rich archaeological sites, and even historic cities, and for ensuring that a sustainable tourism use is made of such places is their designation as protected areas. In this particular case, the following essential guidelines can be suggested for ensuring that tourism contributes to the preservation and improvement of such areas, while not generating negative impacts:

- *Zoning*: it is fundamental to define, in all protected natural areas, zones with different uses and use intensity. Tourists cannot normally be allowed in all parts of the protected area, or at least not all of them at the same time or in the same number.
- *Tourism demand management*: tourism demand for natural areas must be managed, and this can be done through a combination of various instruments: (a) determining the total maximum number of tourists/visitors that can be accepted in the area, per day and/or *per annum*, also known as *tourist carrying capacity*; (b) establishing a pricing policy in line with the acceptable maximum number of visitors; (c) defining marketing, distribution and promotion policies in line with the pricing policy and with maximum demand numbers.
- *Design for tourism management*: management infrastructure as well as tourist facilities in the area should be designed keeping in mind that they are to be used by tourists. Local materials and local styles (ecodesign) should be used in all buildings within the area, incorporating all environmentally friendly technologies available (solar energy, natural ventilation and illumination, recyclable materials, classified waste disposal, etc.) Pedestrian paths should be built and the surface of intensive use areas should be hardened. A comprehensive waste management system should be established.
- *Crowd management*: tourist routes within the area should be designed in order to manage tourists' movements. Timing and sequencing programs should be established and implemented with appropriate information and sign posting. Norms should be set up concerning the use of vehicles within the area. Access and stop points should be established in line with timing and sequencing, etc.
- *Continuous monitoring of impacts*: a comprehensive site inventory should be established with the double purpose of: (a) selecting species of greatest interest to tourists, and (b) undertaking periodic inventories or counts of species. Regular ecological audits should be carried out to measure any impacts from tourism. A battery of indicators and a corresponding data collection system should be established.
- *Behavior management*: rules should be established, disseminated and enforced for the behavior of tourists. A code of practice should be set up for tour operators marketing the area and also for the tourists. Neighboring communities, protected-area staff, and tourists should be educated on the importance of preservation in general and on specific endangered species that may be present in the area. Ample information should be provided to tourists, before and during their visit to the area, including descriptive information about the area and its habitat, dangers and risks, endangered species, do's and don'ts within the area, etc.
- *Pro t sharing for local conservation and improvement*: mechanisms should be established to ensure that part of the financial proceeds resulting from tourism activities within the protected area are re-invested in the same area.

THE ROLES OF DIFFERENT STAKEHOLDERS

The Tourism Private Sector

It is commonly stated that, in a free market economy, the responsibility for ensuring the sustainability of tourism products and services should rest basically with individual companies. It is further argued that the industry will listen to the market, adjusting its behavior to become more environmentally friendly; this can be done either by each company adopting and applying its own environmental management system, or by following industry-wide, commonly agreed but voluntary codes of conduct *vis-à-vis* the environment (several examples can be found among major hotel chains, the International Hotels Environment Initiative, Green Globe 21, the Costa Rica based Certification System for Sustainable Tourism, and many others (see the United Nations Environment Program, 1995)).

Several international hotel chains, as well as many independent hotels have incorporated into their operations these environmental management systems, or at least a number of concrete measures to save energy and water, to reduce waste, to recycle some of this waste, etc. In so doing, they have achieved considerable environmental improvements as well as important cost savings and financial gains. Furthermore, their public image has also improved, thus enhancing their marketability, at least among environmentally conscious tourists.

The Public Sector

The role and responsibility of private tourism companies cannot be understated. However, it might be naive to think that only with such measures would environmental sustainability in tourism be assured. Public authorities, particularly those at the local or municipal level have also various and very important roles to fulfil. Their main functions and responsibilities are:

- setting up environmental, socio-cultural and economic norms, rules, regulations and minimum standards in general or in particular for the tourism sector;
- supervising and controlling that such norms are being enforced at the appropriate levels, and that companies and individuals are satisfying the standards;
- disseminating information among tourism and hotel companies with respect to the technologies available, nationally and internationally, to reduce or arrest the negative environmental impacts which typically occur in tourism and hotel companies;
- establishing loan schemes, subsidies, fiscal and other measures and incentives to encourage the introduction of the latest environmental technologies into the day-to-day operations of tourism companies;
- taking appropriate measures to manage and maintain, in a sustainable manner, those public components of tourism facilities, such as natural and cultural attractions, public beaches, roads and other forms of transport infrastructure, parking grounds, public parks, etc.;
- promoting the establishment of voluntary certification schemes, and their related accreditation mechanisms, for stimulating sustainability in tourism companies and destinations.

CONCLUSION

National, regional and local authorities need to fully take up their responsibilities in tourism. The commercial tourism sector, on its part, must follow the above principles and guidelines in a more rigorous fashion than at present. This will not only ensure environmental sustainability of the tourism industry, but also strengthen its capacity to generate economic benefits for companies and host communities.

Most importantly, the tourism sector will then make a stronger contribution to the overall sustainability of economic development of destination countries, enhancing at the same time the image of the tourism industry, and as a result, obtaining greater financial and other support from governments.

Policy Exercises: a Tool for Solving Environmental Policy Dilemmas

William M Stigliani
Center for Energy and Environmental Education, University of Northern Iowa, Cedar Falls, IA, USA

Environmental problems, particularly those related to global change such as climate change, deforestation, species extinction, and urbanization, are intimately linked to socio-economic activities. Solutions to these problems involve complex trade-offs between economic, social, and technological considerations. Often there are no easy remedies, and policy makers are confronted with the dilemma of choosing from a set of policy options, none of which is appealing for a number of reasons, e.g., high scienti c uncertainty, high-stake economic and political risks, potential for social upheaval.

Moreover, no matter what policy is eventually adopted, there are likely to be winners and losers. For example, real estate developers in coastal areas would be losers in any policy curtailing coastal settlement to reduce the impacts of sea level rise. In contrast, real estate developers of lakeside properties are likely to be winners if the focus of settlement were to shift away from coastal marine areas to scenic freshwater resort areas. How is it possible to secure consensus amongst stakeholders when some will win and others will lose?

There is general agreement that standard means for factoring scientific information into long-term strategies for managing the environment are inadequate. One major problem with tackling policy dilemmas is the large information gaps in scientific knowledge that currently preclude the development of rigorous, quantitative analyses for predicting environmental change. Moreover, for the information that is available, we do not yet know how to use it optimally in the formulation of prudent policies that both protect the environment and foster economic development. Another perhaps more fundamental problem is that currently there is no established mechanism by which scientists and senior policy people can exchange ideas on the long-term management of the environment. As a result, policy makers are often disappointed by the lack of policy relevance in much of the scientific research, and scientists are often discouraged because their research appears to have no impact on public policy.

Historically, two common means of science/policy synthesis have been: (1) Blue Ribbon panels; and (2) large-scale computer simulation models for environment-economic analysis (Brewer, 1986). Although useful under many circumstances, neither is entirely adequate as a stand-alone policy tool for managing the kind of uncertain

Table 1 Environmental issues as policy dilemmas

Issue	Policy dilemma
Managing water resources in an era of climate change	Reservoirs, dams, and municipal water works are built to last at least 50 years under assumption of a stable water supply. For new construction, should planners factor in costly safety factors to protect against fundamental changes in water availability caused by changes in climate?
Long-term forestry management in an era of global deforestation	Currently there is an abundance of harvestable wood for paper pulp, but global deforestation and other factors could cause a severe wood shortage in the future. Increasing wood supply requires planting of new forests decades in advance. Should forestry managers plan to increase forest lands at a time when there is no crisis, and future supply and demand is too uncertain for precise planning?
Development of coastal areas in era of climate instability and sea level rise	Settlement in coastal areas is booming globally, but climate change may cause irreparable damage stemming from sea-level rise and an increase in the frequency and force of hurricanes. Should plans for coastal development factor in concerns about climate change?
Transportation needs versus air quality and greenhouse gas emissions	The rate of increase in the world passenger car fleet is four times higher than the rate of population growth. Much of this increase is in developing countries, causing serious urban air quality problems and large increases in the emission of the greenhouse gas CO_2. Should automobile traffic be regulated to reduce urban air pollution and mitigate against climate change?

environmental futures confronting us over the next 100 years. Table 1 provides examples of such possible problems.

Several authors (Wack, 1985a,b; Beck, 1983) have argued for a scenario approach to managing an uncertain future. They note that the role of scenarios is to enhance the decision-maker's understanding of the future by providing perceptions of several possible future environments against which decisions can be tested. The goal is not to predict the future, but rather to manage the present by learning to live with uncertainty, factoring it into the decision process, and building bridges between decision-makers and scientists.

In the late 1980s, a group at the International Institute for Applied Systems Analysis combined scenarios and computer simulations in the development of a new methodological framework named *policy exercises* (Brewer, 1986; Toth, 1986, 1988, Stigliani *et al.*, 1989). Similar in approach to war games developed half a century ago by the US military, the process utilizes alternative scenarios of possible future environments as the centerpiece for structuring appropriate policy responses. Environmental scientists and senior policy makers are confronted with scenarios dealing with a specific environmental problem posed as a policy dilemma. The full time span of the scenarios is not revealed initially. Rather, the scenario is presented in time slices (e.g., 2005, 2015, 2025). At each time the participants are asked to describe policies for appropriate management of the environment. The suitability of the policies is then tested as the future events in the scenario unfold. In fact, the future evolves partly in response to the succession of policy moves made by the participants. Moreover, the participants are invited not only to partake in the exercise, but also to challenge the validity of the scenario presented. However, the challenger must then defend his or her vision of the future. Such interplay is encouraged to ensure that the scenarios challenge the decision-maker's preconceived ideas about what will happen, and accordingly may teach him or her to think in terms of an uncertain future.

The objective of a policy exercise is not to develop a firm set of environmental policies for the next 50 years but:

- to sensitize policy makers to uncertainties due to natural and human factors and to alert them to the possibility that some of their current policies, even though well intended, may lead to negative consequences over the long term;
- to train policy people in how to use adaptive management strategies, which are continually updated as new information is received;
- to convince policy people of the need for regular policy exercises with scientists, as a preferred method of setting environmental agendas and priorities.

POP (Persistent Organic Pollutants)

see International Environmental Standards (**Volume 4**)

PPP (Polluter Pay Principle)

The PPP holds that the price of a good or service should include all the costs incurred in its production. Thus, the costs imposed by emissions and resource use are internalized. In essence, the polluter pays the cost of pollution. This is akin to a Pigovian tax (named after the economist

Pigou), which in theory is equivalent to the marginal cost of damage at the optimal pollution level. Ideally, if a firm pays the full cost of pollution, then there is an incentive to make improvements in technology and reduce emissions. The PPP is often envisioned in the form of a tax (for an example of ecotax instruments *see* Eco Taxes, Volume 4).

In 1972, the Organization for Economic and Development Co-operation, and the European Community (EC) adopted the PPP as a component of environmental policy. The EC further endorsed the PPP in 1975 in the Single European Act, though the extent of implementation has been variable.

Precautionary Principle

The *precautionary principle* is both a support for, and a criticism against, the science of global environmental change. It places the onus of proof on those who wish to change the *status quo*, and to show beyond reasonable doubt that they are following a duty of care for the planet and its inhabitants.

This dictum carries two important messages. The first is that science has to operate on the assumption that the lack of evidence of cause and effect is not a sufficient condition to adopt the provisional hypothesis that there is no link. In essence, the scientific prognosis must focus on the worst-case set of assumptions and also attend to the possible consequences for the most vulnerable people. At the societal level, *vulnerability* is the incapacity to avoid danger, or to be uninformed of impending threat, or to be so politically powerless and poor as to be forced to live in conditions of danger. On a personal level, vulnerability relates to such a physical condition as to be unable to withstand stress to a weakened immune system. In essence, precaution carries with it both the principle of playing safe, and paying due attention to the physically weak and the politically powerless.

The second quality of precaution is that it relies on a more participatory form of science for its effectiveness. This notion is called *civic science*, and involves a more deliberative, and stakeholder involved, process of analysis and consensus building. The key to this aspect is that outcomes are not given: they are shaped by the very processes of participation that in uence their interpretation, by those whose consent is vital if decisions are to be taken.

Take, for example, the issue of traffic futures for a city, in the face of uncertain evidence over climate change, the role of offsets for car-produced carbon dioxide (CO_2), and the public health effects of vehicle exhausts under changing future climates (possibly longer, drier summers with more sunshine, inversions and concentrations of photochemical smog). Any decision to require the vehicle user to pay for these social costs will require their understanding of what might happen to climate and to public health under differing combinations of vehicle movement over the next 50 years.

The precautionary principle, therefore, encourages interactive (i.e., user-friendly) and integrated (i.e., comprehensive) assessments of various future states. These may be in uenced, in turn, by assumptions in the science of global environmental change and in the likely outcome of certain policy measures (such as eco-taxation, using the revenue for socially constructive investments).

Invoking the precautionary principle is also a re ection of growing distrust of science as a competent and authoritative arbiter of complex problem solving. A majority of citizens in Western countries do not believe that science is free of commercial and political pressures. This loss of faith is evident in the dispute in Europe over the introduction of genetically modified food, though it applies to food safety generally. In the United States, however, precaution is less of an issue, as the American culture supports innovative technology and capitalistic risk taking. Indeed, world trade regulations heavily in uenced by American business interests, do not allow too strict an interpretation of the principle to affect the spirit of free trade. This will remain an area of notable tension between North America and Europe for some time to come.

The precautionary principle, therefore, re ects degrees of trust in the institutions of science, and the culture of risk and innovation in nation states. It is both socially and politically framed, but has significant implications for the future role of environmental science in a global age.

Q

Quotas in International Environmental Negotiations

Amanda Wolf
Victoria University of Wellington, Wellington, New Zealand

A quota in international environmental negotiation refers to a limit or target, designated in units directly related to an environmental problem, chosen by consensus or near-consensus. Limits may be presented as a single gure, or as shares of the total limit. Allocations of shares may be given as percentages of the total or as concrete numbers. Quotas may stand alone as instruments to achieve environmental objectives, or they may form a basis for or be combined with other instruments. Not surprisingly, over time, quotas have become more sophisticated and the range and style of their use have expanded. The most recent instances of quotas underpin key integrated management concepts.

In some theoretical literature, quotas are criticized as crude measures relative to incentive based measures for environmental management. However, particularly at the international level, quotas endure for reasons associated both with their inherent qualities and with the fact that management strategies using quotas, like all other strategies at the international level, must be negotiated. Quotas can be simple, yet exible, and thus suited to the inevitable accommodation of different interests and circumstances.

A balanced assessment of how quotas contribute to better long-term environmental policies requires a review of the various forms of quotas and their historical applications, a consideration of quotas against the key criteria of effectiveness, ef ciency, and equity, and an examination of the features of negotiated decision making that may favor quotas.

Negotiation is the principal means of policy making at the international level. It is a painstaking, incremental process, complicated by the complexity and uncertainty of many environmental problems. What is being negotiated is not some state of nature or environmental quality, but the mechanisms through which it is hoped environmental objectives will be realized. Parties negotiate over rules, standards, and practices, with environmental objectives as indirect in uences. Many factors – science, economics, politics, practice, beliefs, values, behavioral theories – play a part in the negotiation of quotas. A great deal of attention is directed to the features of a basic environmental management framework.

Negotiators of international environmental agreements know that their decisions will have implications in terms of environmental effectiveness, productive, and allocative efficiency, and ethical and distributional features of effects and costs (equity) (Organization for Economic Cooperation and Development, 1994). These criteria form a basis for deciding what instruments to use. In general, instruments are classified on the basis of several features: whether the instrument is direct or indirect, freeing or constraining, process- or effect-focussed, and quantitatively or qualitatively based. This last point distinguishes instruments directed to the quantum of an activity from those directed at the qualities, such as rate and the use of best available technology, of an activity. Bearing in mind that environmental instruments are mostly shades of gray, quotas typically are direct, constraining, effect-focussed, and quantitatively based. In comparison with other instruments, quotas have been thought to give greater weight to the implications for environmental effects and less to costs.

Basic quota instruments have two parts. The first part designates the unit of management and the second, a rule. The unit of account is the focus of limits in activity or behavior. Examples of units of account are elephant tusks over 10 kg taken by non-native hunters in a given year or tonnes of chloro uorocarbons (CFCs) emitted by a developed country in a given year. The second part is a statement of what shall be done and may include conditions and eligibility requirements. A corresponding rule in the tusk example might specify that no more than 50 be internationally traded in the given year between approved buyers and sellers. How a quota is to be implemented, monitored and enforced are key issues for the success of the instrument and will have bearing on the choice of units of account and rules.

The simplest type of quota sets a single total limit, and the management rule requires all participating parties to jointly ensure that the limit is respected. Early whaling regulations used this device to set yearly numbers, by species, for whales that could be taken by members of the International Whaling Commission. A single limit may also be indexed. The whale quota evolved into a total allowable catch denominated in blue whale units. This measure was based on the different amounts of oil that could be extracted from different species of whales. For example, two and one-half humpback whales were considered equivalent to one blue whale. In 1945, the quota was set at 16 000 blue whale units. Similarly, rules based on baskets of chemicals are used in ozone layer and climate change agreements. However, in these cases, the baskets are only a basis for more elaborate rules.

Indeed, while total limits on their own are now rare, many environmental agreements make use of total limits in conjunction with allocations of the total among participating parties. Allocations may be expressed either as a percentage of the total or as a discrete number. Many fisheries treaties use a base-year catch, as a proportion of total catch that year, to allocate shares of successive years' total allowable catch. Occasionally, as in the Convention on Future Multilateral Cooperation in the Conservation of Northwest Atlantic Fisheries (1978), parties will agree on a total catch and divide it up without recourse to a principle or formula. In addition to historical use, formulas may draw on geographic proximity, relative economic development or economic hardship, and traditional use.

Some recent agreements still make use of rather simple quotas. For instance, the Convention for the Conservation of the Southern Bluefin Tuna (1993), essentially set a total allowable catch at the recent catch level in the expectation of subsequent ecologically justified allocations, which, however, have not been achieved. Parties are thus loosely bound to respect an allocation based on their historical catch despite changing conditions. It can be argued that in this instance, the simple quota represents an achievement over open harvest and provides a basis for incremental improvement. In a similar vein, in putting ambient standard pollution agreements into operation approximate measures may be used, due to technology limitations and lack of information. Thus, across the board 50% reduction in total inputs from rivers were called for in the 1987 amendments to the Convention on the Protection of the Marine Environment of the Baltic Sea Area (Helsinki Convention, 1974).

Despite the instances already cited, it is sometimes claimed that pollution-related treaties do not make use of quotas. This claim is likely based on the absence of explicit total limits. Many agreements (in pollution and conservation cases) simply set an allocation formula or otherwise assign limits directly to participants. An example is found in the 1985 sulfur dioxide protocol to the Convention on Long-Range Transboundary Air Pollution (LRTAP, 1979) through which countries agreed to curb their emissions of sulfur dioxide by 30% from a base year. In this case, the effect of the rule on the environment is directly linked to the number and emissions of participating countries.

The definition of a quota easily covers not only temporary bans – a quota limit set at zero until some aspect of the ecosystem recovers – but also some rules associated with limit values. Limit values come in the form of emission or ambient (environmental quality) standards for pollutants in a given period and medium. If the intent is to hold aggregate amounts of the pollutant to some set level, that level is a quota. For example, when Mexico and the United States concluded a treaty for managing the salinity of the Colorado (Brownell and Eaton, 1975), a salinity standard was established. Based on a reference salinity at Imperial Dam, and taking into account a required minimum ow of water, water entering Mexico is to have an annual average salinity of no more than 115 • 30 ppm. The rolling reference value meant that the standard was readily applicable in drought and normal conditions. In addition, in support of this salinity standard, the treaty limits the pumping of groundwater to 160 000 acre feet year$^{\bullet 1}$ country$^{\bullet 1}$ (an acre foot is 1233.5 m^3). The salinity standard is a quota-based standard, since there is a limit value set. The groundwater quota is a resource quota in support of a pollution goal.

Quotas are an essential part of tradeable permit schemes and joint implementation. In both cases initial allocations are made in the form of limits, but bilateral arrangements are permitted to enhance the cost-effectiveness of meeting the established limits.

Given the variety of treaty classification systems in use, it is difficult to estimate the overall incidence of quotas in environmental management. Some evidence is provided in a comprehensive review of the management provisions of 72 treaties concerned with fisheries and the conservation of other resources and 55 air and water pollution agreements (Wolf, 1997). This review showed that quotas were used in 33 conservation agreements. In these applications, quota units are typically individuals of a species, such as whales or elephants, or other biomass measures, such as a tonne of fish. Since agreements often serve several objectives, quotas are frequently combined with other measures. For example, fish size limits may be used in conjunction with quotas in order to protect reproductive-size stock preferentially.

Habitat protection measures may make use of a different sort of quota. The 1991 framework Convention for the Protection of the Alps suggests that imposing limits on leisure and tourist activities that harm the environment is one possible measure. The Convention on Biological Diversity (1992) calls for regulations to limit the introduction of living modified organisms. Such regulations could be expressed as quotas.

Quotas have had a prominent role in air pollution management. The acid rain and ozone layer agreements make extensive use of phased reductions, essentially providing each country, or source emitter, with an emission limit. The Framework Convention on Climate Change (FCCC, 1992) is underpinned by limits on greenhouse gases in the atmosphere. The 1997 Kyoto Protocol to the FCCC sets out a legally binding commitment for countries to meet country-specific quantitative emission limitation and reduction objectives for six greenhouse gases. The limits range from an increase of 10% to a decrease of 8% of 1990 levels to be achieved between 2008 and 2012.

In agreements to reduce water pollution, quotas in the form of ambient standards are used to allocate indirectly the costs of pollution abatement, rather than directly allocating a resource (as in conservation uses). This indirect approach contrasts with the direct allocation of resources in conservation applications. The 1991 revision to the Convention on the Protection of the Rhine Against Pollution by Chlorides establishes an ambient standard for chloride loading in the river ($15\,kg\,s^{-1}$), which may be increased whenever the concentration at the German-Dutch border exceeds $200\,mg\,l^{-1}$ of chloride ion (Bernauer, 1995). Ambient standards are also prominent in marine pollution agreements. Lists of banned and restricted substances form the basis of environmental management. Restricted substances (the gray list) in the Convention for the Protection of the Mediterranean Against Pollution (1979) and protocols, for instance, are to be managed by establishing ambient standards at various locations, depending on factors such as effects on human health, availability of waste technologies and characteristics of the receiving environment. Ambient standards, however, are costly to establish, and in practice may be approximated by rules on emissions. In these cases, the quota basis is not rendered irrelevant, since ambient standards remain an essential component in judging the effectiveness of a management regime. Moreover, because ambient and emission standards draw upon different normative assumptions, the negotiations surrounding a choice of mechanism may make use of the different bases. Emission standards, while technically and administratively simple, cannot take account of varying ambient conditions which may be linked to relevant variables, such as economic development, as the Mediterranean negotiations made clear (Bliss-Guest, 1981).

Over the last quarter of a century, environmental agreements have favored a multi-criterion approach as negotiators seek to balance the costs and environmental and distributional impacts of agreement terms. Once parties agree to jointly seek an environmental outcome (not an insignificant achievement) emphasis shifts to cost and distributional matters. It is in this context that the issue of instrument choice rises to the surface. If quotas are then judged to have a role, either alone or in conjunction with other regulations and incentives, negotiators must address the details of the quota in order to achieve an acceptable balance of effectiveness, efficiency, and equity.

Assuming quotas work as intended, are fully implemented and universally respected, and are not combined with other instruments, then some conclusions are possible about the various types of quotas with respect to the key criteria. Some of the conclusions hinge on the fact that quotas in international agreements must be negotiated giving rise to transaction costs and certain strategic behaviors with respect to setting up terms of agreements. Quotas that set a total limit are more effective than those that do not, since the limit guarantees an environmental effect. In this manner whale quotas (set in numbers of whales) are distinguished from the sulfur dioxide 30% club, since in the latter case the environmental effect is contingent on the number of participating countries. In the absence of an explicit total limit, negotiators' efforts to revise rules may be hampered by the difficulty in projecting the impacts of the existing rules. For instance, the impact of the Montreal Protocol on Substances that Deplete the Ozone Layer (1987) was contingent on the trend in CFC emissions in developing countries, where overall use was allowed to rise to a threshold 0.3 kg *per capita*.

The efficiency of a quota derives from the degree to which it both facilitates the rational use of resources and minimizes the costs of coming to a joint allocation of the regulated units. Thus, a total limit without allocated shares is inefficient, as parties overcapitalize in an effort to exploit the regulated resource before the limit is reached. If the quota mechanism establishes rules or a formula for allocating shares of the limit that stand from year to year, bargaining costs and the costs of delays are reduced. Parties are better able to anticipate their allotment for future years and plan accordingly. They are not required to bargain repeatedly to maintain or increase their share. Of course, if the initial allocation formula contains embedded inefficiencies, then it may ultimately be more efficient to bargain until shares find their most efficient owner.

It is not possible to generalize about the equity objective. This objective may be best met if the mechanism eschews global rules in favor of adjustments in allocations for relevant differences in parties' situations. Allocation formulas, for instance, may make it more difficult to make exceptions on equity grounds. On the other hand, if powerful parties are overly self-serving, the exceptions may ow in the wrong direction. Furthermore, equity is tied closely with effectiveness and efficiency. In the final analysis, only the specific context and details of a given quota mechanism can provide a basis for equity judgements. This is not to say that equity is ambiguous or that it is a wild-card in negotiations.

Experience shows that equity is increasingly integral to successful negotiations. A close examination of a sample of some of the most important treaties negotiated in the 1990s

reveals an emphasis on the precautionary and sustainable development principles (*see* Precautionary Principle, Volume 4; Sustainable Development Policy, Volume 4). Both principles require a balance of attention to the main criteria of effectiveness, efficiency, and equity. In addition, it is also important diplomatically to build in the highest extent of exibility feasible, in order to allow individual countries to best tailor their obligations to their domestic circumstances. A final feature of these recent exercises is the move to independently ground quotas (limit values) on the basis of an explicit balancing of criteria. These criteria cover ecology, economic development, and allocation of costs and benefits.

Most importantly, recent quotas exhibit a far greater degree of differentiation in units of account than earlier examples. The critical loads modeling used to help negotiators reach allocations of allowable sulfur emissions is the most clear-cut instance of this trend. There are three general features: (1) the establishment of management cells, such as a grid over space or the determinations of stocks and sub-stocks of living resources; (2) the establishment for each of these cells of a limit based, to the extent possible, on scientific knowledge; (3) the translation of the scientifically justified targets into management targets, for instance by setting a concrete target on the basis of a scientific range or by adjusting for technical feasibility. The management targets for different cells need not all be based on the same principles. The final determination of targets, which may be thought of as local quotas, is settled in a negotiation, which takes into account costs and distributions of costs. The end result is that scientific targets, modified for pragmatic reasons are approached as closely as possible in light of constraints set by factors such as economic development, costs of various technologies, as well as differences in parties' views of fairness. Essentially management targets are finalized only after significant debate on the relevance and effect of constraining factors.

Experienced negotiators will recognize the generic format of this procedure. Advances in information and modeling have, at least since the well-documented law of the sea (Sebenius, 1992) enabled the approach to be conducted transparently. Further refinements are possible with devices such as indexing (as used in setting ozone depleting potentials for various chemicals and allowing countries to assemble their own baskets). The approach also has conservation applications. Proposals have, at various times, been discussed for managing whales and elephants by subspecies stock and for establishing criteria for the sustainable management of tropical timber, which would allow for quota-based harvests where criteria are met.

In summary, quotas are an integral part of the international management of global environmental change. They are a focal solution in negotiations, based on precedent, on the direct links to environmental impacts, and on the lack of compelling alternatives. When the key features of quotas are borne in mind – rather than a crude caricature – quotas are revealed as essential components of a rich variety of environmental management instruments. As quantities, quotas are relatively simple to work with – akin to bargaining over a wage rate in labor negotiations – even if agreement is difficult. Quotas facilitate reporting and monitoring in a manner relevant for assessing environmental impacts. In the current globalized economy, quotas are ready currency, needing no exchange rate calculations. State parties to a quota agreement remain free to use a wide range of instruments to meet their obligations. Finally, quotas fit with the incremental and evolutionary process of global environmental management.

Risk Management in an Era of Global Environmental Change

Howard Kunreuther
University of Pennsylvania, Philadelphia, PA, USA

Society faces large challenges as to how to deal with the increasing losses from natural, technological and environmental hazards. Residents in hazard-prone areas are reluctant to protect themselves before the event occurs. The insurance and reinsurance industry is concerned that insurers cannot provide protection against these catastrophic risks without exposing themselves to the danger of insolvency or signi cant loss of surplus. There has also been a concern that these losses will increase due to population growth in hazard prone areas and climate change creating more disasters than in the past.

This article explores the importance of insurance coupled with other policy instruments, such as regulations and standards, and can be used by interested parties (e.g., banks and nancial institutions) to encourage loss reduction measures and provide nancial protection against these hazards. New advances in information technology and risk assessment coupled with the emergence of new nancial instruments for covering large losses provide the ingredients for rethinking the way society deals with catastrophic risks. To encourage investment in cost effective loss-reduction measures, there is a need for well-enforced building codes as well as nancial incentives such as long-term loans tied to an insurance policy.

INTRODUCTION

There is grave concern, by the property and casualty insurance and reinsurance industry, that insurers cannot continue along their current path of providing protection against certain risks or taking on additional risks, without exposing themselves to the danger of insolvency or significant loss of surplus, which will threaten the availability of future coverage (Kunreuther and Roth, Sr, 1998).

More specifically, since 1989 insurance and reinsurance firms have suffered losses from disasters that have wreaked havoc with their balance sheets. Figure 1 depicts the magnitude of the catastrophic losses experienced by the insurance industry in the United States from 1949 to 1999. The drastic change from 1989 to 1999 is obvious. Prior to Hurricane Hugo in 1989 (where insured losses were over $4 billion), the insurance industry had never suffered any loss of over $1 billion from a single disaster. Since that time Hurricane Andrew in 1992 caused over $15 billion in insured losses and the Northridge earthquake in California resulted in over $12 billion in insurance claims Between 1989 and 1999 another 15 disasters exceeded $1 billion in insured losses (Swiss Re, 2000). Commercial development has followed the population's movement to coastal areas, and this has increased the potential economic losses from natural disasters in this part of the country.

The purpose of this article is to explore how insurance can be combined with other policy instruments, such as mitigation measures, building codes and well specified standards, to better manage safety and reduce losses from

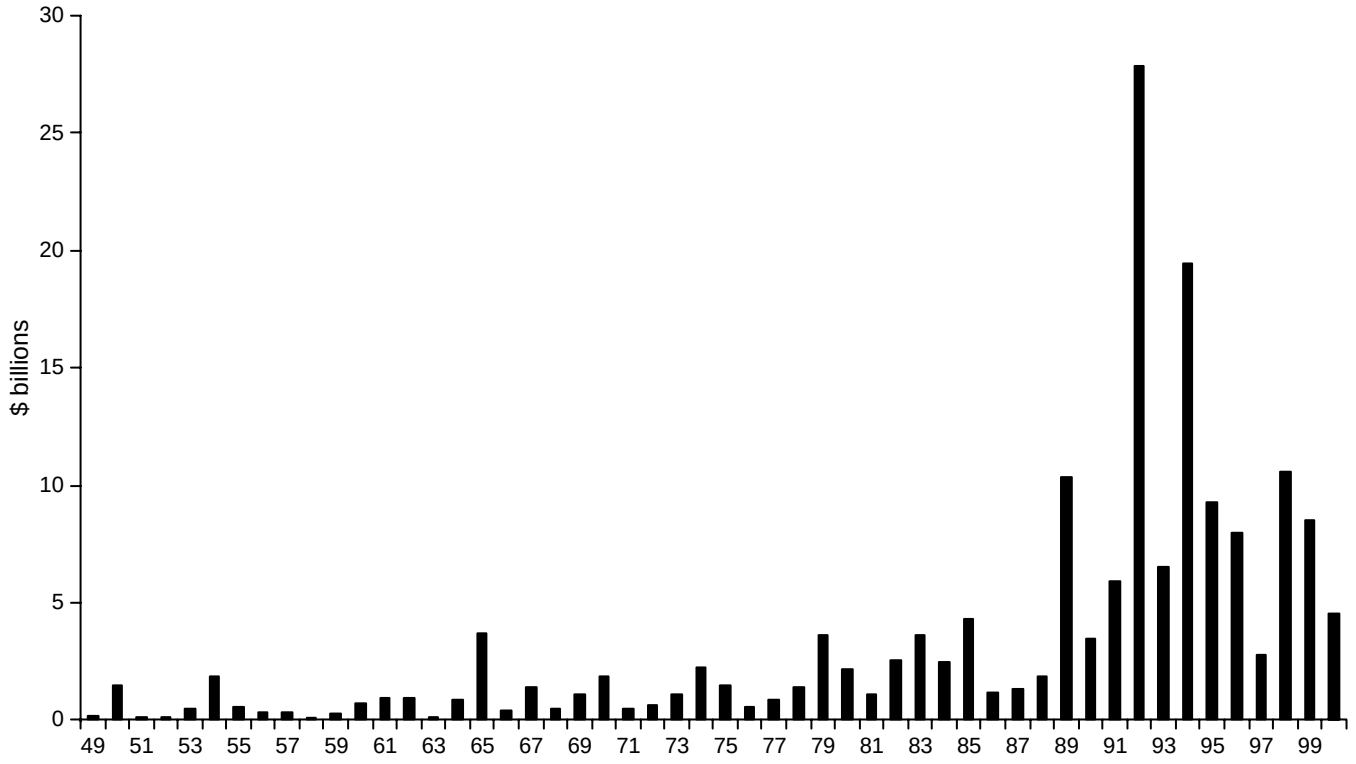

Figure 1 Insured catastrophe losses (1949–2000) (in 2000 dollars). (*Source:* Insurance Services Office)

catastrophic risks from technological and natural hazards. In particular, there is a need for a public–private partnership for dealing with these challenging issues. The principal focus will be on reducing losses from natural disasters, but the concepts and principles discussed below are relevant for dealing with safety systems for technological hazards. Three recent developments provide the ingredients for rethinking the way society deals with these risks:

1. There has been an emergence of new capital market instruments, such as catastrophe bonds for dealing with losses from mega-disasters. Although the volume of business to date in these instruments is relatively small, they offer promise for protection in the future, both in the developed countries as well as emerging economies (Insurance Services Office, 1999; Standard and Poors, 2000).
2. New advances in information technology (IT) and risk assessment offer an opportunity to estimate the chances and potential losses of future disasters and catastrophic events more accurately than in the past. On the IT side, the development of faster and more powerful computers enables one to examine extremely complex phenomena in ways that were impossible even five years ago. Scientific advances in risk assessment have reduced the uncertainty associated with predicting the chances and consequences of these low probability–high consequence (LP–HC) events.
3. Mitigation measures promise to reduce losses from natural disasters and catastrophic accidents. In particular, there are many benefits, which have traditionally not been considered as part of standard benefit cost analysis. These benefits may make mitigation extremely attractive to all of the concerned parties (Heinz Center, 1999; Mileti, 1999).
4. Global mean surface temperature has increased by between about 0.3 and 0.6 °C since the late 19th century. The change is unlikely to be entirely natural in origin and suggests a noticeable human in uence, although there are uncertainties in key factors, including the magnitude and patterns of long-term natural variability. Global sea level has risen by between 10 and 25 cm over the past 100 years and much of the rise may be related to the increase in global mean temperature (Intergovernmental Panel on Climate Change, 1995). In its Third Scientific Assessment (IPCC, 2001), the Intergovernmental Panel on Climate Change (IPCC) concluded that there has been a discernible human in uence on global climate . This is the strongest official pronouncement yet that human-induced warming is real (Kerr, 2000) (*see* Intergovernmental Panel on Climate Change (IPCC): an Historical Review, Volume 4).

FRAMEWORK FOR ANALYZING CATASTROPHIC RISKS: THE CASE OF NATURAL DISASTERS

To analyze the impact of catastrophic risks on society it is important to consider the following elements:

Population and Property at Risk

One way to characterize who is at risk is to construct a community or region consisting of homes, businesses and other properties, which are subject to future disasters. One needs to know the design of each structure, whether specific mitigation measures are in place or could be utilized, and the property's location in relation to the hazard (e.g., distance from an earthquake fault line or proximity to the coast in a hurricane-prone area) as well as other risk-related factors.

There has been a large in ux of residents and businesses into hazard prone areas in recent years. By the year 2010 the population in regions of the Southeast Atlantic Coast of the United States, having annual hurricane probabilities of 10% or more, is projected to increase by 23% from 64 to 73 million people compared with 14% for the entire United States (Mills *et al.*, 2000). The reasons often given for moving to these areas is because they are seen as desirable places to live. This may be true in many developed countries. In emerging economies, such as Bangladesh, people are forced to live in these high-risk areas because there is no other place for them to go (Etkin, 1999).

Risk Assessment and Potential Damage

The potential damage to a community is determined by estimating the probability that disasters of specific magnitudes will occur and specifying the resulting losses to structures in harm's way. Relatively sophisticated models of catastrophic losses have been developed in recent years to model these distributions (Dong *et al.*, 1996). There is still considerable uncertainty as to what impact climate change will have on future disasters and their magnitudes. For example, with respect to hurricanes, Pielke and Landsea (1998) found no trend in damages when the data were corrected for in a- tion, population in ux to these areas and changes in wealth. On the other hand, climate models suggest there is likely to be an increase in ooding events due to more precipitation and greater atmospheric absolute humidity (White and Etkin, 1997).

Key Stakeholders

There are a number of interested parties concerned with natural disaster damage. Government agencies such as the Federal Emergency Management Agency (FEMA) in the United States, have stressed the importance of building codes and enforcement of regulations to reduce losses from natural disasters. The primary insurance companies provide protection to residential and commercial sectors for losses such as those caused by fires (including those resulting from earthquakes) and wind damage from tornadoes and hurricanes. In the United States this coverage is offered through the standard homeowners' policies normally required as a condition for a mortgage, and through commercial multi-peril policies. The types of policies offered and the nature of the requirements vary from country to country.

Reinsurers relate to insurers in the same manner that insurers do to property owners. They provide protection to primary insurers by insuring a portion of their claims in exchange for a premium. For all but the largest insurance companies, reinsurance is a prerequisite to offering insurance against natural disasters when there is a potential for catastrophic losses. As pointed out above, the capital markets have recently provided private insurers access to funds in the form of catastrophe bonds. The insurer borrows from investors or an institution at higher than normal interest rates to cover extreme losses from hurricanes and earthquakes that exceed a trigger amount. If this amount is exceeded, then the interest on the bond, the principal, or both, are forgiven. For more details on these catastrophe bonds and other financing and hedging instruments, see Doherty (1997).

A number of other interested parties play key roles in the design and enforcement of insurance and damage mitigation requirements. These parties include financial institutions, through specific conditions for obtaining a mortgage; the construction industry, by designing safer structures; state and local governments, through ordinances and building codes; and the real estate sector through provision of information on hazards to potential buyers and owners.

Decision Processes

An understanding of the decision processes of the property owner and insurer provides guidance for developing a set of strategies for reducing losses from future natural hazards. If residents in hazard-prone areas are reluctant to voluntarily adopt mitigation measures that are cost effective, then this provides a rationale for developing and enforcing building codes. The involvement of municipalities, contractors, third-party inspectors and other key stakeholders is essential if this measure is to work. Similarly if insurers are willing to give premium discounts for adopting mitigation measures, then there is an opportunity for banks and financial institutions to partner with the insurers to develop a financially attractive mitigation loan/insurance package.

Policy Implications

One question that needs to be addressed in developing strategies for managing catastrophic risks is the appropriate

roles of the private and public sectors, in financing the cost of large-scale disasters. To the extent that private insurance markets provide protection against catastrophe risk, policymakers must decide how these markets should be regulated. They must also determine the role of regulations (e.g., restricting developments through land-use restrictions) and standards (e.g., well-enforced building codes) and the extent to which private choice and incentives will guide hazard mitigation efforts. Within the realm of public choice, decisions also must be made with respect to the delegation of authority among the different levels of government and its agencies. In evaluating these options, policymakers must consider how various governmental actions affect the behavior of firms and individuals in responding to catastrophe risk.

WHY IS THERE LIMITED INTEREST IN MITIGATION?

The decision on whether to adopt risk mitigation measures (RMMs) to reduce losses from catastrophic accidents or natural disasters can be framed in a very straightforward manner. There is an upfront cost of the mitigation measure which will either reduce the probability of the accident or disaster occurring and/or the magnitude of the loss should the event take place. The benefits of the mitigation measure will be reaped for the length of time that the property is in place. In reality there are several reasons why a firm or individual will decide not to invest in such measures. Some individuals may perceive the probability of a disaster causing damage to their property as being sufficiently low that the investment in the protective measure will not be justified. Individuals may have relatively short time horizons over which they want to recoup their investment. Even if the expected life of the house is 25 or 30 years, the person may only look at the potential benefits from the mitigation measure over the next 3 to 5 years.

If people have budget constraints, then they will be averse to investing in the upfront costs associated with protective measures simply because they feel they cannot afford these measures. It is not unusual for one to hear the phrase We live from payday to payday when asked why a household has not invested in protective measures. Individuals may have little interest in investing in protective measures if they believe that they will be financially responsible for only a small portion of their losses should a disaster occur. For example, if residents anticipate liberal disaster relief from the government should they suffer damage, they would have less reason to invest in an RMM.

The empirical data on studies of mitigation adoption in hazard-prone areas of the United States suggest that individuals are not willing to invest in RMMs despite the rather large damage that either they and/or their friends and neighbors suffered from recent disasters. For example, after Hurricane Andrew in Florida in 1992, most residents in hurricane-prone areas appear not to have made cost effective improvements to existing dwellings that could reduce amount of damage from another storm at relatively low cost. A July 1994 telephone survey of 1241 residents in six hurricane-prone areas along the Atlantic and Gulf Coasts revealed that 62% of the respondents had not installed hurricane shutters, used laminated glass in windows, installed roof bracing, and/or made sure that side walls were bolted to the foundation either before or after Hurricane Andrew (Insurance Institute for Property Loss Reduction, 1995).

Measures, such as strapping a water heater with simple plumbers tape, can normally be undertaken by property owners at a cost of under $5 in materials and one hour of their own time (Levenson, 1992). This RMM can reduce damage by preventing the heater from toppling during an earthquake, creating gas leaks and causing a fire. Yet these and other mitigation investments are not being adopted by residents in earthquake-prone areas in the United States. A 1989 survey of 3500 homeowners in four California counties subject to the hazard reported that only between 5 and 9% of the respondents reported adopting any loss reduction measures (Palm *et al.*, 1990). This behavior suggests that individuals do not believe that investing in the RMM will increase their residence's property value, or that they have either short time horizons and/or severe budget constraints, which either reduce their perceived net benefits from RMMs or simply prevent them from making the investment (Kunreuther, 1996).

Turning to the relationship between insurance and mitigation, some interesting findings emerge from recent surveys undertaken by Palm and Carroll (1998) who report that those who had adopted mitigation measures were also more likely to buy earthquake insurance than those who had not taken these loss reduction measures. This raises the interesting question as to whether certain types of individuals and managers want protection for reasons that have less to do with their perception of the risk than their intrinsic worries and concerns.

IMPROVING THE ESTIMATES OF THE RISK

In setting rates for catastrophic risks, insurers have traditionally looked backwards by relying on historical data to estimate future risks. Such procedures are likely to work well only if there is a large database of past experience, which forms the basis for extrapolation into the future, and if the time series does not contain a trend. LP–HC events generally have a relatively small historical database. In addition, many technological and environmental risks are associated with new processes, so that past performance data are lacking. One thus has to rely on scientific modeling and epidemiological data to estimate these risks.

Fortunately there is considerable scientific work undertaken in the areas of natural, technological and environmental hazards to provide estimates of the probabilities and consequences of events of different magnitudes. A discussion of recent advances in seismology and earthquake engineering can be found in Federal Emergency Management Agency (1994) and Office of Technology Assessment (1995). Regarding technological hazards, the Wharton Risk Management and Decision Processes Center is now compiling a comprehensive database on the impact of large-scale catastrophic accidents on health and safety risks (Kleindorfer *et al.*, 1997). With respect to environmental risks to health, such as groundwater contamination, databases have been assembled which open up opportunities for providing insurance protection on risks that recently had previously been considered uninsurable by firms in the industry (Freeman and Kunreuther, 1997). As we better understand the effects that climate change is likely to have on the frequency and magnitude of natural hazards, then these impacts need to be incorporated in future risk estimates (see Mills *et al.*, 2000 for the current perspective of the US Insurance Industry on climate change).

Today there are growing numbers of catastrophe models that have been utilized to generate data on the likelihood and expected damage to different communities or regions from disasters of different magnitudes or intensity. Each model uses different assumptions, different methodologies, different data and different parameters in generating its results. Hence, there is need for a better understanding as to why these models differ and for attempts to reconcile these differences in a more scientific manner than has been done up until now (see Insurance Services Office, 1996).

BROADENING PROTECTION AGAINST CATASTROPHIC LOSSES

New sources of capital from the private and public sectors could provide insurers with funds against losses from catastrophic events, which would alleviate insurers' concerns that the next major disaster might leave them insolvent. Recently investment banks and brokerage firms have shown considerable interest in developing new financial instruments for protecting against catastrophic risks. Their objective is to find ways to make investors comfortable trading new insurance-linked secured instruments covering catastrophic exposures, just like the securities of any other asset class. In other words, catastrophe exposures would be treated as a new asset class (Insurance Services Office, 1999). A description of recent trends in this market can be found in Lane and Beckwith (2000) and Standard and Poors (2000).

Turning to the role of the public sector, Lewis and Murdoch (1996) developed a proposal that the federal government offer catastrophe reinsurance contracts, which would be auctioned annually. Another option is for the government to provide reinsurance protection against catastrophic losses. Private insurers would build up the fund by being assessed premium charges in the same manner that a private reinsurance company would levy a fee for excess loss coverage or other protection.

POLICY IMPLICATIONS: NEED FOR A PUBLIC–PRIVATE PARTNERSHIP

The key to a successful hazard management program is to design ways for reducing losses while providing protection should a disaster occur. The empirical data suggest that there is a need for new public–private partnerships to address this problem. Today most property owners have limited interest in investing in loss reduction measures. Insurers have little reason to encourage mitigation in hazard-prone areas since they feel that the rates they are allowed to charge are inadequate. Hence they want to charge the same premiums with and without mitigation and hope that some policyholders will decide not to renew their insurance policies (Kunreuther and Roth, 1998).

Three types of public–private partnership programs are proposed that can reduce losses from future disasters based on our understanding of the decision processes of the relevant interested parties. In order to successfully implement these programs, there needs to be a better understanding of the nature of the risks associated with natural hazards.

Importance of Building Codes

Building codes mandate that property owners adopt mitigation measures. Such codes may be desirable, when property owners would otherwise not adopt cost-effective RMMs because they either misperceive the benefits from adopting the RMM and/or underestimate the probability of a disaster occurring.

Cohen and Noll (1981) provide an additional rationale for building codes. When a building collapses, it may create externalities in the form of economic dislocations and other social costs that are beyond the economic loss suffered by the owners. These may not be taken into account when the owners evaluate the importance of adopting a specific mitigation measure. For example, if a building topples off its foundation after an earthquake, it could break a pipeline and cause a major fire that would damage homes not affected by the earthquake in the first place. In other words, there may be an additional annual expected benefit from mitigation over and above the reduction in losses to the specific structure adopting this RMM.

One way to encourage the adoption of cost-effective mitigation measures is for banks and financial institutions to provide a seal of approval to each structure that meets

or exceeds building code standards. Upon receipt of that certificate, there would be a set of incentives provided by banks (e.g., lower mortgage rates) as well as insurers (e.g., lower premiums). The success of such a program requires the support of the building industry and a cadre of qualified inspectors to provide accurate information as to whether existing codes and standards are being met. Insurers may want to limit coverage only to those structures that are given a certificate of disaster resistance. For more details on ways to make communities disaster-resistant, see Central US Earthquake Consortium (1997).

Premium Reductions Linked with Long-term Loans

Premium reductions for undertaking loss prevention actions can be an important first step in encouraging property owners to adopt these measures. The basic rule in this case is a simple one: if the premium reduction is less than the savings in expected claim payments due to mitigation, it is a desirable action for the insurer to promote. If homeowners are reluctant to incur the upfront cost of mitigation due to budget constraints, then one way to make this measure financially attractive to the property owner is for the bank to provide funds for mitigation through a home improvement loan, with a payback period identical to the life of the mortgage. The cost of the loan will then be less than the reduction in insurance premiums if the mitigation measure is a cost-effective one with respect to reducing property damage (Kunreuther, 1997).

Many poorly constructed homes are owned by low-income families, who cannot afford the costs of mitigation measures on their existing structure or the costs of reconstruction should their house suffer damage from a natural disaster. Equity considerations argue for providing this group with low interest loans and grants for the purpose of adopting cost-effective RRMs or for them to relocate to a safer area. Since low-income victims are likely to receive federal assistance after a disaster, subsidizing these mitigation measures can also be justified on efficiency grounds.

Lower Deductibles Tied to Mitigation

An alternative way to encourage consumers to adopt mitigation measures is to change the nature of their insurance coverage rather than reducing the premium. More specifically, the insurer could offer a lower deductible to those who adopt mitigation at the same or lower price than if they had decided not to invest in the RMM. Such a program is likely to be very attractive given the empirical and experimental evidence that suggests that consumers appear to dislike deductibles even though they offer considerable savings in premiums (Johnson *et al.*, 1993).

CONCLUSIONS AND SUGGESTIONS FOR FUTURE RESEARCH

This article makes the case for a new approach for dealing with catastrophic accidents and disasters that takes advantage of recent developments in IT and the emergence of new financial instruments to deal with non-diversifiable risks. These two major changes open up opportunities for residents and firms to undertake cost-effective loss protection measures while at the same time providing a financial cushion to insurers concerned with catastrophic losses that will lead to insolvency.

A strategy for undertaking research in this area suggests analyzing the impact of disaster or accidents of different magnitudes on a set of structures, industrial plants or their equipment. In order to determine expected losses and the maximum probable losses arising from worst case scenarios, it may be necessary to undertake long-term simulations. For example, one could examine the impacts of earthquakes or hurricanes of different magnitudes and intensities on the losses to a community or region over a 10 000 year period. In the process one could determine expected losses based on the probabilistic scenarios for each of these disasters as well as the maximum credible loss during this period based on a worst-case scenario. By constructing large, medium and small representative insurers with specific balance sheets, types of insurance portfolios, premium structures and a wide range of potential financial instruments, one could examine the impact of different disasters and accidents on the insurer's profitability, solvency and performance through a simulation. Examples of the application of such an approach to a model city in California facing an earthquake risk and one in Florida facing a hurricane risk can be found in Kleindorfer and Kunreuther (1999a,b).

There is considerable uncertainty in estimating the probability of disasters of different magnitudes occurring and the magnitude of the resulting losses. Future studies could examine how one can incorporate these uncertainties in an analysis as to which mitigation measures are cost effective and how to price new financial instruments. Will mitigation reduce the uncertainty of future losses, so that these new financial instruments could be more easily marketed to investors?

This is a very exciting time for key stakeholders in the public and private sectors to explore new opportunities for dealing with catastrophic risks. If insurance can be used as a catalyst to bring other interested parties and new financial instruments to the table, it will have served an important purpose in helping both the insurance industry and society deal with the critical issue of reducing future losses, and providing protection against natural, technological and environmental disasters.

SCEP (Study of Critical Environmental Problems)

International environment assessments have become important policy tools in recent years. See, for example, the various Intergovernmental Panel on Climate Change (IPCC) assessments. The SCEP (1970) and the Study of Man's Impact on Climate (SMIC) (1971) (*see* SMIC (Study of Man s Impact on Climate), Volume 4) were forerunners of this approach with respect to large-scale long-term issues, and are of considerable historical interest. A principal motivation for these particular studies was to provide delegates to the Stockholm Conference on the Human Environment with syntheses on these emerging scientific issues.

Recognizing the need for focussing international attention on the global environment, Professor Carroll Wilson of the Massachusetts Institute of Technology (MIT) organized a conference to consider some of the more critical environmental problems of the world. The month-long meeting took place in Williamstown, MA, in July 1970, and involved some 40 scientists and professionals. The 319 page report of the conference was published by the MIT Press (SCEP, 1970).

The focus of the study was on global problems, and was primarily concerned with the effects of pollution on mankind through changes in climate, ocean ecology, and in large terrestrial ecosystems. In order to assess these effects it was clear that an extensive data base should be prepared covering all types of data – scientific, technical, economic, industrial, and social. Such a data base was assembled, and (though it was considered deficient in many respects) it marked a major step forward in this kind of study.

The final report summarizes, among other things, the climatic impacts of mankind's activities, some of the ecological effects, the impacts of industrial products and pollutants, problems of disposal of domestic and agricultural wastes, and energy consumption. The part that seemed to have attracted the most public attention was the possibility of weakening the protective ozone layer in the stratosphere by large eets of high ying (supersonic) aircraft.

Throughout the report there is an expression of the dire need for more good information and further analysis, and it stresses the importance of monitoring the many factors that govern mankind's existence on our planet.

Scientific Responses in an Era of Global Environmental Change

see Scientific Responses in an Era of Global Environmental Change (*Opening essay*, **Volume 4**)

SCOPE (Scientific Committee on Problems of the Environment)

SCOPE, is one of the scientific committees of the International Council for Science (ICSU) (*see* ICSU (International Council for Science), Volume 4). The mandate of SCOPE is to assemble, review and assess the information available on human-induced environmental changes and the effects of these changes on people and the biosphere; to assess and evaluate the methodologies of measurement of environmental parameters; to provide an intelligence service on current research; and by the recruitment of the best scientific information and constructive thinking, to establish itself as a corpus of informed advice for the benefit of centers of fundamental research and of organizations and agencies operationally engaged in studies of the environment. SCOPE acts as the interface between the science and the decision-making spheres, providing analytical tools to promote sound management and policy practices. Many of the SCOPE syntheses of major environmental issues were published by John Wiley & Sons Ltd., Chichester, UK. In the context of global environmental change, SCOPE 29 (The Greenhouse Effect, Climatic Change and Ecosystems, 1986) provided the intellectual framework for many of the policy debates on greenhouse gas emissions that have taken place over the last decade. Similarly, SCOPE 55 (Functional Roles of Biodiversity: A Global Perspective, 1996) has been a basic reference in the development of the United Nations Convention on Biological Diversity.

At present, representatives of 40 member countries and 22 International Unions and Scientific Committees participate in the work of SCOPE, with scientists from around the world contributing their time and expertise to the projects in the scientific program. SCOPE is governed by a General Assembly, which meets every 3 years. Between Assemblies, SCOPE's activities are directed by an Executive Committee, and managed by an Executive Director, whose office is at 51 Boulevard de Montmorency, 75016 Paris, France (Fax: +33 1 4288 1466, E-mail: secretariat@icsu-scope.org).

Seismic Risk (and Risk Assessment)

Chen Yong
China Seismological Bureau, Beijing, China

A key question that must be addressed in earthquake disaster reduction is: how much loss might a city or a region suffer in future earthquakes? There are two components comprising the basic structure of a loss estimate study: (1) the seismic hazard analysis, involving the identi cation and quantitative description of strong ground motion caused by the future earthquakes, and (2) the seismic risk analysis, involving the vulnerability analysis of buildings and other facilities to earthquake damage and the losses that may result from this damage.

Seismic hazard (Box 1) describes the potential for dangerous, earthquake-related natural phenomena such as ground shaking, fault rupture, or soil liquefaction. These phenomena could result in adverse consequences to society, such as the destruction of buildings or the loss of life. *Seismic risk* is the probability of occurrence of these consequences. The output of a seismic hazard analysis could be a description of the intensity of shaking of a nearby magnitude-eight earthquake, or a map which shows the level of ground shaking in various parts of the country that have an equal chance of being exceeded. The output of a seismic risk analysis could be the probability of damage (in some unit of currency) from a nearby magnitude-eight earthquake, or the probability of fatalities due to seismically induced nuclear power-plant accidents. Seismic risk is a probabilistic expression of the product of seismic hazard

Box 1 Definitions of seismic hazard, vulnerability and seismic risk

Earthquake hazard is defined as the probability that a certain value of a macroscopic intensity or of a ground motion parameter (i.e., particle acceleration, velocity and displacement) will not be exceeded at a specific site in a specific period of time.

Vulnerability is the expected degree of loss within a defined area resulting from the occurrence of earthquakes, vulnerability is expressed on a scale from 0 (no damage) to 1 (full damage).

Seismic risk is the expected degree of losses caused by earthquakes, and therefore the product of seismic hazard and vulnerability:

$$\text{Risk} = \text{Hazard} \times \text{Vulnerability}$$

Elements at risk include the number of persons, the value of properties, the level of economic activities such as public service *et al.*, and so on in a given area.

and its consequences. One needs to know the seismic hazard in order to calculate the seismic risk. If not already known, defining the seismic hazard becomes part of the risk estimation process.

Quantification of earthquake disasters is the basis for the reduction of natural disasters and the risk management of which the seismic hazard analysis and the seismic risk assessment are the key scientific problems (Figure 1).

Most earthquake loss studies use an inventory approach in which predicted damages in various categories of structures and facilities in a concerned region are estimated and added together to obtain the total estimated loss for particular intensity ranges (ATC, 1985). Such an approach requires a detailed inventory database of the structures and facilities in the region, which is not always readily available in many regions of the world. There is an alternative means of estimating earthquake losses based on several macroeconomic indices such as the gross domestic product (GDP) and population (Chen *et al.*, 1998). Based

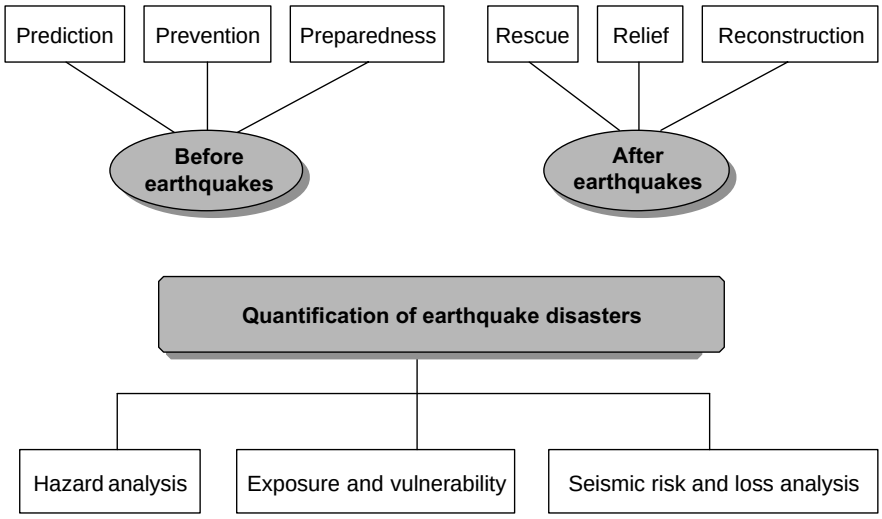

Figure 1 Quantification of earthquake disaster is essentially a scientific problem

Table 1 Twenty countries or regions of the world with the highest expected loss in the next 50 years (exceeding 10% probability) (population and GDP data are from a report of the World Bank (1998))

Region	Population in 1996 (million)	GDP in 1996 (billion US$)	Loss (billion US$)	Loss per year (billion US$)
World	5678	28 584	1181	22.6
Japan	126	4600	354	7.1
China (Mainland)	1218	805	125	2.5

Italy	57	1208	40	0.8
Greece	10	123	40	0.8
Mexico	97	335	29	0.6
Philippines	72	84	22	0.4

Table 1 (*continued*)

Region	Population in 1996 (million)	GDP in 1996 (billion US$)	Loss (billion US$)	Loss per year (billion US$)
Turkey	63	181	19	0.4
Chile	14	52	18	0.4
Argentina	35	294	18	0.4
India	939	356	18	0.4
Colombia	34	64	17	0.3
Pakistan	134	65	16	0.3
Russia	148	440	16	0.3
Peru	24	61	15	0.3
Iran	61	111	11	0.2
Venezuela	23	67	9	0.2
Afghanistan	21	10	7	0.2

on the published earthquake loss data during 1980–1995, the relations between GDP and earthquake loss have been formulated empirically for several intensity ranges. The world's land surface was divided into unit cells $0{\bullet}5 \times 0{\bullet}5^{\circ}$ in size; then the GDP of each cell was apportioned based on its population and the GDP and population of the region to which it belongs. The predicted seismic loss of the cell was then estimated from the seismic hazard probability function, its GDP, and the empirical relation between GDP and seismic loss. Employing readily available socioeconomic data as the basis for the vulnerability analysis, the method enables us to obtain seismic loss estimates for regions without a detailed inventory of exposed structures or the required collateral geological information. Seismic loss estimates can also be upgraded easily with socioeconomic data for the rapidly developing areas of the world.

Table 1 shows the expected earthquake loss in selected countries or regions. In the last two decades, property damage is estimated at \$25–100 billion resulting from natural disasters (including earthquakes). Table 1 indicates that the average earthquake loss rate in the future 50 years is about US\$20 billion year^{-1}, which is much higher than the loss in the past two decades. This is because the world today is becoming increasingly vulnerable to the threat of natural hazards. Rapid growth is bringing with it increasing complexity, more extensive systems of infrastructure, dense populations and excessive demands on the immediate environment and essential natural resources.

SMIC (Study of Man's Impact on Climate)

International environment assessments have become important policy tools in recent years. See, for example, the various Intergovernmental Panel on Climate Change (IPCC) assessments. The Study of Critical Environmental Problems (SCEP) (1970) (*see* SCEP (Study of Critical Environmental Problems), Volume 4) and the SMIC (1971) were important forerunners of this approach with respect to large-scale long-term issues, and are of considerable historical interest. A principal motivation for these particular studies

was to provide delegates to the Stockholm Conference on the Human Environment (held in 1972) with syntheses on these emerging scientific issues.

Following the highly successful SCEP in 1970, it was decided to hold a more in-depth study of a special problem that was of growing concern, inadvertent climate modification due to mankind's increasing activities. It was organized by Professor Carroll I Wilson of the Massachusetts Institute of Technology (MIT) and hosted by the Royal Swedish Academy of Sciences at its conference center in Wijk, near Stockholm. It took place for three weeks during July 1971, and involved 30 scientists from 14 countries.

The 308 page report of the meeting, published by the MIT Press (SMIC, 1971), covers what we knew at that time about the Earth's climate system, a brief description of how the climate has changed in the past, and how mankind is changing the climate now. Among the activities that are most likely to affect the global climate are the changes of the land surface due to agriculture and deforestation, the addition of smoke and other particles (which cause cooling), and the addition of vast amounts of CO_2 to the atmosphere from the burning of fossil fuels (which cause warming due to the greenhouse effect).

Although there was considerable discussion about which of the last two opposing effects might dominate, the final report does not answer the question. It states in part: It is clear to us that without additional research and monitoring programs, the scientific community will not be able to provide the firm answers which society may need if large-scale, and possibly irreversible, inadvertent modification of the climate is to be avoided .

Social Assessment

Robert Goodland
World Bank, Washington, DC, USA

Social assessment, a process designed to elucidate the societal relationships of a country and the structure of society, embraces social appraisal (SAp) and social impact assessment (SIA). SAp is broader than and overlaps with SIA. SAp seeks to understand the socio-cultural and demographic characteristics of populations likely to be affected by a project, SIA predicts the negative social impacts likely to accrue from a proposed project, and seeks to prevent or mitigate them.

Social assessment (SA) seeks to understand the societal relationships of a country, the structure of its societies, their cultures, the wishes of their people. This is a subset of *national social analyses*, akin to the series of National Environmental Action Plans and similar national environmental diagnoses, which, despite the name, first identify national environmental priorities, and second, seek to address them.

SA looks beyond project-induced impacts, and towards development effectiveness of projects. SA seeks to ensure that positive social development outputs are achieved by the project. Environmental assessment (EA) remains more impact oriented than SA, but is moving toward achieving a net improvement of the environment with the project, beyond mere mitigation of known impacts.

SAp (social appraisal) is defined as the socio-cultural and demographic characteristics of populations likely to be adversely affected by a proposed project, the social organization of productive activities in the project area, the cultural acceptability of project design, its compatibility with intended beneficiaries, and the social strategy for project implementation. Therefore, the terms SA, social analysis and SAp overlap and are partly focused on identification of national social characteristics, or those of the affected people, and national social priorities, and by implication their fulfillment. These terms also contain the sense of identification of the potentially adverse social impacts of project design, but are not confined only to impact mitigation. SA tends to be more at the individual project level; social analysis is more macro or even national in scope.

SIA is a narrower concept, which is falling into disuse. SIA used to be the identification, prevention, minimization, and mitigation of potentially adverse impacts of a proposed project on human society, carried out as part of project design, closely parallel to EA. SA is becoming a tool to monitor the social impacts of a project during implementation. SA as a monitoring tool allows adaptation or restructuring to ensure that intended social development impacts are indeed achieved. This contrasts with EA which rarely leads to project restructuring or even adaptation of the project after construction. Clearly, effective SA can be achieved only after knowing as much as possible about the socio-cultural characteristics of the country, or at least of the project area.

The reason for overlap of these terms is that social dimensions are often specific to the society surrounding a project. Environmental impacts are biophysical and often less site specific. SO_x air pollution, for example, arises

from specific sources (e.g., from a high-sulfur coal thermal electricity generating plant) and is more independent of the immediate environment into which the sulfur gases are released. Human lungs have similar tolerances for inhaling sulfur dioxide, irrespective of their social characteristics. Social analysis does not focus only on the prediction of adverse impacts and their mitigation to the extent that EA still does. That is why SIA has become rare in the terminology of social analysis. Social analysis takes the broader approach of understanding the social fabric, diagnosing the social map, and assessing the willingness of stakeholders to participate in the proposed project.

Sectoral SAs are clearer; they address the whole sector, ranking all potential projects according to their social acceptabilities, well before a single project is identified. Only the best project from the sectoral ranking is then later taken up and designed. Sectoral SA assesses the social impacts of sectoral changes.

The main topics comprising the sociological dimension of economic development include poverty alleviation, social welfare, social justice, equity, vulnerable groups, gender balance, human and social sustainability, culture, education, resettlement, unemployment, land tenure, common property and open access resources, abolition of slavery, debt peonage, United Nations International Labor Organization (UN ILO) conventions, and slum upgrading.

Social Impact Assessment

Frank Vanclay
Charles Sturt University, Wagga Wagga, Australia

Social impact assessment (SIA) is the process of analyzing and managing the intended and unintended consequences of planned interventions on people so as to bring about a more sustainable and equitable biophysical and human environment. SIA is more than a technique or tool, it is a philosophy about development which considers the negative effects of development, the goals of development, and the processes of development. The objective of SIA is to ensure that development that does occur maximizes the bene ts and minimizes the costs, especially those borne by the community and often not adequately taken into account by decision-makers, regulatory agencies and developers. By identifying impacts in advance, better decisions can be made about which projects should proceed, and mitigation measures can be developed to minimize the harm from a speci c project or policy.

SIA

SIA has three different levels of meaning: (1) a paradigm, field of research and practice, or discipline; (2) a methodology or environmental management instrument; and (3) a discrete step (or specific task) within a methodology. The concept of SIA is applied at different levels, often with some people failing to appreciate that other meanings or levels exist.

As a field of research and practice (or paradigm), SIA consists of a body of knowledge, techniques, and values. Various individuals identify themselves as SIA professionals, or list SIA as one of their disciplines or specialty areas. There is a community of scholars engaged in research and practice of SIA. These people practice the methodology of SIA and undertake associated social and environmental research to inform the practice of SIA.

As a methodology or instrument, SIA is the process (series of steps) that SIA professionals follow in order to assess and manage the social impacts of planned interventions. That process will be described in this entry, and is perhaps the most common understanding of the term, SIA. It should be noted, however, that the discipline of SIA would consider that SIA practitioners have a professional responsibility, or duty of care, that extends beyond the mere undertaking of the SIA process.

In its narrowest meaning, SIA refers to the prediction of the likely social impacts of a proposed project – one of the tasks or steps within an environmental assessment framework. SIA professionals tend not to define SIA this way, although frequently this is how SIA is seen by other environmental professionals. While the prediction of impacts is an important step, it should not be seen as defining of SIA because SIA, as a paradigm or process, is of greater use to governments and communities (and developers) in its role of managing change and mitigating impacts, than in the simple prediction of impacts. Many negative social impacts can be easily lessened or averted by effective participatory processes, implementation of remedial measures, or improved design.

There has been debate over the precise meanings of terms such as SIA, social analysis, social assessment, social appraisal, social monitoring, and social soundness analysis. Much of this debate has been ill-informed, in particular failing to appreciate the three levels of meaning of SIA as highlighted above. New terminology has developed partly in response to changing ideologies, to promote a particular ideological position, or to escape previous poor practice. But a rose is a rose by any other name. Inventing new terms doesn't resolve the situation and, worse, it inevitably creates confusion. It is probably better to decry poor practice, and to argue for a better understanding of the concept as a whole.

Despite the plethora of names, albeit with their nuances, and although there is not a generally-accepted definition, there is widespread agreement within the SIA community about the concept in principle. Such an understanding can be defined as:

> SIA is the process of analyzing (predicting, evaluating and re ecting) and managing the intended and unintended consequences on the human environment of planned interventions (policies, programs, plans, projects) and any social change processes invoked by those interventions so as to bring about a more sustainable and equitable biophysical and human environment.

The important features of this understanding of SIA are that:

1. The goal of impact assessment is to bring about a more ecologically and socially sustainable environment. Impact assessment, therefore, must be about promoting community development and empowerment, strengthening capacity building skills, and developing social capital.
2. The focus of concern of SIA must be better outcomes of development, not just the identification or amelioration of negative or unintended outcomes. Assisting communities to identify development goals, and ensuring that positive outcomes are maximized, are perhaps more important than minimizing harm from negative impacts.
3. The good practice of SIA must include consideration of the second and later order impacts. In order to do so, the discipline of SIA needs to develop a good understanding of impact pathways – that is, the chains of events that lead to impacts. The discipline needs to be aware of the iterative processes that stimulate social change processes that cause social impacts as well as the processes by which changes to the biophysical environment cause social impacts.
4. It is implicit that social and biophysical impacts (and the human and biophysical environments) are interconnected.
5. In order for the discipline of SIA to learn and grow, there must be analysis of the actual impacts that occurred as a result of past activities – SIA must be *re exive* (self critiquing) and evaluative of its theoretical bases as well as of its practice.
6. The methodology of SIA can be applied to a wide range of planned interventions, and can be undertaken on behalf of a wide range of actors, and not just within a regulatory framework.
7. The process of SIA includes the adaptive management of impacts, projects and policies and therefore needs to be involved (at least considered) in the planning of the project or policy from inception.

THE FOCUS OF SOCIAL IMPACT ASSESSMENT

SIA arguably originated with the 1969 National Environmental Policy Act of the USA (NEPA) (see Interorganizational Committee, 1994; Vanclay, 1999). However, the NEPA understanding of SIA is narrowly conceptualized, tending to consider SIA only at the project level, and only considering first-order impacts, the role of SIA being limited to predictive assessment within the context of a regulatory framework. This limited understanding of SIA pervades the legislation (and agencies) of other nations that modeled their legislation on NEPA.

In contrast, nowadays most SIA professionals consider that SIA is more than a technique or step, rather, it is a philosophy about development and democracy. As such, ideally it considers pathologies of development (i.e., harmful impacts), goals of development (such as poverty alleviation), and processes of development (e.g., participation, capacity building) (based on an idea from Robert Goodland).

An important feature of SIA is the professional value system that a practitioner should uphold. While all impact assessment practitioners should have a commitment to sustainability as well as to scientific integrity, they should also uphold an ethic that advocates openness and accountability, fairness and equity, and defends human rights. The role of SIA goes far beyond the *ex-ante* (in advance) prediction of impacts – SIA, in relation to planned interventions, also encompasses: empowerment of local people; enhancement of the position of women, minority groups and other disadvantaged members of society; development of capacity building; alleviation of all forms of dependency; increase in equity; and a focus on poverty reduction. SIA needs to counterbalance the econocratic and technocratic models that characterize the thinking of many development professionals and their agencies.

SIA can be undertaken in different contexts, and for different purposes, creating some difficulties in defining or evaluating SIA. The nature of an SIA done on behalf of a multinational corporation as part of that company's internal procedures (some sort of social environmental management system or environmental audit) may be very different to an SIA undertaken by a consultant in compliance with regulatory agency or funding agency requirements, or an SIA undertaken by development agency officials interested in ensuring best value for their country's development assistance. These, in turn, may be very different to an SIA undertaken by staff or students at a local university on behalf of the local community, or an SIA undertaken by the local community itself. Each of these roles of SIA is worthwhile, and none must pretend to be the definitive statement. Evaluation of an SIA needs to consider the purpose or role that was intended by the SIA.

It could be argued that NEPA-based conceptualizations of SIA are related to protecting individual property rights, with clear statements of impacts required to ensure that individual rights are not transgressed. Where these rights are violated, SIA could be seen as contributing to mitigation and compensation mechanisms. To that extent, SIA tends to concentrate on negative impacts. In other contexts, perhaps there is less need to be concerned about negative impacts on small groups of individuals or on individual property rights. Instead there should be greater concern with maximizing social utility and development potential, while ensuring that such development is generally acceptable to the community, equitable and sustainable. The improvement of social well-being of the wider community should be explicitly recognized as an objective of development projects and plans, and as such should be an indicator considered by any form of impact assessment. However, awareness of the differential distribution of impacts among different groups in society, and the impact burden experienced by vulnerable groups in the community is of prime concern.

WHAT ARE SOCIAL IMPACTS?

Those who perceive SIA as meaning only the prediction step within an environmental assessment framework tend to have a limited view of what social impacts are. They tend to see social impacts only in terms in demographic changes, job issues, financial security, impacts on family life, etc. This limited view of SIA also creates demarcation problems about what the social impacts to be identified by SIA are, versus what is considered by health impact assessment, cultural impact assessment, heritage impact assessment, aesthetic impact assessment, or gender impact assessment.

The SIA community of scholars, on the other hand, considers that all issues that affect people, directly or indirectly, are pertinent to SIA. For example, changes to the environment that affect people are social impacts. In order to address this issue and to escape the confusion about the limited understanding of SIA and of social impacts, there has been some discussion about whether there needs to be a new field called human impact assessment. However this would only lead to more terminology proliferation.

A convenient way of conceptualizing social impacts is as changes to one or more of the following (based on an idea by Audrey Armour):

- people's way of life – that is, how they live, work, play and interact with one another on a day-to-day basis;
- their culture – that is, their shared beliefs, customs, values and language or dialect;
- their community – its cohesion, stability, character, services and facilities;
- their political systems – the extent to which people are able to participate in decisions that affect their lives, the level of democratization that is taking place, and the resources provided for this purpose;
- their environment – the quality of the air and water people use; the availability and quality of the food they eat; the level of hazard or risk, dust and noise they are exposed to; the adequacy of sanitation, their physical safety, and their access to and control over resources;
- their health and wellbeing – where health is understood in a manner similar to the World Health Organization definition: a state of complete physical, mental and social wellbeing and not merely the absence of disease or infirmity ;
- their personal and property rights – particularly whether people are economically affected, or experience personal disadvantage which may include a violation of their civil liberties;
- their fears and aspirations – their perceptions about their safety, their fears about the future of their community, and their aspirations for their future and the future of their children.

A FRAMEWORK FOR UNDERSTANDING IMPACT PATHWAYS

Figure 1 provides a conceptual framework for understanding the ways social and biophysical impacts are interdependent and how all impacts are ultimately social impacts. People experience impacts and/or they give a value to the environment and to the preservation of species. The major difference between Environmental Impact Assessment (EIA) and SIA lies in the pathways through which impacts are generated, and the different levels of attention given to those pathways or impacts by different groups of impact assessment professionals. Impacts are produced either through the physical environment (pollution that threatens health; noise that reduces the quality of life) or

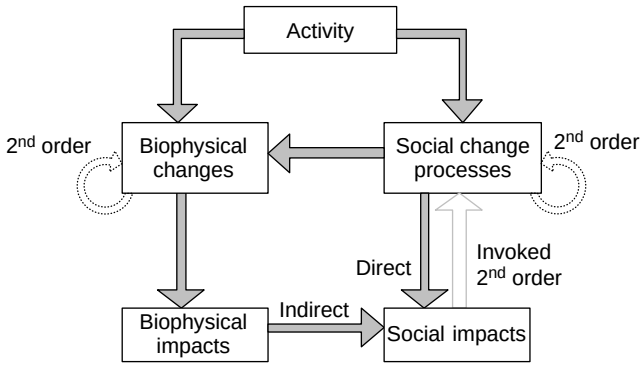

Figure 1 Linkages between biophysical and social impacts. (Reproduced in slightly modified form, with permission of Slootweg *et al.*, 2001)

through the social environment (in ux of foreign tourists creating anxiety in a local community, creation of employment that raises the standard of living, etc.).

In this framework, which is developed more fully in Slootweg *et al.* (2001), direct and indirect social impacts are distinguished. Direct social impacts result directly from an intervention, and may be the intention of specially designed activities to in uence the social setting (intended impacts), or may unintentionally result from the activities. Indirect social impacts are a result of changes in the biophysical environment. Biophysical changes can affect the functions the environment provides for people. For example, if an activity causes land degradation, one of the biophysical impacts can be that the productive capacity of the land will decrease. The resulting reduction of income from farming activities is an indirect social impact. Or, dredging activities may lead to increased turbidity of water, which may alter the ecology of a river ecosystem that may reduce the fish population that forms the nutritional basis for the local people. Other physical changes may have effects on disease organisms or disease vectors such as mosquitoes, rats and snails, which may lead to health impacts. It should be noted that social change processes also cause biophysical changes, which may lead to further biophysical and social impacts.

Figure 1 also differentiates *social change processes* from *social impacts*. Confusion exists in the SIA literature in relation to the lack of distinction between the social change processes that are caused by projects or policies, and the social impacts that are actually experienced. Strictly speaking, an impact must be experienced (felt) by an individual, family or household, or a community or society, whether in corporeal (physical) or perceptual terms. To a large extent, social impacts are socially constructed – they are perceived differently by different people through socially-mediated understandings of what is normal or natural, or to be expected or even acceptable. A social change process, on the other hand, is a process of change that may lead to the experience of impacts in certain circumstances depending on the social context (groups, nations, religions, etc.). Thus, resettlement (relocation of a community), for example, is a social change process, not a social impact. However, it may well *cause* social impacts such as anxiety and stress, uncertainty, disruption to daily living, potential change to family structure, as well as reduction in the feeling of homeliness. Similarly, demographic changes such as a large population increase (or decrease), the presence of seasonal workers, and/or weekend residents, should be considered as social change processes rather than as social impacts. They are not impacts in themselves, but rather they cause other impacts,

Demographic processes	**Institutional processes**
In-migration	Globalization (the incorporation of the local into the global) loss of autonomy of decision making at the local level
Out-migration	Decentralization
Presence of newcomers	Institutionalization and bureaucratization
Presence of (temporary) construction workers	
Presence of seasonal residents	**Empowerment Processes**
Presence of weekenders	Democratization
Presence of tourists	Capacity building
(Involuntary) resettlement	
Rural to urban migration	**Socio-cultural processes**
Urban to rural migration	Globalisation (the incorporation of the local into the global) loss of cultural identification; macdonaldization, coca-cola development; cultural hegemony
Economic processes	Marginalization and exclusion (the process of creating marginal groups in society, which as a result are denied access to services)
Diversification of economic activities	Segregation (the process of creation of social difference within a community)
Concentration of economic activity	
Impoverishment	**Other processes**
Inflation	
Fluctuation in currency	
Job loss/retrenchment	
Tourism	
Geographical processes	
Conversion of landuse	
Urbanization	
Increased transportation and rural accessibility	
Physical splintering (such as caused by major roads)	

Figure 2 Categories of social processes with examples

Individual and household level	Community and institutional level
1. Death, death of family member 2. Arrest, imprisonment, detention, torture, intimidation, or other abuse of human rights inflicted on an individual 3. Reduced availability of food and adequate nutrition 4. Reduced control over fertility (loss of availability of contraception, and gender dis-empowerment to make decisions about birth control) 5. Reduced level of health and fertility (ability to conceive) 6. Reduced mental health, increased stress, anxiety, alienation, apathy, depression 7. Uncertainty about impacts, development possibilities, or about own life or the lives of those one is responsible for, as a result of social change 8. Changed responsibilities 9. Loss of aspirations about the future for self or children 10. Reduced personal safety, increased hazard exposure 11. Experience of stigmatisation and deviance labelling 12. Reduction in perceived quality of life, subjective well-being, self esteem, self image 13. Reduction in standard of living, level of affluence 14. Worsening of economic situation, level of income, property values 15. Decreased autonomy, independence, security of livelihood 16. Change in employment, or becoming unemployed 17. Decrease in occupational opportunities, potential diversity, flexibility in employment 18. Moral outrage, blasphemy, religious affront, violation of sacred sites 19. Upsetness (objection/opposition) to project, NIMBY 20. Dissatisfaction due to failure of a project to achieve heightened expectations 21. Annoyance (dust, noise, strangers, more people) 22. Disruption to daily living, way of life (having to do things differently) 23. Reduction in environmental amenity value 24. Reduced perception of communityness, community cohesion, integration 25. Loss of community identification, connection to place (do I belong here?) 26. Changed attitude towards local community, level of satisfaction with the neighbourhood 27. Disruption to social networks 28. Alteration in family structure, family stability, divorce 29. Increased family violence 30. Deteriorating gender relations within the household 31. Changed cultural values 32. Worsening perceptions about personal health and safety, risk, fear of crime 33. Reduced leisure opportunities 34. Reduced quality of housing 35. Reduced feeling of homeliness 36. Increased density and crowding 37. Reduced aesthetic quality, outlook, visual impacts 38. Increased workload, amount of work needed to be undertaken to survive/live reasonably 39. Inability to meet obligations to living elders or ancestors	1. Death of people in the community 2. Violation of human rights, freedom of speech 3. Reduced adequacy of physical infrastructure (water supply, sewerage, services and utilities) 4. Changed demographic structure 5. Reduced adequacy of community social infrastructure, health welfare education libraries etc. 6. Reduced adequacy of housing in the community 7. Increased workload on institutions, local government, regulatory bodies 8. Diminished cultural integrity (continuation of local culture, tradition, rites) 9. Loss of rights over, and access to, resources 10. Destruction of, or other negative influences on, heritage and other sites of archaeological, cultural, or historical significance 11. Loss of local language or dialect 12. Profanization of culture 13. Increased inequity (economic, social, cultural) 14. Increased concern about social justice issues in relation to minority or indigenous groups 15. Worsening gender relations in the community 16. Decreased economic prosperity 17. Increased dependency, reduced autonomy, reduced diversity, decreased viability of the community 18. Increased unemployment level in the community 19. Loss of other options (opportunity cost) 20. Increased actual crime 21. Increased actual violence 22. Increased social tensions, conflict or serious divisions within the community 23. Increased corruption, decreased credibility or integrity of government 24. Decreased level of community participation in decision making, loss of empowerment 25. Impact on the social values about heritage and biodiversity 26. Burden of national debt *Source*: Vanclay (1999) (updated)

Figure 3 A listing of potential social impacts

such as a breakdown of the social fabric of the community, or changed perceptions about a community by local residents, and they may place too much pressure on the physical and social infrastructure in a community. Alcohol or other drug use is not a social impact but a process, which, depending on the context, may cause social impacts such as family violence and economic hardship.

Figure 1 displays not only how the physical environment and social impacts are integrated, but also the iterative processes affecting social change processes, and between the experience of impact and further social change.

Part of the reason why many SIA scholars have confused issues of social change processes and social impacts, is because demographic processes such as changes in the size and/or composition of the population are more easily measured than the impacts themselves. Because they provide empirical data, documentation of likely social changes has been more acceptable to technically oriented regulatory agencies. But, social change processes do not always cause negative social impacts. The ultimate experience of an impact is determined by the interaction between the characteristics of the proposed project or policy, the characteristics of the affected community, the nature of any mitigation processes, as well as the characteristics of specific individuals. To assist in understanding the differences between social change processes and social impacts, listings of social impacts and social change processes are presented (see Figures 2 and 3).

Figure 2 presents only a few examples of social change processes, because the number of social change processes is potentially infinite, and the processes vary widely according to the activity being planned. The list of impacts in Figure 3, however, is reasonably complete, although some disagreement may exist about the precise wording and categorization of impacts. In Figure 3, impacts are classified according to the level of experience of impact – that is, whether they are experienced at an individual or household level, or whether they are experienced by the community or society as a whole. Of course, impacts on society as a whole will translate into impacts that will ultimately affect individuals as individuals.

All of the social impact variables must be understood in their sociological context, and, of course, in their local cultural context. Homeliness, for example, does not mean the physical quality of the house, but the social relationships among the occupants of the building, and between them and the building. It is a subjective concept, based on people's perceptions and relating to the meaning and experience people attach to the place where they live and build their home.

The list of impacts in Figure 3 is provided to display the full range of potential social impacts, and to assist people not familiar with SIA to become aware of the full extent of it. In order to identify all the likely impacts of a planned intervention, it is necessary to develop an understanding of the impact chains (causal processes) so that the second and subsequent order impacts will be identified. Figure 3 should not be considered a checklist because a checklist approach tends only to identify first-order impacts.

THE METHODOLOGY OF SIA

There are a number of different models about how SIA should be implemented, and about the order in which the various steps should be undertaken. While there is no universal standard for SIA (although perhaps the US Interorganizational Committee 1994 document comes close), it is appropriate to state that a good SIA does the following (Vanclay, 1999):

- identifies interested and affected peoples;
- facilitates and coordinates the participation of stakeholders;
- documents and analyses the local historical setting in which the project will occur so as to be able to interpret likely responses to the project, and to assess cumulative impacts;
- gives a rich picture of the local cultural context, and develops an understanding of local community values, particularly how they might relate to the planned intervention;
- identifies and describes the activities which are likely to cause impacts (scoping);
- predicts likely impacts and how different segments of the community are likely to respond;
- assists in evaluation and selection of program alternatives (including a no-development option);
- assists in site selection;
- recommends mitigation measures;
- provides suggestions about compensation;
- describes potential con icts between stakeholders and advises on resolution processes;
- develops coping strategies in the community for dealing with residual or non-mitigatable impacts;
- contributes to skill development and capacity building in the community;
- advises on appropriate institutional and co-ordination arrangements for all parties;
- assists in the devising and implementation of monitoring and management programs;
- collects baseline data (profiling) to allow evaluation and audit of the impact assessment process and the project itself.

SIA can be applied at the policy level, at the program level and at the project level. Any planned intervention has a so-called life-cycle of four stages: planning, construction (or implementation), operation and decommissioning (phasing-out). Each of the four phases has its unique

impacts and should be considered separately. Importantly, because of the potential presence of fear, anxiety and speculation, social impacts can also occur not only at the level of a plan, but even when an intervention is just an idea. So, not only is an SIA of a plan required to predict what will happen in the implementation of a plan, an SIA can be desirable in the creation of the plan.

CONCLUSION

SIA, at its ideal, is a process that actively brings about sustainable development that consciously considers social issues. In that respect, it should be considered a process of navigation rather than as a process of prediction. Because of the interrelationship between environmental and social issues, ultimately all impacts, including biophysical impacts, can be considered to be social impacts because they are experienced or valued by humans. In effect, then, SIA is environmental assessment. SIA recognizes the dependency of the human world on the biophysical world, and expresses this dependency in terms of the impacts on humans. Effective SIA requires thorough EIA.

SIA is a process which includes aesthetic impacts, economic impacts, health impacts, heritage impacts, psychological impacts, as well as impacts on political and institutional systems. In short, it covers everything, but reports impacts in terms of what matters, or will likely matter, to people as a result of a planned intervention. For thorough analysis of the impacts, the input of specialists from separate disciplines is required.

SIA can be applied in the context of national environmental regulation or because of the requirements of international donor agencies, but it can also be undertaken by a community to ensure optimality of social goals, or for a corporation to ensure triple bottom-line accounting – financial soundness, environmental soundness and social soundness.

Socially Responsible Investment

Rory O'Brien
University of Toronto, Toronto, Canada

In 1993, upon being elected president of South Africa, Nelson Mandela called for an end to the global economic boycott of his country. The boycott, which was instrumental in pressuring the white regime to open elections to black citizens, was spearheaded since the mid-1970s by a movement to curtail investment in South African industries. At the time, a broad coalition of church groups ghting apartheid promoted the idea that it was not ethical to invest in corporations doing business that supported an unethical political regime. This was not a new idea - Quakers had been refusing to invest in military suppliers, and temperance proponents had been advocating the divestment of stock in alcoholic beverage producers, for over a hundred years. It was, however, the rst time that investment as a tool for social change began to be applied systematically on a large scale.

Over the past several decades, the socially responsible investment (SRI) movement has grown considerably, from being practiced by only a handful of church-based investors, to entering the mainstream of the investment community. In the US, for example, currently one in every seven dollars in the stock market is invested according to the criteria and practices of social investment. This has, and will continue to have, a growing impact on the behavior of corporations, making them more likely to adopt environmentally-sustainable business practices, promote diversity and equality in the workplace, and deal

more fairly with employees, customers, and community stakeholders.

TYPES OF SRI

There are three general manifestations of SRI – *screened investments*, *shareholder activism* and *community investment*, each used in particular circumstances, and often in conjunction with one another.

Screened Investments

Regular professional investors judge whether or not to invest in a stock, based on the economic performance of that company. They use certain criteria, known as screens, which tell them how risky the investment is compared to the potential return. A high debt-to-equity ratio, for example, may be a screen that precludes the investor from buying that stock, since it indicates that the company is burdened with debt servicing and is less exible in its strategic options. So, too, do social investors use screens. The difference is that once social investors finish with the economic screening, they then apply other screens that are based on the social or environmental performance of that company.

There are positive and negative SRI screens. Whenever social investors wish to put their money into companies that are doing good things from a values perspective, they apply positive screens. A particular company might be targeted because it has a good track record of employee relations, or produces a product that is beneficial to the environment, such as solar heating panels. Negative screens, on the other hand, can exclude companies doing bad things from the investor's point of view. One of the more commonly applied negative screens are for the so-called sin stocks, in which conscientious investors will not put their money into companies that deal with tobacco, alcohol or gambling. Others include such activities as child labor, weapons production, and nuclear power.

Shareholder Activism

Ultimate control of a corporation rests with its shareholders, who have the right to submit and vote on proposed resolutions at the corporate Annual General Meeting. Traditionally, most resolutions are formulated by a company's management, and relate to election of directors or major financial decisions such as potential mergers. Increasingly, however, socially responsible investors, particularly coalitions of institutional investors such as progressive pension funds, are likely to present resolutions that direct management to change current policies and practices related to both corporate governance issues (such as executive compensation) and issues of social responsibility (such as the environment). A majority of shareholder votes need not be attained to exert a positive in uence – frequently managers will begin creating improvements based on less than 10% of ballots cast in favor of such resolutions. Indeed, the essence of shareholder action is to enter into constructive dialogue with management, and many changes are induced without resorting to formal shareholder proposals.

Community Investment

Investing in one's own community is a socially responsible way to keep the local economy healthy. Institutions and programs such as credit unions and community loan funds provide the capital for housing and small business development for local citizens, particularly those unable to obtain loans from more conventional sources. Communities with a strong base of local enterprise are less likely to suffer the social disruptions resulting from massive layoffs in one-industry towns.

GROWTH OF SRI

Social investment has developed mostly in the US, Canada and Britain (where it is known as *ethical investment*). Though it is widely acknowledged that SRI investments in Britain and Canada have undergone significant growth in the past several years, only in the US have researchers systematically tracked increases in each of the three aspects of the SRI industry. Figure 1 shows the results of comprehensive surveys of the SRI industry done in 1995, 1997 and 1999. Screened investments have grown the most rapidly, due both to the increase in the number and size of screened mutual funds and also to the success of the media-fueled anti-tobacco campaign. In 1999, over $2 trillion in total was socially invested in the US, accounting for roughly 13% of the $16.3 trillion under professional management in the US. SRI investments, up from $695 billion in 1995, have increased at twice the rate of non-SRI investments.

The growing popularity of SRI can be primarily attributed to the debunking of the popular myth that people investing with social concerns had to be content with a lower rate of return. Recent studies have shown that there is no significant difference between SRI and non-SRI investment returns. In fact, there is evidence that companies practicing social responsibility actually perform better than others over the long term. Since its inception in 1991, the Domini 400 Social Index, an American index for tracking socially-screened corporations, has had a slightly higher rate of return than the unscreened Standard and Poor 500 Index.

EFFECT ON CORPORATE PERFORMANCE

While it is clear that values-based screening has become an important factor in the purchase of stock, its impact on

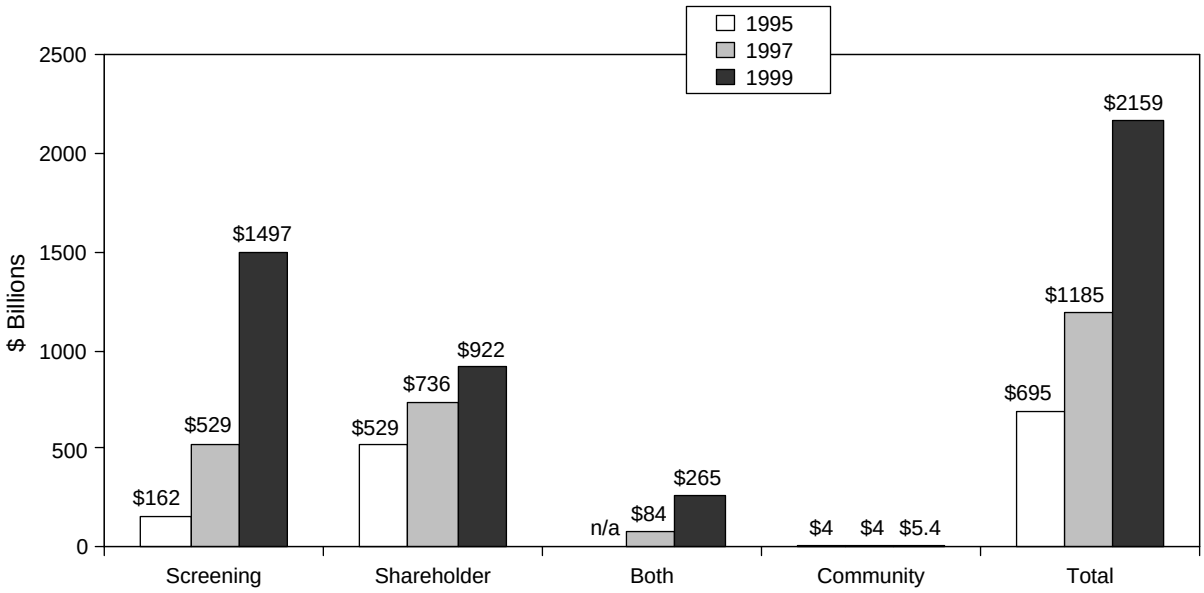

Figure 1 Growth in SRIs in the US 1995–1999 (reproduced from Social Investment Forum, 1999 with permission). Portfolios that both screen and conduct shareholder advocacy include $84 billion of assets in 1997, and $265 billion in 1999. In 1995, any portfolios involved in both screening and shareholder advocacy assets are included in screening. The calculation for total is: total = screening + shareholder + community – both

corporate social performance to date is less clear. There are increasing indications, however, that the effects are beginning to be realized. SRI screens have become valuable benchmarks for corporate leaders; companies are now adopting corporate codes of conduct, such as the Coalition for Environmentally Responsible Economies principles (*see also* Green Investment, Volume 4), which often form the basis for screens. A growing number of advocacy groups, such as Greenpeace, are starting to ally themselves with shareholder activist organizations as part of their issue campaigns, successfully targeting larger institutional investors, such as pension funds, for support. To date, the changes most frequently negotiated involve greater disclosure on activities and their effects, such as reporting on pollution.

Soil Erosion

Harold E Dregne
Texas Tech University, Lubbock, TX, USA

There is good presumptive evidence that soil erosion is a long-continuing problem around the world. There also is much anecdotal evidence, particularly of off-site damage due to erosion, such as increased ooding and frequency of dust storms. Direct quantitative measurements of erosion are dif cult and costly to make, which accounts for the lack of good data in many countries. Better understanding of soil erosion processes has allowed construction of good predictive models of soil loss. Progress is being made on developing models relating soil erosion to reduction in soil productivity. High erosion rates do not necessarily mean high losses in productivity. Effective erosion control practices are known for most situations. They usually are not pro table for farmers for the rst few years.

INTRODUCTION

Accelerated water and wind erosion are widely believed to be a serious global problem. There is no doubt about the increase in water erosion that occurred more than 2000 years ago in the eastern Mediterranean countries. Plato noted the brown plumes of muddy water that Grecian rivers carried into the blue Mediterranean Sea. He lamented the loss of soils from the rocky hills of Greece and the threat it posed to food production. The effects of that early erosion still limit crop production around the Mediterranean basin. Human induced (accelerated) wind erosion also has a long history but usually for small areas in arid regions. One common example is villages along the Silk Road in China which have been covered by moving sands from nearby cultivated or overgrazed fields. Wind erosion also occurs in humid regions, such as in coastal Denmark.

EXTENT AND SEVERITY OF SOIL EROSION

Water and wind erosion are, by far, the most important soil degradation processes. Not only does accelerated erosion reduce soil fertility and increase ooding, along with other damage, but it brings an irreversible loss of potential soil productivity. Once soil is gone, it requires hundreds or thousands of years for nature to restore it to its original condition. The consequence, then, is an irreversible wearing away of the soil as long as erosion continues. That irreversibility is why it is better to stop erosion before it has damaged productivity than to wait until significant damage has been done. Water erosion is the principal type of erosion in humid regions. Wind erosion is dominant in arid regions but water erosion can be significant in cultivated land and overgrazed rangelands in semi-arid climates. Of the approximately 1.5 billion ha of cropland in the world, probably 60% or more has experienced some degree of erosion. Sheet erosion is easy to ignore because it does relatively little damage each year. Gully erosion is much less prevalent than sheet erosion. Gullies are proof that severe damage has been done to the land. Mobile sand dunes and more frequent dust storms provide proof that wind erosion has become severe.

Field measurements of water erosion have been made by many countries. Rather costly techniques of catching runoff water and eroded soil from plots are used. A major drawback to using field plots, beside the expense, is the requirement to maintain records of rainfall and runoff for several years. The principal uncontrolled variable is the difference in rainfall from year to year. Even three years is too short to give high confidence in the results. Wind erosion presents an almost insurmountable difficulty in measuring the amount of soil loss. With water erosion, all the water and soil running off a plot can be measured. With wind erosion, no device yet made can collect all of the soil particles in a vertical cross-section of the air at all heights above an eroding field.

EROSION EQUATIONS

Erosion equations based on experimental data and model development are coming into wide use. The equations use data on crops, soils, rainfall, land slopes, and conservation practices to calculate predicted water erosion rates. Similar data, plus wind direction, are part of the wind erosion equation. The equations are used in the United States, where they were developed, to estimate erosion at about 800 000 sites for 5-year erosion inventories. Since the equations were developed under the conditions that exist in the United States, they must be used with caution in places where soils, crops, and weather conditions are different. Local experimental data are needed to check the accuracy of the equations. A few simpler and less accurate soil erosion equations have been developed in other countries.

A very important question that arises among users of erosion data is the effect that levels of erosion have on potential soil productivity. A water erosion rate of 40 tons ha^{-1} does not affect productivity the same on all soils and with all crops. On shallow soils, 40 tons ha^{-1} of soil loss would be considered high because of the thinness of the soil. On a deep soil, 40 tons ha^{-1} would be moderate or even slight erosion. Erosion control practices are needed much sooner on shallow soils than deep ones to protect productivity.

An erosion-productivity impact calculator (EPIC) has been developed to relate erosion by wind or water to potential soil productivity loss. The equation does reasonably well but needs additional validation of the reliability of the results. EPIC requires considerable input data, which is sometimes not available. Improved erosion model development is an objective of many research groups in many countries.

ON-SITE AND OFF-SITE IMPACTS

Soil loss brings two main types of damage: on-site and off-site. On-site damage by water erosion consists primarily of reduction of soil productivity by removal of the nutrient-rich topsoil. Water ow can also wash soil away from plant roots or cover small plants with soil. Off-site damage includes many things, such as increased ooding downstream, sedimentation of reservoirs, pollution of streams and lakes, eutrophication of lakes, and others. For wind erosion, on-site damage is largely done by strong winds and air-borne soil particles shredding of leaves and stems of young plants, called sand blasting. Removal of soil around plant roots and burying field plants also occurs. Off-site damage from the air-borne sand pollutes air downwind,

abrades buildings and other structures, corrodes machinery, lowers air visibility, covers roads, causes respiratory problems, etc.

There are few studies of on-site versus off-site costs of erosion. Those that have been made indicate that those costs are about equal for water erosion. Wind erosion off-site damages were estimated to be about 45 times greater than on-site costs in one large-scale analysis.

EROSION CONTROL

Control practices for water and wind erosion are based on one principle: slow down the rate of water and wind movement over the soil surface. For water erosion, gently sloping or level (bench) terraces are widely used to control soil and water runoff. Terracing has been practiced successfully for more than 1000 years in China, Yemen, Peru, and elsewhere. In addition to controlling erosion, terracing produces more or less level land that is excellent for crop production, especially in drylands, where water retention is important. Once terraces have been constructed, continued maintenance is essential to prevent gully formation and terrace destruction by runoff during heavy rains.

The best way to reduce water and wind erosion is by having a good vegetative cover on the land. Vegetation serves to protect the soil from the direct impact of raindrops, which causes splash erosion and increases susceptibility of the soil to further erosion. It also slows down runoff and holds soil particles in place. Healthy grasslands and forests usually experience very little erosion by wind or water.

Unfortunately, most croplands are barren for extended periods between growing seasons. For that situation, several land management techniques have been devised. Strip cropping, crop rotations, agroforestry, stubble mulching, intercropping, gravel mulching, no-tillage, and minimum tillage represent various ways to reduce both water and wind erosion on croplands. Gravel mulching (spreading gravel over the soil) stops erosion immediately and reduces evaporation but is so labor intensive that the practice is common only in a small area in central China. No tillage and minimum tillage are high technology practices that generally require use of herbicides and a high level of management.

Certain tillage practices are effective in reducing wind erosion for short periods of time by roughening the soil surface. Throughout the world, wind erosion control relies heavily on windbreaks of trees and shrubs on borders of fields. Windbreaks should be oriented at right angles to the dominant wind direction.

Speth, James Gustave

(1942-)

On 21st May 1997 the United Nations (UN) General Assembly confirmed James Gustave Speth for a second 4-year term as Administrator of the United Nations Development Program (UNDP), following his nomination by UN Secretary-General Kofi Annan.

Speth served as Special Coordinator for Economic and Social Affairs under Secretary-General Boutros Boutros Ghali and now serves as Chair of the United Nations Development Group, created as part of the United Nations reforms initiated by Secretary-General Kofi Annan.

Speth, known as Gus, founded the World Resource Institute (WRI) in 1982 and served as its president until January 1993. WRI, based in Washington, DC, is a center for policy research and technical assistance on environment and development issues. Speth was then a senior advisor to President-elect Clinton's transition team, heading the group that examined the US role in natural resources, energy and the environment.

Before founding WRI, Speth served from 1977 to 1981 as a Member and then for 2 years as Chairman of the Council on Environment Quality (CEQ) in the Executive Office of the President. As President Carter's CEQ chairman, Speth was a principal advisor on matters affecting the environment and had overall responsibility for developing and coordinating the President's environmental program. In 1981 and 1982 he was Professor of Law at Georgetown University Law Center in Washington, DC, teaching environmental and constitutional law.

From 1970 to 1977 Speth was senior attorney with the Natural Resources Defense Council, an environment organization he co-founded.

Among Speth's awards are the National Wildlife Federation's Resources Defense Award, the Natural Resources Council of America's Barbara Swain Award of Honor,

the Keystone Center's National Leadership Award, a 1997 Special Recognition Award from the Society for International Development, the 1998 Leadership Award of the Alliance for UN Sustainable Development Programs, the *Ordre National du Lion* of Senegal, and the *Grand Cordon du Wissam Alaouite* of Morocco.

Prior to joining UNDP, Speth organized numerous leadership initiatives on environment and development. In 1991 he chaired a US task force on international development and environmental security which produced the report *Partnership for Sustainable Development; A US Agenda*. In 1990 he led the Western Hemisphere Dialogue on Environment and Development which produced the seminal report *Compact for a New World*. Among his writings is A Post-Rio Compact , which appeared in the Fall 1992 issue of *Foreign Policy*.

Speth graduated *summa cum laude* from Yale University in 1964, attended Oxford University as a Rhodes Scholar and graduated from Yale Law School, where he was a member of the *Yale Law Journal*, in 1969. In 1995 he received an honorary Doctor of Laws degree from Clark University. He served in 1969 and 1970 as a law clerk to US Supreme Court Justice Hugo L Black. He is married to Cameron Speth and they have three children. He was born in Orangeburg, South Carolina in 1942.

MOSTAFA K TOLBA *Egypt*

START (Global Change System for Analysis Research and Training)

START is an international non-governmental framework for building indigenous capacity in developing regions to cope with the scientific and science-related policy aspects of environmental change. It is co-sponsored by the three international global change science programs, the International Geosphere–Biosphere Program, the International Human Dimensions Program on Global Environmental Change and the World Climate Research Program, all of which are programs of the International Council of Science.

START's challenge is to help meet the needs of developing countries with respect to global change science. It does this through the mechanism of regional research networks established in developing regions, which are intended to:

- develop human and institutional capacities in global change science;
- conduct research on regional aspects of global change;
- assess the impacts of regional findings;
- provide information in appropriate forms to policymakers.

Six regional networks and coordinating offices are now operational:

- Pan-Africa (covering Sub-Saharan Africa);
- Mediterranean (including Northern Africa);
- South Asia;
- Southeast Asia;
- Temperate East Asia;
- Oceania.

START also closely collaborates with the existing Inter-American Institute for Global Change Research on activities in the Americas.

START regional networks address the following themes:

- regional climate variability and change;
- changes in composition of the atmosphere;
- land use/cover change and land degradation;
- impacts of global change on terrestrial ecosystems and biodiversity;
- global change and coastal zones, land–ocean interactions and international waters;
- regional assessments of global change impacts.

A major part of START's initial effort has been capacity building in its broadest sense involving a fellowship and visiting scientist program, recognition of talent in developing regions, development of collaborative research networks, and partnerships between regional scientists and the international scientific community. All are research-linked, recognizing that capacity building is best achieved through continual involvement in research.

For further information, see http://www.start.org.

ROLAND FUCHS *USA*

Stockholm and Beyond

Mostafa K Tolba
International Center for Environment and Development, Cairo, Egypt

The 1972 Stockholm Conference on the Human Environment was a turning point in the history of environmental awareness and action. Its Action Plan for Human Environment, the establishment of the United Nations Environment Program that year, and the enthusiasm of non-governmental organizations (NGOs), both at and after

the conference, gave further impetus to the environmental movement and gave it effective expression in the international community.

Before Stockholm, many developing countries were suspicious of environment as a public issue on a global scale. This was partly due to the way environment was de ned in those days - as a question of pollution and its abatement. It was seen as a technical question, amenable to technological, legal and administrative answers. Few today would be satis ed with this restrictive interpretation, which stemmed from the preoccupations of industrialized societies.

Developing countries were, of course, aware of the threats which uncontrolled pollution posed to the world and to themselves. They realized too that their own societies would increasingly have to face problems of pollution. Some leaders, at least, felt that they should avoid the mistakes already committed by the industrialized countries.

They also recognized that environmental concern in the North might have positive economic spin-offs for the South. For example, developing countries might bene t from the resiting of polluting but productive industries, and from replacement of environmentally suspect synthetic products with the natural ones they produced themselves.

Yet many developing countries had misgivings. Some saw environment as a ploy of the rich to prevent developing nations from industrializing, and to keep developing countries supplying the raw materials on which the development and prosperity of the North depended. Some argued that if pollution meant industry, they would welcome it wholeheartedly. More realistically, perhaps some feared that their development ambitions might suffer as industrialized countries diverted aid to the new problem of the environment. If anyone was going to lose out through a concern for the environment, they argued, it should be the rich countries, who were largely responsible for pollution.

Developing countries also feared that environmental concerns would impose extra burdens upon them - for instance, that stringent standards might put up the cost of imported technology and machinery. They suspected that their export trade would be harmed by the environmental regulations industrialized countries were likely to adopt.

All in all, therefore, environment and development were seen as being in con ict. It was feared that a commitment by the international community to environment was likely to detract from its commitment to development.

During early times, people learned that their actions could damage the natural resources by which they lived. Tree cutting, overgrazing and soil erosion undermined agricultural productivity around the Mediterranean, in southern and central China, in India and Central America. Historical records give evidence of early attempts of conservation, religious taboos protecting some species of animals, some forest groves and plants; the use of organic fertilizer and other practices to maintain soil fertility and prevent erosion; the creation of wildlife or natural reserves. But in spite of these efforts, ourishing civilizations disappeared.

The industrial revolution of the latter 18th and early 19th centuries and the 20th century, and scientific and technological revolutions dramatically increased humanity's need for natural resources and its pressure on the environment. Overwhelmingly, this impact has been negative.

Today – as we stand at the beginning of a new millennium – we face an ecological crisis that has assumed planetary dimensions. The problems are so great that they threaten to derail economic development.

The technological advances in the first half of the 20th century raised fundamental questions about the future. Could the globe continue to support its rapidly growing population? And how appropriate was the technology itself? These questions were first debated in scientific circles, but soon caught the attention of the public.

By the late 1950s public concern was rising: people had died in smog episodes in Belgium, the United States and the United Kingdom; lives had been shattered by mercury pollution in Minamata and Niigata, Japan; acidification was killing lakes in Scandinavia and North America; birds were dying from the side effects of pollution; and oil spills had polluted the sea. This concern gathered momentum in the 1960s and culminated in the convening of the United Nations Conference on the Human Environment in Stockholm in 1972.

Founex 1971: A Stepping Stone to Stockholm

In 1971, a panel of experts from both developed and developing countries met in Founex, Switzerland, to clarify the issues and point out the links between development and environment. They identified many serious environmental problems which were largely concentrated in the Third World. The environmental problems of the South are very often the result of extreme poverty and the lack of economic and social development.

For example, it is in the developing countries that water quality, housing standards, sanitation and nutrition are lowest, disease most prevalent and natural disasters most destructive. It is there too that the destruction of vital natural resources – such as soil, vegetation and wildlife – is most alarming, and the impact of a fast growing population most apparent.

The panel also agreed that problems already distressingly familiar to richer countries would emerge in developing ones, perhaps sooner than many realized, as their industry, agriculture, transport and communications expanded. There were differences between the problems of rich and poor countries, but also many shared concerns.

The panel established beyond doubt that developing countries faced vast environmental difficulties of their own.

STOCKHOLM 1971

Growing world concern for the future of the global environment, as most eloquently exemplified by Racheal Carson in *Silent Spring*, was given focus at the United Nations Conference on the Human Environment held in Stockholm 1972. This created the United Nations Environment Programme (UNEP) to act as a catalyst to the nations of the world.

New understanding of the relationship between environment and development emerged from the Stockholm Conference. Firstly, the concept of the environment was expanded. A more holistic approach, encompassing the socio-economic factors which lie behind many of the problems, replaced the old technocratic approach, with its heavy emphasis on the natural sciences and on consequences rather than causes. The link between development and environment was clarified.

The aims of development were also redefined, to make quality of life, rather than a limitless pursuit of material possession, the main criterion of success. Developing countries came to appreciate the need to incorporate environmental considerations into their development efforts. Finally, it was clear that an already complex issue had become even more complex and that the environmental agenda must be expanded.

At the time of Stockholm, Cocoyoc and the World Commission on Sustainable Development there was enthusiasm and progress. In the 1980s various environmental assessments were made, and several environmental conventions and other binding legal instruments were painstakingly developed and agreed.

COCOYOC 1974

Thinking advanced further at the 1974 Cocoyoc Symposium on Patterns of Resource Use, Environment and Development Strategies, which was jointly organized by UNEP and the United Nations Conference on Trade and Development. It agreed on six main points.

First, economic and social factors were often the root cause of environmental degradation. Patterns of wealth, income distribution and economic behavior, both within and between countries, obstructed development and led to inequities.

Second, meeting the basic needs of the world's population was a chief goal for the international community and nation states. The needs of the poorest strata of mankind were particularly urgent, but they must be met without impinging upon the outer limits of the Earth's carrying capacity.

Third, different nations, and groups with them, placed widely differing demands on the biosphere. Access to many cheap natural resources was preempted by the rich. However, it was not only the rich who wasted natural resources: the poor were often left with no option but to destroy them.

Fourth, developing countries must develop their own self-reliant approach to development, rather than following in the footsteps of the industrialized countries.

Fifth, the search for alternative patterns of development and lifestyles, in both developed and developing countries, were the principal means of achieving environmental and development goals.

Finally, this generation must look ahead and not so preempt the planet's limited resources or pollute its life support systems that it jeopardizes the wellbeing – even existence – of future generations.

SUSTAINABLE DEVELOPMENT

At the beginning of the 1970s, the Club of Rome (*see* Club of Rome, Volume 4) formulated the limits to growth' theory. The idea was that the planet's physical limits were being reached. What had seemed infinite to a relatively small human population was now alarmingly finite. If we pushed beyond those limits, the Earth's environment would break down, lose its ability to sustain us and our industries and our agriculture. We would be the end losers.

Of course, the theory is only partly correct – as was shown by later studies, including those of the Club of Rome itself. But it was an eye opener. For we now have the ability to destroy the environment completely. In so doing we would write off the economic machine which feeds six billion people.

The Club of Rome initially assumed that all resources were limited. They pointed to the oil crisis and to the impending dearth of all petroleum products. They pointed out that resources could only be exploited at the margin, and that in most cases we had already crossed the margin of increase. They pointed out that many of the world's fish populations were declining due to overexploitation. They pointed out that more species had been extinguished during the 20th century than in the last million years. Resources that could have sustained a smaller population forever were being snuffed out.

They were right. But they ignored the fact that the Earth still has on essentially infinite supply of sunlight, and that that resource is still largely untapped except through natural means such as photosynthesis and the cycling of water between the oceans and atmosphere. They also ignored the fact that many of Man's economic activities can be effectively altered to make them work with the biosphere instead of in competition.

WORLD COMMISSION ON ENVIRONMENT AND DEVELOPMENT

The World Commission on Environment and Development gave a powerful example of resource depletion in its report *Our Common Future*, published in 1987. The Commission pointed out that most of the new wealth created in the 1980s was created in non-polluting industries. It was the service industries such as information and data which were the hub of present growth.

This growth which works in tandem with the environment is what we call sustainable development'. Sustainable development will be the foundation of economic and social planning in the next century. If it is not, Malthusian laws will take over again. What we see in the Horn of Africa will spread and will take its toll on the whole Earth. Famine in Africa, ooding in South Asia, and the proliferation of small wars are signs of what could happen to a world which fails to regulate its growth according to the constraints of the biosphere.

The 1987 report of the World Commission on Environment and Development, was released at around the same time as UNEP released its own report, *Environmental Perspective to the Year 2000 and Beyond*. The reports are complementary; both were called for by the 1983 Governing Council of UNEP. Both elaborated environmental strategies for agriculture, health, transport, urban planning and other key economic sectors.

At the core of the concept of sustainable development is the requirement that current practices should not undercut future living standards. In other words, present economic systems should maintain or improve the resource and environmental base, so that future generations will be able to live equally well or better. Sustainable development does not require the preservation of the current stock of natural resources or any particular mix of human, physical and natural assets. Nor does it place artificial limits on economic growth, provided that growth is both economically and environmentally sustainable.

Two points, however, are crucial. First, there is nothing new about the link between environment and development and the criteria for sustainable development. We have grappled with them for some time. Sometimes we have succeeded. But so often development has proceeded as usual, becoming the cause – instead of the cure – of ecological destruction.

Secondly, we remain at the starting gate of policy implementation. Economic priorities and ecological goals remain a dialogue of the deaf, both sides presenting generalities, critiques and simplistic alternatives. Too much rhetoric; too much lip service; too little action.

Of course, there are no quick fixes. Sustainable development is not a ready-made policy menu. It is a demanding series of concrete, costed and draconian reforms which confront failed economic policies and instigate new structural adjustment programs. These reforms work to alleviate poverty, meet basic human needs and lead to economic conditions that promote improved environmental quality. Throughout the global South, a rigidly unfair, protectionist international economic order, commodity price volatility, debt and poverty all tighten the stranglehold of natural resource destruction, chronic pollution and skyrocketing population.

THE UNITED NATIONS CONFERENCE ON ENVIRONMENT AND DEVELOPMENT (UNCED) (1992)

The environmental problems facing our planet and its peoples are still very great. Human populations continue to climb worldwide. Larger and larger numbers of people mean ever greater demands on the Earth's natural resources. More land is taken for agriculture and with it go the wilder spaces. As a consequence, planetary biological diversity drops. As standards of living rise, consumer demand increases and so industry spreads. Vast amounts of industrial wastes are released into air and water and so onto the land; as industry spreads so the wastes increase. People, their actions, and their wastes are undermining the physical and chemical basis of global life support systems. Never before in the long history of Earth has a single species ever threatened the entire planet. Life on earth is in danger and humans are the main cause.

Modern scientific understanding of the world in which we live began in the 17th century but comprehension of the true complexity of the interactions between environmental forces that enable the planet to function as a home to life has only emerged during the last five or six decades. Increasingly, it is realized that many of these interacting systems must be looked at on a planetary scale. This means that more attention must be given to investigating how the planet functions as a whole.

It is no longer sufficient to say simply This is what happens.' The quest now is to find out why and how it happens. Only when we have this knowledge will it be possible for us to put environmental and resource management on a sound long-term footing. Only then will true sustainable development be possible. For this we need better data and information. It is often said that we do not need more environmental data, that we have enough, even too much. We now realize that this simply is not true. We need many more data, not fewer – but data of the right kind and for specific purposes, carefully chosen and carefully collected. In the meantime, we must press ahead regardless, using every scrap of existing knowledge and experience that we have; development and people cannot wait for the results of lengthy research and analysis.

To this end scientists are increasingly considering the developmental applications of their research, and have realized that sustainable development is actually both a desirable and an attainable goal. The Ivory Tower approach is no longer the norm.

Most scientists know that they will have to work more and more closely with national planners and managers to translate their findings into practical actions. This is a major and important change in philosophy that will certainly have far reaching benefits for us all.

Nevertheless, the environment continues to worsen. Deforestation and land degradation spread and their rates increase. Poverty is identified as one of the major causes of environmental deterioration as people struggle just to survive in a world where it is becoming increasingly obvious that most natural resources are used, squandered some would say, by a fortunate few at the expense of the unfortunate majority. At the same time, scientists identify whole new categories of global environmental threats whose implications are enormous, devastating – and expensive to evaluate.

More and more NGOs are founded all over the world and they begin to act as the voice of human consciousness alerting people everywhere to what was happening. The larger of these, such as *Friends of the Earth*, *Greenpeace*, the *World Watch Institute* and the *World Resources Institute* attract global followings. However, to many, it begins to seem that everything done by society is shown to have adverse and expensive consequences for the environment.

Those in power in rich countries are appalled at the implied costs and time scales of suggested remedies. Most people in poor countries are already too devastated to notice; their long-term concern is, as always, to keep their families alive. NGOs trying to pressure governments shout constantly and ever louder about what is happening and what is needed.

Not surprisingly, in the rich countries reaction has set in and people have begun to turn away from the environment. Their local environment looks much the same as it always has so the scientists, and environmental prophets of doom are probably wrong. In the poor countries reaction also sets in, but of a different kind. Here remedial measures to control environmental degradation proposed by aid donor countries are often viewed as attempts to hold back national development. Aid programs to help assess natural resources are seen by some governments as attempts by the rich to get specialist knowledge for their own economic gain.

Remote sensing of these resources from satellites is viewed with particular suspicion. This attitude, coupled with the constant accounts of how huge amounts of aid money and supplies are being siphoned off by some developing country leaders for personal benefit, adds in the industrialized nations to the growing sense of disillusionment with environment and development concerns.

This disillusionment reached its peak at UNCED held in Rio de Janeiro in June 1992. Fortunately, the main outcome of the conference was a carefully thought out and well-structured program for the future which would take environment and development safely through the 21st century. Agenda 21 as it is called, idealistic though it may be, is a worthy and genuine blueprint for world action, setting out what needs to be done to ensure that humanity has a long-term future. The postulated cost outlay of Agenda 21 is staggering, although in the long run the returns and benefits will be many times that outlay. What it immediately resulted in, however, is that before the conclusion of the conference, developing countries called upon the rich nations for billions of dollars of additional aid for national development, stressing Agenda 21 and the need to alleviate poverty. There is no doubt that this money is needed, but the size of the demand, coming when it did, coupled with a growing dissatisfaction with what is considered, probably more wrongly than rightly, as an overly-bureaucratic and costly United Nations system made most developed-country governments back away from worries about the world environment and almost all of them from responding properly to requests for sizeable additional financial resources, particularly from the Official Development Assistance (ODA).

UN SPECIAL ASSEMBLY (1997)

Five years after the Rio conference, the UN General Assembly held a Special Session to review the implementation of Agenda 21. The conclusion of the Special Session was that while some improvement was achieved, overall the situation in 1997 was worse than in 1992. What annoyed developing countries most is that instead of increasing ODA as promised at Rio, it fell from 0.34% in 1992 to 0.29% in 1996.

However, people think, learn and, above all, can reason. These are features that make them unique among Earth's life forms. Because of this, there has to be hope. There are signs that people everywhere are starting to take a fresh look at the world. This time it is a quieter, more restrained, less belligerent and more realistic view. There is a growing awareness that environment and development really are linked – in all countries. Environmentalists (and even conservationists) are increasingly recognizing that life without industry is very difficult in the modern world; at the same time industrialists have become aware that environmental care by them may have long-term cash benefits, as well as being good for customer relations. Several developing countries have successfully become industrialized nation states and are starting to realize that environmental regulations and controls really are needed and that they do bring practical benefits to their peoples. Other less developed countries are looking for leadership to these

newly industrialized nations and are starting to emulate their growing environmental awareness and concern.

Many ordinary folk have begun to realize that all peoples on Earth are but slightly different genetic and cultural variants of the same basic human model.

Strategic Environmental Assessment

Robert Goodland
World Bank, Washington, DC

Strategic environmental assessment (SEA) is the systematic and comprehensive process of evaluating the environmental and social impacts of a policy, plan or program and its alternatives. SEA identi es potential impacts, designs measures to mitigate them, then ranks - on environmental and social grounds - all potential projects in that sector, to be used in decision making by stakeholders. The implication is that only the projects at the top of the social and environmental rankings will be taken up, assuming they are similarly good on economic, engineering and other criteria.

Traditional, reactive, project-level EA is necessary but not suf cient to exploit opportunities which exist today but which may be gone tomorrow. Reactive EA must be transformed into proactive or strategic EA. SEAs improve investments over the long term and should be fed by long term projections. Thus, SEA is a process by which environmental implications are integrated into decision making above the project level. SEA extends EA into nontraditional areas such as entire sectors, policies and programs. Sectoral EAs are a subset of SEAs, which began almost a decade ago to great effect. SEA has started internationally, and has been used most successfully in the power and transport sectors, and in water supply.

SEAs, those that look at programs, policies, treaties and other nontraditional areas, are the newest types of EA. SEA is the application of EA above the project-level. Although already promulgated by the European Union and several countries, and although provided for by United States National Environmental Protection Agency (NEPA), SEAs are still not yet routine. For example, during the decades of trade negotiations between USA and Canada, the North American Free Trade Agreement (NAFTA) was not subject to SEA procedures.

SECTORAL SEAs

Sectoral SEA, the commonest form of SEA, is the process of examining potential environmental and social implications of all or most of the potential projects proposed for the same sector. Sectoral SEA can in uence project selection, which project level SEA almost entirely cannot. Sectoral SEAs provide an environmental ranking of all proposed projects in one sector before prefeasibility. This helps in project selection (e.g., gas vs. coal vs. hydro vs. nuclear energy in the power sector; or road vs. rail vs. air in the transport sector).

Sectoral SEA begins with a development objective or goal and then evaluates the numerous possibilities of meeting agreed, desired results. Instead of beginning with, say, a preconceived proposal of a 200 MW coal-fired power plant at spot x, a Sectoral SEA would begin with the premise of meeting projected power needs by optimal methods, including energy conservation and development of renewable energy. Sectoral SEAs reduce the costs of subsequent project level EAs, but do not obviate the need for them. Sectoral SEAs have started to be used, especially in improving traditional least-cost economic analyses into economic, social and environmental least-cost sequences. Power sector expansion sequences increasingly have environmental and social rankings alongside the conventional economic ranking, and this constitutes a form of sectoral SEA. Sectoral SEAs are most frequent in the power sector, less so in transport sector, and rare so far in the agricultural sector.

A strategic EA seeks to integrate environmental considerations into decision-making above the project level, while sectoral SEAs are viewed as a subset of SEAs. In the power sector for example, once the case for new generation

capacity has been made, demand side management (DSM), such as improvements in efficiency, reduction of losses, and conservation, is well in hand, and long-run marginal cost is being achieved, then sectoral SEAs help decide first what sort of new capacity would be preferable: DSM and conservation vs. coal vs. hydro vs. gas vs. oil vs. nuclear energy (*see* Demand Management, Volume 4).

Another value of sectoral SEAs is in the detection of gaps in existing data, thus allowing timely collection of relevant additional data required to make informed decisions about the selection of the next project in the sector. Sectoral EA makes project-specific SEAs much faster, cheaper and more robust because data are already assembled into information management systems and data gaps are already identified. The great power of a sectoral SEA is that it helps rank potential projects in an environmental sequence, so that environmentally sound projects are taken up before environmentally weaker ones. Environmental ranking of all potential projects exposes society to tradeoffs. The ranking itself should largely be as a result of participation by civil society. By such rankings, SEA fosters transparency into long range plans. This helps acceptance by taxpayers and affected people. It also decreases the likelihood of purely political decisions. Pork barrel selection of a project in a politician's home area is less likely because it becomes clear that better or cheaper sites or technologies are available elsewhere.

For example, if an EA team conducts an EA on a nuclear power plant, the team should first explore the possibility that demand management may reduce demand enough to allow postponement of the need to increase capacity. Secondly, the team should determine if other power generation alternatives are economically and environmentally feasible, such as hydro or natural gas. As a general rule, the power sector has long-term least-cost sequence plans which sometimes include environmental considerations, such as human involuntary resettlement and wildlands, but these often get lost in the hurry to complete engineering and economic analyses. These environmental and social costs then reemerge after heavy expenditures on detailed engineering studies have been completed and the proposed project has become more firmly entrenched in national development plans. Sectoral SEAs should identify the real options at a stage before expenditures for design have become too great.

In a recent case, preparation of Nepal's Arun 201 MW hydro was criticized because not enough alternatives sites had been socially, environmentally and economically compared with the single proposed big one. Often, dams are proposed as a part of a cascade series with one large dam controlling the ow to several smaller downstream dams. The SEA must consider the entire proposed sequence when assessing the first dam of the series. This holds even if dams subsequent to the first one are not immediately envisaged.

The same holds for highway projects. If a good SEA team is asked to assess the impacts of a new highway, they may well recommend a railroad, not a highway. Such a response would not please the National Highway Authority that requested the highway SEA and would likely result in dismissal of the SEA team. This might not be the best course for the environment nor for the nation.

STRUCTURAL ADJUSTMENT SEAs

A structural adjustment SEA of a country or group of countries has economic development as its primary goal – through deregulation, privatization of national industries, subsidy removal or free trade, for example. At the March 1995 UN Social Summit, there were major differences over the social and environmental impacts of structural adjustment. Some claimed poverty and equity had decreased after structural adjustment, others the contrary. Some claimed that growth is a prerequisite for reducing poverty and that for growth, structural adjustment is needed. The poor are the first to be harmed by environmental damage. Most subsidy removal harms the poor more than other groups. The environment does not have needs; it is the life support system of all life, including humans. Systematic SEAs of structural adjustments during the design phase would eliminate most major impacts and could readily mitigate other significant ones.

While the precise details of the environmental and social effects of structural adjustment loans (SAL) are too complicated to be teased out, the major impacts are clear, easy to identify, and relatively easy to mitigate. Unless major potential impacts are designed out or otherwise mitigated, SALs impose major social and environmental costs – usually on the poor. Most SALs have much in common although precise details differ from country to country. SEA should analyze the potential impacts of the common elements in each case.

- *Devaluation* (aimed at fostering exports): Will imported food prices rise? Will the poor expand small-scale agriculture into marginal lands?
- *Removal of subsidies* (on food, fuel and agricultural inputs): In general, environmentalists encourage removal of subsidies, because it reduces waste. In specific cases, will higher prices for food and kerosene and other domestic fuels result in impacts on the poor?
- *Removal of fuel subsidies*: Will they lead to increased fuelwood use, with resulting deforestation, loss of biodiversity and carbon fixing capacity, soil erosion, and possible trends in desertification?
- *Removal of agricultural input subsidies*: Will fertilizer and biocide prices rise? Will agricultural intensification increase or decrease? Will extensification increase in developing/developed countries?

- *Developing compared with Developed Country Impacts*: Will the situation in industrial countries be the opposite of that in developing countries? In Western Europe, for example, would removal of price and land set-aside subsidies cause intensification of production on the same plots?
- *Extensi cation vs. intensi cation*: In poorer countries, instead of seeking productivity gains by intensifying production on the same-sized plot, are farmers more likely to extensify into marginal areas, hoping to get the same production from a larger area farmed with fewer inputs? What are the risks of small farmers expanding the agricultural frontier? Will output productivity and biodiversity suffer? Will long-term soil productivity decline?
- *Natural resource depletion*: Will the SALs accelerate natural resource depletion (e.g., soil fertility, fuelwood, timber, fish)?
- *Exchange rate adjustment*: Will natural resources depletion accelerate if the exchange rate falls because the exporting country has to export more, but import the same amount?

SEA of structural adjustment can prevent environmental damage by:

1. Systematic monitoring of environmental trends and anticipating emerging problems when policy reforms are being prepared.
2. Identification and assessment of serious potential environmental impacts of proposed economy-wide reforms, which should begin at the design stage of structural adjustment.
3. Following identification, potential impacts need to be prevented by design changes. For example, in subsidy removal, the first step is to start with the subsidies benefiting mainly the rich (e.g., air travel, limousines, mansions, non-staple foods, electricity and water consumption over a minimal level per household), leaving subsidies benefiting the poor until later or not at all (staple foods, cooking oil and fuel, public transit). Where design changes are not possible, mitigation measures are necessary, such as social safety nets.

SEA of Privatization

Corporations owe allegiance to shareholders; government's first priority is the well being of their citizens. While these two groups overlap to a limited extent, there remains a major role for government regulation following privatization. Privatization should proceed only after an SEA has identified the impacts, such as major unemployment, when a government agency sheds workers as part of privatization. In addition, government regulatory capacity needs to be in place so it becomes adequate as soon as privatization begins. The government needs to ensure that the private sector is well regulated in order to balance shareholder interests with those of the citizens.

SEA of International Treaties

Many international treaties create major impacts, such as enabling polluting industry to relocate to countries where social, labor and pollution standards are less expensive. Such treaties need to be environmentally assessed during the drafting stage because once negotiated it is too late to mitigate, as was the case in the NAFTA. Also, if social and environmental impacts are assessed and agreed upon in advance, signing and ratification is faster.

ENVIRONMENTAL ASSESSMENT OF NATIONAL BUDGETS

The national budget is arguably the most important statement of environmental priorities that any government ever makes. A budget containing two orders of magnitude more money for the military than for education reveals a government's priorities. For example, the US Federal budget shows that the government thinks military threats are 15 times more important to national security than threats from poverty, population growth or the environment. At least at a superficial level, it is relatively easy to identify anti-environmental expenditures in a budget. The most detailed analysis of any national budget so far is that of the US federal budget by Friends of the Earth, which also shows how to cut environmentally harmful expenditures.

The first need is a systematic SEA of the budget to seek to reduce anti-environmental budget expenditures such as subsidies to grazing, mining, water and timber interests. Tax breaks for oil drilling means the oil industry is spreading its own private risk across the public domain, which does not equally participate in any future profits. Subsidies and other inducements to civilian nuclear power are strongly asymmetrical at best. About 75% of total research and development expenditures have been consumed by the nuclear industry over the last four decades, although it generates only about 3% of global commercial energy.

The second need is to identify the pro-environmental expenditures in the budget and compare them with other expenditures to force taxpayers to ask if those are the priorities for which they voted. Also, where defence expenditures are deemed to be excessive, the SEA should highlight this for voter's consideration. The social side of the assessment will address the employment implications of the budget proposals. Fortunately, more environmental attention almost always increases employment, rather than reducing it. Annual reviews of public expenditures can include environmental and social analysis too.

Strong, Maurice

(1929-)

Maurice Strong was born in Manitoba, Canada. He is married with two sons and two daughters and a foster daughter. In recognition of his achievements over the last 30 years, Strong has received honorary Doctorates from 41 universities in Canada, the US and Europe. He has also become a fellow of the Royal Society (Great Britain), the Royal Society of Canada, and the Royal Architectural Society of Canada. Apart from these academic honors, Strong has received close to 30 awards from various bodies in different parts of the world, including the Blue Planet Prize in 1987.

Strong is one of a small number of godfathers of the new environmental movement. He is the architect of the two major United Nations (UN) Conferences, which dealt with environmental issues. As secretary general of the UN Conferences on the Human Environment held at Stockholm in 1972, he toured the globe twice to preach the need for quick action to stop environmental deterioration for the benefit of the human race. He met ominous resistance from developing countries who felt that his call was a plot by the developed countries to stop developing countries from pursing their development activities. Strong did not budge and kept at it until the successful completion of the Stockholm Conference with the adoption of the Stockholm Declaration and Action Plan. The latter was a blueprint for action that needed to be taken by all governments, intergovernmental bodies and non-governmental organizations.

The Stockholm Conference also recommended that the UN establish a new global body to implement the Stockholm Action Plan and to become the environment conscience of the world. This was accepted by the UN General Assembly; and the United Nations Environment Programme (UNEP) was established on 1st January 1972. Strong became its first executive director (under-secretary general of the UN). Under his leadership during the first three years of its life, UNEP set a very strong course forward.

Twenty years later, Strong organized, again as secretary general, the much more difficult UN Conference on Environment and Development held in Rio de Janeiro in 1992. The Rio Conference advocated integration of environmental considerations into all development plans. After more than two years of difficult negotiations during the preparatory process for the Conference, Strong and his secretariat prepared the conference documents, the Rio Declaration, Agenda 21 and the Guidelines for Forest Management. At the Conference two major global agreements: the UN Convention on Climate Change and the Biodiversity Convention were signed and a third, the Convention to Combat Desertification was launched.

These two major achievements are more than enough for anybody to be recognized with high respect in the environment field. However, Strong did not retire then. He now leads and chairs a huge number of environmental institutions including Earth Council, Stockholm Environment Institute, Technology Development, World Resources Institute and is director of the Environment Capital Corporation.

Sustainable Cities Policies

Rodney R White
University of Toronto, Toronto, Canada

Of the many changes in the nature of the human habitat, the process of urbanization is one of the most dominant. Without any encouragement from government, people

worldwide continue to move into cities, such that we are now approaching a situation where half of the world's population is urban. The trend is continuing strongly, especially in poorer countries where this movement started much more recently than in the older industrialized countries. In richer countries, cities now account for nearly 80% of the total population.

As people become urban, they tend to use more resources and produce more wastes. Yet their very concentration provides opportunities to conserve resources and reduce wastes. Until recently this potential has been seized by very few cities and it has been largely ignored by national governments (City of Toronto, 1991). This lack of connection is very evident in documents such as those produced by the Inter-governmental Panel on Climate Change where urban systems receive little or no attention. For their part, only a minority of urban governments have addressed global issues such as climate change. It is as if, by becoming arti cial environments, cities and their inhabitants have decided to ignore the biosphere on which they are utterly dependent.

CONCEPTS

The Global Scale

The concept of sustainable development has evolved as a response to the numerous challenges posed by global environmental change. Given the problems, there must be solutions. If sustainability of the human species and its material wants is in question, there must be an alternative path to lead us out of trouble. Sustainable urban development is an assumption added on top of the first assumption. As half the world's population now lives in cities, there must be a sustainable variant of urban life (Stren *et al.*, 1992).

This is not the place to debate the wider issue of the long-term sustainability of the human species; instead we can examine some of the policy options that might make cities more sustainable than they currently are, without making any guarantees that this way of life can last for ever. In place of the absolute notion of sustainable (for all time) cities, let us consider the encouragement of ecological cities – meaning built environments that operate in harmony with the ecosystems on which they depend.

Impacts on a global scale are a product of the magnitude of the world's population and the throughput of materials used to support their lifestyle (Daly and Cobb, 1990). As people become wealthier, this throughput, or impact, increases inexorably. So far we have not discovered a lifestyle which brings greater longevity and material comfort without increasing the impact of the individual on the biosphere. The following argument relates to the richer countries of the world and the lifestyle associated with their inhabitants.

The Urban Scale

Our present condition of unsustainability is a function of the deepening divorce of our actions (such as buying groceries and driving an automobile), from knowledge of their physical consequences for the biosphere. Improved awareness of this connection is an essential step in developing ecological cities. Several concepts have been developed to make this connection clearer to urban inhabitants and to urban decision makers beginning with Abel Wolman's model of urban metabolism which produced measurements of the main physical inputs – water, food and fuel and outputs – mainly sewage, solid waste, and air pollutants (Wolman, 1965; White, 1994). The measurement of these ows provides an approximate notion of how a city functions as an ecosystem, interacting with the bio-geochemical cycles on which it depends. Valuable as this model is, it has had little impact on urban planning or the individual's awareness of the environmental consequences of his/her daily actions. Perhaps its usefulness was limited by the need to collect data at the level of the entire urban system.

The ecological footprint has been more successful in improving awareness of the link between behavior and action. Developed by William Rees and Mathis Wackernagel, the ecological footprint is an accounting tool of the land requirements for the individual which he or she can measure based on a simple audit of his/her activities for a period as short as one or two weeks (Wackernagel and Rees, 1996) (*see* Ecological Capacity, Volume 3; Ecological Footprint, Volume 3). Repeated assessments at this individual scale have produced estimates of how much land is required to support an individual in a city in one of the rich countries of the world. The range lies between four and eight hectares per person (Onisto *et al.*, 1998), depending on the degree of automobile dependence and the individual's diet, hobbies and commitment to conservation. If all the world's people made similar demands, we would need between three and four Planet Earths to support us. The footprint demonstrates the extent to which our present trajectory is not sustainable.

The ecological footprint provides a strong link between behavior and impact, because it measures the extent of the need to rebalance our demands with the physical possibilities in the long term. Scenarios, based on the footprint concept, give us useful indications of the new directions that we should consider for urban policy. Thus, urban policy has the potential to act as a link between individual behavior and global environmental change. This provides a possible mechanism for repairing the rupture between the behavior of modern urban individuals and those persons'

understanding of their impact on the planet that supports them.

UNDERSTANDING HOLISM

There are several barriers to understanding the linkage between the individual, urban and global scales of behavior and response. One major barrier is the difficulty we have in conceptualizing the city as a singular physical entity, like a lake or a forest. Urban dwellers – if they think about the city as a whole at all – might see it as a mark on a map, or from an aircraft, but the way in which the city responds to the physical environment and, in turn, affects that environment is difficult to envisage.

One opportunity to see the city as a whole in a dynamic context is when the city is stressed or threatened by a physical catastrophe such as a hurricane, an earthquake or, more rarely, an ice storm. One recent example of this response was the landfall of hurricane Georges in September 1998. As for all hurricanes the path of Georges was carefully plotted as it made its way westwards; hourly estimates were made for its probable landfall. Twelve hours before it was expected on America's Gulf coast it seemed that it would strike New Orleans. Nearly all the property damage from hurricanes is caused by the storm surge and accompanying rainfall, to which downtown New Orleans was exceptionally vulnerable, being below sea level. Most of the nearly three million inhabitants left the city by automobile and bus; others were sheltered in a major sports stadium. As it approached land, the hurricane veered to the north-east, just missing New Orleans but nonetheless causing US$10 billion of damage, of which $3.3 billion was insured. The near miss demonstrated the vulnerability of a major city located in a delta and lying in a hurricane zone. Yet people continue to move to the city and industry continues to invest in the region.

An extreme weather event of similar magnitude, in January 1998, had a very different impact. The January ice storm that fell on the Ottawa Valley, Eastern Ontario and parts of New England completely blanketed Montreal and downed most of the power lines into the city. At one time only one line was still functioning and only four hours' supply of water remained in the city. Households without power moved into nearby shelters, but the city was not evacuated because the blocked roads and bridges made mass evacuation impossible and there was nowhere nearby to move to. This eventuality had not been foreseen. Fortunately none of the small fires caused by downed power lines went out of control. Damage amounted to US$2.5 billion (of which $1.15 billion was insured) and generated more than 800 000 insurance claims – the largest number of claims ever made for a single event. Most of the damage resulted from loss of power to household refrigerators and freezers causing food spoilage as four million people were left without power in their homes for several weeks (Munich Re, 1999).

Both events affected entire cities and both could have been very much worse if circumstances had been slightly different. In one case vulnerability resulted from a location below sea level on a major storm track, in the other from dependence on a few above-ground power lines in a Northern city in winter. Once the entire urban system is stressed simultaneously, the vulnerability of modern technology based societies is suddenly exposed – we are not separate from nature after all, but still very much part of it. This revelation might help us to reexamine the conditions necessary for developing more sustainable urban systems, in terms of making preparations to reduce the impact of natural disasters.

POVERTY AND URBAN VULNERABILITY

The above examples of system-wide urban response to extreme weather events are taken from the richest countries of the world and even there, the capacity to respond to sudden stress was weak. Yet the poorer countries contain more than 200 cities with more than a million people, including 20 with more than 10 million (Dowdeswell, 1996). Seven of the world's ten largest cities are in the poorer countries (N'Dow, 1996). The inhabitants of these cities are even more vulnerable to extreme weather events than people in the cities of the rich, due to scarcity of infrastructure of all kinds. They are also vulnerable to the everyday risks associated with widespread poverty.

> Pollution particularly affects those already suffering from malnutrition and infectious disease, which lower their ability to resist chemical pollutants. For most children in the large cities of developing countries, breathing the air may be as harmful as smoking two packs of cigarettes a day.
>
> (World Bank, 2000, 141)

Although the risks of climate change are great, the solution is very obvious. Humanity must adopt technologies and lifestyles that are compatible with a stabilization of greenhouse gas emissions in the very near future. It will be difficult. Yet choices are available to people in those countries, who emit more than a ton of carbon per person per year. The solution to the problem of poverty is far less obvious. Currently the development model on offer is that of the West, based on urbanization, industrialization, heavy use of fossil fuels, and overuse of potentially renewable resources, water and other materials.

In the face of this complex set of problems the tentative offer of a clean development mechanism in a traditional technology transfer format is unlikely to do much either for the long-standing problems of poverty, or for the stabilization of greenhouse gas emissions (Grubb *et al.*, 1999). If even the cities of the richer countries are vulnerable

to climate change, then they are hardly in a position to pass on clean development to cities in the poorer countries. Only when cities in rich countries have implemented such technology and lifestyles at home, will they be able to assess the relevance of this experience for other parts of the world.

THE ECOLOGICAL CITY – OPPORTUNITIES AND RISKS

An ecological city, being one that operates in harmony with the ecosystems on which it depends, should reduce some of the system-wide risks caused by extreme weather events. Thus, a city in New Orleans' location would discourage further development in areas exposed to storm surges or lying below sea level. In Montreal the power supply could be protected by laying power lines underground or by providing more transmission lines into the city. Alternatively, households could provide their own protection by installing backup power supply.

Most cities would enjoy multiple benefits from encouraging the development of the urban forest from a few scattered trees and parks to a denser canopy that would provide energy savings from shade in the summer and protection from the wind in a northern winter. Trees could also be useful for reducing the adverse impact that the city has on the hydrological cycle, whereby stormwater runoff is intensified and infiltration to the groundwater is reduced. Yet increased tree cover would also bring some additional risks. In Montreal many ice-laden trees fell over, or limbs broke off, blocking the roadway and causing property damage. In cities like Toronto with a large population of raccoons, more trees would provide more habitats for a pest that is likely to become a reservoir for a rabies infestation moving up from the United States. The Northeastern United States is also threatened by the spread of Lyme disease which is carried by ticks, hosted by deer which live in the forests, which in turn are being penetrated by urban development (Longstreth and Wiseman, 1989). In drier regions, like the American Southwest, urban forests provide tinder for wildfires which have become recurrent events in recent years (Insurance Services Office, 1997).

The advantages of restoring some natural ecosystem functions are thus, to some extent, balanced by attendant dangers. In the above examples, extending the urban forest cover might encourage the return of the urban threats of disease and fire, just as in the previous century when inadequate water supply led to outbreaks of cholera, typhoid and yellow fever, and wooden buildings were very susceptible to fire. Modern urban risk management is thus an integral element for developing cities that are more in harmony with the physical environment, including both local and global weather events.

MOVING TOWARDS SUSTAINABILITY

The local issues of urban vulnerability are intertwined with the global issues of climate change, stratospheric ozone depletion and acid deposition. The fossil fuel basis of modern urban and industrial technology contributes to many local, regional and global problems. Some urban citizens and governments are aware of these connections and understand that action to reduce one problem may also reduce others. Thus a reduction in fossil fuel use will improve air quality and reduce a community's contribution to climate change. The reduction will also bring immediate economic benefits through fuel savings and a reduction in damage to human health and to buildings and infrastructure. For those cities which are members of Climate Protection Network managed by the International Council for Local Environmental Initiatives (ICLEI), it is the combined benefits that form the basis for policies designed to make their communities more sustainable. So far the number of urban governments with a broad perspective on these issues, and the environmentally aware citizens needed to support their efforts, are few in number. Even in cities like Toronto, which made an early start on reducing carbon dioxide emissions, support for a drive towards a more ecologically harmonious urban system is not extensive and can easily be disrupted by changes in the political situation and external economic factors, such as a fall in the price of petroleum.

In general, Western European cities are much further ahead on this issue than cities in the rest of the industrial world where dependence on the automobile is growing, not decreasing (Nijkamp and Perrels, 1994; Lafferty and Eckerberg, 1998). Hard-won gains against point source polluters like power stations are being swamped by uncontrolled increases in automobile use and urban sprawl. One city which is held up as an example of what can be done to reduce dependency on the automobile is Curitiba, Brazil, which reversed the worldwide tendency toward automobile dependency and actually brought drivers back to public transport, based on buses running in priority lanes. The watchword for this 20 year effort has been that a city must know where it is growing, how and why (Rabinovitch, 1992; Rabinovitch and Leitman, 1996). In Northwest Europe new communities are being built, in which private automobile ownership is excluded. Instead, communal ownership allows shared use and less dependence. Such schemes are even making a foothold in North America. However, these initiatives are the exceptions. Generally, powerful forces still make the shift towards sustainability quite difficult.

One reason why the worldwide trend towards urbanization has not captured the potential environmental benefits over the last 20 years is that the price of petroleum has fallen steadily in real terms, so that it is now cheaper than it was in the early 1970s at the time of the OPEC

(Organization of Petroleum Exporting Countries) oil price hike. In Europe gasoline taxes are significant, but in North America they are very much lower. Cheap oil encourages suburban sprawl which planners have been generally powerless to oppose.

In the face of the mandatory greenhouse gas emission reductions instigated by the Kyoto Conference of the Parties (to the Framework Convention on Climate Change) the industrialized countries (especially those outside Europe) have vigorously searched for ways to avoid major lifestyle changes (such as automobile dependence) and still move towards the Kyoto target. They champion options such as joint implementation and carbon trading, which suggests that they are prepared to pay financially for the privilege of continuing to emit four or five tons of carbon per person per year. One way to encourage them to change their lifestyle is to apply this willingness to pay to a carbon tax, which would then provide support for urban planners to develop more energy efficient land use patterns which are already well understood (Owens, 1986, 1991). Higher residential density makes public transport viable. It is not a complicated concept.

No mention has been made so far in this article about the role of the private sector, although many companies have taken initiatives that urban governments have been reluctant to follow. Some major fossil fuel companies have publicly stated their intention to restructure their operations for a post fossil fuel world. They anticipate that the threat of climate change will eventually force national governments to mandate reductions of greenhouse gases and these companies intend to position themselves to prosper under a new regime (Browne, 1997).

Even if the price signals could be changed, a further obstacle blocks concerted urban action in favor of the adoption of more efficient land use and transportation systems, reduction in other energy uses, fuel switching and full-cost life cycle accounting. There is a sense that the actions of one city will make little difference to a globally distributed and still growing problem. Within the richer world one response to this objection is that there is a powerful demonstration effect from one successful, ecological city which respects the ecosystems on which it depends. Like an antidote to a disease, once it has been discovered, it can be replicated and applied throughout the world – at least to those parts of the world that can afford it.

For the poorer countries, the simple existence of more appropriate technology is not a solution in itself. At the Kyoto conference, there was much discussion of the role of joint implementation (of greenhouse gas reduction technologies) and the development of a clean development mechanism, with rich and poor countries acting in partnership. However, there is deep suspicion among the poorer countries that these proposals are simply a means of richer countries getting credit for reducing emissions without having to implement any lifestyle changes at home. One way – perhaps the only way – to counter this suspicion is for the richer countries to adoption clean development technology themselves. Without such a commitment, the invention of friendlier technologies and the provision of financial and training assistance to poorer countries will fail to bridge the gap between rich and poor countries (White, 1992, 1993).

If the richer countries fail to clear this hurdle, then a paradox may emerge for those individual cities that embrace more sustainable policies. They may become islands of quasi sustainability in a chaotic world of ecosystem breakdown. That is why it is essential that urban governments and their citizens who have developed a more sustainable lifestyle, to get the message out to those societies that either cannot, or will not, adapt to environmental change.

Sustainable Development

Sustainable development was popularized as a concept by the World Commission on Environmental and Development (WCED) (WCED, 1987), which defined it as development which meets the needs of the present without compromising the ability of future generations to meet their own needs. Despite the elusiveness of a robust and practical definition (Munn, 1992), scores of definitions have since been proposed. For example, the National Task Force on Environment and Economy (1987) of Canada defined sustainable economic development as development which ensures that the utilization of resources and the environment today does not damage prospects for their use by future generations. In *Caring for the Earth* (IUCN/UNEP/WWF, 1991), sustainable development is seen as development that provides real improvements in the quality of human life and at the same time conserves the vitality and diversity of the Earth. Some scholars have worked vigorously to develop comprehensive definitions. Rees (1990) defined sustainable development as positive socio-economic change that does not undermine the ecological and social systems upon which communities and society are dependent. Its successful implementation requires integrated policy, planning, and social learning processes; its political viability depends on the full support of the people it affects through their governments, their social institutions, and their private activities.

Discussions about sustainable development have been complemented with debates on the meanings of the general concept of sustainability (e.g., Brown *et al.*, 1987; Dovers, 1990; Shearman, 1990), with no clear, widely accepted definition in sight. Robinson *et al.* (1990) offered the following: sustainability is defined as the persistence over an apparently indefinite future of certain necessary and desired characteristics of the socio-political system and its natural environment. Brown *et al.* (1987) provided a useful characterization of sustainability through a set of demands: (a) continued human life on earth, (b) long-term maintenance of biotic resources and agricultural productivity, (c) stable human populations, (d) limited-growth economies, (e) emphasis on local-scale self-reliance, and (f) continued environmental quality. Both sustainable development and sustainability will doubtless remain much discussed concepts, each defying precise, broadly acceptable definition but both providing strong conceptual frameworks in support of debate and action design for improving human welfare.

Sustainable Development of Energy Resources in Small Island Developing States (SIDS)

Anilla Cherian
American Foundation for the University of West Indies, New York, NY, USA

A 1999 United Nations review of the development of sustainable energy resources in SIDS, points out that little or no progress has been made in the majority of SIDS in increasing the availability of energy services. For SIDS, the nexus between energy services and economic development has been complicated by two factors: (a) heavy dependence on imported petroleum for commercial energy needs and (b) the problem of global climate change and the attendant growth of fossil fuel related emissions of carbon dioxide. Although SIDS are among those that contribute the least to the problem of global climate change in terms of low per capita and aggregate greenhouse gas emissions, these states would suffer most from the adverse effects of global climate change (such as sea-level rise, coastal zone inundation, and escalations in the frequency and intensity of hurricanes and typhoons) which threaten their very existence. The sustainable development of energy resources in SIDS is therefore an urgent priority.

ENERGY RESOURCES IN SMALL ISLAND DEVELOPING STATES

Small island developing states (SIDS) share a number of challenges that affect the provision of energy services such as: limited internal markets; lack of economies of scale; high transportation costs; grave vulnerability to natural disasters and to the adverse effects of global climate change, limited availability of human and institutional capacity to manage and use available energy resources on a sustainable basis, and ever increasing pressures on biomass resources.

To provide a better understanding of the linkages between energy and sustainable development in SIDS, two key issues need to be highlighted: energy consumption and the impacts of energy dependence and expanding access to renewable energy technologies (RETs).

Energy Consumption and Impacts of Energy Dependence

For the majority of SIDS, imported petroleum (mainly end-use products) is the chief source of primary commercial energy and is used largely for transportation and electricity generation. It is estimated that petroleum will remain the most important commercial energy source for SIDS in the foreseeable future, despite ongoing efforts to develop alternative energy sources. While the total petroleum consumption of SIDS increased by an average of 3.7% during the period 1992–1995, a number of SIDS registered negative or no growth in their total oil consumption and also experienced declines in *per capita* consumption of commercial primary energy. The ratio of petroleum imports to total merchandise exports in most of SIDS remains comparatively higher than in other developing countries and has remained almost unchanged since 1992 (see Table 1).

The almost total dependence of SIDS on imported petroleum for their commercial energy needs continues to cause severe imbalances in trade and the rising costs of petroleum imports have put a serious drain on limited national financial resources. The recent economic devastation wrought by tropical hurricanes has worsened existing fiscal stresses on SIDS. Prices of petroleum products in SIDS are among the highest in the world. Prices of petroleum fuels landed in the Pacific SIDS for instance, are typically 200–300% higher than international values. The cost of electricity generation using petroleum products is much higher in SIDS given added costs of fuel distribution for small-scale generation systems.

Most SIDS remain heavily dependent on traditional forms of energy such as fuel wood and bagasse (dry pulp residue from sugar canes), particularly in rural and remote areas where biomass products (fuel wood from natural forests, coconut shells, husks and stem wood, residues from crops such as coffee, cocoa, maize, cassava, peanuts and rice) are used primarily for cooking purposes. In SIDS with large-scale sugar cultivation, bagasse is used for fuel in sugar mills and for electricity generation. Unfortunately, the energy secured from biomass usage in rural areas is neither efficiently produced nor efficiently used. Savings accruing from a reduction in SIDS' dependence on imported petroleum or from increased use of energy efficiency and conservation measures and RETs could contribute significantly to improving the economic well-being of many SIDS.

Expanding Access to RETs

Many SIDS have significant renewable energy resources but these resources vary significantly across countries. SIDS have a high and relatively constant supply of solar energy. Direct solar energy is currently used in many SIDS for heating water, and to some extent in the Caribbean for crop drying and processing. In a number of SIDS, the use of small-scale solar photovoltaic (PV) power to provide electricity in rural areas and remote islands with

isolated pockets of low load densities appears to have been successful but more work on financing and institutional arrangements needs to be done to promote further commercialization.

Wind power and biomass resources vary significantly with location, both within and between countries while hydroelectric power is available only in a few countries. Wind energy does not appear to offer great potential for many SIDS, as wind energy generation is seasonal, site specific and unsuited for atolls where trees block wind paths. Hydropower resources for primary electricity production are extensive only in a few islands for example; Fiji, Jamaica, Solomon Islands, Samoa and Vanuatu, but many island countries have mini hydropower capacity of a few megawatts.

Although traditional biomass fuel usage in SIDS is both inefficient and unsustainable, biomass energy offers tremendous potential for RET applications (see Table 2). Since the management and disposal of wastes is a major concern for SIDS, waste-to-energy or biogas systems, need to be seriously considered for their role in converting organic wastes into sustainable energy and organic fertilizer. Comprehensive technical feasibility assessments for geothermal and wind energy are still to be undertaken. However, feasibility assessments are being seriously considered and were discussed at a recent meeting convened by the Scientific and Technical Advisory Panel of the UN Global Environment Facility in Barbados.

Despite some growth in the use of modern RETs, particularly solar PV systems in SIDS, the wide-scale application and use of RETs has not occurred in SIDS. One of the principal reasons has been the lack of technical and policy-related knowledge concerning RETs within SIDS. Currently most SIDS lack appropriate institutions and do not have adequate technical capacity to evaluate RETs and implement their usage. Policy makers in SIDS need to be able to make informed decisions on the economic and technical viability of appropriate RETs and need to

Table 2 A brief overview of RET applications in selected SIDS

Biomass	Bagasse: Mauritius has initiated a Bagasse Energy Development Program. Bagasse is used as fuel for sugar mills in Barbados, Fiji and Jamaica
	Biogas: biogas systems (differing in size, design and feedstock) have been built in Barbados, Guyana, Jamaica, St. Lucia, St. Vincent and the Grenadines and Trinidad and Tobago
	Biofuels: used to run small diesel generators in Fiji, Tuvalu and Samoa
Solar	PV systems: increased usage in rural areas and remote islands particularly in Pacific SIDS such as Kiribati and Tuvalu, also in Cape Verde and Jamaica
	Solar thermal: most widely used RE application in the Caribbean. Solar water heaters offer exciting market opportunities for the growing tourist and hotel industry, used widely in Barbados, Mauritius and Seychelles
	Solar drying: research on this application being conducted in the Caribbean, particularly in Jamaica and Trinidad and Tobago
Hydro-electric	There is a wide range of hydropower capacity in SIDS. Several islands have mini-hydro power capacity of a few megawatts and others like Fiji, Solomon Islands, Samoa and Jamaica have more extensive installed capacity
Wind	Wind turbines have been used in Cape Verde and Jamaica. The potential for wind energy and in particular small diesel hybrid power systems is being studied by several Pacific SIDS
Hybrid and other new technologies	Wave power, PV and OTEC are some of the other technologies that offer interesting opportunities for SIDS. The Scientific and Technical Advisory Panel of the Global Environment Facility has recommended that OTEC be studied more closely for application in Caribbean and Pacific SIDS

OTEC, ocean thermal energy conversion; PV, photovoltaic.

have a detailed understanding of how best to encourage technology transfer and the national/regional adaptation of RETs.

The wider use of RETs has also been held back because of lagging capital investments and financing of renewable energy systems in SIDS. Sustainable energy development requires affordable credit financing but many SIDS do not have the available resources or the institutional capability to afford the relatively high up-front costs of RETs. Expanding access to RETs in SIDS will require political commitment and financial investments to build appropriate institutional and human capacity, to develop the necessary regulatory frameworks, energy policies, and financing mechanisms and to catalyze public sector involvement.

POLICY OPTIONS FOR THE SUSTAINABLE DEVELOPMENT OF ENERGY RESOURCES IN SIDS

Energy policies are an effective mechanism for promoting integrated economic and sustainable development goals. This section will examine three options for improving the accessibility of sustainable energy services in SIDS.

Improving Energy Efficiency

Energy efficiency measures play an important role in the overall economic productivity of SIDS. One of the crucial components of a sustainable energy system is the improved efficiency of energy end-use, particularly in the tourism, agriculture and industry sectors. Targeted technical options for energy efficiency currently exist within specific target sectors including commercial and residential construction, transportation, manufacturing and agriculture. Given the unique characteristics of SIDS energy consumption patterns and the small internal markets, a detailed understanding of energy efficiency options based on regional needs is vital.

Policy options that support the adoption of energy efficiency measures in SIDS include the following:

1. Identification and adoption of low and no-cost energy efficiency improvements in key sectors such as tourism and agriculture;
2. development of new regulatory and market frameworks that encourage improvements in energy efficiency;
3. establishment of comprehensive national/regional energy policies with clearly defined energy and material efficiency goals;
4. technical cooperation efforts particularly among other SIDS to promote energy efficiency, especially in the areas of technological innovation and adaptation, local capacity building and increased training and information; and

5. coordinated public awareness campaigns to emphasize importance of economic and environmental gains of energy and material efficiency.

Development and Use of Cost-effective RETs

Given the decentralized nature of RETs, renewable energy can clearly provide reliable, cost-effective energy services for populations living in rural and remote areas in SIDS. However, specific policy problems associated with the implementation in RETs in SIDS need to be urgently addressed, such as variations in renewable energy resources availability, variations in local and national production processes, institutional barriers, financial constraints and human capacity limitations that prevent the wide-scale application and adoption of RETs.

In order to increase the accessibility of modern and sustainable energy services, the following policy options should be considered:

1. Introduction of innovative institutional and financing mechanisms such as micro-financing, cooperative credit and leasing arrangements that allow access to energy services especially for low-income rural populations.
2. Building appropriate institutional mechanisms that promote increased investments in decentralized rural energy systems.
3. Creation of an enabling regulatory and financial environment to encourage increased private sector investment in relevant RETs applications.
4. Training of personnel associated with rural energy service systems.
5. Establishment of networks at the regional and subregional levels to encourage cooperation in adapting RETs for use in SIDS and renewable energy related technology transfer.

Institutional Strengthening and Capacity Building for Sustainable Energy Systems

Limitations in institutional and human capacity at national and regional level seriously impair the ability of SIDS to meet the dual challenge of developing sustainable energy resources and responding to global environmental problems. The United Nations Secretary General's Report on the status of the implementation of the Barbados Programme of Action (BPOA) for SIDS highlights two key constraints related to institutional capacity building, namely, the limited availability of human resources and a lack of financial resources for developing and strengthening institutions/mechanisms. Both these constraints restrict the extent to which effective action on sustainable energy issues and global environmental challenges such as global climate change can occur in individual SIDS. The central challenge is therefore to build regional capacity (technical and institutional) that would promote effective policy responses within the Caribbean, develop data and monitoring networks to provide early warning of changes in climate and sea-level, and strengthen legal and institutional mechanisms for addressing the challenge of developing sustainable energy resources.

The specific issues that need to be addressed are:

1. Development of human and institutional capacity for technological assessment and effective adaptation of relevant options in areas such as energy efficiency and renewable energy;
2. Establishment of training programs that would develop technical capacity among SIDS decision makers in the areas of integrated energy planning, energy financing, energy efficiency, rural energy development and renewable energy.

CONCLUSION

Under the aegis of the Alliance of Small Island States (AOSIS) whose member states are most vulnerable to the adverse effects of climate change, SIDS' negotiators have played an active role in international negotiations on global climate change. Focusing on the linkages between the climate change negotiations and energy issues, AOSIS convened a workshop in January 2001 to prepare for the April 2001 meeting of Ninth session of the Commission on Sustainable Development (CSD-9) in which energy was a principal sectoral theme. It is important to note that a key document under consideration by CSD-9 entitled, Energy for Sustainable Development – Options and Strategies , recognizes that one of the challenges to improving the accessibility of energy includes the unique and diverse set of conditions that impinge on SIDS energy supply and energy security concerns. The AOSIS workshop assisted in the preparation and development of SIDS-specific options and issues related to the goal of energy sufficiency for sustainable development. AOSIS negotiators played a key role in the CSD-9 negotiations on energy for sustainable development and were able to ensure that key SIDS concerns such as an emphasis on development of relevant capacity and the promotion of renewable energy resources were included in the final CSD-9 decision on energy for sustainable development. In order to continue to address the dual challenge of securing sustainable energy resources and addressing global climate change concerns, SIDS negotiators need to focus on the most appropriate mechanisms and strategies that could promote energy efficiency, enhance institutional and human capacity in energy management, and promote effective diffusion of RETs.

Sustainable Development Policies in Small Island Developing States

John W Ashe

Permanent Mission of Antigua and Barbuda to the United Nations, New York, NY, USA

Small island developing States (SIDS) share a number of disadvantages: vulnerable economies; dependence upon narrow resource bases and on international trade; lack of economies of scale; high transportation and communication costs; susceptibility to natural disasters, including long-term threats due to sea-level rise in the 21st century; scarce land resources, inordinate pressures on coastal and marine environment and resources; and a limited availability of the means to exploit natural resources on a sustainable basis.

In recognition of these special circumstances and particular vulnerabilities, which are embodied in Agenda 21, which in itself re ects a global consensus and political commitment at the highest level on development and environment co-operation, the United Nations convened a Global Conference on SIDS to translate Agenda 21 into speci c policies, actions and measures to be taken at all levels (national, regional and international) to enable SIDS to achieve sustainable development. At this Conference, held in Bridgetown, Barbados in 1994, the international community, inter alia, concluded that SIDS are a special case for both environment and development because they are ecologically fragile and vulnerable, and because they face particular constraints in their efforts to achieve sustainable development. The Conference adopted the Barbados Program of Action (BPOA) which contained a blueprint for the sustainable development of SIDS.

THE 1999 REVIEW OF THE BARBADOS PROGRAM OF ACTION (BPOA)

At the 1999 review of the 1994 BPOA, by the United Nations Commission on Sustainable Development (CSD), almost 5 years to the date of the Global Conference, one of key areas highlighted for action by SIDS in their quest for sustainable development was the formulation of national and regional sustainable development strategies and policies which would allow for a more effective use of national and regional human, institutional, financial and natural resources, as well as co-operation at the regional and inter-regional levels. In the context of the review of the BPOA, it was agreed that the development of these comprehensive and collaborative national and regional strategies can also provide a solid basis for the more efficient and cost-effective implementation of donor-assisted programs and projects. This was deemed to be especially the case if these strategies were conceived as action-oriented, allowing for a process of step-by-step improvements and adjustments, and as an instrument to promote broader participation of all relevant groups and civil society.

It was also recognized and agreed that the formulation of sustainable development strategies and policies, through transparent and participatory approaches, would require an appropriate national policy framework that would, *inter alia*, set out clear indicators and benchmarks of progress, which, while re ecting the circumstances of individual countries, would also re ect wider goals, including regional objectives, and that such indicators would also provide a

framework for measuring and evaluating the effectiveness of national implementation strategies and international co-operation.

The challenges that SIDS face in formulating and developing policies for sustainable development remain daunting, given their existing political, socio-economic and environmental conditions. Despite commendable efforts to date by them, difficult decisions, complex trade-offs and arduous work need to be undertaken in the policy arena. For SIDS policy planners, planning for sustainable development will require a clear definition of national needs, a better fit between resources and needs, and a more realistic appraisal of the implications of any proposed development, in terms of the demand for resources which remain invariably scarce and the balancing of frequently competing demands of various stakeholders.

In highlighting the progress made to date, SIDS have emphasized their considerable efforts in the pursuit of sustainable development at the national and regional levels, complemented by international support. These efforts include *inter alia*, respective measures which have been undertaken to formulate national development strategies, action plans and policies and to strengthen regulatory frameworks; the establishment and/or strengthening of national institutions to co-ordinate implementation of the BPOA at the national level; and the establishment or strengthening of regional institutions for effective regional co-ordination.

SIDS have also identified significant constraints to the implementation of the BPOA, including the lack of financial support from the international community, inadequate human resources and a lack of appropriate training, inadequate institutional capacity, inadequate capacity for the enforcement of environmental legislation and regulations, and investment resources. Attention was also drawn to: long-term constraints emerging from the globalization of production, distribution and finance, which are based on the ability – in terms of skilled human resources, technology and natural resource endowments – to take advantage of economies of scale and achieve a reduction of costs; and to the short-term constraints emerging from trade liberalization, which have eroded the trade preferences from which SIDS have hitherto benefited.

Assessments of country experiences in institutional and administrative capacity building have highlighted a number of constraints in SIDS. Those shared by most SIDS include a limited availability of human resources, and a lack of training and financial resources. The majority of SIDS have very small populations, which seriously restricts their ability to staff specialized resource and environmental management institutions. Additionally, the brain drain from many SIDS, and the traditional dependence in some SIDS on specialized expertise from expatriates, have hindered efforts at institutional and administrative capacity building. A lack of adequate training has further weakened the local capacity to deal with complex issues. In several SIDS that have established or upgraded institutions charged with resource conservation and environmental protection, inadequate national budgets have seriously limited the scope of their operations. Even in situations where local expertise exists for dealing with environmental protection and resource management problems, shortages of funds hinder action.

NATIONAL POLICIES FOR SUSTAINABLE DEVELOPMENT

While continuing to stress the importance of continued international support, including financial support, to assist them with their efforts to achieve sustainable development, SIDS have begun the process to attain this goal and simultaneously address the constraints through the introduction of policies at the national level. Table 1 summarizes the national actions taken by a selected number of SIDS from the Caribbean, Pacific and Indian Ocean regions.

Sector-specific Policies

Tourism

Tourism is often identified as a promising growth sector in SIDS. Tourism offers one of the few opportunities for economic diversification and has many linkages with other economic sectors, and if integrated into national development plans with adequate provisions for intersectoral linkages, it can contribute to the growth of all tourism-related activities in all of the major economic sectors: agriculture, including fishing; industry; and services, including transportation. At present, the extent of tourism activities in SIDS varies widely between geographical regions, as well as among countries within regions. Likewise, the economic benefits derived from tourism are diverse. In some SIDS (Barbados, Antigua and Barbuda, Seychelles), tourism has become the major contributor to the gross domestic product (GDP), while in others, it is still relatively undeveloped.

For SIDS, the main objectives of the promotion of tourism as a growth sector are to accelerate the growth of national incomes, provide employment opportunities, and generate foreign exchange earnings and government tax revenues. In view of the serious constraints faced by SIDS in promoting export-led development in the context of an increasingly competitive and fast-changing global economy, a large number of SIDS are giving increasing importance to tourism as a source of increasing foreign exchange earnings. Tourism is a labor-intensive activity that does not require a high level of specialization, and if effectively managed, it could exert a strong

Table 1 National actions taken by a selected number of SIDS from the Caribbean, Pacific and Indian Ocean regions

Country	National strategies and policies for sustainable development	Legislative framework plans	Initiatives taken and achievements	Focal areas
Barbados	Established a national CSD to develop a national sustainable policy and plan	Legislative instruments have been put in place to ensure coastal protection and conservation, and all-encompassing environmental management legislation has been proposed	Establishment of a separate Ministry of Environment, Energy and Natural Resources; a solid waste management project is near completion; a coastal zone unit has been created	Ensuring the input and involvement of the private sector and civil society; coastal zones and fragile marine ecosystems
Jamaica	National Environmental Action Plan and numerous other policy documents: national land policy (1997); national industrial policy and the policy for a system of protected areas (1997)	Natural Resources Conservation Act (1991); drafted natural irrigation master plan (1998) watershed management plan, national environment education action plan for sustainable development (1999–2000)	Creation of the Natural Resources Conservation Authority (1991); additional initiatives include the establishment of the Sustainable Development Council (1996) and a Sustainable Network Program (1997)	Water resource management, tourism, taxes, disposal of non-biodegradable materials, economic instruments in environmental management, sustainable indicators
Fiji	Parliamentary approval of a strategic plan for 1999–2001	Parliamentary consideration of a bill to ensure the sustainable use of resources	Establishment of a national council for sustainable development; environmental management units within government ministries, departments and agencies; an environmental trust fund; a tribunal; the strengthening of the focal environmental agency in government and the establishment of an ozone depleting substance and climate change unit, energy conservation unit and natural resource management unit	Development plan highlights the strategies to achieve sustainable economic and social progress at the end of the 20th century and points to the positive indicators for sustainable economic recovery; provision of infrastructure and other essential utilities, provision of core social services, education, health and housing

Solomon Islands	National environment management strategy; incorporation of environmental issues and strategies into 3-year medium-term development strategy	Wildlife Protection Act (1998) and Environment Protection Act (1998) have been approved by parliament	Formulation of a national biodiversity strategy action being pursued as part of the national response to the Convention on Biological Diversity	
Maldives	First National Action Plan (1990); second National Action Plan (1997)	Formulation and enactment of the Environmental Protection Act; ratification and implementation of various global conventions and agreements	Introduction of EIA procedures; establishment of an environment research center; designation of protected areas and species; restructuring of national commission for the protection of the environment	Climate change and sea-level rise, coastal zone management; biological diversity, conservation; integrated reef resources management; integrated water resource management; management of solid waste and sewage; pollution control and hazardous wastes; sustainable agriculture; human settlements and urbanization
Seychelles	Environmental management plan (1990); new plan will be articulated for the period 2000–2010		In the process of finalizing the 1997–2007 Tourism Master Plan; completed national biodiversity action plan for submission to the Convention on Biological Diversity; National Biodiversity Center has been launched	Focus on strengthening the legal and institutional arrangements for environmental protection and natural resources management

Table 2 Some of the major initiatives undertaken by some SIDS

Country	Goals	Measures adopted	Outcomes
Mauritius	Enhance cohesion among economic development, socio-cultural change and ecology	Establishment of a Ministry of the Environment and Quality of Life; Master Tourism Plan to ensure sustainability; legislative measures for conserving the environment in tourism areas	Intense tourism development; diversification of economy
Maldive Islands	Rapid tourism development: planning of physical plants and incentives for foreign capital investment and reduction of environmental impact	Partial moratorium on tourist accommodations; regulations strengthened; Environmental Protection and Conservation Act enacted; environmental impact studies carried out and work on development indicators initiated; measures put in place for the protection of coral reefs and coastal systems and the conservation of ecosystems	Rapid development of the sector; major contributor to all sectors of the economy
Dutch Antilles	Promotion of tourism without overloading carrying capacity	Tourism Master Plan; measures to protect ecosystems; 7-year moratorium on new construction; legal, institutional and organizational changes	Environmental impact minimized

attractive force on the rest of an island's economic system, including the conservation of certain traditional activities, such as agriculture and fishing, and the preservation of an island's cultural heritage and natural assets. However, the sudden, rapid development of tourism can cause significant social and environmental disruptions in some SIDS. Among other things, potential long-run effects could be a reduction in the living standards of high proportions of island populations and a sense of alienation brought about by their lack of access to limited land resources.

More importantly, the fragile ecosystems of SIDS and their generally more limited scope for pursuing alternative development strategies make concerns for the environmental impact of tourism very acute. These are particularly important concerns because the tourism sector, which is almost totally dependent on the natural environment, is viewed by many SIDS as a fast route to social and economic development. The environmental impacts of tourism are attributable to the development of tourism infrastructures and facilities and to the impacts of tourist activities. Rising prices of land increase the pressure to build on agricultural land, land under forest cover, and land close to sandy beaches and coral reefs. Deforestation, and intensified or unsustainable land use, cause erosion and loss of biological diversity.

As more and more SIDS seek to make their tourism industry sustainable, many have begun to develop measures for coping with the adverse social and cultural impacts of tourism. These include: (1), efforts to keep the ratio of the visitor population to the local population at an acceptable level through appropriate diversification of the tourism product and the tourist market, particularly if mass tourism has been promoted for a long time in the past; (2), effective educational programs to raise the awareness of the local population about the good and bad aspects of tourism; and (3), countrywide, effective security measures against crime and drugs, particularly in areas most frequented by tourists.

Some SIDS have also introduced measures for coping with environmental impacts, including: (1), the development of a multidisciplinary approach for rigorous vetting of tourism development proposals, taking into account prospective cumulative impacts of tourism development, and the establishment of environmental standards for approval of projects; (2), appropriate review and revision of existing taxes and subsidies to ensure that they are in fact conducive to sustainable development, and the development of additional economic instruments to better internalize environmental costs; (3), the imposition of appropriate user fees for the use of national terrestrial and marine parks and reserves, and earmarking the accrued receipts for the purposes of improvement and management of sensitive areas; (4), inducing the tourism industry, through appropriate user charges, to meet the full cost of freshwater that it uses, and to contribute adequately to solid waste management and the cleaning of beaches; (5), implementing a sustainable marketing strategy in co-operation with all partners involved in the tourism industry; and (6), encouraging voluntary initiatives and adherence to codes of conduct by the business community.

Table 2 provides a summary of some of the major initiatives undertaken by some SIDS.

INSTITUTIONAL STRENGTHENING AND ADMINISTRATIVE CAPACITY BUILDING

Most SIDS have realized that their inherent characteristics (small size, small populations, ecologically fragile ecosystems, limited natural resources) make it all the more necessary for them to develop effective institutions and an administrative capacity in order to meet the multitude of challenges arising from the imperatives of resource conservation and environmental protection. Recent country assessments reveal that since the 1994 Global Conference, a substantial number of SIDS have taken a number of policy initiatives aimed at institutional strengthening and administrative capacity building. These initiatives include the following:

1. The establishment of a high-level policy-making or co-ordinating body. A considerable number of SIDS have set up high-level bodies to guide and co-ordinate sustainable development policies and measures. These bodies often assume the institutional structure of a high-level commission or council, headed by the head of government or a senior minister, with a broad membership of government departments and, in a number of cases, major groups and private sector representatives. While not all such bodies have policy-making mandates, most have advisory and co-ordination functions among their principal responsibilities. Their establishment and leadership have provided a catalyst for energizing action.
2. The establishment of specialized bodies. Some SIDS have set up new offices or units within government departments, and have entrusted them with responsibilities for specific sectors, such as waste management or fisheries resources. In other SIDS, existing structures have been upgraded and strengthened in terms of administrative status, manpower and funding. The reinforcement has enabled them to deal with the emerging problems more effectively.
3. The enactment of new legislation. A large number of SIDS have enacted legislation to chart a new course for economic growth and development while complying with regional and international legal instruments. Such steps are often followed by the formulation of a national strategy addressing different sectors and issues in the broader context of sustainable development. The enactment of new laws and the subsequent promulgation of executive rules and regulations have provided an overall legal and policy framework for strengthening institutions and building administrative capacity.
4. The introduction of environmental impact assessment (EIA) and economic instruments. In some SIDS, EIA has been applied to an increasing number of projects, making it an important environmental management tool. In others, economic instruments, such as user fees, deposit refunds and tax incentives have been introduced on a limited scale with a view to promoting behavioral changes in favor of sustainable development practices, while at the same time, generating revenues to help strengthen the institutional and administrative capacity. In such instances, the appropriate use of economic instruments is becoming an effective administrative tool for environmental management and resource conservation.

AREAS REQUIRING FURTHER ACTION

As noted earlier, the challenges SIDS face in formulating and developing polices for sustainable development remain daunting. As SIDS respond to the challenges of sustainable development, key areas that will need to be addressed from the policy perspective include:

1. Inadequate enforcement of legislation. For those SIDS which have enacted new legislation, weakness of enforcement has emerged as a major problem; the new laws on resource conservation and environmental protection, essential as they are, take time and substantial resources to enforce. Among other things, enforcement requires the training of personnel and upgrading of law enforcement structures; there are indications that suggest a weakening of the commitment to enforce the laws in recent years in several SIDS. In some SIDS, enforcement has become sporadic; individual instances of resistance to enforcement, often associated with economic considerations, have compounded the problems.
2. Lack of co-ordination. Despite the fact that most newly-created high-level bodies in SIDS are entrusted with the functions of co-ordination, plenty of problems remain in this area. By its very nature, co-ordination is a difficult undertaking; this is certainly made more so in SIDS by the variety of inter-sectoral issues involved, the different types of inter-disciplinary expertise required and the large number of agencies involved. Country assessments suggest that most SIDS remain at the lower end of the performance curve in the co-ordination of sustainable development policies and measures.
3. Lack of pro-active strategy. Recent experience in SIDS shows that government action in institutional and capacity building is often taken in response to emerging needs and/or new regional/international obligations; while emergency responses are necessary, SIDS governments need to adopt a more pro-active stance in institutional and administrative capacity building through a vision of the country's long-run socio-economic development and its institutional and administrative capacity requirements. Such a pro-active stance is necessary for SIDS to improve planning, and to enhance their capacity for tackling future problems.

4. Lack of recognition. Despite some strides in environmental awareness, the problem of inadequate public recognition of the importance of institutions dealing with resource conservation and environmental protection has impeded progress in strengthening these institutions and their capacity; the lack of public recognition has also affected the effectiveness of the co-ordination of sustainable development policies and measures, as the co-ordination mechanisms are not always accorded the authority and recognition due to them.
5. Sea level rise. Simulations obtained from global climate change models indicate the possibility that sea level will rise significantly in this century. For SIDS such as the Maldives, which are not very far above sea level at their highest point, this is a major concern and a serious policy question (Ashe, 1999) (*see* Sea Level, Volume 1).

NOTES

The author served as the Chairman of the Committee of the entire 22nd Special Session of the United Nations General Assembly for the comprehensive review and appraisal of the implementation of the BPOA for the sustainable development of SIDS.

The United Nations Department of Economic and Social Affairs, which monitors the progress made in the implementation of the BPOA for the Sustainable Development of SIDS, adopted at the Global Conference, currently includes 41 SIDS: Africa (Cape Verde, Comoros, Mauritius, Sao Tome and Principe, Seychelles); West Asia (Bahrain); Asia and the Pacific (Cook Islands, Fiji, Kiribati, Maldives, Marshall Islands, Micronesia, Nauru, Niue, Palau, Papua New Guinea, Samoa, Singapore, Solomon Islands, Tokelau, Tonga, Tuvalu, Vanuatu); Europe (Cyprus, Malta); Latin America and the Caribbean (Antigua and Barbuda, Aruba, Bahamas, Barbados, Cuba, Dominica, Dominican Republic, Grenada, Haiti, Jamaica, Netherlands Antilles, St Lucia, St Kitts and Nevis, St Vincent and the Grenadines, Trinidad and Tobago, United States Virgin Islands.

Sustainable Development Policy

John Middleton
Brock University, St. Catharines, Canada

Sustainable development is an approach that seeks to provide quality of life for all people. It is based on the notion that economic growth (particularly in poorer countries) and social equity are essential, but that they alone are not adequate; life in environmental harmony with the planet is also essential, even from a purely human point of view. The well-known de nition of the Brundtland Commission (World Commission on Environment and Development, 1987) is widely accepted in principle: " sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own needs."

*The global community invested heavily in negotiations on sustainable development in the 1990s, trying to agree on ways to put this principle into practice. The Rio Earth Summit in 1992 (*see *UNCED (United Nations Conference on Environment and Development), Volume 4) was a mammoth event, and included the largest meeting of national Heads of State and of Government on any subject up to that time. Post-Rio negotiations on parts of the sustainable development agenda have seen even larger of cial summits.*

As a result, our collective understanding of the relationship between sustainable development and global change, and our ideas on how to proceed towards solutions, are much more sophisticated now than they were 10 years ago. On the other hand, the critical link between principle and practice, or between theory and action, still requires much work.

The global negotiations on sustainable development (Box 1) sometimes resemble an exotic ritual theatre with words (many, many words) bearing little resemblance to the everyday reality of our planet. On the surface, there is little relation to the biophysical understanding of environment, and even less to the complex science of atmospheric chemistry and global climate change. Nevertheless there is a compelling logic, albeit not primarily a scientific one. Sustainable development policy often makes more sense when organized along the following four dimensions.

1. *Ecology, economy, society*: the sustainable development approach to global change, as to other issues, is based on the idea (or theory, or article of faith), that development and environment need each other. That is, considered properly, there is no necessary trade-off between environmental and human values, with one or the other winning at the expense of the other. Instead, any rational, sustainable policy will be a seamless integration of ecological, economic, and social factors, sometimes expressed as the three E's, i.e., ecology, economy, and equity. Climate change policy offers a clear example. It would be a foolish waste of time to try to deal with global climate change by trying to ignore the enormous economic forces at stake linked by way of carbon to the fossil fuel economy. Equally, it would be politically impossible (even before entering into questions of global justice) to negotiate a global climate change policy without recognizing that some countries will have to take more responsibility for action than others, based on their respective levels of socio-economic development – *common but differentiated responsibilities* (*see* Common but Differentiated Responsibility Principle (Stockholm/Rio), Volume 4), according to the standard jargon. By this logic, a sustainable development approach incorporating ecological, social, and economic factors is not the best approach, it is the *only* feasible approach to a global climate policy. This is a technical, not a moral conclusion.
2. *Scale*: sustainable development makes explicit statements about scale, both spatial and temporal. The environmentalist agenda once focused on ensuring a healthy environment for future generations (temporal or intergenerational equity). The sustainable development agenda has evolved to give equal attention to the environmental problems faced by the current generation (spatial inequalities). This understanding was key to getting all countries, not just the rich minority, to the negotiating table at the same time.

   The nature of proposed actions has also evolved considerably through the course of the sustainable development negotiations. Once it was assumed that most actions would be by national governments, because the biophysical reality of global change demands action at the national and global scales, and because national governments are the traditional actors in global diplomacy. Now it is increasingly accepted that real change will also require action closer to the ground, by municipalities, communities, private companies, and local non-governmental organizations (NGOs). For example, one of the most useful products of the sustainable development negotiations is the Best Practices Database produced by the UN Centre for Human Settlements in conjunction with the Habitat II conference. The database lists dozens of practical (albeit incremental) initiatives relevant to climate change, in categories such as land use management and environmental management, for emulation elsewhere, most at the municipal or community (rather than national) scale.

Box 1 The principal sustainable development negotiations

- United Nations Conference on Environment and Development (UNCED); Rio de Janeiro, 1992, and subsequent annual meetings of the United Nations Commission on Sustainable Development (CSD) since 1993;
- Convention on Biological Diversity (CBD); Rio de Janeiro, 1992, and subsequent meetings of the Conference of the Parties (COP) to the convention in Nassau (1994), Jakarta (1995), Buenos Aires (1996), Bratislava (1998) and Nairobi (2000);
- Framework Convention on Climate Change (FCCC); Rio de Janeiro, 1992, and subsequent meetings of the COP in Berlin (1995), Geneva (1996), Kyoto (1997), Buenos Aires (1998), Bonn (1999) the Hague (2000) and Bonn (2001);
- World Conference on Sustainable Development in Small Island Developing States; Bridgetown, Barbados, 1994;
- International Convention to Combat Desertification and Drought Particularly in Africa; Paris, 1994, and subsequent meetings of the COP in Rome (1997), Dakar (1998), Recife (1999) and Bonn (2001);
- International Conference on Population and Development (ICPD), Cairo, 1994;
- World Summit for Social Development (WSSD), Copenhagen, 1995;
- Fourth World Conference on Women (FWCW), Beijing, 1995;
- United Nations (UN) Conference on Human Settlements (Habitat II), Istanbul, 1996.

Local scale actions can contribute to sustainability only if they are widespread and general; otherwise, improvements in one area may be at the expense of increased problems elsewhere. For example, a rich country could reduce its emissions of greenhouse gases by moving some heavy industry to developing countries, but the net impact on global climate would be nil. Calculation of net impact requires comparable data from both countries, in other words, a monitoring and reporting system with agreed standards among all countries. Unfortunately this remains a very controversial topic, tied up with perceived (or real) threats to national sovereignty. In the short term, progress may be easier (albeit still difficult) by way of bilateral agreements between two countries, under the Actions Implemented Jointly (AIJ or JI – Article 6.1) provisions of the Kyoto Protocol.

3. *Reactive, anticipatory, radical*: responses to environmental problems such as climate change can be thought of on a continuum from reactive to anticipatory to radical (or fundamental). The proposal to store liquefied carbon dioxide in ocean trenches, for example, is reactive: it attempts to undo, partially and temporarily, a symptom of global change rather than deal with causes. An anticipatory policy, such as for example more concentrated urban design, aims to reduce emissions in the first place, working within existing mechanisms and structures of the economy. A radical (in the word's original sense of root) policy, bioregionalism or deindustrialization for example, questions the fundamental assumptions of the basic social economic model. Policies at all points on the continuum can be useful. In general, the sustainable development negotiations have tended to shy away from decisions at the extremes of the policy continuum. The poorer countries tend to be suspicious of reactive options, as these leave unquestioned the unsatisfactory status quo that keeps them in a position of weakness. On the other hand most parties to the negotiations are suspicious of radical options that are impossible to apply given the fragile political consensus that keeps all parties at the negotiating table. Judgments about what is too radical have evolved over the course of the 1990s, especially as NGOs have been allowed a larger and more official role in the negotiations. For example, resolutions accepted unanimously by the world community to eliminate poverty (World Summit on Social Development, 1995), and to provide adequate shelter for all (Habitat II, 1996) are considered fundamental breakthroughs in the context of the UN system.
4. *Values, ideology, strategy*: all thoughtful actions are ultimately grounded in some set of basic values. The values are typically crystallized in an ideology, a short form summary of basic values that eliminates the need to engage in deep philosophical investigations every time action is required. In turn, the ideology is put into place via some coherent strategy linking theory and practice (Macdonald, 1991). The basic ideology of the sustainable development negotiations is very explicit: Human beings are at the centre of concerns for sustainable development. They are entitled to a healthy and productive life in harmony with nature (Rio Declaration on Environment and Development, Principle 1, 1992). The remaining 26 principles of the Rio Declaration, and the many follow-up negotiations (Box 1) have expanded and elaborated this fundamental statement, but have remained notably consistent with it. In this sense, sustainable development is clearly not just another word for environmentalism. The links among values, ideology, and strategy are incomplete until the results of actions are compared against basic values, to check whether the right results are being attained in practice. In the end, sustainable development policies will have to be judged by their real impacts on the world, just as will competing ideologies such as environmentalism or global free trade.

International decisions cannot be implemented in the same way as national ones; the UN is not a super government. Indeed member countries of the UN are obsessive in avoiding any language that would compromise national sovereignty. Instead, the in uence required for making decisions and taking actions at the global scale comes from two different sources.

The first source of in uence is by way of the traditional mechanism of diplomacy and negotiation among national governments for mutually beneficial goals. Sometimes reluctant nations feel compelled to enter such negotiations based on fear of economic pressure, although other kinds of in uence (for example military, or neocolonial) are still sometimes in play as well. In other circumstances national self-interest is clearly advanced by forming alliances. A classic example is the Association of Small Island States (AOSIS). Individually the nations involved are tiny and almost powerless, whereas together they form an important lobby within the UN's one country-one vote system. AOSIS has become an important force in support of quicker action on global climate change, based on the reasonable fears of some of its members that their whole countries may disappear as a result of modest increases in sea level.

The second source of in uence available for implementing sustainable development policy comes in the form of pressure from members of civil society on their own national and sub-national governments. This is a relatively new development in most parts of the world, but one that has the potential to change significantly the actions of national governments. In the preparatory meetings for

the Rio conference, security guards were routinely posted outside committee rooms to ensure that only official government delegates were permitted to enter. At Rio the large parallel meeting of NGOs caught the world's attention. By the time of the Desertification negotiations, NGOs were participants at the subcommittee level, and this changed the philosophy of how to attack desertification, stressing community-scale approaches. By the time of the FWCW (Fourth World Conference on Women) in Beijing, NGO complaints about how they were being treated by the organizers very nearly forced national governments to cancel their own participation. In the end almost 10 000 non-governmental delegates participated. By the Habitat II conference in Istanbul in 1996, non-governmental and community-based organizations, including municipal governments, were participating on an equal legal footing with national delegations in some circumstances, and were beginning to be included as part of national delegations. It is no coincidence that this blossoming of the in uence of civil society coincided with the rapid expansion of the Internet as a routine means of communication beyond most direct government control.

As national governments were engaged in the official sustainable development negotiations, they were simultaneously coming to an in uential agreement on more open world trade through the General Agreement on Tariffs and Trade (GATT) and the World Trade Organization (WTO) process. These parallel trade negotiations also use the phrase sustainable development, but have used a strikingly different rhetoric, and different ideological assumptions about means and ends. Sustainable development argues that ecological, economic, and social factors are and must be inextricably linked. By contrast the WTO produced a Singapore Declaration on the occasion of its first summit in 1996 that mentioned environment only once, in paragraph 16, referring to the existence of a subcommittee. The same document argued strongly against any attempt to use discrepancies in income or working conditions as grounds for decisions about international trade, that is, against linking economic with environmental or social issues. The differences between the two sets of negotiations were stark, even though the national governments participating were almost the same.

Despite the differences, there are some interesting signs of movement towards a common understanding that may well provide the most promising tool for a practical sustainable development approach to global change. On the one hand, the traditional sustainable development community realizes that it must of necessity come to terms with, and harness, the tremendous power of the private sector and of the international market if it is to make practical changes in the world. The Global Environmental Facility, a joint program of the World Bank, the UN Development Programme, and the UN Environment Programme, has provided useful experience. The official participation of the CBD (Convention on Biological Diversity) in activities of the WTO, linking, for example, forestry practices, timber export markets, carbon cycles, and global change, is an even more promising development.

On the other hand, the WTO is learning that an exclusively technocratic, market-based economic approach is not adequate even when there is near unanimity among national governments. The spectacular failure of the Seattle summit of the WTO (December, 1999) was a very public demonstration of this new reality. The experience with the Multilateral Agreement on Investment was also educational. This agship initiative, negotiated mainly behind closed doors by the world's most economically powerful countries, was in the end defeated, primarily by the concerted action of non-governmental and community-based organizations, using the experience and tools learned during the sustainable development negotiations, among others, on how to use the internet as a sophisticated global-scale organizational tool. Since that embarrassing episode, the WTO rhetoric has evolved quickly to bring social and environmental considerations closer to the heart of the issue. The WTO Secretariat's Trade and Environment Report of October 1999 is essentially indistinguishable from the view of the sustainable development lobby:

> ••• [T] here is no basis for the sweeping generalizations that are often heard in the public debate, arguing that trade is either good for the environment, or bad for the environment. The real world linkages are a little bit of both, or a shade of grey. Win-win outcomes can be assured through well designed policies in both the trade and environmental fields.
>
> (World Trade Organization, 1999)

Actions rather than words will determine whether sustainable development policy is a breakthrough in decision-making at the global scale, or a costly waste of time and resources. Great progress has been made at the conceptual level, but progress towards implementation of significant changes remains very slow. It is now difficult to imagine action that does not incorporate the logic of sustainable development policy, but it remains unclear whether this framework is sufficient to bring about changes of the scale necessary to confront the social, economic, and ecological impacts of global environmental change.

Sustainable Energy Policies

see Sustainable Energy Policies (*Opening essay*, **Volume 4**)

Sustainable Transportation

Richard Gilbert
Centre for Sustainable Transport, Toronto, Canada

Travel and the movement of freight have been part of human experience since the migrations of our distant ancestors out of Africa, first to Europe and Asia and then to Australasia and the Pacific islands. Among the most remarkable journeys have been those to the Americas: from Asia in the millennia before history - across what is now the Bering Strait to as far south as Terra del Fuego - and from Europe and Africa during the last millennium and perhaps before.

Societies across the world have prospered in military conquest, trade, and economic progress to the extent they have rationalized the movement of people and freight. Over the years, effective transport brought advantage to numerous peoples: the Phoenicians, Romans, Mongols, Venetians, Incas, Dutch, British, and Americans, among others. During the last 200 years, the links between transport and economic progress have become especially tight.

Until the 19th century, travel everywhere was uncomfortable, dangerous, and enormously time-consuming. Freight movement posed even greater difficulties. Rail transport made the difference. The linking of two earlier inventions - wheels on smooth iron rails and the steam engine - allowed widespread motorized transport across land, and the beginning of a new era in the mobility of people and goods. Also important was the linking of the steam engine to the paddle wheel and propeller to provide motorized water transport.

Rail transport began to give way to road transport in the first part of the 20th century, although the main expansion in the use of road vehicles has occurred since 1945. Air transport arrived soon after motorized road transport, allowing high-speed travel over great distances and ready access to remote places. Ocean freight still dominates the carriage of products and raw materials.

Motorized transport has facilitated and even stimulated just about everything now regarded as progress. It has helped expand intellectual horizons and deter starvation. Comfort in travel is now commonplace, at a level hardly dreamed of in former years even by royalty, as is ready access to the products of distant places.

The growth of personal road transport - chiefly the automobile - has been closely associated with two of the major phenomena of the 20th century: growth in material well-being and extension of voting rights. Ownership and use of an automobile - usually the most expensive of consumer purchases - have assumed in rich countries the status of democratic rights. As tokens of passage into adulthood, they can be more important than the ability to vote.

The evident benefits of mass motorization have begun to pall, and a strong case can be made that the disadvantages it brings are beginning to outweigh the numerous advantages. This case has been put well by Greene and Wegener (1997) "Near the end of the 20th century, the belief in the desirability of perpetual growth in mobility and transport has started to fade. In metropolitan areas, the myth that rising travel demand will ever be satisfied by more motorways has been shattered by reappearing congestion. People have realized that the car has not only brought freedom of movement but also air pollution, traffic noise and accidents. It has become obvious that, in the face of finite fossil fuel resources and the need to reduce greenhouse gas (GHG) emissions, the use of petroleum cannot grow forever. There is now broad agreement that present trends in transport are not sustainable, and many conclude that fundamental changes in the technology, design, operation, and financing of transport systems are needed."

TRANSPORT'S RESOURCE USE IS UNSUSTAINABLE

Figure 1 shows the remarkable increases in the motorized movement of people and freight during the last 150 years, particularly since 1945. Worldwide averages are shown; they hide up to 100-fold differences between countries in the amounts of movement of both people and freight.

Transport makes use of large portions of the world's renewable and non-renewable resources. Vehicle manufacture is a major user – and re-user – of steel,

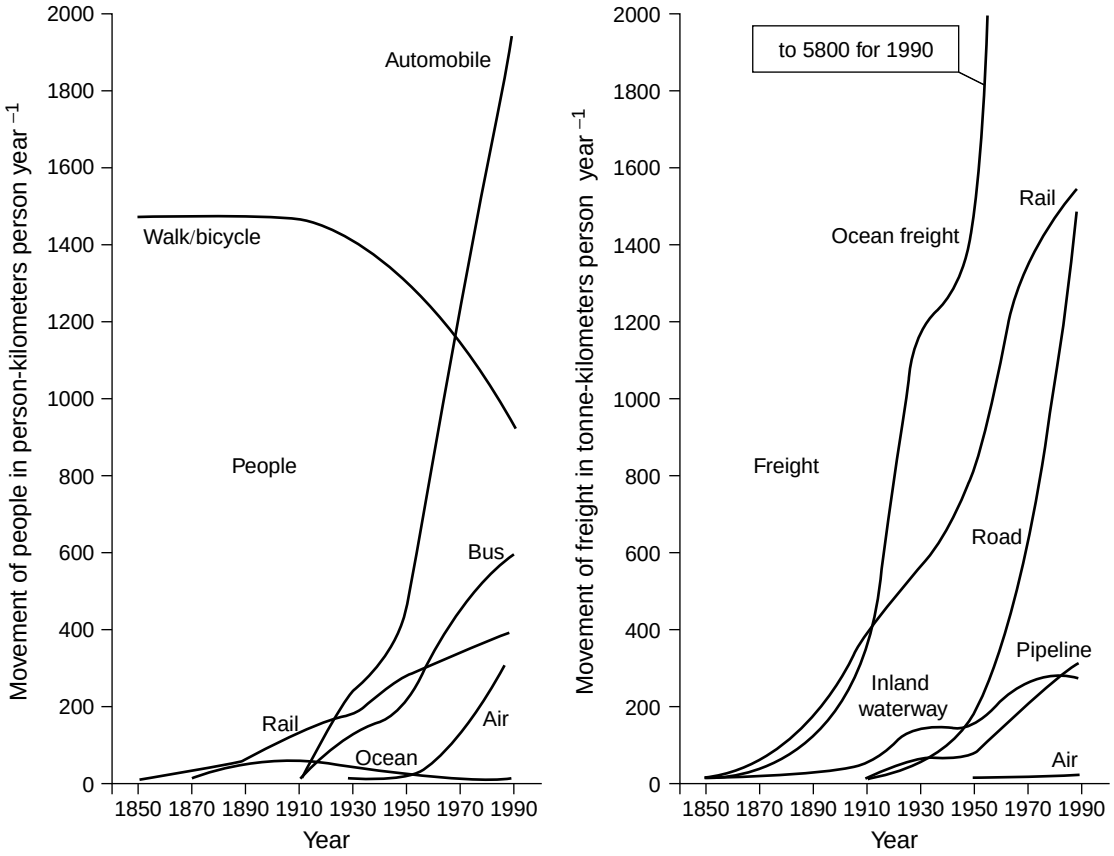

Figure 1 Worldwide *per capita* annual movement of people and freight by motorized transport since 1850, showing for comparison estimates of average distances moved by walking/bicycling. The graphs comprise estimates based on several sources, notably Mitchell (1992, 1993, 1995)

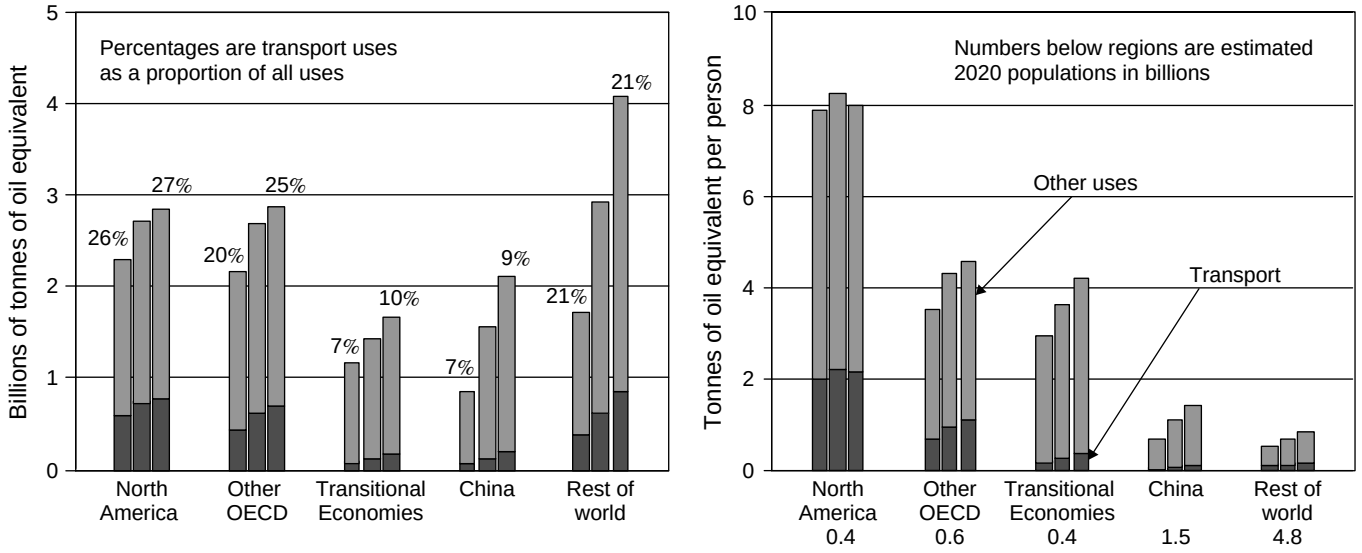

Figure 2 Total and *per capita* energy use for transport and other activities, 1995, 2010, and 2020. (Based on data presented in Part 4 of IEA, 1998)

aluminum, numerous minerals and rarer metals, and plastics. Highway construction involves between one-third and one-half of all material ows for buildings and infrastructure. Above all, transport is a user of petroleum (crude oil), whose refined products provide the energy for more than 95% of the motorized movement of people and freight. Transport accounts for about 60% of the total use of oil products. (These products also heat buildings, fuel industrial processes, and serve as basic ingredients for over 6000 products including numerous plastics and pharmaceuticals.)

Figure 2 shows that in 1995 the average North American was responsible for the use of about two tonnes of oil for transport. About two-thirds of this was for personal automobile use; most of the remainder fueled freight trucks and trains. If indirect energy use for transport is counted – including the energy involved in the manufacture of vehicles, the construction and maintenance of infrastructure (mostly roads), and the production of fuels – the average North American's transport energy use in 1995 was closer to the equivalent of three tonnes of oil.

The projections for 2010 and 2020 in Figure 2 are the business-as-usual (*see* Business-as-usual Scenarios, Volume 5) projections of the International Energy Agency (IEA, 1998). Without special intervention, energy use for transport is set to increase dramatically in all regions and at a higher rate than energy use for all other purposes (by 78% vs. 6% from 1995 to 2020). Transport activity is expected to increase even more than transport energy use, because the IEA's projections assume some increase in the energy efficiency of transport.

The rates of increase in use of energy for transportation are projected to be greater in the poorer countries of the world, represented by the transitional economies, China, and the rest of the world groupings in Figure 2. Their energy use for transport is projected to increase by 142% between 1995 and 2020, compared with an average increase of 46% in the richer countries of the Organization for Economic Cooperation and Development (OECD). *Per capita* rates in the poorer countries will remain relatively low.

While demand for oil continues to grow, production of conventional oil, i.e., cheap oil, is projected to peak within the next 15 years (IEA, 1998). Consequent price rises will increase the economic feasibility of production of other forms of oil and of other fuels. The most promising early replacement for conventional oil is oil from oil sands, which already comprises a quarter of Canada's oil production, and is set to comprise more than half by 2005. Large deposits of material from which oil can be processed, including shale and bitumen, are also found in Russia, the United States, Venezuela, and other countries.

Along with many other replacements for conventional oil, oil from oil sands has a high energy cost of production. The use of this extra energy, plus local adverse impacts, means that the environmental cost of transport activity will increase, other things being equal (*see* Oil Shales and Tar Sands, Volume 3).

There are readier supplies of two other transport fuels, coal and natural gas. Coal cannot be burned cleanly and efficiently in vehicles. Natural gas can, but it is difficult to transport and its use – as with all fossil fuels – results in globally acting emissions. The cleanest, readily available transport fuel is electricity from renewable sources (solar, wind, moving water), but its use in freely moving vehicles is limited by battery technology. The cleanest fuel for freely moving vehicles is hydrogen, but its potential is limited by challenges in production, storage, and conversion to motive power.

TRANSPORT HAS MANY ADVERSE EFFECTS ON THE ENVIRONMENT

Transport makes a substantial adverse contribution to global climate change. The largest part comprises emissions of carbon dioxide (CO_2), the most important GHG. CO_2 emissions are almost precisely correlated with fossil fuel use. Transport activity results in release of several other GHGs, chie y methane (natural gas), hydrochloro uorocarbons (HCFCs) used as the coolant in vehicle air-conditioners, and nitrous oxide (N_2O, produced in vehicle pollution-control devices). Further GHGs are produced by aircraft at cruising heights, effectively doubling or tripling the contribution of aviation to climate change (Intergovernmental Panel on Climate Change, 1999). In total, transport contributes directly and indirectly well over a third of the current human contribution towards climate change. This is the main reason that transport is presently unsustainable.

Stratospheric ozone depletion is another global impact of transport, mostly through release of HCFCs from the air-conditioning systems that feature in most of the world's vehicles. Their more potent predecessor coolants – chloro- uorocarbons (CFC) – are being phased out. As a consequence, estimation of the current contribution of transport to ozone depletion is difficult.

Transport has numerous regional and local effects that are unsustainable to the extent that they result in cumulative, irreversible changes in ecosystems or human health. Most of these effects involve emissions into the atmosphere from fossil fuel combustion. In OECD countries, such emissions of harmful substances from road transport have mostly declined in recent years in spite of the large increases in transport activity indicated in Figures 1 and 2.

At the leading edge of these changes – both in increased transport activity and in reduced environmental impacts – is the United States, whose trends for emissions from transport of the major local and regional pollutants are illustrated

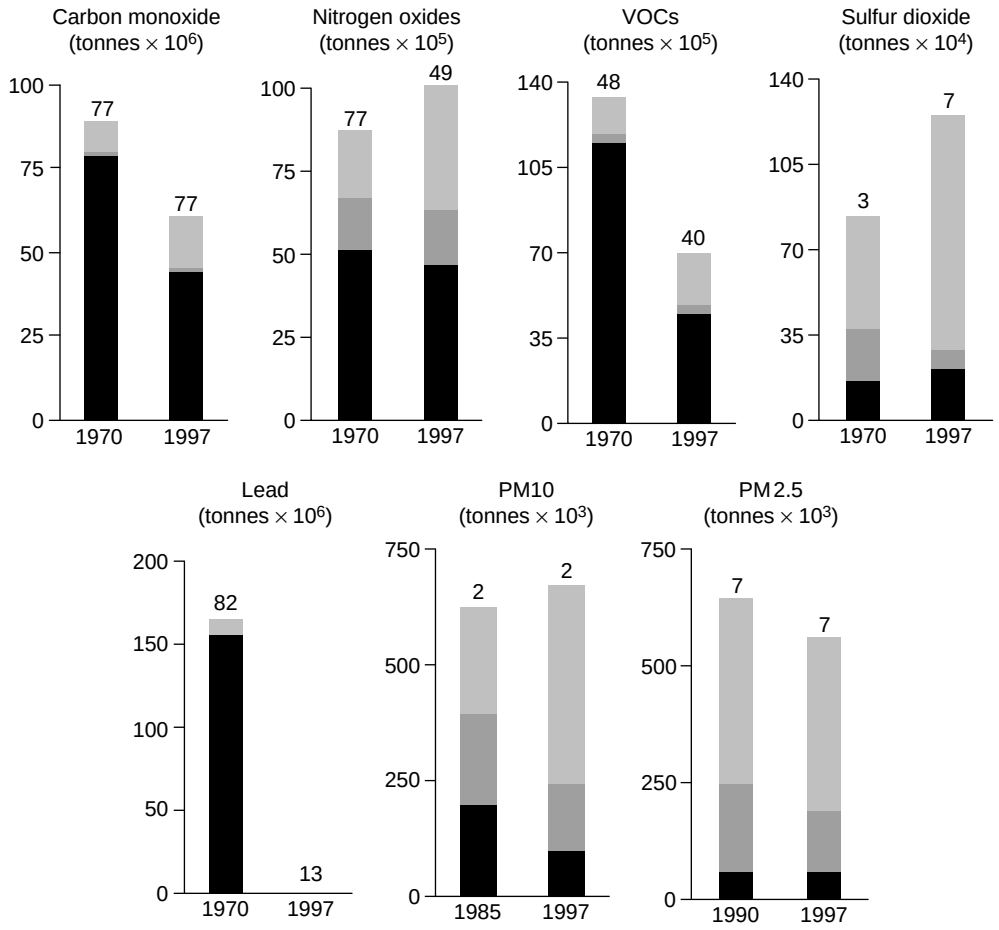

Figure 3 Trends in emissions of local and regional pollutants from on-road and other transport activity in the United States. The bar graphs are based on data provided in US EPA (1998). Scales, units, and base years vary according to extent of emissions and availability of data. Black parts of bars show emissions from gasoline-powered road vehicles; dark grey parts show emissions from diesel-powered road vehicles; light grey parts show emissions from non-road vehicles and engines, including aircraft, commercial and pleasure watercraft, agricultural and construction vehicles, and several other categories. VOCs are VOC; PM10/2.5 is particulate matter of diameter less than 10/2.5 μm. Numbers above bars show on-road and non-road transport emissions as a percentage of all such emissions from transport and other sources for the respective years

in Figure 3. Total amounts emitted from road vehicles, particularly gasoline-powered vehicles, have declined on account of improved vehicles (notably through the use of three-way catalytic converters in the exhaust systems) and improved fuels (notably through the use of lead-free gasoline). Figure 3 shows, however, some large increases in emissions from non-road vehicles and engines – enough in the cases of several pollutants to offset the reductions from on-road vehicles. Construction vehicles and lawn mowers contribute the most to the non-road category.

It is the concentrations of harmful substances in the air that affect ecosystem and human health. They do not have a straightforward relation to transport emissions. This is because of local differences in dilution and because there are many non-transport sources of pollution. Relevant data on air quality are surprisingly few, notwithstanding much public concern. Available data suggest that concentrations of transport-related harmful substances in the air are mostly declining in the richer countries, but that levels of these compounds near traffic and within vehicles continue to be hazardous. However, the rates of decline are often regarded as insufficient to remove the risk to health and ecosystems in a timely manner. For many pollutants, reductions to below 10% of current levels are considered necessary for sustainability. At current rates of decline, many pollutants will still be at unacceptable levels in 2050.

Residents of poorer countries are mostly experiencing increasing levels of these pollutants. In the industrializing countries of the world, notably China, transport is replacing industry as the major source of pollution in urban areas (Gilbert, 1997).

Other effects of concern are noise – a more frequent source of complaint about nearby traffic than air pollution – and the occupation and contamination of land and water. Traffic noise is often sufficiently loud to impair human health through sleep disturbance and in other ways; some 70% of urban and suburban residents in Europe and North America feel they are adversely affected in this way.

The use of land for transport has many serious consequences. Transport infrastructure sterilizes land that could be used for other purposes. It disrupts natural drainage patterns and presents barriers to species movement that can reduce local biodiversity. Transport activities, particularly refueling facilities, are associated with contamination of land and water. A special concern is contamination of water systems by fuels, lubricating oil, and volatile organic compounds (VOC) from water-borne transport, whether ocean freight carriers or small pleasure craft.

THE NATURE OF SUSTAINABLE TRANSPORTATION

The World Bank has proposed a comprehensive approach to sustainable transportation that speaks to three kinds of sustainability. Economic and financial sustainability is put first. It is a matter of requiring that resources be used efficiently and that assets be maintained properly. For the Bank, environmental and ecological sustainability is a matter of ensuring that the external effects of transport be taken into account fully when public or private decisions are made that determine future development. As well, the World Bank speaks to social sustainability, which requires that the benefits of improved transport reach all sections of the community.

Canada's Centre for Sustainable Transportation has defined a sustainable transportation system as one that:

- allows the basic access needs of individuals and societies to be met safely and in a manner consistent with human and ecosystem health, and with equity within and between generations;
- is affordable, operates efficiently, offers choice of transport mode, and supports a vibrant economy; and
- limits emissions and waste within the planet's ability to absorb them, minimizes consumption of non-renewable resources, reuses and recycles its components, and minimizes the use of land and the production of noise (Centre for Sustainable Transportation, 1998).

The OECD has defined environmentally sustainable transport (EST) as follows:

> Transportation that does not endanger public health or ecosystems and meets mobility needs consistent with (a) the use of renewable resources at below their rates of regeneration and (b) use of non-renewable resources at below the rates of development of renewable substitutes.

This definition has been elaborated in terms of six quantitative criteria whose attainment would involve major reductions in the adverse impacts of transport. The criteria values are rooted in scientific assessments and other formulations as to what is required for sustainability from OECD countries. For example, the CO_2 criterion speaks to an 80% reduction from 1990 levels in emissions of CO_2 from transport in OECD countries (OECD, 1999). This is derived from what is required to stabilize atmospheric CO_2 levels, which appears to be a worldwide reduction in the order of 50% (Intergovernmental Panel on Climate Change, 1996). The scientific assessment is then augmented by consideration of the need to provide some room for growth in transport activity in poorer countries (United Nations Environment Programme, 1999).

The OECD work has involved articulation of three visions or scenarios of EST for 2030 as well as a business-as-usual projection. In one of the three scenarios, the EST criteria are met through technological change alone. In another, the criteria are met through activity change alone. In the third scenario, the criteria are met through changes in both transport technology and transport activity.

The attainment year of 2030 and the number of criteria – and to a lesser extent their character – are somewhat arbitrary. Both shorter and longer timeframes incur difficulties, the former because the pace of change itself could be overly disruptive, the latter because what has to be attained could become more unreachable as time passes. Criteria concerning several more adverse impacts could be applied. However, the OECD work suggests that the number of criteria could be reduced to three – concerning carbon dioxide, noise, and the use of land – because other criteria are usually met if the CO_2 criterion is met.

HOW TRANSPORTATION MIGHT BECOME AND REMAIN SUSTAINABLE

A central consideration in planning for and moving towards the attainment of EST concerns the relative effort to be placed on technological factors and on other factors such as shifting transport modes and reducing transport activity. Figure 4 illustrates the relative effort assigned to the different factors in the OECDs EST project and in a parallel project concerning countries in Central and Eastern Europe (Central European Initiative, 1999).

The broad strategies developed during the two studies illustrated in Figure 4 suggest that about 45% of the movement towards EST – whether in the richer OECD countries or the poorer Central European Initiative (CEI) countries – will have to be achieved through improvements in the technology of vehicles, fuels, and infrastructure. This implies reductions in the full life cycle fuel

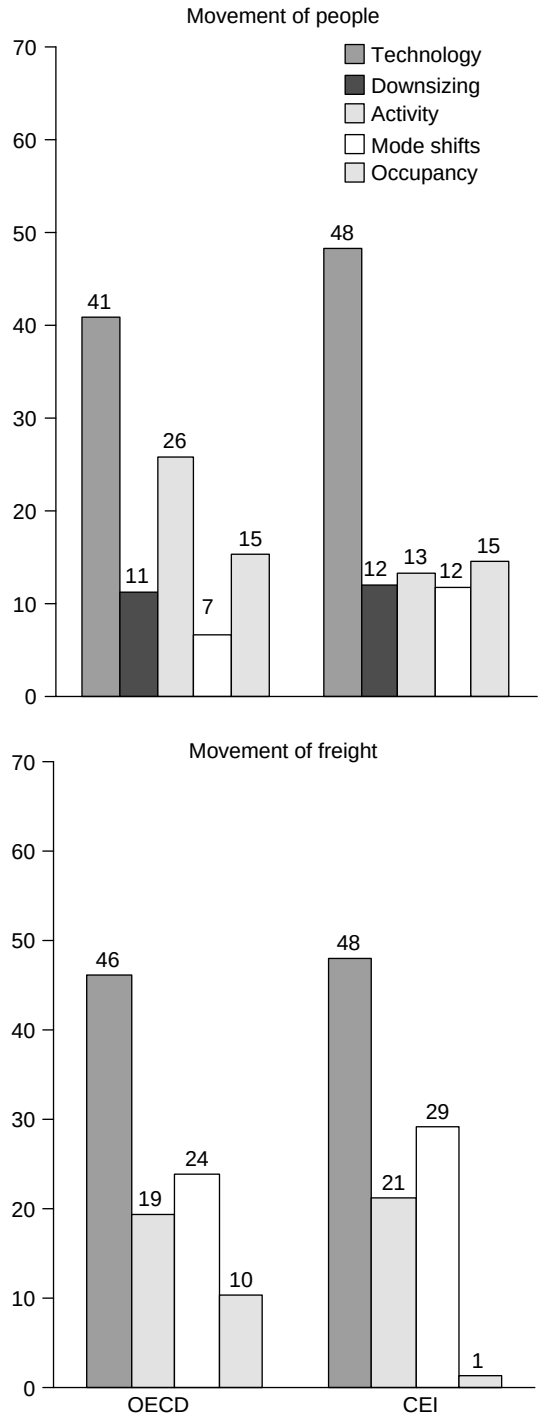

Figure 4 Balance of effort required for the attainment of sustainable movement of people and freight in OECD and CEI countries. The bar graphs are based on information in OECD (1999) and Central European Initiative (1999). Bars and numbers above bars show estimates of the percentage shares of the effort involving different means required to achieve EST. The various means are described in the text

intensity of vehicles in the order of 50%, which is an attainable objective. Private automobiles used in OECD countries – responsible for more than 80% of person-kilometers – now require on average about 10 l of gasoline for each 100 km driven. Hybrid gasoline–electric vehicles already on sale in Japan and North America require less than half as much fuel, as do diesel-fuelled vehicles on sale in Germany. The studies suggest further that a stronger emphasis on gains through technology would likely require widespread use of hydrogen as a fuel for combustion engines or for fuel-cells. Even if the in-car technology becomes adequate and affordable by 2030, the supporting infrastructure will not likely be in place. Achieving comparable gains for aviation will be much more difficult.

The other means of attainment of EST all involve changes in behavior that in many cases will be highly unacceptable at first. Figure 4 suggests that about a quarter of the result will come from reductions in the overall amounts of motorized transport activity. Substitution by walking and bicycling will be a factor, as will reductions in trip length facilitated by increased heterogeneity and density of settlements. Reductions in automobile ownership, discussed further below, may have a special role in reducing transport activity.

Downsizing of vehicles will play a significant role, particularly for automobiles. Recent rates of weight reduction per unit of engine power will likely be sustained and engine sizes will drop. Mode shifts, chie y from automobiles to various forms of public transport, will play a relatively minor role in changing the movement of people. In some areas, nevertheless, quite large expansions of public transport will be required, for environmental reasons and to prevent congestion associated with denser settlement patterns. Mode shifts, from road to rail or water, could play a much larger role in the movement of freight.

Increased occupancy has a large role to play in the movement of people, whether for private automobiles or for public transport vehicles. Indeed, public transport occupancy levels have become so low in the US, journeys by car are now on average more environmentally sound. Typically a bus uses six times as much fuel per kilometer as a car, but currently carries only five times as many people – while being capable of carrying 15–20 times as many people as a car (Centre for Sustainable Transportation, 1998). The comparable factor for freight movement – increased loading – was considered to require less emphasis.

When buses are well occupied, they are clearly environmentally superior to cars. Their better performance in terms of emissions per passenger-kilometer when well occupied is not the only source of their advantage. Perhaps the most important feature of good public transport is that it makes ownership of a car unnecessary or less necessary. As discussed below, car ownership is a major cause of car use. The mere availability of a bus may in uence whether or not a car is bought. If the proximity of the bus route prevents

some car ownership, it may be making a strong although not obvious contribution towards sustainable transportation.

CAUSES OF THE TRENDS IN TRANSPORT ACTIVITY

If the strategies developed in the course of the OECD and CEI studies were followed, there would have to be substantial emphasis on behavioral change as well as on technological improvement. The necessary changes in behavior will be achieved more readily if the causes of patterns of transport activity are better understood. These causes are numerous, ranging from circumstance (people who live in remote suburbs often have no choice but to drive often and alone) to distaste for public transport (buses are loser-cruisers).

A prominent but overlooked cause of automobile use is automobile ownership. Figure 5 shows how closely ownership and use have been linked in Canada during the last few decades. Similar data are available for several other countries, notably the US. The figure suggests a very tight link between ownership and use, and a possible causal relationship whereby purchase of a car inevitably leads to what happens in Canada to be an average of some 16 500 km driven annually. It follows that curbing ownership may be among the most effective ways of curbing use. Certainly in places where ownership is limited by government action (e.g., Singapore, Tokyo, and countries with command economies) automobile use is consequently at a relatively low level.

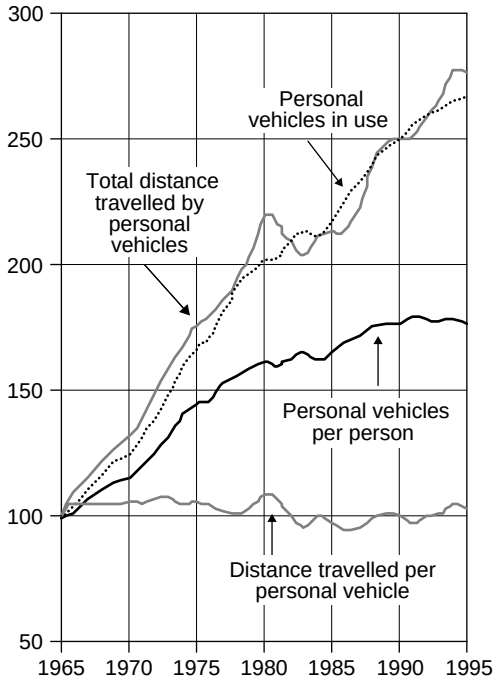

Figure 5 Distances traveled and ownership of personal vehicles in Canada, 1965–1995 (normalized so that 1965 = 100 for each variable). From Centre for Sustainable Transportation (1999). Personal vehicles include light trucks, vans, and sport-utility vehicles used as personal automobiles as well as regular automobiles

Acknowledgement of the tight link between the ownership and use begs questions as to the causes of ownership, but also broadens the scope for investigation of causes. As important, it broadens the selection of instruments for reducing use to include those for reducing ownership.

Curbs on ownership are often considered to be more unacceptable – and undemocratic – than curbs on use, although logically there is no case to be made for the democratic superiority of one over the other. Attempts to limit ownership need not be coercive. Land-use planning policies can ensure equal advantages for non-ownership by mandating higher densities, a mix of activities, much public transport, and services supporting non-ownership – in short, all of the attributes of successful downtown areas that have many residents (Gilbert, 1999).

INSTRUMENTS FOR CHANGE

There are basically five kinds of policy and other instruments available to governments for achieving the changes in transport technology and transport activity required for sustainable transportation. Two key types of instrument are regulatory instruments and fiscal instruments. An example of a regulatory instrument is the setting of mandatory performance requirements for new automobiles. Charges for road use and incentives to scrap polluting vehicles are fiscal instruments. As well, governments can invest funds, for example in bicycle lanes and public transport. They can engage in education and other persuasive activities. Finally, they can change administrative or governance arrangements so that effective bodies with appropriate objectives have the means and the authority to ensure progress towards sustainable transport.

Economists prefer fiscal instruments. Indeed, some economists argue that sustainability is a matter of getting the prices right. (The World Bank's view, noted above, comes close to this position.) One of many problems with this argument is that transport activity seems to be relatively inelastic, at least in the short term: large increases in prices produce only small changes in behavior. Given that sustainability may require relatively large changes in transport activity, price increases may be insufficient.

Price increases appear to be more effective in the longer term, i.e., raising gasoline prices today will have a more noticeable effect five or ten years from now. This suggests that fuel price increases cause people to buy more fuel-efficient cars rather than to drive less.

Regulatory instruments have a stronger record of effectiveness than fiscal instruments; nevertheless, they are less favored by economists and increasingly less favored by

policy-makers. The best-known regulatory instrument may be the fuel-efficiency requirements for new automobiles introduced by the US government in the 1970s (the so-called Corporate Average Fleet Efficiency or CAFE standards). The precise extent of their effect is debated, but these seems general acknowledgement of their responsibility for at least part of the major improvements in fuel efficiency recorded in North America in the 1970s and 1980s, and for maintaining the gains in the 1990s while fuel prices fell steeply in real terms. Meanwhile, without CAFE-like instruments, the fuel efficiency of European cars has worsened, to the point that the efficiencies for North America and European cars are now similar.

More fuel is used in North America because there are many more personal vehicles per person, because vehicles are driven farther on average, and because well over one-third of the personal vehicles on the road are the larger-engined light trucks, vans or sport-utility vehicles, which have been subject to less strict CAFE standards. These vehicles may soon have to meet the CAFE standards of regular automobiles.

Instruments are generally more effective if – such as the CAFE standards – they are tied to clear performance goals with regular monitoring and penalties for non-compliance.

Perhaps the most promising instrument in terms of moving towards sustainable transportation would be a sophisticated form of fuel rationing that involves equal distribution to each citizen of tradable entitlements to emit CO_2 from transport. The total of all distributed entitlements in a year would be equal to what the country in question had agreed would be its total CO_2 emissions from transport for the year. For example, each person could be entitled to emit a tonne of CO_2 each year from transport. Persons who required more, for business or personal use, could purchase entitlements from persons who required less, through a readily accessible entitlements market. Heavy users of freight transport would be among those who would ensure an attractive market price. Such a hybrid fiscal-regulatory instrument would be the ultimate expression of the principle of tying instruments to sustainability goals.

The essential feature of any rationing scheme is that proper enforcement ensures a cap on what is rationed. Marketable entitlements provide for exibility while maintaining the integrity of the cap. Indeed, market-based rationing of one kind or another seems inevitable if transportation is to be made more sustainable, either in the form of a separate scheme for transport or as part of a broader-based scheme covering emissions of all GHGs from all sources. Rationing of automobile ownership is already in place in Singapore, where there are monthly auctions for entitlements to purchase new vehicles. Rationing of automobile use has been proposed for Mexico City, involving marketable permits to drive on a particular day (Goddard, 1997) (*see* Tradable Permits for Greenhouse Gases, Volume 4).

SUSTAINABLE TRANSPORTATION IN DEVELOPING COUNTRIES

Projections for China and for the rest of the world in Figure 2 suggest that in 2020 developing countries will have more than 80% of the world's population but be responsible for less than half of the energy used for transport, and thus contribute less than half of the overall environmental impacts of transportation. Issues of transport sustainability will thus continue to be largely those of OECD members and other richer countries. Nevertheless, already in most of the major urban areas of developing countries, transport is a major environmental problem and often a cause of social and economic distress.

A major part of the current problem in the urban areas of developing countries is the widespread use of highly polluting vehicles and poor quality fuels. Improvements in vehicles and fuels would still leave the basic challenge, which is unrelenting growth in transport activity. Moreover, reliance on technology is an expensive option for a developing country and its beneficial effects are evident only after several years. Focusing on reducing use can be more cost-effective, especially in the short term.

This is the logic behind the best known of the measures taken in a developing country to address the environmental problems posed by transport: Mexico City's *Hoy no circula* (HNC) system, which requires that private cars be off the road for one working day each week. The Mexico City region is the largest urban region in the developing countries, and among the areas of the world with the worst air quality. Goddard (1997) has observed:

> for many years Mexico City residents have complained about the unlivability of the city. These complaints have centered principally on the high levels of air pollution, congestion and noise, problems cause principally by private automobiles. ••• One recent estimate for Mexico City estimates that the total economic losses associated with the unrestricted use of the private car exceed $7.1 billion annually. ••• Of the 29.5 million trips made daily, 39% are in private automobiles.

Other evidence suggests that these private automobiles are owned almost exclusively by the wealthiest 20% of households, and that the burden of the resulting pollution falls primarily on the remaining 80%.

The HNC system may have had the perverse effect of increasing pollution levels as numerous car owning households purchased an additional car – often an inexpensive, old, polluting model – just to have a vehicle available every day. One already noted solution is to transform the HNC system into one involving marketable permits.

In Beijing, China's most populous city, average household incomes and levels of car ownership are lower than in Mexico City, but transport has nevertheless become the major cause of poor air quality in the urban region. A policy emphasis on encouraging bicycle use – the number of

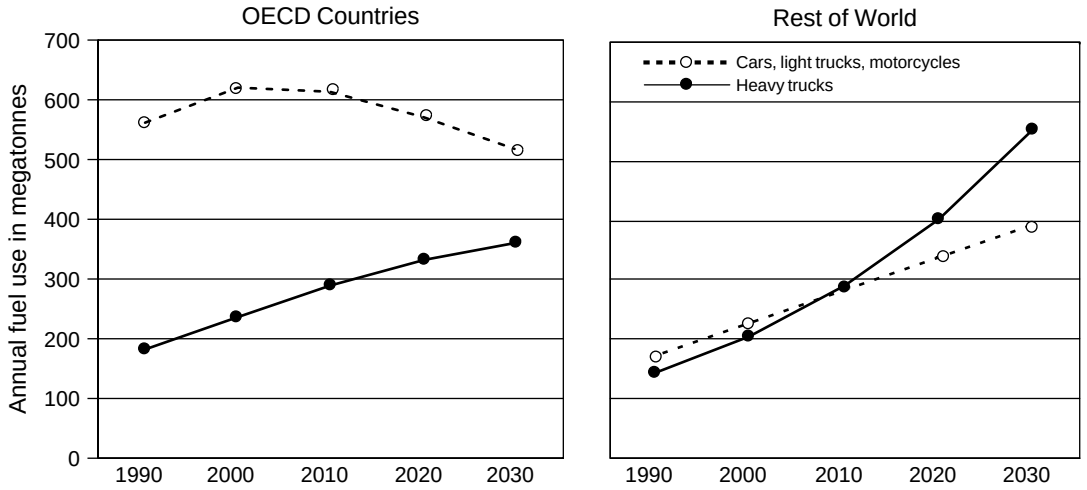

Figure 6 Projected fuel use for transport in OECD and other countries, 1990–2030

bicycles in use in Beijing tripled in the 1980s – appears to be being replaced by encouragement of private automobile ownership. Projections of the resulting environmental impacts are alarming (Mackett, 1999).

Also alarming have been business-as-usual projections for India that speak to a 5.5-fold increase in energy consumption for transport between 1990 and 2020. Proposals have been made to halve the rate of increase in order to reduce local and global pollution and avoid importation of petroleum-based fuels (Ramanathan and Parikh, 1999). The main features of the proposals are discouragement of private automobile use and truck use, expansion of public transport and rail freight capacity, and discouragement of air transport. The proponents argued that the resulting extent of avoidance of emissions of GHGs would make the Indian rail system a strong contender for investment under Joint Implementation programs (*see* Joint Implementation, Volume 4). Such programs allow richer countries to meet part of their commitments to reduce emissions of GHGs at lower cost by contributing to appropriate developments in poorer countries.

The transport and environment challenges of India, Mexico City, and Beijing are variants of those found throughout the developing world, most especially but not only in large urban areas. It might seem that rapid growth in automobile use is the major problem. Figure 6 suggests that in the poorer countries of the world, heavy truck traffic may already have as much environmental impact as private cars, and is set to have more.

Many of the solutions proposed for both richer and poorer countries call for more public transport. This is already used more in developing countries but almost everywhere has the potential for further expansion as an alternative to further growth in private automobile use. However, public transport can ourish alongside the private automobile only if it is given priority, which usually means imposing more onerous restrictions on automobile ownership or use than most governments – in rich or poor countries – are ready to impose.

CONCLUDING COMMENTS

Major increases in motorized transport activity were among the defining characteristics of human existence in the 20th century. Accompanying these increases were profound adverse environmental impacts, largely a consequence of the dependence of transport on the combustion of fossil fuels. During the 21st century, technological improvements will provide part of the response to the growing disadvantages posed by trends in transport activity. The major part, however, will likely have to come from changes in transport behavior.

Developing countries pose particular challenges, especially if their projected growth in transport activity continues beyond the next few decades. Preventing poorer countries from eventually achieving the amount of transport activity found in what are now the richer countries would be inequitable and perhaps unfeasible. On the other hand, dependence of all humanity on motorized transport to the present extent of rich countries would be unsustainable.

The only feasible solution may be massive restraint on transport activity in rich countries. This would be part of a new development strategy directed towards helping people in the South (developing countries) become as free from want as people in the North and having people in the North use as few non-renewable resources, particularly fossil fuels, as people in the South. Accordingly, a goal of sustainable development should be as much to make the North like the South, as it is to make the South like the North. Indeed, protection of the global environment may

require that in terms of the overall amount of transport activity, the North be made more like the South than *vice versa*.

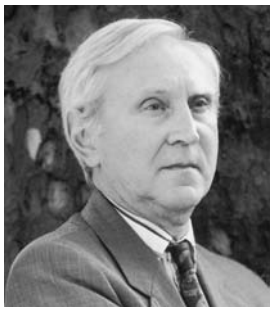
T



Tickell, Crispin

(1930-)

Sir Crispin Tickell, the British diplomat, was educated at Westminster School and Christ Church Oxford. He received a BA with 1st class honors in modern history 1952. He was a fellow at the Center for International Affairs, Harvard University, 1975–1976, and a visiting fellow of all Souls College, Oxford 1981.

Tickell comes from the diplomatic community, probably the reason for his outstanding diplomatic skills that prepared him for his leadership role. He joined the British Diplomatic Service in 1954 and served at the Foreign Office, and British Embassies at The Hague, Mexico and Paris (1954–1970). At the Foreign and Commonwealth Office, he was private secretary to successive Chancellors of the Duchy of Lancaster as ministers responsible for the negotiations for British entry into the European Community 1970–1972 and then head of the Western Organizations Department (1972–1975) responsible for North Atlantic Treaty Organization (NATO) matters, European security problems and political military affairs generally.

Tickell is probably one of a very limited number of those active in the field of the environment to chair or lead an enormous number of environmental and conservation institutions. Since 1990 he has been, president of the Marine Biological Association, chairman of the Climate Institute, Washington DC, director of the Green College Center for Environmental Policy and Understanding, chairman of the Advisory Committee on the Darwin Initiative for the Survival of Species, convenor of the UK Government Panel on Sustainable Development, president of the Earth Center, chancellor of the University of Kent at Canterbury, president of the UK National Society for Clean Air and Environmental Protection, and president of the Gaia Society. Recently he has also been president of the Royal Geographical Society (1990–1993), chairman of the International Institute for Environment and Development (1990–1994), warden of Green College, Oxford (1990–1997) and chairman of Earthwatch Europe (1991–1997).

Tickell has received a huge number of honors including eleven honorary decorate degrees from academies and universities in Mexico and UK and four honorary fellowships.

Tickell has been a very active environmental advocate particularly since 1990, meaningfully addressing global environmental and sustainable development issues. He has authored many books and reports and has appeared on several radio and television programmes. Among his major contributions is his book on *Climate Change and World Affairs* (Tickell, 1977).

Toepfer, Klaus

(1938-)

Klaus Toepfer is the current Executive Director of the United Nations Environment Programme (UNEP). Toepfer

graduated from the University of Munster Germany in 1964, and obtained his doctorate in economics in 1968. Toepfer began his academic career at the same institution in the economics department, with an emphasis on regional planning and development. He has also lectured at universities in Hagen, Bielefeld, Speyer, Hanover, Mainz, and most recently, as an Honorary Professor at Tongji University in Shanghai, China.

Toepfer began his 4-year term as the Executive Director of UNEP on 1 February 1998. He is well known in United Nations (UN) circles from his tenure as Chairman of the United Nations Commission on Sustainable Development, from May 1994 to May 1995. In addition to his duties at UNEP, Toepfer is Director-General of the United Nations Office at Nairobi.

Toepfer is a member of the Senior Management Group of the UN. He also chaired a Task Force, set up by the Secretary-General, to review existing structures and arrangements through which environment and environment-related activities are carried out within the UN, and to prepare proposals on reforming and strengthening UN activities in the environment and human settlement areas.

The professional life of Toepfer has combined extensive work in government and politics with a concurrent career in academia. His government service began in 1971, as the Head of the Department for Planning and Information in the State Chancellery of the Saarland. Subsequently, from 1978 to 1985, he served as the State Secretary and in 1985–1987 as Minister for Social Affairs, Health and Environment of Rhineland-Palatinate. He was elected to the German Bundestag in December 1990.

Toepfer held the post of Federal Minister for the Environment, Nature Conservation and Nuclear Safety from May 1987 to November 1994. From November 1994 until joining UNEP, he was the Federal Minister for Regional Planning, Building and Urban Development and Coordinator for the Transfer of the Bundestag (Parliament) and Federal Government to Berlin.

Toepfer has also held various positions in a national political party, (the Christian Democratic Union (CDU)) at local, regional and national levels. He has been a member of the CDU's presiding committee since October 1992.

Toepfer is the author of numerous articles and publications on economics, development, the environment, human settlements and international affairs. In 1986 he was awarded the Cross of the Order of Merit of the Federal Republic of Germany; and, in 1989, the Commander's Cross of the Order of Merit, for exceptional service to his country.

Born on 29 July 1938 in Waldenburg, Silesia, Klaus Toepfer is married with three children.

MOSTAFA K TOLBA *Egypt*

Tolba, Mostafa

(1922-)

Mostafa Tolba was born in the town of Zifta, north of Cairo in 1922. He graduated with first class honors from Cairo University in 1943, and obtained his PhD from the Imperial College, in 1948. He returned to Cairo to eventually become Professor in the Faculty of Science, Cairo University, where he established his own school in microbiology and is currently Emeritus Professor. He was also Professor in Bagdad University, 1954–1959.

After this distinguished academic career, Dr Tolba joined the Egyptian civil service as Undersecretary of State for Higher Education and Minister of Youth, and on the international scene as an alternate member of the United Nations Educational, Scientific and Cultural Organization (UNESCO's) Executive Board. He became the first president of the newly established Academy for Scientific Research and Technology in 1971.

In 1972, he led Egypt's delegation to the Stockholm conference on the Human Environment, thus starting a lifetime commitment to environmental issues. In the preparatory meetings leading to the conference, as well as during the conference itself, he was among the first representatives of developing countries to realize and promote the view that there are no irreconcilable con icts between the environment and development. He argued that concern for the environment should extend to the social as well as the physical aspects. At the time, quite a number of developing countries saw environmental issues merely as problems of pollution that were the concern of developed countries. It was no wonder that he was nominated, immediately after Stockholm, as Deputy Executive Director of the newly established United Nations Environment Program (UNEP).

Within 2 years, he became the Executive Director – a post he held until retiring at the end of 1992.

Under his leadership, UNEP became the core organization within the United Nations (UN) family acting as the catalyst spurring governments, business, academia, international governmental organizations (IGOs) and non-government organizations (NGOs) to meaningful action. UNEP, one of the small members in the UN family, could leverage on the average four times its modest budget to carry out more than a thousand projects.

Following up on his position during Stockholm, he diligently promoted his philosophy of development without destruction . Its implications are clearly re ected in his speeches, books and in UNEP's programs, in many fields, and at many levels.

It is difficult to single out Tolba's most significant qualities and contributions. He is by nature an optimist who pursues his vision and objectives with remarkable diligence combined with communication skills. His obvious mastery of the subject, sincerity, and dedication to the causes he is pursuing, command the respect of those who deal with him, be they heads of states or ordinary people. As a negotiator he is respected by all parties who usually hold con icting and, what seem to many, irreconcilable views. He patiently leads them to agree to compromises that many have despaired of reaching.

Combined with this, is his uncanny vision of emerging environmental problems. As early as the mid-1970s, he concentrated on the issue of stratospheric ozone layer depletion as meriting careful monitoring on the scientific front. At the right moment, he could manage, whether in Vienna, Montreal and later on in London, to formulate the prototype model for dealing with global environmental issues and the effective mechanisms for the transfer of technology and funds to developing countries, as and when necessary. Other examples of his skills as a diplomatic negotiator on the international arena are the Basel, and the Biodiversity Conventions, which were concluded after tortuous and tricky negotiations.

Dr Tolba has received many awards and prizes, both from academic institutions, governments and NGOs in many countries. These include honorary doctorates, awards, medals, and high decorations. He cherishes in particular the DSc degrees from Moscow State University, and the University of Guadalajara; DLL, Williams College; fellowship of Imperial College, London; the Sasakawa Prize; the Only One Earth Award of the René Dubos Center; the Distinguished International Service Award of the Regents of the University of Minnesota; and the First Order Decoration of the Arab Republic of Egypt.

Back in Egypt, he established in 1994 the International Center for Environment and Development (ICED), a not for profit organization financing environmental projects in the less developed countries through an endowment fund administered by an independent board of trustees.

OSAMA A EL-KHOLY *Bahrain*

Tradable Permits for Greenhouse Gases

Christiaan Vrolijk and Michael Grubb
The Royal Institute of International Affairs, London, UK

In December 1997 over 180 countries agreed with the Kyoto Protocol to take action against the threat of global climate change. This Protocol sets the aggregate target for industrialized countries to reduce their emissions to 5% below the 1990 base year level by the commitment period of 2008- 2012. However emissions of greenhouse gases (GHGs) are projected to grow substantially, over 30% for some Organization for Economic Cooperation and Development (OECD) countries. To ease the burden of the Kyoto Protocol, several measures have been included, such as differentiated targets across the industrialized countries, including Eastern Europe and Russia, and spreading the effort over a basket of GHGs and sinks (such as forests). The Protocol further introduced the so-called " Kyoto Mechanisms" , international emissions trading, joint implementation and the clean development mechanism (CDM). These mechanisms allow international transfers of emission allowances and reduction credits between the Parties to the Protocol. Even though this Protocol is the most likely regime for trading GHGs, a trading system can also be used in other circumstances, such as domestic regulation.

Tradable permits can reduce substantially the costs of emission abatement (and compliance with the Kyoto Protocol). Experience with various schemes, such as the US Acid Rain Program, has shown cost reductions of over 75%. Some modeling work on emissions trading under the Kyoto Protocol projects even greater advantages. Because of emissions trading, emission reductions will take place where they cost least, anywhere in the world and in any of the GHGs targeted. However, some problems do

exist that could undermine the legitimacy of emissions trading.

The climate is changing. Ten years ago, that was a very controversial claim. Now it is widely accepted that changes are being observed, that human emissions of GHGs are a possible cause, and that such emissions may lead to far greater climatic changes during the coming decades. In 1990, governments began to negotiate what to do about it, and in the mid-1990s they started to debate more substantive commitments.

*The Framework Convention on Climate Change (FCCC) was negotiated at the 'Earth Summit' in Rio de Janeiro in 1992 and entered into force in 1994. Under the Convention the Parties committed themselves to stabilize greenhouse gas concentrations 'at a level that would prevent dangerous anthropogenic interference with the climate system' (FCCC, Article 2). The headline commitment for the industrialized countries (the Annex I Parties) was to return greenhouse gas emissions to 1990 levels, and to show a reversal in the trend of growing emissions before the year 2000. The Conference of Parties (COP) meets annually as the supreme body of the Convention, dealing with various issues related to it (*see *Conference of Parties, Volume 4). At the first COP in 1995 in Berlin, the Parties agreed that these commitments were inadequate and they began 'a process to enable it to take appropriate action for the period beyond 2000, including the strengthening of the commitments of Annex I Parties' (Decision 1/CP.1, 7 April 1995, the 'Berlin Mandate'). Specifically it was decided to 'set quantified emission limitation and reduction objectives within specified timeframes'. The negotiating process based upon this 'Berlin Mandate' culminated at the Third Conference of Parties (COP-3) in Kyoto, Japan, December 1997.*

The Kyoto Protocol that was negotiated at the COP-3 sets out renewed, legally binding emission reduction commitments for the Parties listed in Annex B (Annex B of the Kyoto Protocol is virtually equivalent to Annex I of the Convention, the industrialized countries, including Eastern Europe and Russia.) of the Protocol in the period of 2008- 2012. The overall commitments sum up to a 5.2% emission reduction from 1990 for a basket of GHGs, including carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), some industrial gases (hydrofluorocarbons (HFC), perfluorocarbons (PFC), sulfur hexafluoride (SF_6)) and emissions and removals from land-use change and forestry (LUCF or 'sinks').

TRADING GREENHOUSE GASES

The main greenhouse gas, carbon dioxide (CO_2), is released when burning fossil fuels, which supply most of the industrialized countries' energy needs. A Protocol to limit these emissions, and thus the use of fossil fuels, would therefore limit the potential for economic growth. Some early studies suggested substantial losses of Gross Domestic Product (GDP) if limitations on greenhouse gas emissions were imposed. However, recent studies all show losses of under 1%, even for domestic implementation without any flexibility, equivalent to forgoing a few months of GDP growth and [it] is hardly discernible compared to the projected overall growth and uncertainties therein' (Grubb *et al.*, 1999). As a result many have argued for flexible commitments as the most cost-effective way of limiting emissions.

In the late 1980s tradable permits were proposed as an efficient solution, which was both practical and equitable (Grubb, 1989). Increased flexibility with emissions trading made it more plausible for governments to agree to greater emissions control, at lower cost. International emissions trading was seen as the most efficient and direct route to the international flexibility sought by the US and some other countries – and was viewed with suspicion by most of the rest of the world.

The principal idea behind emissions trading is simple; two entities exchange their emission quota if that is in their common economic interest. One Party reduces its emissions further than necessary and sells its spare quota to another Party that has not been able to reduce enough, or would not be able to do so for the present market price.

In the late 1980s and the beginning of the 1990s, interest in emissions trading for controlling GHGs had grown, particularly in the US, for several reasons. First, the US experience with its tradable permit system to control sulfur dioxide (and ozone-depleting substances) was widely seen to have been a success: emissions were reduced at much lower cost than originally predicted, because of the flexibility of the permit system and the incentives it gives for innovation. Second, emissions-trading is more attractive to industry than other economic instruments (such as carbon taxes), because the system creates a tradable asset: the permit or allowance. Even if a company has to buy permits to cover all its emissions, it still acquires the value of those permits as an asset, which can in principle be sold in the future if emissions can be reduced. This contrasts with a tax, which extracts revenue from the firm without adding any compensating value. In addition, governments may give out some or all of the permits initially, reducing the cost to industry. In many countries, taxes have proved extremely controversial and difficult to implement, primarily because of industrial opposition, so that other market-based approaches are attracting growing interest.

Emissions trading in principle separates who has the reduction commitments and bears the costs, from where and by whom the emission abatement actually take place. Where emissions have a direct regional impact, the split between the reductions and the location is not trivial and free trading of emissions is impossible, because it could lead to local pollution 'hot spots'. Although there will

be large regional differences in the effects of climate change – some regions will get warmer, others colder, wetter or drier – this does not depend on regional differences in the concentrations of the gases, the problem is global. Unlike many other cases, such as acid rain and smog, local climatic changes cannot be stopped by local measures: the location of emissions is unimportant. From a climate point of view, GHG emissions are homogenous: a ton emitted in New York is the same as a ton emitted in New Delhi. GHGs, therefore, are ideally suited for emissions trading.

The FCCC indicates that Parties can act on their commitments jointly with other Parties. The Convention itself did not establish a mechanism, then controversial, for joint implementation, or any other form of international transfers of emissions. However, an activities-implemented-jointly (AIJ) pilot phase was set up in Berlin, as a first step towards such a mechanism. The Kyoto Protocol, strengthening the commitments of the Convention, established several forms of international transfers of emission allowances and credits.

The COP decided that no credits shall accrue to any Party as a result of greenhouse gas emissions reduced or sequestered during the pilot phase from AIJ (Decision 5/CP.1, 7 April 1995, In this decision the COP recognized that AIJ will not be seen as fulfillment of current commitments), it can therefore not be considered as emissions trading in order to meet commitments. However, the experience with AIJ, gathered before Kyoto, showed the vast potential for cheap emission reductions, with projects mainly situated in the economies in transition (Central and Eastern Europe and the former Soviet Union.) and some developing countries. This pilot phase is now extended to gain further experience.

Other trades' have also taken place between countries and companies. The Nordic countries set up a shadow market in 1996 between the four governments, to meet their commitments under the Framework Convention. Some companies have traded emission reductions or invested in sequestration to meet voluntary emission targets.

However, the most important prospect for a market for greenhouse gas emissions was established with the Kyoto Protocol. The Protocol identified three different mechanisms for international transfers, discussed in the next section. It also opens the opportunity for domestic industrial emissions trading schemes.

MERITS AND PROBLEMS OF TRADING

Some of the merits of international exibility through emissions trading and other mechanisms of international transfers have been discussed previously. These arguments were used throughout the Kyoto negotiations by many of the non-European Union (EU) countries of Annex I, the major proponents of the exibility mechanisms. Because it is politically much easier to take cheap actions than expensive ones, cost-effectiveness is very important for the success of the Protocol. The establishment of an emissions trading market will automatically create a price for emission allowances. A decision not to take emission reduction measures would then forego the opportunity cost of selling these allowances. This way a market gives incentives to reduce emissions. The international transfers could also meet another objective of the Convention, technology transfer, and it establishes a ow of financial resources to developing countries and economies in transition, that could be used to fund sustainable development and adaptation measures.

However, some problems also occur from international transfers, often brought to the table by non-governmental organizations (NGOs). Emissions trading and the other mechanisms of Kyoto are very innovative and their effectiveness is still uncertain. Before Kyoto, it was also argued that negotiating these mechanisms would take more time than was available, time that could better be spent on other issues. In particular the monitoring and compliance systems of the Protocol are now substantially more complicated and need more time to be negotiated and put in place. Apart from this, the large financial resource ows from international transfers, resulting from trades in allowances necessary to gain substantially from the mechanisms, will also be politically difficult to implement.

Since Kyoto, the debate has changed. The Kyoto mechanisms are seen as an integral part of the deal of the Kyoto Protocol; without this exibility, many Parties would not have been able to agree. In particular the environmental NGOs are seeking restrictions on the use of the mechanisms, to ensure that the mechanisms do not diminish the environmental gains of the Protocol and to restrict trade in the excess allowances granted to some of the Economies in Transition (sometimes called hot air'). Also the EU has submitted proposals for ceilings on the use of the international transfer mechanisms, for similar arguments as the NGOs, to encourage domestic action in all Annex B Parties, and other political reasons.

Proponents of the trading mechanisms argue that it gives incentives for innovation. Opponents, however, argue the opposite. Trading encourages those with low marginal abatement costs to reduce their emissions further, while reducing the reductions taken by the high-abatement cost polluters. Overall, trading reduces the pressure to innovate for those with high abatement costs, and increases reductions from the other sources, who may be able to do this with conventional technology, since their abatement costs are relatively low. Consequently, short-term costs are reduced, but less innovation takes places that reduces costs in the long term (Driesen, 1998).

A more philosophical argument is that trading would imply rights to emit', as opposed to obligations to reduce

emissions'. Particularly for developing countries, this is an important distinction. The Convention and Protocol clearly state common but differentiated commitments' and developed country leadership' (in particular Articles 3 (Principles) and Article 4 (Commitments) of the Convention). The international transfer mechanisms could lead to a violation of these principles, since the developed countries could buy their way out of taking action and maintain growing emissions. Violation of the leadership principle could seriously undermine the further evolution of the climate regime.

MECHANISMS FOR INTERNATIONAL TRANSFER UNDER THE KYOTO PROTOCOL

Before Kyoto, some industrialized-country Parties were pushing for exibility in the commitments. This took the form in many proposals of differentiation of emission targets between Parties and in the development of some form of international trading of emissions quota. The Kyoto Protocol now includes several forms of exibility:

1. The commitments include a basket of GHGs and sinks, not only CO_2.
2. The commitments vary between countries, according to their opportunities and willingness to reduce emissions, in theory leveling the effort for all Parties.
3. The bubbling provision (Article 4) makes it possible to share the commitments with a group of countries (the EU uses a bubble').
4. Three mechanisms are available for international transfers of emission allowances.

The Kyoto Mechanisms' for international transfers of emission allowances are *joint implementation* (JI, Article 6) (*see* Joint Implementation, Volume 4) the *clean development mechanism* (CDM, Article 12) (*see* Clean Development Mechanism, Volume 4), and international emissions trading (Article 17). The Protocol only provides a framework for the mechanisms, and referred the design of rules and guidelines to later sessions of the COP. The Buenos Aires meeting resulted in a work program for these mechanisms, with a view to taking decisions on all the mechanisms under Articles 6, 12 and 17 of the Kyoto Protocol at its sixth session [in 2000 in The Hague]' (Decision 7/CP.4, 14 November 1998).

Emissions trading is defined in Article 17 of the Kyoto Protocol: The Parties included in Annex B may participate in emissions trading for the purposes of fulfilling their commitments under Article 3 [i.e., the emission reduction targets]. Any such trading shall be supplemental to domestic actions for the purpose of meeting quantified emission limitation and reduction commitments under that Article. The Article gives no detail of how this trading would work; in Buenos Aires the COP decided on a deadline for these issues by the Sixth Conference of Parties (COP-6). Article 17 states that Parties may trade. It is therefore questionable whether a domestic emissions trading scheme or an international industrial emissions trading scheme will be governed by Article 17.

It is possible that a domestic trading scheme would fall under Article 2: Each Party ••• shall implement and/or further elaborate policies and measures in accordance with its national circumstances ••• . Intergovernmental transfers must be conducted in units of assigned amounts, i.e., measured in the basket of gases and sinks during the commitment period. Private sector trading, however, may be denominated in any subset of these gases and periods, and will probably begin with CO_2 emissions from power generation and industrial processes.

Article 6 of the Protocol on joint implementation says, any Party included in Annex I may transfer to, or acquire from, any other such Party emission reduction units resulting from projects . Some provisions are made in the Protocol, and the COP can define additional rules. Interestingly the Protocol allows Parties to authorize legal entities (e.g., industry) to participate in this project-based mechanism. The traded emission reduction units include all gases and sinks.

The CDM is defined in Article 12 of the Kyoto Protocol. It has three main purposes: to assist Parties not included in Annex I in achieving sustainable development and in contributing to the ultimate objective of the Convention, and to assist Parties included in Annex I in achieving compliance with their quantified emission limitation and reduction commitments under Article 3 . Projects under the CDM can generate certified emission reductions. The inclusion of sinks in this mechanism is still uncertain; sinks are not mentioned (as under joint implementation), but also not excluded from the CDM. As under joint implementation, legal entities can be authorized to undertake CDM projects. Article 12.10 explicitly states, in contrast to emissions trading or joint implementation, that credits can be obtained from 2000 onwards.

The Buenos Aires Plan of Action set a negotiating track for deciding on the issues of all three of the Kyoto Mechanisms by the COP-6, at the end of the year 2000 in The Hague, Netherlands.

The Fourth Conference of Parties (COP-4) in Buenos Aires also decided to continue the pilot phase of AIJ, for continued capacity building for the (project-based) Kyoto Mechanisms – especially in the Parties of Annex B with economies in transition and the developing countries that lacked experience so far (decision 6/CP.4, 14 November 1998). The review process should be finished at or before COP-6 in 2000. This would mean that the final conclusions of the pilot phase experience would be drawn up before the start of crediting of CDM projects. However, of the 95 projects in the second synthesis report (FCCC/CP/1998/2), only 27 took place in the developing countries, the other 68 were situated in the Annex I economies in transition.

Therefore, experience for developing countries (CDM-type projects) has been limited.

The Kyoto Mechanisms are perceived to be crucial for reaching the targets set by the Kyoto Protocol. Some studies suggest that most of the reductions compared to a business-as-usual emissions path would come through one of the mechanisms. According to a study by the Massachusetts Institute of Technology (MIT), and supported by other studies, emissions trading would deliver up to 25% of all reductions for limited trading, or nearly 75% with worldwide trading (Ellerman and Decaux, 1998).

Apart from the options of international transfers and a domestic trading system, taxes, technology standards and emission caps can be used. In the UK, e.g., the government has released its plans for an energy tax, despite protests. How this tax and any other measure will actually interact with a possible emissions trading market is still being discussed, but some compatibility problems may arise. Some other countries too have introduced carbon taxes, but the lessons learned are limited because the taxes are low and the main emitters are excluded. The Kyoto Mechanisms will have to compare favorably with these other measures in order for this novel, still relatively unknown instrument to be implemented.

All three of the international transfer mechanisms of the Kyoto Protocol are variations on the simple emissions trading model. Article 17 emissions trading allows transfers between Parties, governments, of Annex B. Joint implementation, Article 6, involves investments in specific projects that will reap the emission reduction credits. The CDM of Article 12 is similar to joint implementation, because it is based on investments in specific projects, but for political reasons it carries tougher conditions on sustainable development and developing-country adaptation to climatic changes. Both project-based mechanisms seem to be more credible, steering investment to climate-friendly technology, where emissions trading leaves the possibility of large trades in assigned amounts without action being taken.

THE IMPACT OF THE KYOTO MECHANISMS

A first indication of the task facing industrialized countries in implementing the Kyoto commitments may be observed simply by considering the reductions required from the levels already attained during the 1990s. Emissions data available up to 1995–1996 show that the aggregate emissions of Annex I countries has gone down by about 5% since 1990. This would mean that the Kyoto commitment would stabilize emissions roughly at this level (of the mid-1990s) fifteen years hence (Grubb and Vrolijk, 1998).

Depending on the projections used, business-as-usual emissions in the commitment period for the OECD countries could be between 20 and 30% above the Kyoto target. Emissions of all of Annex I countries, including those of the Economies in Transition, are expected to exceed the target only by about 10–20% (Ellerman and Decaux, 1998; Grubb *et al.*, 1999).

In terms of distribution, the story is radically different. In the EU, emissions have declined – albeit not primarily due to climate change policies – and the recent projections suggest that member states would just achieve the Convention's aim of holding emissions of CO_2 and other GHGs below 1990 levels in the year 2000 (in aggregate). The US, Japan and Canada are committed to bigger reductions from the higher levels they had reached in the mid-1990s, while the Economies in Transition have scope for a big increase. Figure 1 illustrates the specific changes from 1995 levels needed to reach the Kyoto targets for different groups within Annex I. This confirms that the Kyoto commitments represent a big reduction from 1995 levels for the OECD countries, and a big increase for all the Central and Eastern European Countries (CEEC), especially the ones less advanced in their economic transition, that are not currently on track for EU membership.

Quantitative Impact of the International Transfer Mechanisms

These large regional differences in commitments are based on political will, the limitation and reduction opportunities perceived by the various parties and also on development indicators. This and the large difference in projected emissions open up a large potential for trade between the Parties.

The exact regime of the mechanisms is still under debate. Under this political uncertainty, industry is not willing to invest and only a few trades have taken places so far. It is, however, industry that eventually has to make the reductions. The likely impact of emissions trading and the other mechanisms can be estimated from experience from other pollution-trading regimes, such as the Acid Rain Program of the US and modeling studies.

The estimates for the aggregate mitigation costs are still wide-ranging. A study by the MIT (Ellerman and Decaux, 1998) estimated the global costs of the Kyoto commitments to be around $120 bn, without using any exibility. Including the other GHGs of the Protocol could reduce costs by a quarter. Other studies (Grubb *et al.*, 1999) estimate reductions in GDP in the range of 0.2–2.0% by the end of the compliance period, or 0.3–1.4% neglecting the outlying studies, with an average around $115 bn, for domestic implementation. A few of these studies analyze the impact of the trading mechanisms, they indicate aggregate cost reductions from trading of between 50 and 75%. The estimates of cost reductions from domestic abatement only through international transfers between

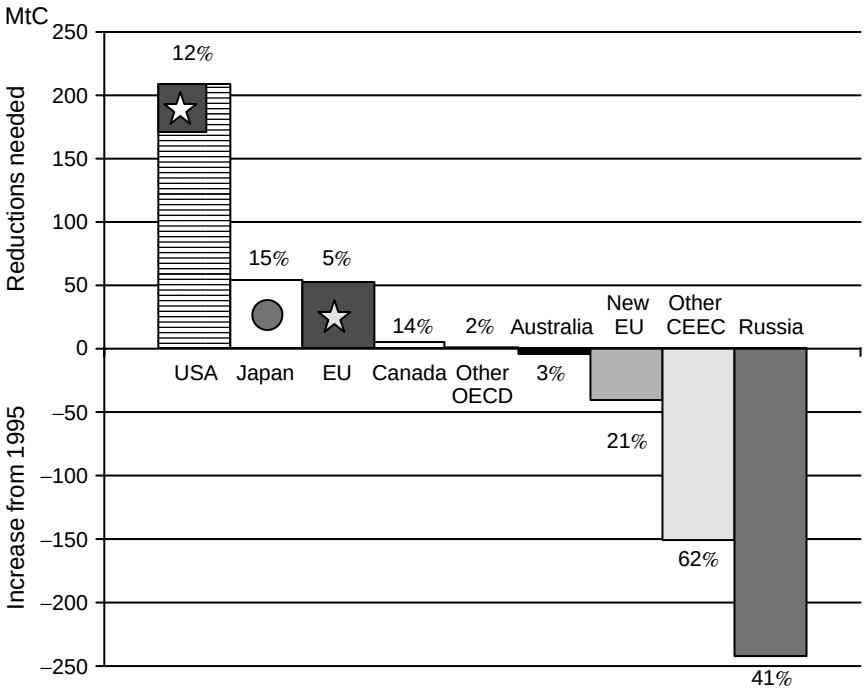

Figure 1 Gap between Kyoto commitments and 1995 emission levels in principal Annex I groups. The bars show the difference between reported emissions in 1995 and the Kyoto commitments in absolute terms; negative data indicate scope for increase from 1995 levels. The percentage difference between reported emissions and the target is also indicated next to the bars. The group the ''Other OECD'' consists of Iceland, New Zealand, Norway, and Switzerland. ''New EU'' is the countries set to join the EU. Other countries are the ''CEEC'', including Ukraine and the other Baltic countries

Annex B Parties range from around 10–75% for the US and the EU, on average nearly 50%; cost-saving in Japan is slightly higher. For full global trading (through the CDM), cost reductions are much higher: 60–90% for the US and the EU (ignoring one outlying estimate of only 33%); again cost-saving in Japan is higher, around 80–95% (Weyant, 1999; Ellerman and Decaux, 1998; Grubb *et al.*, 1999).

Taken at face value, these predictions of global cost are not very high, even without any international exibility. Compared to the economic growth and uncertainties about growth in the coming decade, the impact of Kyoto' might not be discernible.

The total scope of exibility' (including the mechanisms and the basket of gases) in the Kyoto Protocol has a profound effect on the emission distribution between the Parties. According to some studies, the OECD Parties will import on average about a quarter of their reductions, and with full global trading nearly three quarters, much of it through trading with developing countries. The Kyoto agreement could leave CO_2 emissions in the US and Japan around 10% above 1990 levels (and even much more for some other countries) without breaching the letter of the formal agreement – and that is before considering additional exibility from sinks and some further exibilities sought after. Figure 2 displays the results of a study by the Authors for the US, as a large importer.

Some Practical Problems

The international transfer mechanisms of the Kyoto Protocol as presented in the previous section are an attractive option for implementing the Kyoto commitments. Apart from the problems discussed earlier, that have to be addressed in the negotiations, there are numerous practical problems to be solved before a market could develop.

The Kyoto Protocol defines three mechanisms for transfers of emission allowances. The extent to which the credits from the mechanisms are equivalent will be crucial. The important questions are: who will be able to trade in the various mechanisms, e.g., will there be an industry-equivalent of Article 17 emissions trading; what gases will be covered by the various mechanisms; will the quota' from the three mechanisms carry the same risk, compliance procedures and therefore price?

The specific design of the CDM faces dilemmas of integrity and size. If the rules on additionality, contributions to sustainable development, etc., are rigorous, then governance could be very complex and administration costs high, thereby deterring investment. Weak rules and governance

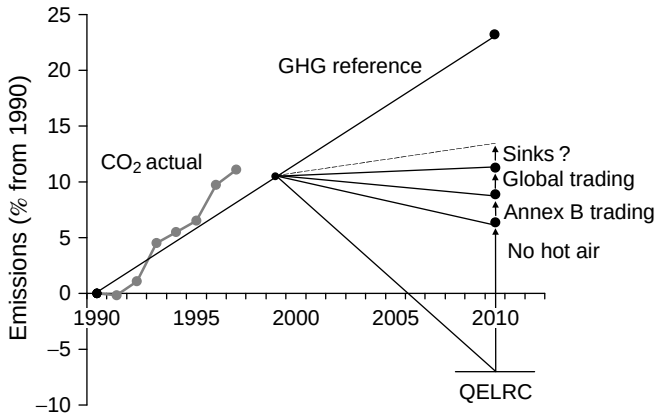

Figure 2 Assigned amounts and possible greenhouse gas emissions under the Kyoto Protocol, United States. Least cost trading in the commitment period, for the base case used in the emissions trading model developed at the Royal Institute of International Affairs, would leave US GHG emissions about 11% above 1990 levels. CO_2 emissions would be around 2–3% higher assuming greater abatement in other GHGs; the use of sinks would add to this difference. Excluding 'hot air' from the emissions market (''No hot air'' in the diagram) would result in additional domestic abatement of about 2.5%

may attract more investment at the risk of corrupting and discrediting the system, as well as undermining the criteria of sustainable development and the objectives of the Convention, since maximizing emission credits' under the CDM is equivalent to minimizing action within Annex I'. However, for both better or for worse this mechanism as generally conceived is likely to be constrained by the inherent limitations of credit-based, project-based systems, and for some countries it may be primarily a bridge towards adopting commitments and joining the international trading system.

The project mechanisms explicitly (and necessarily) involve private entities. Emissions trading will also be most effective when conducted by private entities acting internationally. However, this requires either new legal procedures that transfer part of governmental obligations – assigned amounts – to private entities, or procedures for automating simultaneous transfers of private sector permits alongside governmental assigned amounts.

The Danger of Inflation of Commitments

The political and economic circumstances in which the Kyoto Protocol was negotiated led to some perverse emission allocations, and an overall pattern that may induce large-scale emissions trading, principally from Russia and Eastern Europe to the US, Canada and Japan. The allocations of Russia and the Ukraine in particular could represent surpluses amounting to 5–10% of total Annex I assigned amounts. Transferring this surplus to other Parties would undermine the legitimacy of emissions trading and the further evolution of the whole climate regime.

The emission restrictions of the Kyoto Protocol are not trivial politically, but are clearly inadequate to lead efficiently towards atmospheric stabilization below a doubling of pre-industrial CO_2 levels, or to induce necessary technological changes. Indeed under some scenarios we find real resource abatement costs to be negligible, though Russia and Ukraine might still extract a price and they could act as monopoly suppliers. The implied scale of West–East transfer of both emissions and finance (if the price does stay up) would also raise serious political debate. Extensive use of sinks or the CDM would further reduce the level of effort required in Annex I.

If emission trends and further analysis do point towards such outcomes, debate will be reinforced about various kinds of restrictions on the use of the transfer mechanisms. Excluding trading of surplus, allocations could reduce national and aggregate emissions by several percentage points (as compared with no restrictions), and increase the value of the trades with developing countries (and of trading for most Parties within Annex B). Achieving this is politically and procedurally problematic. The EU has proposed to introduce caps on the amounts traded, stimulating domestic action, quantifying the term supplemental in the Protocol, reducing trades in reductions that would have taken place anyway (hot air'), etc. However, these discussions do not seem to lead to a quick politically feasible solution. Other approaches could focus upon assessing the adequacy of domestic actions.

Also, significant use of the CDM or sinks would violate the collective aim of the Protocol to reduce industrialized-country emissions to at least 5% below 1990 levels; it would allow their emissions to grow from the 5% reduction already achieved by 1995. Excluding trading of surplus entitlements could be one way of making room for the use of sinks and the CDM without violating the collective Annex I commitment, while shoring up the value of emission credits.

A classical economic perspective would suggest that, providing the reductions are real and not fraudulent, this is not a problem: it simply re ects the fact that the exibilities can uncover a huge potential for low-cost reductions. However, this perspective is static, it takes no account of induced innovation or a host of other issues associated with developing long-term efficient trajectories towards atmospheric stabilization. There is, in short, a potential tension between cost minimization in the first commitment period, and the generation of sufficient and efficient pressures required to change course towards long-term stabilization. These complex dynamic questions thus combine with political debates about the appropriate degree of exibility in implementing the Kyoto Protocol, in which some parties fear that *too much* exibility would enable the richest countries to

avoid making the changes and innovations that are central to establishing leadership and long-term resolution of the climate problem.

PROSPECTS AND CONCLUSIONS

The outcome of the Buenos Aires conference focuses most key decisions, including those on the Kyoto Mechanisms, upon the COP-6. Many countries will seek ratification based on the outcome of this conference and re ect other aspects of meaningful participation' of developing countries. Breaking the trend of continuously growing emissions, stabilizing or even reducing emissions of the OECD countries (the Worldwatch Institute, of Washington, DC, reported in late July 1999 that its latest emission estimates show a global decline in emissions (0.5%), while the economy is growing (2.5%)), and entry into force of the Protocol would plausibly establish leadership by the industrialized countries, and create a stronger basis for discussing subsequent global commitments, that are to start in 2005. However, there is also reason to believe that some countries will not ratify the Protocol, and consequently it might never enter into force. Entry into force of the Kyoto Protocol, requires countries emitting 55% of industrialized country emissions to ratify. None of the industrialized Parties on its own could block entry into force. However, the Parties with a large share of emissions, such as the US (over 35%), EU (nearly 25%) and Russia (nearly 20%), are of crucial importance.

Apart from resolving the outstanding issues of the Protocol, experience in the use of the Kyoto Mechanisms has to be built in coming years: experience is growing slowly. Without properly working trading mechanisms it will be politically impossible to keep the Kyoto Protocol from collapsing. Just over 100 projects are reported under the AIJ pilot phase (the second synthesis report on AIJ, FCCC/CP/1998/2, reported 95 projects by June 1998, with total emission reductions of 44 million tons of carbon and annual reductions of 1.91 million tons. One year later the *Joint Implementation Quarterly*, June 1999, reported in total 129 AIJ projects.)

The total emission reductions through these projects is still modest, around 2 million tons of carbon-equivalent, only a tiny fraction of what the forecast of demand is. The Nordic countries have run an emissions trading shadow market with good result. And some companies have started with emissions trading.

One of the most promising examples of industrial involvement in emissions trading is the internal emissions trading scheme of British Petroleum (now BP-Amoco) in September 1998. In the early stages of this experiment, a small number of trades have taken place for a price of $17–$22 per ton of CO_2. The too-perfect allocation of permits between the participating business units may have substantially reduced the number and size of the trades. Incorporation of methane and the other business units, including the newly acquired Amoco units, will broaden the basis of trading.

Many other initiatives have been taken, including more internal trading regimes in industry, industrial trades in emission reduction options, pilot trading schemes in some industrialized countries and (emission) brokers and exchanges diversifying into carbon trading.

The Kyoto Protocol set emission reduction targets for industrialized countries. In environmental terms these targets are modest, but compared to present emission trends the targets that the countries set themselves in Kyoto are tough. For economic and political reasons the Kyoto mechanisms, various forms of exibility through international trade in emission allowances, are an essential tool for reaching the target, since experience from other environmental regimes shows that the potential for cost-savings through trading is substantial.

However, the Protocol settles few of the core issues about how such mechanisms might actually work and be governed in the international context. That task is complicated by the inconsistencies between the mechanisms. The commitments are defined for 2008–2012, but companies need incentives now if they are to find it profitable to take the actions that will be required to meet them. Early and cumulated crediting is allowed for the CDM, the most complex and novel of the mechanisms, which will involve investment in regions where typically projects may take many years to get going. Early and cumulated crediting is not specified for joint implementation among Annex I countries, where governments and companies are already more geared for action. Sinks are allowed under joint implementation, but remain disputed in the CDM. Monitoring and certification procedures are different between the two project-level mechanisms; emissions trading, in theory the simplest mechanism but one on which a great deal hangs politically, remains wholly undefined. The unfinished business of Kyoto's mechanisms for international transfer is immense, as the subsequent Buenos Aires conference illustrated starkly. There is some, but still too little, experience with the trading mechanisms to date.

This article re ects developments up to early 2001.

Tradable Permits for Limiting Stratospheric Ozone Depletion

Rory O'Brien
University of Toronto, Toronto, Canada

Tradable permits are being increasingly used as a policy instrument to encourage industries to reduce their pollution emissions. In 1987, they were rst used in a global context when they were written into the Montreal Protocol on Substances that Deplete the Ozone Layer as the main option for regulating international trade in ozone-depleting substances (ODS) among its signatories. Internationally, production quotas for ODS, such as chloro uorocarbons (CFCs), were allowed to be transferred between Parties to the Protocol, with the stipulations that the total combined levels of the Parties involved not exceed the agreed-on production limits, and that the United Nations (UN) Environmental Programme Secretariat be noti ed of the transfer. Trade restrictions were also effected between Parties and non-Parties.

The trading regime was most useful, however, when it was applied at the domestic level, helping achieve national reduction targets among the major ODS producers, notably the US, through inter-corporate trades. Trading has not been extensively used at an international level, with only one transfer of production quotas between countries to 1998, and only 20 international trades with US companies from 1992 to 1995. This does not mean it has been a failure, however. Its main success lies in being an integral part of a precedent-setting political and economic system implemented between and among governments and industries on a worldwide scale. It also has been instrumental in encouraging universal participation in the Protocol and discouraging participants from relocating operations to non-Party countries.

At a domestic level, as evidenced by the United States, permits have been used in conjunction with other economic incentives to successfully ensure that the phase-out of ozone depleting chemicals was accomplished by 1995 year-end, in accordance with the schedule set out in the Protocol. Over 238 million kg of ODS in the US were transferred in 494 inter-company trades between 1992 and 1995.

One of the main issues arising out of the implementation of the global trading system is that of ensuring compliance. One manifestation of this problem is the rise in illegal imports and exports, mainly between developed and developing nations. This has led to an increased emphasis on licensing systems and customs monitoring. Another situation, wherein certain countries not in compliance with the Protocol were exporting new ODS under the legal provision for exporting recycled ODS, was resolved in 1997 by prohibiting those countries from exporting any ODS.

OVERVIEW OF POLICY INSTRUMENTS

There are two main types of policy instruments available to government seeking to in uence the environmental performance of polluters. These are *command-and-control regulations* and *market-based incentives.*

Command and control regulation has usually been the predominant public policy instrument to deal with the problem of corporate environmental pollution. In many cases, legislation is used to set limits on the amount of pollution a company is allowed to create. It also can ensure compliance through a system of mandatory reporting. Besides emission controls, other examples include: bans, production input controls, consumption controls, price controls, rate of return regulation, technology standards, licensing and certification, and standards of environmental impact. Anyone failing to comply faces penalties.

Market-based instruments (also called economic instruments) place financial burdens on polluters, to the extent that these costs provide an incentive to reduce pollution. Though still generally requiring a regulative framework, market-based instruments allow more scope for initiative, financially rewarding those who make the most effort to comply.

Examples of market-based instruments include: charges (to industry and consumers to cover costs of pollution), market creation (tradable permits, market/price intervention, liability insurance), subsidies (grants, soft loans, tax allowances), deposit-refund systems, and financial enforcement incentives (non-compliance fees, performance bonds).

Final policy choices are frequently a mixture of several options, depending on the circumstances. In general, industry prefers market-based incentives to command

and control regulations, as it gives more autonomy and exibility.

TRADABLE PERMITS

One of the policy options used in the case of the Montreal Protocol was that of a regime of tradable permits. The basic operation of a permit-trading system is fairly simple – an overall limit on the total emission of a pollutant is established, followed by a schedule for periodically reducing that total amount. A reasonable unit of pollution is set, divided into the total amount, and allocated to the individual countries, or firms in an industry, on some kind of equitable basis (such as an historical baseline, or an auction). These units become permits to pollute, and the owners treat them as property rights which, like other assets, they are allowed to sell or use as they see fit.

To illustrate the utility of such a system of tradable permits, we can look at US efforts to reduce the level of toxic lead in the environment. In 1973, the US Environmental Protection Agency (EPA) instituted a program of mandated reductions in the amount of lead added to gasoline. In 1982, to provide small refiners with more exibility in meeting new, lower lead limits, the EPA set up a system for allowing refineries to trade their rights to add specified quantities of lead to their gasoline. The difference between the amount a refiner was allowed, and the reduced amount it actually added, could be sold to other refiners, or, beginning in 1985, banked for future use or sale. The program, which ended in 1987 with the complete phase-out of lead additives, was considered to be quite successful. It resulted in the elimination of lead in gasoline within a short timeframe, and did so in a cost-effective manner – it was estimated that the program saved refiners $226 million (*see* Tradable Permits for Sulfur Emission Reductions, Volume 4).

TRADABLE PERMITS AND THE MONTREAL PROTOCOL

In 1985, the Vienna Convention for the Protection of the Ozone Layer was put in place as an international framework convention to deal with the problem of atmospheric ozone depletion. The Convention's Montreal Protocol on Substances That Deplete the Ozone Layer, which came into effect in 1989, regulated the details of policies and implementations (*see* Ozone Layer: Vienna Convention and the Montreal Protocol, Volume 4).

The Montreal Protocol was the first multi-national agreement to use tradable permits as part of a major policy package addressing a global environmental problem. The system that was put into place had to address the problems of encouraging a fair, equitable, cost-efficient reduction in ODS, while at the same time ensuring inclusivity and compliance among nations.

Designating Participants and Terms of Trade

The trading participants are those countries that have signed the Protocol (173 states in 1999). Each participant, however, is bound only to adhere to the initial Protocol, unless they are also signatories to its subsequent amendments.

Parties are considered developing countries if they have less than an annual consumption of the controlled substances of 0.3 kg *per capita*. To avoid the economic hardship of having to quickly adopt new and expensive ODS substitutes, developing countries were given extensions of approximately 10 years beyond that of the developed countries to meet reduction targets. In setting baseline amounts of ODS, developing countries have the choice of using the average of its national annual consumption between 1995 and 1997, or the 0.3 kg *per capita* consumption.

The actual traders of permits have been those companies in developed nations that produce ODS. While there were only 17 producing companies in the world in 1985, in 2000 there are almost 80, with most ODS being produced in India and China.

In the US, the federal government allocates production and consumption allowances that can be traded with domestic or foreign companies. Companies in the European Union (EU) can trade with any company that is part of the Union, or with any other Party, provided their combined quota levels do not exceed the pooled limits of the EU as a whole.

ODS trading with countries not party to the Protocol is restricted. Imports of ODS from non-Parties have been prohibited since 1990, and exports to non-Parties banned since 1993. This is designed to prevent leakage, i.e., reduction strategies pursued in one region that could result in an increase in emissions in another region (such as when an ODS producer finds it decreases expenses by transferring operations to a country that has not set emission limits and therefore does not impose costly compliance measures). The Parties also encourage non-Parties to sign the Protocol.

Setting Quotas and Schedules

The quotas for production and consumption of substances and their schedule for phase-out were set according to a complex formula for various substances grouped according to their molecular structures. The groups, or baskets, of ODS are weighted according to their ozone-depleting potential (ODP). This means that one chemical in the group can be replaced with another, enabling the Party to find other chemical substitutes in the least costly manner. In the Protocol, *production is* defined as the amount of controlled substances produced, minus the amount destroyed by approved technologies and minus the amount entirely used as feedstock in the manufacture of other chemicals. The amount recycled and reused is not to be considered as

production. *Consumption* means production plus imports minus exports of controlled substances.

Production and consumption limits are based on an allowed proportion of production and consumption by a Party in a particular base year. In post-Montreal meetings of the Parties, this proportion and the time limits changed. CFCs, the most important type of ODS, for example, were originally supposed to be cut to 50% of 1986 levels by 1998, but were later set to be 100% eliminated by the end of 1995 as a result of new scientific evidence on the rate of ozone destruction. Stockpiling of surplus ODS produced within production limits is allowed, but unused production quotas are forfeited.

Ensuring Compliance

The Ozone Secretariat in Nairobi acts as the Administrator of the system. Information on baseline year amounts, periodic reports on ODS production and consumption, and documentation on all trades, including imports and export, must be filed with the Secretariat in a timely manner. Such reporting has shown a need for improvement – in 1997, 38 of 151 countries had not filed their 1995 data, and only 43 had reported their 1996 data.

Illegal imports/exports, i.e., smuggling, is becoming more of a problem as the price differentials increase between developed and developing countries and demand remains for inexpensive supplies. Such trade is reported to be over 20 000 tonnes of ODS per year in 2000. Protocol signatories have begun implementing harmonized' customs codes and tracking procedures, and now require import/export licensing systems to be in place. Individual Parties are also increasing enforcement efforts, with strict penalties being imposed on smugglers – in the US, for example, 20 individuals have received jail sentences and fines totaling $60 million.

Several states, including Latvia, Lithuania, and the Russian Federation were found to be in non-compliance in 1996, meaning they were continuing to produce a controlled substance past its phase-out date. This was accompanied by notice of some instances of illegal exports of newly produced ODS falsely labeled as recycled and reused substances (which are allowed under the Protocol). As a consequence, a prohibition against all exports of non-complying substances by those countries went into effect in 1997.

A number of signatories to the Protocol have used tradable permits as a policy option, including Canada, members of the EU, New Zealand, Singapore, and recently China, but it has been the United States that has used it most extensively. In 1985, the United States, the European Community, and Japan accounted for 70% of the global production of CFCs. Over 40% was produced by the US alone, with a single company, Du Pont, controlling half the North American market. As the US was the largest producer and user of CFCs and other ozone destroying chemicals, it is worthwhile reviewing its experience in implementing the permits system.

THE TRADABLE PERMIT SYSTEM IN THE UNITED STATES

In 1978, regulations were enacted in the US to prohibit the use of CFCs as aerosol propellants. Anticipating that further regulation would be needed to resolve the ozone issue, the EPA in 1980 solicited responses from industry regarding other possible CFC control measures. Such measures included mandatory controls (such as requiring the use of alternative technologies), taxes and marketable permits.

The EPA considered economic incentives primarily for two reasons. First, CFCs are not of concern near emission sources (no direct health or biospheric impacts there) but they have long residence times, disperse widely through the global atmosphere and ultimately participate in stratospheric chemical reactions. So a single national tax or permit system, which is relatively simple to set up, can be applied uniformly.

The second reason had to do with the large numbers of small firms that used CFCs in their production processes. Any attempt to come up with acceptable regulations covering the gamut of uses, as well as monitoring and enforcing control measures would be almost impossible. A general limit on CFC production and use, or a tax, however, allows the voluntary use of a wide range of economic and technological options.

Economic studies commissioned by the EPA also indicated that a permit system was a cost-effective solution, particularly if it were applied to the small number of producers and importers of CFCs. In 1988, regulations were put into place to create a permit system based on the Montreal Protocol (and in 1990, Congress passed an amendment to the Clean Air Act specifically enacting the provisions of the Protocol).

Tradable allowances were allocated to a handful of firms (eight producers and 20 importers) using 1986 as the baseline year. These firms were allowed to trade their allowances within their own companies and with other firms, both within and outside of the US. It is interesting to note that providing allowances to a limited number of large corporations produced windfall profits in the billions of dollars for those companies. Congress took the opportunity to institute an excise tax on ODS transactions, both to cover costs of administering the EPA's program as well as providing another incentive to switch to untaxed chemical substitutes.

There were several other pertinent regulations:

- to help speed up the retirement of allowances, and hence quicken ODS reductions, an offset discount'

was imposed on each trade, reducing the transferor's stock of permits by 1% of the amount traded;
- in accord with the Protocol's formulaic definition of production and consumption, producers of ODS were required to hold both production and consumption allowances, while importers needed only to have consumption allowances;
- producers were allotted an additional 10% of their quota to be used for exporting to developing nations, in the period prior to 1993, provided records were kept and the recipient country did not re-export the materials; and
- allowances were provided for the destruction of controlled substances.

Data on the number, size and frequency of trades reveals that the system was well used. In 1992, 171 trades totaling 73 million kg were made, representing 13% of the allowances available for that year. The great majority of these trades were intra-company trades, and international trades were almost negligible.

Was the US permits regime successful? It appears it was. From 1989 to 1994, CFC production and consumption in the US remained well below that required by the Protocol, with full phase-out occurring on schedule by 1996. It is difficult to separate the effects of tradable permits from those of the many other related regulatory initiatives, but there are some assertions that can be made. One is that it was cost-effective, due mainly to the decision to regulate only a few large producers and importers, which resulted in low administrative overhead. Another is that the overall simplicity of the regulatory environment enabled the exibility to quickly adapt to the changing adjustments to the Protocol. A third is that it contributed to marketplace efficiency, stemming from the fact that no specific technologies were mandated to achieve targets. This allowed industry to rapidly develop and adopt new technologies in order to realize cost savings.

CONCLUSION

The drafting of the Montreal Protocol and its subsequent amendments has been the result of some enlightened experimentation in the fields of politics, science, and economics. Such experimentation has produced, in a relatively short time span, a workable system of production, trade and consumption that, along with other policy instruments, has succeeded in reducing the amounts of ozone-depleting substances in the world. One of the mainstays of this system is the allocation of permits to produce and consume a variety of controlled substances, as well as the option to transfer them to other Parties. This permit trading model, which operates simultaneously at a supra-national level, and, with somewhat more vigor, at the national level, has been very good at promoting reductions in ODS in the developed nations, but has not yet had much opportunity to prove itself a good mechanism for reducing ODS in the developing world.

Tradable permits have proved to be a good choice as a policy instrument. They are accepted by business because they allow for exibility in operations, and promote cost-efficient methods of complying with the required abatement in pollution. Governments tend to prefer them as well, as they often require less costly and bureaucratic infrastructures to implement than traditional command and control measures. But this is not to say that they can and should be used in all circumstances. They are a tool that holds promise, surely, as shown so far in the case of the Montreal Protocol. However it remains to be seen whether they will prove to be as versatile or as effective when applied to the remaining accumulating stocks of ozone depleting chemicals, or to the far larger problem of reducing greenhouse gas emissions.

Tradable Permits for Sulfur Emission Reductions

Roderick W Shaw
Rodshaw Environmental Consulting Inc., Nova Scotia, Canada

Acidic deposition from the atmosphere (more commonly known as acid rain) has been considered to be an environmental problem for several decades in various regions of the world, including eastern North America, Europe and Asia. Emission trading is a market-based approach to controlling emissions of acidic deposition through the buying and selling of allowances to emit acidifying pollutants such as sulfur and nitrogen. In contrast to the command and control approach where the maximum allowable emissions from each source are regulated, in emission trading a limit (i.e., the total number of emission allowances) is placed upon the total emissions from those sources involved in the trading. The sources may then trade amongst themselves. For example, if a source could reduce its emissions at a cost per tonne which is less than that it could receive from selling its excess emission allowances to another source, it has the potential to reduce its emissions and make a pro t. On the other hand, a source which nds itself in need of additional emission allowances (for instance because it is planning an expansion, or because the number of allowances to which it is entitled has been reduced for environmental reasons by the regulating body) may purchase the necessary emission allowances if they are available at a cost which is less than its cost of reducing emissions. Through trading, therefore, the cost of maintaining or reducing emissions in the trading area may be less than that of the command and control approach, and managers of individual sources may have more exibility in meeting air pollution requirements. Ideally the only restrictions would be that the total number of allowances is not exceeded and that environmental requirements such as local air quality standards or maximum rates of acidic deposition are met.

By far, the most experience with emission trading to reduce acid-forming emissions has been in the US. The US Environmental Protection Agency (USEPA) estimated in 1994 that compliance costs in the US could be reduced by 3.1 billion dollars per year as compared to conventional regulatory approaches. In 1996, emissions of sulfur dioxide were 2.9 million tons, or 35% below the emissions cap for that year. The agency also claims that these emission reductions resulted in a decrease of 10- 25% in deposition of sulfur by precipitation. Emission trading is being discussed in Canada and Europe but has not been adopted to any great degree there.

INTRODUCTION

The need to Reduce Acidic Deposition from the Atmosphere

Acidic deposition from the atmosphere (more commonly known as acid rain) has been considered to be an environmental problem for several decades in various regions of the world including eastern North America, Europe and Asia. This deposition originates with the emission to the atmosphere of sulfur and nitrogen oxides from both natural and human sources, with the latter being dominant in populated areas. Human sources of sulfur oxides include thermal–electric generating stations fueled by fossil fuels containing sulfur, and industrial sources such as non-ferrous ore smelters and oil refineries. These emissions are transported hundreds or even thousands of kilometers through the atmosphere, converted to acidic precipitation and fog, and deposited on receptors of varying sensitivities. Where fresh water bodies and forest soils are relatively sensitive to acidic deposition, this deposition is believed to result in adverse environmental effects such as decreases in fish populations and increased stress upon forests.

Approaches to Reducing Emissions of Acidifying Air Pollutants

The traditional approach has been command and control which sets rigid upper limits to the release of pollutants by a specified type of emission source, such as power plants or smelters. These limits are based upon generally accepted technologies. To allow for factors such as the general health of the local economy, some leeway may be given in the emission limits, or in the timetable for implementing them. While the command and control approach appears to be fair and relatively simple from an administrative point of view, it does not take into account the costs of controlling emissions at a particular installation (even if those costs are much higher than average). Nor does it take into account whether the emission reductions will result in levels of acidic deposition that are within the assimilative capacity of the environment.

In contrast, with emission trading, the regulating body sets a limit to the total emissions by all sources involved in the trading, and distributes an emission allowance to each source involved in the trading. If a source could reduce its emissions at a cost per tonne, which is less than that it could receive from selling its excess emission allowances to another source, it has the potential to reduce its emissions and make a profit. On the other hand, a source which finds itself in need of additional

emission allowances (for instance because it is planning an expansion, or because the number of allowances to which it is entitled has been reduced for environmental reasons by the regulating body), has a choice. It can reduce its emissions (usually through technological means such as abatement equipment) or, alternatively, it can purchase the necessary emission allowances if they are available at a cost, which is less than its cost of reducing emissions.

Therefore, it can be seen that emission trading will not only keep the total emissions among the trading sources within the prescribed limit, but it will also give individual sources the exibility of how they go about managing their emissions. Studies have shown that the total cost of keeping emissions within the total allowance can be less than that incurred through the command and control approach. Individual sources can benefit by having the potential to make a profit from creating surplus emission allowances for sale, or by purchasing emission allowances that cost less than the emission abatement that would be otherwise needed.

HOW EMISSION TRADING WORKS

There are several steps involved in setting up a scheme to trade emission allowances.

1. The area within which trading will occur is delineated. Trading can occur at many levels:

   - within a given site such as a plant;
   - within several plants owned by a particular firm;
   - among several firms;
   - among jurisdictions or;
   - within a specified geographical area.

   As will be shown in the section on taking the environment into account, the trading area must be large enough to include enough sources such that trading will bring about the required reductions in deposition.
2. The total number of emission allowances is determined. One possibility is that the initial total allowance should be approximately equal to the total emissions of the trading sources at the present time. This assumes that the present rate of acidic deposition be approximately maintained, although a shift of emissions through trading could conceivably concentrate emissions in a particular area, and result in undesirable increases in acidic deposition in certain parts of the trading area. If the present rate of acidic deposition is already too high (as it often is), then the total number of allowances may have to be gradually reduced with time.
3. The emission allowances are allocated among the trading sources. One simple approach is to initially distribute the allowances in proportion to the sources' emissions in a given reference year. This could be potentially unfair because sources which have not in the past reduced their emissions receive more than their fair share of the allocation. In addition, before the trading scheme has been initiated, it is important not to give sources the opportunity to increase their emissions artificially, so as to gain an unfair advantage in the initial allocation of emission allowances.
   Some proponents of emission trading suggest that the initial allocation of emission allowances be done by auction. There is a danger, however, that larger firms could artificially drive up the price of emission allowances, thereby sti ing competition from smaller firms. In the US, initial auctioning of all allowances has been rejected, although a small fraction is auctioned each year to provide opportunities for trading.
   It should be noted that an emission allowance gives the holder the right to emit a specified amount of the air pollutant not for perpetuity but for a fixed period, usually a year. It would be only fair that a source permit would be reissued each year with the same number of allowances that it held the previous year although, if the acid deposition situation requires it, a certain fraction of a source's emission allowances could be withdrawn from one year to the next, to reduce the overall emissions. In the US, to maintain a competitive market, 2.8% of a source's sulfur dioxide allowances each year are set aside to make them available in a sealed-bid auction.
4. An organization is established for keeping track of the ownership of emission allowances, ensuring that sources possess enough allowances to cover their emissions, and disciplining those who emit in excess of their allowances.
   Monitoring of emissions will be important to reduce the chances of cheating. In the command and control approach, the very existence of an installed piece of abatement equipment would be a strong indication that emissions are likely within the required limits. (If an emitter goes to the considerable expense of installing equipment, there is a good chance that they might operate it properly). In contrast, emission trading would require closer monitoring of emissions, perhaps on a continuous basis.
   Enforcement of the emission limits is similar for the command and control and for the emission trading approaches. Financial penalties for emissions exceeding the allowances should, of course, be greater than the cost of abating emissions to be within the allowances. Revenues from fines could be used at least to partially recover the costs of emission monitoring, and the administrative costs of the trading scheme.

More detailed descriptions of various aspects of emission trading may be found in Klaassen and Forsund (1994); NERA (1991) and UN (1995).

TAKING THE ENVIRONMENT INTO ACCOUNT

Trading emission permits for gases that lead to acidic deposition has to take into account where the trades take place. This is because these gases have relatively short atmospheric lifetimes (hours to days to at most weeks) and do not have time to become uniformly mixed. As a result, emissions of acidifying gases from a given source will lead to more acidic deposition at some receptor points than at others, because of patterns of prevailing winds and precipitation.

The relationships between emissions at given sources and deposition at given downwind receptors are called source–receptor relationships which are estimated through the use of computer models of the long-range atmospheric transport of air pollutants. Usually, these models track a unit or puff of emissions, which is emitted from a source and transported with the observed wind. During successive time intervals (typically one or several hours) the sulfur dioxide and nitrogen dioxide in the puff are transformed chemically to sulfates and nitrates, and incorporated into cloud droplets and precipitation, which are acidified. In addition these pollutants are deposited to the ground by dry deposition (in the absence of precipitation), and by wet deposition (e.g., precipitation).

The computer model repeats the above calculation for all time intervals over an extended period (typically months or years), and for all sources. It is obvious that generating source–receptor relationships can be a very computer intensive (and expensive) undertaking. Nevertheless, once the task has been completed, one has an estimate not only of the total amount of acidic deposition at a given receptor point, but how much of it originated from each source. Given the great expense of installing pollution control equipment, spending money to generate the best possible source–receptor relationships to aid in devising more efficient air pollution control strategies is a good investment.

A model that has been extensively used for developing an assessing control strategies for acidic deposition in Europe for the past decade or so is the regional acidification information and acidification (RAINS) model, developed at the International Institute for Applied Systems Analysis (IIASA) in Laxenburg, Austria. The RAINS model consists of many modules describing energy use, emissions of acidifying pollutants, atmospheric transport and deposition using source–receptor relationships, and environmental impacts. The model has been a valuable tool for the United Nations Economic Commission for Europe (UN–ECE) in developing sulfur and nitrogen emission protocols under the aegis of the Convention on Long-range Transboundary Air Pollution (*see* RAINS (Regional Air Pollution Information and Simulation), Volume 4).

The importance of source–receptor relationships has several implications for acidic deposition control strategies, including emission trading schemes. On the assumption that we want to control deposition at certain sensitive, ecologically valuable receptor sites,

1. It is essential that as many sources as possible affecting the sensitive receptor sites in a substantial way be included in the trading scheme. A study of the feasibility of trading sulfur dioxide emissions within the four Atlantic provinces of Canada to reduce acidic deposition there found that, to bring deposition to within ecologically acceptable ranges, the trading area would have to be expanded beyond the four provinces to include parts of the eastern US and central Canada.
2. Conversely, apart from considerations of local air quality, emissions from sources that do not affect sensitive receptor areas should receive less priority in any control scheme.
3. The effects on acidic deposition of any trading of sulfur and nitrogen emissions must be assessed, and the best way of doing this is through the use of source–receptor relationships. Both the command and control and the emission trading approaches can assure that the total emissions from a group of sources stay within a pre-determined limit, but they do not ensure that acidic deposition will be reduced. In fact, emission trading, if carried out strictly on the basis of profitable buying and selling, could result in emissions being shifted geographically such that acidic deposition would *increase* at some receptor points.

In the US, sulfur dioxide emission trading among power plants has not taken into consideration the effects upon reducing acidic deposition; the assumption has been that reducing emissions will result in an overall reduction in deposition. Indeed, a study by the USEPA concludes that, by 2010 when the emission trading program will have been implemented, there will be no more than a 10% difference in acid deposition with or without trading. This suggests that trading will perform as well as command and control in preventing hot spots of acidic deposition.

In the above mentioned study in Atlantic Canada, a computer model maximized trading within the region but with no restraints upon changes in acidic deposition; acidic deposition at several sensitive receptor areas was calculated to actually *increase*. Another experiment was then carried out, also maximizing trading but not allowing deposition to increase anywhere. In this second experiment, it was still possible to carry out the maximum number of trades, but deposition actually *decreased* in several receptor areas.

SOME QUESTIONS AND ANSWERS ABOUT EMISSION TRADING

Is Emission Trading not just Trading Licenses to Pollute?

Anyone operating a plant or device, whose pollutant emissions are regulated in some way, has in effect a license to pollute. For example, an operator of an automobile is allowed to emit so many grams of carbon monoxide per kilometer travel. Therefore, there is no difference between command and control and emission trading with respect to being licensed or entitled to emit air pollutants. With command and control the entitlement is attached to a single source whereas in emission trading the entitlement is held by a group of sources that may share it in ways determined by market forces. One advantage of emission trading is that the entitlement is not increased as new sources are added, while with command and control this could happen, to the detriment of the environment.

Can Emission Allowances be Stockpiled and could this not be Detrimental to the Environment?

An emitter can create surplus allowances (either by reducing emissions or by purchasing allowances on the market), declare them surplus and, rather than sell them right away, formally register them in a bank. This formal banking of allowances has advantages over informally held surplus allowances that are lost at the end of their valid period. Formally banked surpluses retain their validity for a longer period and can either be used by the holder in the future when it is more advantageous from an operational point of view (e.g., when undergoing an expansion). Alternatively, they can be sold at a profit in the future if the holder anticipates that the market price will rise because of a scarcity (e.g., the emission cap or total number of allowances is expected to shrink because of tighter environmental restrictions, or because new sources are expected to join the market).

Banking can in the short run actually benefit the environment because it may give emitters an incentive to reduce emissions and create bankable surpluses. However, the unrestricted use of banked allowances at a future time could be detrimental to the environment by leading to a spike of emissions unless, as was discussed in the section on taking the environment into account, their use is restricted by considerations of local air quality, or maximum allowable rates of acidic deposition.

It is important, however, that sources contemplating the banking of allowances feel confident that the banked allowances will not be devalued or confiscated. This could happen, e.g., when the authorities feel at some point in the future that emissions must be reduced at any cost for environmental reasons. Should this be required, it would be fairer to reduce the value of *all* allowances (banked and in use), so that everyone and not just those holding banked allowances shares the burden of reducing emissions.

WHERE EMISSION TRADING HAS BEEN USED FOR SULFUR AND NITROGEN EMISSIONS

United States of America

Early steps

By far, the most experience with emission trading to reduce acid-forming emissions has been in the US where various types of trading have been carried out since the 1970s. The 1970 US Clean Air Act amendments required each area of the US to attain ambient air quality standards for oxides of nitrogen and oxides of sulfur, among other pollutants. The principal means of improving air quality was through the traditional command and control approach. However, following this amendment, various policies were introduced to complement the command and control approach and in particular to accommodate economic growth and to provide the managers of facilities with more exibility. In 1976, the USEPA adopted its *offset* policy. This was the first in a series of policies that eventually evolved into a full- edged emissions trading policy.

The basic currency of any US emission trading scheme is an emission reduction credit (ERC), which is any emission reduction created when a company controls its emissions to a degree greater than the law requires. This may be done through changing its process (including changing fuels), installing pollution control technology, curtailing production or, in an extreme case, shutting down production.

Offsets are required for companies wishing to build or expand their operations in areas where air quality standards have not yet been attained. Normally, approval of new or expanded plants would have been impossible to obtain in these non-attainment areas. The offset policy allowed proposed new or expanded sources to purchase offsetting emission reductions from another source in the non-attainment area. In this way, the new or expanded source would not result in a net increase of emissions in the area.

Over the next 10 years, the emissions trading policy in the US evolved into a more sophisticated four-pronged approach, involving offsets, netting, bubbles and banking. *Netting* allows a firm to balance expected emission increases at some stacks at a given plant with emission decreases at other stacks at the same plant.

Bubbles provide exibility to managers of sources in that they can cover a single plant or a set of plants owned by the same firm. A manager can make emission control decisions in aggregate for all sources covered by the imaginary bubble rather than by each emission point within the firm's bubble.

For example, it might be much cheaper to control emissions at one stack than at another within the bubble; it would make economic sense, therefore, to over-control emissions at that one stack and under-control at others.

Banking, as has already been described, gives firms a legal means of storing surplus emissions (ERCs) for later use.

Recent Experience in the United States

In 1990 the Clean Air Act in the US was amended again; Title 4 of the Amendments set three major goals to combat acidic deposition:

- by the year 2000, a reduction in sulfur dioxide emissions of 10 million tons per year from 1980 levels, primarily from coal-fired electric generating stations. (In the US, English tons (equal to 2000 lbs or 908 kg) are used, rather than the metric tonne (equal to 1000 kg).
- a nationwide cap of sulfur dioxide emissions, beginning in the year 2000.
- a two million ton per year reduction in nitrogen dioxide emissions.

These goals were to be met through a two-phase program. In Phase I, beginning in 1995, part of the sulfur and nitrogen oxide reductions were to be achieved through emission reductions at the largest, highest-emitting plants. During Phase II (beginning in 2000), the emission reductions are to be attained through more stringent measures at virtually all fossil-fuel power plants.

Title 4 of the Clean Air Act Amendments allows for the creation of tradable *emission allowances*, an authorization to emit one ton of sulfur dioxide (or nitrogen dioxide) for a specific year. At the end of each year, each unit is to hold allowances at least equal to its annual emissions. If a unit emits more than it is allowed, a penalty of $2000 must be paid per excess ton of emissions (this fine was set to make it uneconomical to emit in excess of allowances). Moreover, the excess emissions must be offset (deducted) in the following year. Regardless of the number of allowances a unit holds, it is never entitled to exceed the local air-quality standards.

Beginning in 1995, allowances were allocated for each year but could be stored (banked) for future use. The distribution of allowances was based upon average fossil fuel consumption from 1985–1987. Allowances can also be obtained from three US reserves. The major one is a setting aside of 2.8% of the annual allowances for an annual auction and direct sales at a cost of $1500 per ton. Allowances can also be purchased on the secondary market from those sources that have created excess emission allowances for sale. New sources (those that begin operating in 1996 or later) do not receive any allowances but must buy them from the secondary market or at EPA auctions.

Allowances may be bought, sold or banked by any person, not only electric utilities, but also individual corporations, brokers, environmental groups or private citizens. For example, an environmental group, if it can raise the necessary funds, can buy emission allowances and then not use them, thus improving local air quality, and decreasing acidic deposition.

The USEPA estimated in 1994 that compliance costs in the US could be reduced by 3.1 billion dollars per year as compared to conventional regulatory approaches. In 1995, the largest one-year drop in emissions since 1970 occurred. In 1996, emissions of sulfur dioxide were 2.9 million tons, or 35% below the emissions cap for that year. The agency also claims that these emission reductions resulted in a decrease of 10–25% in deposition of sulfur by precipitation. Some researchers believe, however, that the environmental benefits and costs savings from emission trading have yet to be demonstrated. Concentrations in ambient air of sulfur dioxide also decreased by 17% between 1994 and 1995. However, it may still be somewhat early for a full evaluation. At least one researcher suggests that there is as yet very little hard evidence that trading has provided any increase in environmental benefits, or encouraged innovation and technological change, or economic efficiency over what might have occurred under a command and control program with appropriately designed incentive structures.

Trading among sulfur and nitrogen oxides (both of which contribute to acidic deposition) and other pollutants could theoretically take place, but this has not yet occurred in the US or elsewhere.

Canada

In Canada, experience in the trading of acid-forming air pollution emissions has been limited to within-firm trading of sulfur dioxide and nitrogen dioxide emissions by several industries in Ontario, and of sulfur dioxide emissions by power utilities in the province of Nova Scotia. In Ontario's Countdown Acid Rain program, a schedule was imposed upon the four large industries (three copper–zinc smelters and the provincial electricity generating utility) to reduce emissions between 1986 and 1994. All four companies are now operating under their own emission bubble. Although there is no trading permitted among the four companies, within the electric utility, trading of emissions can take place among the 28 boilers involved; it is estimated that trading has resulted in substantial cost savings. In Nova Scotia, the power utility operates within a sulfur dioxide bubble of 145 000 tonnes per year; trading of emissions among plants of the utility is permitted.

Europe

To date, experience with trading emissions within Europe has been relatively limited as reliance is still placed mainly

on the command and control approach. However, as will be described below, some aspects of emission trading such as offsets and bubbles have been used in several countries.

In Germany and Austria, it is possible for a new or expanded plant to be built in an area where air quality standards are not met, if the new plant replaces an existing plant of the same type, or if the existing plant is renovated such that its emissions are reduced. The offset would, however, have to result in a reduction of the annual average pollutant concentration in the area, and the new plant would have to meet state-of-the-art emission standards.

As early as 1984 in Denmark, a bubble of 116 000 kilotonnes of sulfur dioxide (to be attained in 1995) was imposed upon emissions from power plants. In 1987, an additional bubble for nitrogen oxides of 85 000 kilotonnes was set. Data suggest that actual emissions of both sulfur and nitrogen oxides were around 10% less than the allowed bubbles. It has not been possible to estimate what cost savings the bubble approach might have brought about to the power producers.

In the Netherlands, the state and provincial governments signed an agreement with the association of electricity producers to reduce sulfur dioxide emissions from 41 kilotonnes in 1989 to 18 kilotonnes by 2000, and nitrogen dioxide emissions from 74–30 kilotonnes during the same period, on the basis of a shrinking bubble. It is estimated that the trading will save the electricity producers about half the cost of 500 million guilders (about $250 million) of using uniform emission standards.

Despite the above use of offsets and bubbles, there has been no evidence in Europe of a market where permissions to emit were transferred from one party to another in exchange for money. Researchers suggest that there are no sound economic and environmental reasons for European reluctance to adopt more aspects of emission trading. One difference between the US and Europe is that there is a greater geographical differentiation of sensitivity to acidic deposition in Europe. This means that, e.g., credits or allowances obtained by reducing emissions at sources, which affect Scandinavia (a relatively sensitive area) might be considered to be worth more than those from sources, which affect southern Europe (a relatively less sensitive area). *See also* Tradable Permits for Greenhouse Gases, Volume 4; Tradable Permits for Limiting Stratospheric Ozone Depletion, Volume 4.

There may also be a cultural reason for the differences in degree of acceptance of trading in the US and Europe. In the US, government intervention is less than in Europe, and more reliance is placed upon a market-based approach to solving problems, including air pollution. In Europe, government intervention and regulation is more accepted. Furthermore, there is more uniformity of environmental policy in North America than there is in Europe; e.g., in southern Europe, environmental policy in still in the inception stage. One should also keep in mind that emission trading has been evolving in the US for more than 25 years and might take a similar period to do so in Europe.

Transferable Fisheries Quotas (TFQs)

Ross Shotton
Food and Agriculture Organization, Rome, Italy

Quotas are used in sheries management to control the amount of harvest. Thus, they can be used to prevent the biological productivity of a sh stock from being excessively reduced so that catches are less than they can otherwise be. Most commonly, quotas determine how much catch can be harvested during a shing season - in these cases, the quotas are used as a form of output control. Fisheries managers also use quotas in the form of limitations on the amount of shing that is permitted, e.g., number of traps, eet size or number of vessels permitted to operate

in the shery. These regulations are a form of input control. Commonly, both measures may be used in the same shery.

The amount of quota that may be caught - the total allowable catch (TAC) - is determined from stock assessments (the current amount of stock biomass) and analyses of the state of the stock, e.g., its spawning biomass - how much of the stock is mature and can reproduce - the age structure, and factors affecting its productivity, such as the oceanographic conditions. In traditionally managed sheries, once the quota is determined, shermen compete among themselves to maximize their share of the xed amount permitted. To be competitive in doing this, they increase the shing power of the vessels by replacing them with newer, larger, more expensive vessels and installing the most modern technology to aid shing. To pay for these, incentives to cheat are increased and the pro tability of the industry is reduced by the extra capital costs involved.

The solution that has developed over the last 20 years, at least in industrial sheries, is to assign to shermen, vessel owners or investors, rights to harvest a speci c amount of sh (in output controlled sheries), or to use a certain amount of shing gear (in input controlled sheries). Thus, once the operator is awarded his individual quota, he can then harvest it in the manner that he nds most economically ef cient. No longer is there any incentive to invest in a vessel that is larger than required to physically take the harvest; his individual quota assures him of his share.

Quotas, when assigned, may be granted to individuals or companies. In several management jurisdictions, they have been assigned to the vessel that has been responsible for past harvests (e.g., Alaska, Iceland and the UK). Once assigned, when the management regime permits, these harvest, or access, rights may be sold or leased to other sheries operators; hence, the term transferable.

WHY IS THERE INTEREST IN THIS FORM OF FISHERIES MANAGEMENT?

Granting of transferable harvest rights implies a form of property rights. Just as in other endeavors, when there is ownership, there is greater incentive to look after the resource. This is particularly so in fisheries because of the way in which transferable quota systems are characteristically designed. Harvest rights are usually assigned as a certain fraction of the TAC (Total Allowable Catch). If the resource is managed well, e.g., if nursery areas are protected and small fish are left to grow, the TAC can be increased, and an initial quota of 100 tons may be increased to 110 tons if there is a 10% increase in the TAC. Experience shows that this is changing the way fishermen view, and participate in, the management of their fisheries. Instead of reacting to government managers, they now participate in the decision-making and often fund activities that bring about an increase in stock abundance, and hence, in future TACs. As a consequence of their property rights, industry has an incentive to ensure that research and stock assessments are adequately funded (and has an incentive to minimize the costs of doing so).

WHAT ARE THE FEATURES OF TFQs?

Not all TFQ schemes are alike; neither are the biological, social, economic, cultural and political situations in which fisheries operate. However, one of the underlying characteristics is that to be able to transfer a catch right, it must be owned in the first place, i.e., it has the characteristics of property. In the case of fishing entitlements, these may be seen from the perspective of their durability, security, exclusivity and transferability.

Durable fishing rights are those that holders can possess for long periods; in New Zealand, fishermen hold their rights in perpetuity. In Namibia, the period varies between seven and 14 years, depending on a government assessment of the rights holder's success in contributing to national policy objectives. Clearly, more durable rights are worth more to the holder, though they provide the government with less exibility to change policy if they wish.

Exclusive fishing rights exclude others, who are not bound by the same rules of ownership, from participating in the fishery. Weakness in the exclusivity of quota rights may occur in a stock if it is shared with another country or migrates to the high seas where it is also fished. In a national context, weak exclusivity can arise where recreational fishermen share a commercially exploited stock or where two different sectors, e.g., artisanal and industrial fisheries, target the same stock. Usually recreational fishermen, though often individually restricted to daily limits, can collectively catch as much as they can harvest. Government policy may allocate the remaining to the commercial sector. Clearly, this lack of exclusivity affects the value of the commercial sector's harvesting rights.

Secure fishing rights are those that are not easily removed from a fisherman. Of course, unless constitutionally guaranteed, laws can always be changed to allow appropriation of the rights. In many countries, the constitution may specify that the government must act as a trustee on behalf of the people and it is impossible to grant ownership of fisheries rights to individuals. In these cases, access rights are commonly considered to be privileges. Noteworthy though, is the common practice that even where governments can legally appropriate fishing rights, they never do so without compensating the holders, even when there is no legal requirement to do so.

The right of quota transfer is the most important criterion in the use of property rights in fisheries management. Fishermen often hold licenses that provide a fair degree of exclusivity, durability, and security, but do not have the

right to sell them. It is the right of transferability that leads to most of the benefits that can be derived from this form of management. There are several aspects of transferability. Usually there is a minimum holding that can be transferred, e.g., 100 kg, though fishermen may need to own more than this to obtain a license to participate in the fishery. There may be a limit on the maximum amount of quota that a single owner may hold, e.g., from 0.5% in some Pacific Halibut fisheries to 35% in deepwater fisheries in New Zealand. There may be restrictions on the nationality of the rights owner – in New Zealand, only citizens or New Zealand owned companies can buy quota. In the US, the rule depends on the fishery. For surf clams, no such restrictions exist, but only US fishermen are entitled to physically harvest the clams. Quota holders may be able to lease their holdings to other operators. Alternatively, rules may require that the quota holder is present on the vessel that harvests the catch.

WHERE ARE TFQs USED?

TFQs have been in use for about two decades. In New Zealand, they were introduced as a result of changes to national legislation, while in other management jurisdictions they have been implemented within the scope of existing national legislation, e.g., Iceland, Holland and Canada. In Canada, participants in several fisheries, with the support of the Department of Fisheries and Oceans, have created their own legal agreements through civil contracts, whereby fishers agree to abide by rules that, in effect, create property rights in the fisheries. In addition, property can only exist when it is respected and the associated rights are enforceable.

Most marine fisheries on the Pacific coast of Canada operate on an individual transferable quota (ITQ) basis, though salmon and herring are exceptions. Fisheries for whitefish in lakes on the Canadian prairies and many fisheries in the Maritimes of Canada also function using ITQs. On the east coast, many fisheries have mixed management, with different fleet sectors using different management methods. For example, the offshore scallop fleet has long used enterprise allocations but the inshore Bay of Fundy sector has used boat limits or competitive quota. In the US, the major fishery to use individual vessel quotas is that for sablefish and Pacific Halibut in Alaska. There is a surf clam and ocean quahog fishery based on a similar approach in the mid-Atlantic states, and a small fishery for wreckfish in the southern US that also uses transferable quota. Iceland started its individual fishing quota program with herring and then expanded it to include most important demersal species. Holland also started its transferable quota program for just one species group – plaice and sole – and then expanded to cod and related demersal fishes. The UK has a form of transferable quota management, run through national producers organizations, bodies that formerly were primarily concerned with marketing.

In the Southern Hemisphere, New Zealand operates a quota management system; ITQs have been issued for 42 species, or groups of species, managed as 257 separate fish stocks within this system. In Australia, nearly 100 fish stocks are managed using transferable quotas. Two of Australia's most important fisheries, that of the Western Australian lobster fishery and the Northern Prawn Fishery (NPF), are managed using input controls. For the lobster fishery, the input units are individual traps (or pots). For the NPF, the tradable units were initially a function of vessel engine power and gross tonnage, but were later changed to units (12 inches–1 foot) (3.05 cm) of trawl headrope length. Chile has had some fisheries managed through an ITQ approach and Namibia has a rights-based program, which is unique in Africa, though its conditions of quota transferability are restricted relative to other such programs.

WHAT DO TFQs NOT DO?

TFQs do not solve all the problems of fisheries management. Where the right is to harvest a part of the TAC, the TAC must still be properly calculated and the decision on the level of the TAC must withstand risk-prone lobbying efforts to increase them. Thus, the administrative resource requirements (staff and funding) for data collection and analyses remain.

TFQs do not decrease the amount of administration that is required to manage a fishery; in fact, the contrary. Catches must be recorded against those who have the entitlement (either by ownership or lease); registries of quota owners, including those who have leased some or all of their entitlement must be as accurate as the records of a bank. In some cases, the TFQs can be securitized, are liable to liens and have been declared marital assets in divorce proceedings.

Provisions are often necessary to handle situations where fishermen have inadvertently caught more than their holding permits, and some or all of this excess must be debited against the following year's allowance. Where the fishery exploits several species simultaneously, fishermen may need to balance their quota holdings across all the species they have caught – and when the species mix taken does not reflect their holdings, trading is necessary to achieve the required balance.

TFQs are often tied to particular stocks or fishing areas, so enforcement is needed to ensure that catches are taken from the stock area of the specified rights. If there are seasonal closures or closed areas for conservation reasons, marine surveillance will be required, as with conventional forms of (quota) management.

TFQs reduce the incentives, and frequency of fishermen who cheat, as it is clear that those who are robbed are

the other fishermen themselves. In this way, peer pressure facilitates the success of the programs. However, TFQs do not abolish the free rider problem, and some fishermen or fishing companies may exceed their quota if they believe it can be done without detection and punishment. Because the usual limit on landings is an amount of fish, as with traditional forms of quota-controlled fisheries, incentives will remain for fishermen to discard the less valuable fish they catch (called hi-grading). These fish are usually smaller and often immature, so that in landing their quota fishermen may have caught significantly more than their entitlement. The result is that fishing mortality is higher than the management plan calls for. A measure that has attempted to resolve this problem is to require that all fish caught are landed, i.e., fishermen are not allowed to discard fish at sea. Another approach is to allow such fish within reason, to be sold at a lower price to the administrating authority.

WHAT ARE THE CONCERNS REGARDING TFQs?

While there are concerns that TFQ systems may not achieve their biological, resource-oriented objective, the main concerns relate to their social and community implications. Because one common policy objective of TFQs is to increase the economic efficiency of a fishery, not surprisingly, when quota entitlements are sold, the most profitable operators usually buy them. These new owners may wish to land and process this fish in different locations than before. If this process continues, communities may become impoverished as the economic activity associated with the fishing activity is moved elsewhere.

Another concern arises from the success of this form of management. Often, TFQ management systems are introduced to remedy severe structural problems in a fishery, e.g., too many fishing boats, excessive capitalization, lack of profitability and other deficiencies. To promote TFQ management and because of the industry conservatism, but more to the point, because of the absence of any value in the fishing rights arising from the unprofitable nature of the fishery, governments commonly gift the future rights to the fishermen. As the scheme starts to work – as intended – rights that had no major value when granted, may come to assume great value. Many find the gain by individuals of such windfall profits from the privatization of a public asset morally wrong.

Others are concerned that TFQs may prevent young fishermen from entering the industry, because as quota rapidly assumes great value, the capital entry requirements become beyond the reach of a new fisherman to secure. Consequently, the structure of the fishery may change from an owner-operated industry to one where fishermen are essentially salaried employees. This situation is viewed with great aversion in many traditional fishing communities.

Another concern relates to the benefits that society should expect in the way of resource rents from those who have gained ownership of a resource that was recently public property (albeit usually with little access for those not already owners of a fishing license). Should rights-holders pay society some rent for their entitlement beyond funding the management costs of the fishery? Or should they, as the rights-owners usually claim, simply pay their contribution to society through normal taxes on profits realized?

On an operational basis, many believe that the way these systems have been introduced in the past have not appropriately recognized the rights of the many, created through their past participation in the industry as workers. In many applications, the rights have been assigned to the vessel, i.e., implicitly to the vessel's owners. Many argue that crews too should participate in receiving rights. But, the complication in doing this is in reaching agreement on the basis by how this could be done, not least because the available records of employment may not permit such a procedure without excessive legal challenges to the reliability of the information that is to be used.

HOW ARE TFQs IMPLEMENTED?

One of the major concerns of those with the option of entering a TFQ management program is determining the share of the future TAC they will receive. The most common method has been to base the initial allocation on the past catches of the operator. Different management regimes have used different formulae, but usually an earlier fishing period is taken, e.g., the last five years, and then the option may be taken of selecting, e.g., the three best years in terms of catch taken. The total of the selected catches represents the number of shares in the fishery, which are then divided into the TAC to give a catch per share.

In other management jurisdictions, a participant's current investment in the fishery may be considered with, e.g., 30% of the new allocation based on past catch and 70% based on an assessed value of the operator's investments. Where rights are being assigned to a new fishery, and there are no claims to precedence, the administrator may choose to auction the rights to the highest bidder. If there are concerns about quota eeing an area, regulations may tie the ownership of the quota to those who are members of a particular community. Thus the term in these situations is called *community quota*. Once allocated, sale of the quota may be restricted for a specified period to ensure that the new owners appreciate the value of the asset they have acquired. But, what these variations mainly show is

the exibility that exists in the way TFQ systems can be designed and implemented.

PROSPECTS FOR THE 21ST CENTURY

TFQ systems of fisheries management increase, rather than decrease, the administrative requirements of fisheries management. Thus, to the extent that current fisheries management is constrained, owing to inadequate commitment of human and financial resources, then so will the potential for expansion of this form of management be constrained. A pessimistic view is that little expansion is likely of the existing club of countries benefiting from this form of management (Canada, Iceland, US, Australia, New Zealand, Holland, Namibia and perhaps, Chile and the UK) during the next one to two decades.

An optimistic view is that, in view of the undeniable benefits of TFQ management, fishermen, industry and other stakeholders will successfully pressure governments into allowing this form of management. This process will be facilitated as recognition of governments grows that granting of property rights in fisheries does not diminish their sovereign rights or responsibilities.

U

ULYSSES (Urban Lifestyles, Sustainability, and Integrated Environmental Assessment)

ULYSSES has been an innovative European research program (commissioned by EC DG XII, part of the Fourth Framework program), which has developed a procedure for citizen participation in integrated assessment (IA) (*see* Integrated Assessment, Definition of, Volume 4). The procedure comprises a process based on the *focus group* method. A group of citizens debates climate policy and sustainable development, having been given access to state of the art IA models to support their debates.

Between 1996 and 1999 ULYSSES has conducted and analyzed group discussions with over 400 citizens in eight European cities. Participants approached the climate change issue from a broad range of criteria including fairness, justice, and personal values and beliefs, and they related climate change to their own experiences and lifestyles. Participants usually preferred strong reductions of energy use in the next decades to business-as-usual trends. They were often in favor of actions to be taken in order to reduce the risks of climate change, even if there were substantial scientific uncertainties. The issue of trust in science and policy communities is essential in this context.

ULYSSES has demonstrated that IA–Focus Groups can increase the possibilities for citizens to articulate their views on environmental issues in a thoughtful manner. This can help to bridge gaps between decisions by policy makers and citizens' views. Exploring alternative explanatory and moral frames in such processes can complement expert assessments on complex environmental issues. Focus group procedures involving open-ended discussions add a richer dimension to the traditional quantitative survey methods. In IA–Focus Groups, the discussions can broaden into directions impossible for the researchers to imagine beforehand. This is vital if we are to learn more about how the diversity of everyday life and experience affects the understanding, values, and objectives that different social groups bring to global change issues (*see also* Integrated Assessment, Volume 4).

UNCED (United Nations Conference on Environment and Development)

UNCED was held at Rio de Janeiro in June 1992; 20 years after the United Nations (UN) Conference on the Human Environment held at Stockholm. UNCED is also commonly known as the Rio or Earth summit/conference. The UNCED event re ected a growing concern among all nations about the deterioration of the global environment. Global problems such as climate change, ozone depletion, and the loss of biological diversity had become significant issues in the public conscience, and this was gradually re ected in interest at the political level. The importance of integrating environmental and economic objectives into public policy had also gained prominence. The growing use of the terms *sustainable development* and *sustainability* is, in part, a re ection of this realization. The UNCED was intended to recognize the importance of a healthy environment to sustainable economic and social development.

UNCED was the culmination of several years of negotiation which led to the signing of the non-binding UNCED (Rio) Declaration, Agenda 21, and the Statement on Forest Principles. Two formal binding treaties, the Framework Convention on Climate Change and the Convention on Biological Diversity, were negotiated outside the preparatory process for the Rio Conference, but signed during the Rio Conference. The Conference involved representatives of UN member nations and a large number of non-government organizations (NGOs) concerned with environment and conservation. In addition, parallel NGO events were held to critique the UNCED. The Rio Declaration lists 27 principles

of sustainability. Several themes are particularly worth noting: the principle of common but differentiated responsibility for environmental degradation and improvement; the importance of integrating economy and environment in the development of policy and strategies; attention to private and intellectual property rights (including technology transfers); and the need for new and innovative approaches to environmental regulation (including economic instruments). Though signatory nations recognize the Declaration's Principles, adoption into national policy and legislation is not legally binding.

KEVIN S HANNA *Canada*

UNCHS (United Nations Centre for Human Settlements)

The UNCHS (Habitat) was established in 1978, 2 years after the United Nations (UN) Conference on Human Settlements in Vancouver, Canada. Based in Nairobi, Kenya, UNCHS (Habitat) is the lead agency within the UN system for coordinating activities in the field of human settlements.

Currently the structure of the center comprises:

1. A governing body called the UN Commission on Human Settlements composed of 53 governments elected by the general assembly of the UN from its membership on a rotational basis and representing the five UN recognized regional groups: Africa, Asia and the Pacific, East Europe, Latin America and the Caribbean, West Asia and West Europe and others.
2. A secretariat headed by an executive director with the rank of under secretary general of the UN and appointed by the secretary general.

The center was the secretariat for the second UN Conference on Human Settlements (Habitat II), held in Istanbul, Turkey, in June 1996. This conference formulated the Habitat Agenda and the Istanbul Declaration which together form Habitat's Global Plan of Action. In this document governments commit themselves to the goals of adequate shelter for all and sustainable urban development. Habitat is the focal point for the implementation of these commitments.

Habitat's operational activities focus on the following priorities: promoting housing for all, improving urban governance, reducing urban poverty, improving the living environment and managing disaster mitigation and post-con ict rehabilitation. Acting as a catalyst in the mobilization of technical cooperation, the center is supporting the implementation of the Habitat Agenda at local, national and regional levels.

During the biennium 2000–2001, Habitat will undertake two significant global campaigns, one for secure tenure and the other on urban governance. The aim of both campaigns is to reduce urban poverty through policies, which emphasize equity, sustainability and social justice. Strategic and operational partnerships with different levels of government, local authorities, non-governmental and community based organizations, the private sector and agencies within the UN system are crucial to the success of these campaigns.

UNCHS (HABITAT) ACTIVITIES

The Urban Management Programme

This is a long-term technical cooperation program designed to strengthen the contribution that cities and towns in developing countries make towards human development. The program is a partnership of the international community, involving a broad range of actors in developing countries at the national, regional, municipal and community levels. UNCHS (Habitat) is the executing agency, the World Bank is an associated agency and the UN Development Programme provides core funding and overall monitoring.

The Sustainable Cities Programme

This is a joint program of UNCHS (Habitat) and the United Nations Environment Programme (UNEP) dealing with the urban environment; uncollected garbage, poor drainage and impassable roads, unsafe water supply and inadequate infrastructure, polluted rivers and air. The program supports urban environmental planning and management at city and national levels through system-wide capacity building and networking. More than 20 cities are now primary participants in this program with several thousand professionals directly and regularly associated with it in over 40 cities and 30 partner organizations around the world.

Localising the Agenda 21 Programme

UNCHS (Habitat) is the UN task manager for the human settlements aspects of Agenda 21, adopted by the United

Nations Conference on Environment and Development (UNCED) in Rio de Janeiro in 1992. To reinforce the process of localization, this project offers a multi-layered support system to selected medium-sized cities in Kenya, Morocco and Vietnam.

The Safer Cities Programme

This joint Habitat–UNEP program was launched in 1996 at the request of African cities who want to address urban violence by developing a prevention strategy at city level. The objective is to establish a community-wide consultation process to reduce crime and address its causes through the development of crime prevention measures, methods and strategies.

The Local Leadership and Management Training Programme

This program supports national capacity-building institutions to provide training in local leadership and management to local government elected officials and other urban managers. Some of the program's main activities include preparing innovative training manuals and management tools as well as the development of assessment needs methodologies.

The Women and Habitat Programme

The objective of this program is to empower women within human settlements and urban development by improving their participation and decision-making power at all levels. The program works on capacity building, monitoring and research, particularly in the role of women in leadership and governance, management and negotiation, construction skills and finance for urban development.

The Community Development Programme

This is designed to build capacity among urban managers, practitioners and community organizations to improve the physical, social and economic infrastructure in low-income settlements through participatory concepts and approaches.

The Global Urban Observatory (GUO)

The GUO monitors the implementation of the Habitat Agenda through the development and application of policy-oriented urban indicators (The Urban Indicators Programme) and the sharing of lessons learnt from best practices at local and national levels (The Best Practices Programme). Urban indicators cover essential issues such as poverty, employment, infrastructure and transport, environmental management, local government performance and housing. The Best Practices database allows users to identify and access information, knowledge and expertise and provides solutions to some of the most pressing challenges facing an urbanizing world.

REGIONAL AND INFORMATION OFFICES

To improve the efficiency of in-country program preparation and management, as well as to raise the profile of Habitat's work worldwide, the center has established three regional offices, in Rio de Janeiro, Brazil (covering Latin America and the Caribbean), Fukuoka, Japan (covering Asia and the Pacific) and Nairobi (covering Africa and the Arab States). The center also has active information offices in Budapest, Geneva, New York, Beijing, Moscow and others.

WORLD HABITAT DAY AND PUBLIC AWARENESS

Through its publications, websites, exhibitions and public events, Habitat has played a leading role in raising global awareness about shelter and urbanization issues. World Habitat Day is celebrated on the first Monday of October every year and each year embraces a different theme. 1998s theme was Safer Cities; 1999s theme took on the idea of Cities for All.

Habitat produces two agship publications: *The Global Report on Human Settlements* provides a review of human settlements conditions, including their development and continuing evolution. *Habitat Debate* is the center's quarterly magazine, designed to be a forum for dialogue and debate on urban issues. It is disseminated to over 8000 readers worldwide, including non-governmental organizations, local authorities, governments, academic institutions, libraries and the media. It is also available on the Internet via the center's website http://habitat.unchs.org/home.htm.

ROBYN LYONS *Kenya*

UNCLOS (United Nations Convention on the Law of the Sea)

The Convention was adopted by the Third UNCLOS convened by General Assembly resolution 2750 C (XXV) of the 17th of December 1970. The conference worked for more than a decade before it was able to agree on a Convention that was acceptable to the majority of the participating

states. The Convention adopted by the conference was finally opened for signature on the 10th of December, 1982 at Montego Bay, Jamaica. On the 28th of July 1994 the General Assembly, by resolution 48/263, adopted the agreement relating to the implementation of the UNCLOS of the 10th of December 1982 (the 1994 Agreement). The 1994 Agreement is to be interpreted and applied together with Part XI (of the Convention) as a single instrument. Accordingly, UNCLOS refers to the 1982 Convention as modified by the 1994 Agreement.

UNCLOS establishes a comprehensive framework for the regulations of all ocean space. The 17 parts and nine annexes contain provisions governing, *inter alia*, the limits of the territorial sea, contiguous zone, exclusive economic zone and continental shelf of individual states; the right of access to the sea, freedom of navigation and other lawful uses of the sea in various maritime zones; exploitation, conservation and management of living resources of the sea; deep sea mining in the area beyond the limits of national jurisdiction; marine scientific research; protection and preservation of the marine environment; and the settlement of disputes. The provisions set out the rights and obligations of coastal and other states, including landlocked states, in the use and management of the seas and their resources.

UNCLOS establishes new international bodies to perform specific functions in connection with the implementation of its provision. Among these are the International Seabed Authority, which is responsible for regulation and control of deep-sea mining; the Commission on the Limits of the Continental Shelf; and the International Tribunal for the Law of the Sea for the peaceful settlement of disputes concerning the interpretation and application of the provisions of the Convention.

UNCLOS entered into force on the 16th of November 1994. (As on the 30 June 2001, there were 135 states parties to the Convention. This includes the European Union, which is a state party' in its own right, pursuant to Annex IX to the Convention.)

Further information on the Convention is available on the website of the United Nations: http://www.un.org/depts/los.

THOMAS A MENSAH *UK*

UNCTAD (United Nations Conference on Trade and Development)

The UNCTAD was established in 1964 as a body of the United Nations (UN) General Assembly. Its objective is to promote international trade, particularly between countries at different stages of development, in order to accelerate economic growth in developing countries. In light of their particular economic structures, most of these countries are very trade-dependent. UNCTAD provides policy advice and technical assistance to developing countries in the areas of institution-building and policy-making so that they may take full advantage of their enhanced participation in international trade and the global division of labor.

UNCTAD was founded at a time when many developing countries were in the process of gaining their political independence and thought their interests were underrepresented by other multilateral organizations, particularly by the General Agreement on Tariffs and Trade. In the first two decades of its existence, UNCTAD focused on the shaping of a new international economic order, the stabilization of commodity prices, and the achievement of fair terms of trade. More recently, it has shifted emphasis towards issues of globalization and structural reform, based on the new consensus that market-oriented economic policies, supplemented by active government support and founded on political pluralism, are the basis for fostering development.

UNCTAD is now recognized as a central forum for North–South dialogue. Conferences of UNCTAD are held every four or five years. It also conducts a number of analytical activities to advise developing countries in multilateral negotiations on liberalization of trade within the framework of the World Trade Organization (WTO).

UNCTAD increasingly views environmental issues as an integral part of the relationship between trade and development, as manifest in the important role it was assigned by Agenda 21 to make trade and environment mutually supportive in favor of sustainable development. To support this mission, UNCTAD undertakes analytical work on trade, environment and development, including in the field of competitiveness, market access, eco-labeling, multilateral environmental agreements, enabling measures, and trade liberalization and sustainable development. It also assists developing countries in the area of trade and environment through country studies, technical assistance programs and training to enhance the capacity of the public and private sectors of developing countries to address, in a participatory framework, trade and sustainable development issues.

Many of UNCTAD's research and training activities on trade and environment issues are coordinated with other international organizations, in particular the United Nations Environment Programme, the United Nations Development Program, the WTO and the Organization for Economic Cooperation and Development (OECD).

For further information, see http://www.unctad.org.

HUSSEIN ABAZA *Switzerland*

UNDP (United Nations Development Program)

UNDP, The United Nations Development Programme is part of the United Nations. Its mission is to help countries in their efforts to achieve sustainable human development by assisting them to build their capacity to design and carry out development programs in poverty eradication, employment creation and sustainable livelihoods, the empowerment of women and the protection and regeneration of the environment, giving first priority to poverty eradication.

UNDP also acts to help the United Nations family to become a unified and powerful force for sustainable human development and works to strengthen international cooperation for sustainable human development. UNDP, at the request of governments and in support of its areas of focus, assists in building capacity for good governance, popular participation, private and public sector development and growth with equity, stressing that national plans and priorities constitute the only viable frame of reference for the national programming of operational activities for development within the United Nations system.

UNDP acts through a unique network of 145 country offices in 140 countries and territories. Each of these offices is headed by a resident representative. UNDP resident representatives normally serve as resident coordinators of the operational activities of the United Nations system, supporting at the request of governments the coordination of development and humanitarian assistance. Resident coordinators also help to orchestrate the full intellectual and technical resources of the United Nations system in support of national development.

UNDP receives voluntary contributions from nearly every country in the world. It seeks to ensure a predictable ow of resources to support its programs. It provides grant funds through criteria on universality that strongly favor low-income countries, particularly the least developed.

MOSTAFA K TOLBA *Egypt*

UNEP (United Nations Environment Programme)

The establishment of UNEP was recommended by the Stockholm Conference. The recommendation was endorsed by the general assembly of the United Nations (UN) in or through its resolution 2997 (XXVII) of December 1972. Accordingly, four entities were established:

- a 58-nation governing council to act as the UN's intergovernmental organ for the environment;
- a small secretariat to provide a focal point for environmental action and coordination within the UN system;
- a voluntary environment fund to finance new environmental initiatives in whole or in part including those suggested by the Stockholm Action Plan, particularly integrated projects, and other activities agreed by the governing council;
- an Environment Coordination Board, to ensure cooperation among all UN bodies involved in environmental programs.

By resolution 3004 (XXVII) the general assembly decided to locate the small secretariat, in Nairobi, Kenya. UNEP was thus the first UN agency to be based in a developing country. It also has offices and UNEP-administered convention secretariats in Bangkok, Bonn, Geneva, Manama (Bahrain), Mexico City, Nairobi, New York, Washington, DC, Osaka, Paris, Montreal, The Hague, Athens, Kingston (Jamaica) and other cities.

UNEP's governing bodies include:

- the governing council composed of 58 governments, from five geographical regions, elected by the general assembly for four-year terms;
- the committee of permanent representatives;
- the high-level committee of ministers and officials.

UNEP works closely with UN agencies, international scientific and professional communities, non-governmental organizations, civil society and, in particular, governments, to ensure that important environmental issues facing the world are properly addressed.

UNEP's activities cover a wide range of environmental issues and environmentally related problems and sustainable development. Its present program of work focuses on five areas:

- environmental information, assessment and research, including environmental emergency response capacity and strengthening of early warning and assessment functions;
- enhanced coordination of environmental conventions and development of environmental policy instruments;
- fresh water;
- industry and technology transfer;
- support to Africa.

UNEP's functional programs are:

- environmental early warning and assessment;
- environmental policy development and law;
- environmental policy implementation;
- technology, industry and economics;
- regional cooperation and representation;

- cooperation with environmental conventions;
- communications and public information.

The resources available to UNEP for the administration and implementation of its program come from four distinct sources:

- the regular budget of the UN;
- the Environment Fund;
- trust funds;
- counterpart contributions.

For further information, contact United Nations Environment Programme, PO Box 30552, Nairobi, Kenya, http://www.unep.org.

NAOMI POULTON *Kenya*

UNESCO (United Nations Educational Scientific and Cultural Organization) and the Environment

Although the concept had not been brought forward when the UNESCO was set up in 1946, a number of activities clearly focusing on the environment were introduced from the beginning in the programs of this new agency. One of these first steps was the convening by UNESCO in October 1948, jointly with the French government in Fontainebleau, of a conference for the creation of what is today known as the World Conservation Union (IUCN).

A particularly important effort took place, from 1948 onwards, aiming at the scientific study of the problems of the arid lands of the world. This research program was placed under the guidance of an expert advisory committee, which held its first session in Algiers in 1951. The last session, held in Jodhpur (India) in 1964, marked the end of this long-term venture which had considerable in uence on the future environmental activities of UNESCO, focusing on world wide cooperation of specialists, interdisciplinary, problem oriented research and capacity building.

While many countries at the end of the 1950s were gaining their independence and were looking for economic development, based in particular on better knowledge of their natural resources, UNESCO was invited to extend its scientific programs into other areas. This included the humid tropics, with the launching of a modest international program in 1957, and the vast domain of marine sciences, with a first major operation, the International Indian Ocean Expedition (1959–1965), and the establishment of the Intergovernmental Oceanographic Commission (IOC) (*see* IOC (Intergovernmental Oceanographic Commission), Volume 4).

UNESCO is an intergovernmental organization and it appeared at this period that certain scientific issues related to the environment and its natural resources, called for an intergovernmental cooperative approach because of their geographic nature in the context of national sovereignty.

Thus, following a US proposal, UNESCO launched in 1965 a 10 year worldwide effort to understand and analyze the Earth's water cycle, to evaluate surface and ground water resources, to establish a basis for their sound management, to train the appropriate specialists and to enhance the place of hydrology among scientific disciplines. During this International Hydrological Decade (IHD) (*see* IHP (International Hydrological Program), Volume 1) a common program of research and monitoring was defined and its coordination ensured by a council, where a limited number of countries were represented at expert level, together with representatives from other United Nation (UN) or non-governmental organizations (NGOs) concerned. In all countries, a National IHD Committee was set up to arrange for the participation of the country in the world program.

The success of IHD, and the fact that water related issues were becoming more acute in most parts of the world, led to the establishment of a longer-term cooperation program. This International Hydrological Program (IHP) continues today, with successive four-year planning phases and national committees in some 140 countries. Particular stress is placed on concrete problems in water resources management. However, more purely scientific issues, including for instance the in uence of climatic change on these resources or the relations between hydrology and ecology, are also covered.

The development of UNESCO's environmental programs has always been closely linked to research on natural resources. While in the UN system scientific matters concerning the atmosphere are the responsibility of World Meteorological Organization (WMO), those concerning the hydrosphere, the lithosphere and the terrestrial biosphere have fallen largely within UNESCO's purview. This has given rise to an important production of thematic continental or world maps such as the *Soil Map of the World* (with Food And Agriculture Organization (FAO)), the continental climatic atlases (with WMO) and a host of maps on vegetation or on geology and related fields. The study of natural hazards (earthquakes, eruptions, oods, tsunamis, etc.) has been developed, particularly through emergency scientific missions. An International Geological Correlation Program has been in operation since 1973.

It is, however, in the vast area of interactions between human activities and the different eco-systems of the planet that UNESCO has pioneered a major innovative

program. In September 1968, it convened in Paris, a world conference on the scientific basis for the rational use and conservation of the resources of the biosphere. Four years before the UN Stockholm Conference on the Human Environment, this Biosphere Conference represented the first intergovernmental forum looking explicitly at reconciling environment and development, or in other words at promoting what would be called 20 years later sustainable development.

A major outcome of that Conference was the launching by UNESCO in 1970 of an intergovernmental and interdisciplinary program on Man and the Biosphere (MAB). This program was devised along the same principles as IHD, with a coordinating council and national committees, which operate today in 120 countries. However, the subject matter of MAB is more diversified since it deals practically with the entire spectrum of economic and social activities in the various eco-systems of the world, from tropical forests to urban systems, from coasts and islands to mountains. Until 1985, the different MAB projects attempted to cover exhaustively all domains. Since then, while these projects are maintained actively in many countries, a more selective approach has been followed.

One of the original MAB projects has emerged as a backbone for most other activities and is providing an exceptional tool for conservation of biodiversity as well as for ecological research and monitoring or for experimental management of resources towards sustainable development. This project concerns the establishment of a World Network of *Biosphere Reserves* (*see* Biosphere Reserves, Volume 2). Each Biosphere Reserve (there are at the moment 356 in 90 countries) consists schematically of a core area (terrestrial or coastal) legally protected for its biodiversity, surrounded by a well-defined buffer zone where only activities compatible with the conservation objectives of the core are permitted, itself included in a transition area where local communities are invited to participate in the management of the system and share in its economic and social benefits.

While a number of the existing Biosphere Reserves are not yet fulfilling adequately their multifunctional role, the network, which they constitute, and which is governed by a statutory framework calling for periodic review, is progressively improving. In 1995, an important conference held in Seville adopted a global strategy for Biosphere Reserves and formulated this statutory framework. Biosphere Reserves allow local communities to participate and benefit from conservation measures, thus ensuring long term protection of biodiversity, offering a tool for land use planning and constituting a large set of sites available for environmental research and monitoring on a variety of issues.

This brief review of natural and social science activities of UNESCO in the field of environment should not omit two paramount dimensions of its mission, namely education and culture. Environmental education has been for 25 years a major concern of the organization, where it has actively cooperated with United Nations Environment Programme (UNEP), including joint sponsorship of a series of world conferences (Tbilissi (1997), Moscow (1987), Toronto (1992)). Culture is associated with nature in the 1972 UNESCO Convention concerning the protection of the world heritage and many sites listed under this Convention show symbolically the link between these two fundamental poles of the human destiny.

UNFPA (United Nations Population Fund)

UNFPA, the world's largest internationally financed source of assistance regarding population issues, became operational in 1969. The fund concentrates its programs and resources in three priority areas: reproductive and sexual health, including family planning; population and development strategies; as well as advocacy. It seeks to ensure universal access to reproductive health services to all couples and individuals by the year 2015, support population and development strategies that enable capacity building in population programming, promote awareness of population and development issues, and advocate for the political will and mobilization of resources necessary to accomplish its mission. It is guided by, and promotes, the principles of the Program of Action adopted by 179 countries and entities at the International Conference on Population and

Development (ICPD, 1994). The fund currently extends assistance to some 145 developing countries and those with economies in transition, to enable them to address population and development concerns in the context of their respective priorities and cultures.

UNFPA began its mission to promote awareness of population concerns, and of the social, economic and environmental implications of national and international population problems in both developed and developing countries at a time when understanding of the linkage between population, socio-economic development and the environment was limited. Recognizing the complex relationship between population and the environment, and aware that meeting the basic human needs of growing populations is dependent on a healthy environment, UNFPA played an active role in all the recent United Nations (UN) conferences, including the UN Conference on Environment and Development (Earth Summit) held in Rio de Janeiro in 1992 and the World Food Summit held in Rome in 1996. At each of these Conferences, UNFRA advocated the integration of population, development and environment issues, pointing out that such factors as population, health, education, poverty, patterns of production and consumption, the empowerment of women, and the environment are closely interconnected and should be considered through an integrated approach. Consistent with Agenda 21 adopted by the Earth Summit and the ICPD Program of Action, the fund seeks to promote the eradication of poverty and the reduction of both unsustainable production and consumption patterns, as well as negative impacts of demographic factors on the environment in order to meet the needs of current generations without compromising the ability of future generations to meet their own needs.

As part of the follow-up activities to these major Conferences, UNFPA seeks to ensure that population, development and environment concerns are adequately addressed in all its program activities. UNFPA assists countries to incorporate population, development and environmental factors in planning and decision-making at all levels, and integrate these dimensions in national development policies and programs. UNFPA promotes cooperation and collaboration among UN system organizations, bilateral agencies, governments, non-governmental organizations, and the private sector in addressing issues of population, development and the environment. It works with a broad range of partners, including civil society, to promote sustained and sustainable social and economic development that meets human needs, ensures well-being and protects the natural resources upon which life depends.

UNFPA has funded research and analysis on the relationship between population pressures, poverty and environmental degradation; the population dimension of the food supply system, including the causes of food insecurity and imbalances in supply and distribution. Support has also been provided for research on the population dimension of desertification; population factors related to water-scarce and water-short regions, including effective strategies to conserve and utilize the resource in a sustainable manner; the causes and consequences of environmental refugees; and the roles of women and men as resource stewards.

UNFPA has prepared a guidebook on population, resources and environment in collaboration with the World Conservation Union (IUCN) and has provided support for activities with the United Nations Environmental Programme (UNEP). UNFPA has worked with the Food and Agriculture Organization of the UN and the International Institute for Applied Systems Analysis (IIASA) on the preparation of a major report on the carrying capacity of agricultural land in the developing world. UNFPA also published an advocacy booklet entitled, *Food for the Future: Women, Population and Food Security*, as input to the World Food Summit. It co-organized, together with UNEP and the IUCN, an International Workshop on Population–Poverty–Environment Linkages to review case studies from various regions that would serve to identify the nature of these linkages, as well as the policy and the programmatic responses that could address them.

To promote awareness of the linkages between population, development and the environment, UNFPA, together with the International Planned Parenthood Federation, the Swedish International Development Cooperation Agency, the World Wide Fund for Nature and the IUCN, publishes a joint quarterly publication entitled, *People and the Planet*. This publication informs a wider audience on how demographic factors, combined with poverty and lack of access to resources in some areas and excessive consumption and wasteful production patterns in others, can exacerbate environmental degradation and resource depletion.

UNFPA has recently signed a Memorandum of Understanding with UNEP, the leading global environmental agency that sets the global environment agenda, to ensure that both population and environmental factors are integrated into policy and program planning, development, monitoring and implementation. Areas of collaboration include technical guidance and research, advocacy, public awareness, education and training, and strengthened coordination.

UNFPA, which became operational in 1969, is a subsidiary organ of the UN General Assembly and has as its governing body the Executive Board of the UN Development Program and of UNFPA. As of the 1st January 2001, the total number of staff was about 840. These included some 200 at headquarters in New York. The rest are distributed between Geneva and various field offices. The percentage of women on UNFPA's professional staff at headquarters and in the field was 50%, one of the highest percentages among UN agencies and organizations.

Incumbents to the post of executive director, held by Thoraya Obaid since 1 January 2001, are appointed by the UN Secretary General.

Among the most important publications issued by the UNFPA are:

- *POPULI*, the UNFPA magazine (two issues a year);
- *The State of World Population* (annual).

NAFIS SADIK *USA*

UNIDO (United Nations Industrial Development Organization)

UNIDO is the specialist United Nations (UN) agency helping developing countries and transition economies to pursue sustainable industrial development.

The UNIDO secretariat carries out programs and activities approved by the UNIDO's policy-making organs. UNIDO's current membership consists of 168 countries. They meet once every two years at the General Conference, which approves the budget and work program of UNIDO and appoints the director general. The Industrial Development Board (53 member states) reviews the implementation of the work program and the budget, which is prepared by a subsidiary body, the Program and Budget Committee (27 member states).

UNIDO headquarters are at the Vienna International Center in Vienna, Austria. UNIDO Offices in New York and Geneva maintain on-the-spot contacts with member states and the other UN organizations based there.

UNIDO field offices are maintained in the following countries:

- Africa: Cameroon, Cote d'Ivoire, Ethiopia, Ghana, Guinea, Kenya, Nigeria, Senegal, Tanzania, and Zambia;
- Arab countries: Algeria, Egypt, Lebanon and Sudan;
- Asia and the Pacific: China, India, Indonesia, Iran, Pakistan, and Vietnam;
- Latin America and the Caribbean: Argentina, Bolivia, Colombia, Honduras, Jamaica and Mexico.

UNIDO operates a network of Investment Promotion Service (IPS) offices which promote business contacts between industrialized and developing countries and economies in transition. The UNIDO IPS offices are financed by the countries in which they are located: Austria, Bahrain, Belgium, China, Egypt, France, Greece, India, Italy, Japan, Poland, Republic of Korea, Russian Federation and the United Kingdom.

UNIDO's financial resources come from regular and operational budgets, as well as contributions for technical cooperation activities. Derived from member states' assessed contributions, the regular budget of UNIDO for 1998–1999 amounted to about US$130 million.

UNIDO's new integrated package of services was developed and approved by its member states. The 16 service modules were designed to meet specific needs and requests of developing countries and economies in transition. Once adapted and customized to the specific needs of individual countries, these services promote the three Es of the UNIDO's Business Plan: competitive economy, productive employment and sound environment.

In the areas of sound environment, UNIDO concentrates on:

- environmental policy framework;
- climate convention and the Kyoto Protocol;
- energy efficiency;
- rural energy development;
- cleaner production;
- pollution control and waste management;
- Montreal Protocol.

United Nations Conferences on the Environment

Peter M Haas
University of Massachusetts, Amherst, MA, USA

Global United Nations (UN) conferences on the environment are an institutional innovation of the 1970s. With mounting concern about the degradation of the physical environment, governments approached the UN to convene a number of global conferences to address the host of human activities with transboundary and global environmental consequences. These environmental conferences were part of a broader effort at global problem-solving for a new class of global problems associated with international interdependence. As global interdependence became increasingly politicized in the 1970s, the UN system turned to global conferences as a way to highlight the interconnections between issues that had previously been treated in isolation. The topics of the global conferences were new to the international agenda, as previous multilateral conferences had principally addressed international economic topics. The UN, as the only venue with global participation, was the logical forum for such meetings to include all the affected countries.

The 1972 UN Conference on the Human Environment, and the 1992 UN Conference on Environment and Development directly addressed the subject of environmental protection, but UN Conferences devoted to specialized aspects of human impacts on the environment were commonplace in the 1970s. Conferences were convened to address climate, food, population, water, deserti cation, and other instances of global environmental threats. The frequency with which such global conferences were held diminished in the 1980s and 1990s. Other than the decadal meetings of conferences on population, women, and food, the follow-up annual reviews to the United Nations Conference on Environment and Development (UNCED) of the UNCED commitments, and the more comprehensive and high pro le UNCED + 5 meeting in 1997 and UNCED + 10 in 2002, states have been less willing to support specialized UN global conferences.

These global conferences were intended to mobilize concern about new problems, and to coordinate national actions to study and monitor environmental quality and human activities with environmental consequences. They also were intended to develop joint measures to prevent various sources of environmental degradation and attenuate the effects of human actions on the environment. Economic and equity concerns cut across most of the other specialized conferences.

A full list of global environmental conferences is presented in Table 1, of Global Environmental Conferences, along with their formal results.

Typically, global UN conferences on the environment last for several weeks, with high level diplomatic attendance for the last two or three days to overcome political deadlocks and to sign legally binding resolutions and other commitments developed at the Conference. Decisions are generally reached by consensus, so negotiations are slow. Preceding the Conferences are often several rounds of preparatory meetings (Prep Coms), often spread over one or two years, at which national delegations are presented with background papers and preliminary negotiations are conducted on the documents intended to be approved at the Conferences themselves. Most of the arduous work of reconciling political differences occurs during the preparatory conferences.

Generally the global UN conferences on the environment have produced declarations and action plans. The most successful conferences endorsed new policy doctrines and policy targets for the international community, and also authorized the creation of new international organizations, approved legal commitments and generated new financial resources. Others have failed to spark international concern or to catalyze robust international commitments and action, and have remained virtual dead letters, such as the 1977 Desertification Conference, the 1979 Conference on Science & Technology for Development, and the Conferences on Human Settlements. The most successful, in terms of their administrative accomplishments, have been the 1972 UNCHE, the 1974 World Food Conference, 1992 UNCED, and the 1994 International Conference on Population and Development (Weiss and Jordan, 1976).

The 1972 UNCHE, held in Stockholm, Sweden was the first major global environmental conference. Sponsored by the UN, it convened 113 countries to discuss contemporary environmental issues. UNCHE adopted the Stockholm Declaration, establishing 26 principles of behavior and responsibility to serve as the basis for future legally binding multilateral accords; the Action Plan for the Human Environment that specified 109 recommendations in the areas of environmental assessment, environmental management, and supporting institutional measures (Schmidt,

Table 1 Global Environmental Conferences[a]

Year	Name/location	Product/outcome
1972	United Nations Conference on the Human Environment (UNCHE) (Stockholm)	Declaration of Principles Action Plan UN Environment Programme

1996	Habitat II (Istanbul)	The Habitat Agenda and Istanbul Declaration on Human Settlements
1996	World Food Summit (Rome)	Rome Declaration on World Food Security and World Food Summit Plan of Action
1997	UN General Assembly Special session on Sustainable Development (UNCED + 5)	Towards the Further Implementation of Agenda 21

[a] *Source:* Fomerand (1996); Weiss *et al.* (1997) especially Chapter 9; Caldwell (1996). I am grateful to Zuhre Aksoy for help in compiling this table.

1973). Implementation was intended for governments and international organizations.

The 1992 UNCED, held in Rio de Janeiro, marks the high water mark of these institutional outputs. UNCED adopted the Rio Declaration, Agenda 21, and the Forestry Principles. The Convention on Climate Change and the Biodiversity Convention were adopted by their respective diplomatic conferences at the time of UNCED. The Rio Declaration contains 287 principles to guide subsequent action. Agenda 21 is a sweeping action plan to promote sustainability, with 2509 specific recommendations elements, applying to states, international institutions, and members of civil society. The Commission on Sustainable Development was created to ensure effective follow-up of UNCED; to enhance international cooperation and rationalize intergovernmental decision-making capacity; and examine progress in Agenda 21 implementation at the local, national, regional and international levels (Grubb *et al.*, 1993).

The variation in the degree of success of conferences is due to a number of factors. The more successful

conferences were free of profound political schisms or geopolitical tensions amongst major parties including Cold War tensions between the US and the USSR and profound North–South cleavages. The issue at hand was of immediate concern to the industrialized countries that would be willing to commit resources.

UNCHE, for instance, was held at a fortuitous moment. Domestic environmental movements were becoming particularly active in the US and Europe. Potentially profound North–South disagreements were avoided by prior high-level discussions that rejected the conceptual dichotomy between economic growth and environmental protection, extended the international agenda to include environmental concerns of the South, regarded natural resource policy as well as the pollution concerns of the industrialized countries, and provided a notional commitment to additional financial assistance on behalf of the North. Environmental protection was not seen as being inconsistent with other established goals in international negotiations, including national security and economic liberalization. UNCHE also provided the first opportunity for China to stake a position in international diplomacy following US recognition. North–South relations became more acrimonious with the New International Economic Order (NIEO) discussions in the late 1970s, and it proved harder to forge consensus at international conferences. Even with these factors, Cold War divides still modestly in uenced the Conference, as the Soviet Union and the Eastern bloc countries withdrew at the last minute over the participation of West Germany, yet because the superpowers were in a period of détente, such tactical linkages were not perceived as provocative with cold war overtones.

Effectiveness

It is difficult to evaluate the effectiveness of many of these conferences, in part due too weaknesses and gaps in our ability to monitor subsequent progress. The record is generally mixed, at best, in terms of achieving the targets and aspirations expressed in the action plans and declarations of the Conferences. It is difficult to directly measure effects on the environment, and the record of states in complying is mixed or uncertain. At UNCED + 5 the Commission on Sustainable Development tried to evaluate overall progress achieved since UNCED. It determined, amongst many observations, that production and consumption patterns had become more energy efficient in industrialized countries; land use con icts were more acute in developing countries between competing demands for agriculture, forest cover and urban uses; and that water scarcity remained a major threat to development and human health in developing countries (UNCED, 1997).

In short, it is difficult to evaluate the effectiveness of the conferences on states' policies and on observable environmental impacts. This is because it would be unreasonable to expect such conferences to yield lasting and clear effects on states' policies and on the environment. It is equally unreasonable to assign blame to conferences for failing to reverse environmental decline.

Ultimately, international conferences are modest institutional features of international relations and are unlikely to induce profound changes by themselves or exercise sustained in uence on states. Because of their one-off frequency, there is limited access to top-level officials, and it is difficulty to maintain long-term pressure on governments through national reporting, information circulation, oversight, or lobbying. Thus it is difficult for transnational policy networks to sustain consolidated political in uence on states through global environmental conferences. Such conferences generally lack significant political or financial resources for inducing change, and lack any lock-in mechanisms by which decisions become deeply institutionalized within the legal and political systems of attending countries.

Functions of Conference Diplomacy

Global environmental conferences also have a number of indirect effects with longer-term effects on national policies affecting the prospects for sustainable development. While you cannot directly stop human activities that degrade the environment through universal declarations or conferences, global UN conferences have served a number of distinctive political and social purposes that in uence governments' concern about the environment and their willingness to commit scarce political and financial resources to its protection. The effects of the most successful conferences have been to increase national concern, and to increase government capacity to politically and technically address problems by means of agenda setting, consciousness raising, expanding participation, monitoring, knowledge generation and diffusion, target setting, norm development and diffusion, and administrative reforms (Hass *et al.*, 1993; Reinecke and Deng, 2000; Fomerand, 1996).

Agenda Setting

Global environmental conferences can place new issues on the global agenda and galvanize national concern by publicizing new issues. The conferences often have the effect of reframing issues for decision-makers. For instance, environmental protection was firmly placed on the international agenda at the UNCHE conference, and the preliminary Founex meeting effectively reconciled North–South differences about the priority accorded to environmental considerations in economic planning, establishing the principal that the two goals could be compatible, especially with concessionaire finance from the North to pay for incremental pollution control costs in the developing countries. UNCHE also helped inform Northern governments of Southern countries' concern with an alternate

agenda that would supplement the North's primary focus on industrial pollution, waste management, and transboundary environmental threats: with a focus on resource deterioration, deforestation and water quality, and the underlying problems of insufficient money for sewage treatment and effective resource management.

The 1994 International Conference on Population and Development shifted the public debate on population issues to a focus on the underlying social and political and economic forces that in uence population growth. The Program of Action marked a distinctive shift in population policy towards cooperation to eradicate poverty; encouragement of universal access to health care services; and empowerment of women.

Popularizing Issues and Raising Consciousness

Conferences provide a brief window of opportunity for educating mass publics and government officials about environmental issues. Conferences spawn publicity about the declarations and statements of principles issued at them. Because many journalists attend the conferences, they provide an opportunity for NGOs and the media to publicize issues in their national media as well as for educating members of the media about environmental issues.

Generating New Information and Identifying New Challenges for Governments

Preparation for conferences often generates information for countries about their environmental problems, the array of policies available for addressing such issues, and the political coalitions organized around them. States are invited to submit national reports about conditions in their countries in advance of the conference, and this process can lead states to learn of new problems, clarify their recognition of their national interest, and identify the potential for political compromise. These reports are often synthesized by the secretariats for subsequent dissemination.

Early Warning of New Threats

Conferences help focus attention on new problems, and also help to identify institutional gaps and needs in addressing such problems. The *Assessment of the World Food Situation*, presented to 1984 World Food Conference, helped focus attention on the world food gap that threatened developing countries. UNCHE helped to identify the urgency of addressing land-based marine pollution, as well as identifying the institutional need of creating a global environmental monitoring system (GEMS) that subsequently became one of UNEP's core activities.

Galvanize Administrative Reform

Conferences also prompt governments to create or reform national bodies responsible for forms of environmental protection. National administrative bodies serve as the nodes of transnational environmental policy networks. At the time of UNCHE only 26 governments had administrative agencies responsible for environmental protection (15 in the developing countries, 11 in developing). The preparation for UNCHE led many governments to recognize the need for creating national environmental agencies. By 1982 the total number was up to 144 (34 in Developed, 110 in developing), UNCED led to the establishment of Sustainable Development committees and bodies in nearly 150 countries.

Adopt New Norms, Certify New Doctrinal Consensus and Set Global Standards

Global conferences are sites of doctrinal contests. UNCHE developed new principles of soft law that have been interpreted and applied by international lawyers to inform a generation of international environmental law. Specific programmatic action, such as the 2,509 specific proposals in Agenda 21 set the stage for legitimate responses to international conferences. The identification of numbers of people at risk from malnutrition, and targets for Official Development Assistance (ODA) and hunger reduction stipulated at World Food Conferences similarly established standards and aspirations for subsequent governmental practices.

Mass Involvement of New Concerns

International environmental conferences contribute to the participation of new concerns in international environmental politics through the invitation of new groups to attend international conferences. Environmental conferences have been leaders in the introduction of NGOs to international diplomacy. These meetings developed the practice of parallel NGO conferences to the governmental conferences, as well as allowing NGO participation as observers at the governmental conferences. Roughly 178 NGOs participated at UNCHE (Thompson Feraru, 1982). Over 1400 were represented at UNCED.

Despite the vast increase in numbers of NGOs attending international environmental conferences, the participation is still heavily tilted towards the North, where NGOs have greater financial support and are better able to find resources to attend conferences. At UNCED, 70% of the registered NGOs came from industrialized countries.

Conferences provide the potential for networking and developing transnational issue networks to coordinate international campaigns, and NGOs may subsequently provide information to governments and apply pressure on governments.

Conferences often invite participation from major nonstate groups, including NGOs, the transnational scientific community (*see* Environmental Movement the Rise of Non-government Organizations (NGOs), Volume 5), and, since UNCED, multinational corporations (Schmidheiny, 1992). Such groups are invited to attend expert group meetings in advance of the conference as well as parallel NGO

events and even as observers at governmental meetings. Participation is often, particularly in preliminary meetings, by umbrella groups such as GESAMP and ICSU, or the ICC.

Global environmental conferences may be deliberately designed to foster new coalitions more generally, and to build support for environmental protection at the national level by including the political in uence of transnational policy networks. Maurice Strong, the secretary general of UNCHE and UNCED coined the phrase the process is the policy to capture the idea that through conference diplomacy more concerns and perspectives could be introduced to international environmental policy making.

There is still wide variation in the extent of NGO in uence at conferences. The rules of participation remains set by states' decisions in ECOSOC and the organizations are continually constrained (if not totally hamstrung) by state choices to allocate resources and set rules of behavior for the organizational dealings with NGOs.

International Conferences and Governance

Global environmental conferences play a part in a broader shift in global environmental governance. It is now widely accepted that governance occurs in a decentralized manner, though loosely tied networks of multiple states, functional state agencies, and non-state concerns. The environment is no different.

Accumulated conferences over the last 30 years have contributed to an aggregate shift in international politics by extending participation and access to environmental diplomacy to national environmental agencies and to NGOs and networks of scientists: a process that Jacques Fomerand (1996) describes as a large-scale process of social mobilization . The most successful conferences have promoted broader processes of social learning and the construction of new, more comprehensive conceptual frameworks for global environmental governance through issue clarification, popularization of issues, and the introduction of new approaches to environmental policy making. Through this institutionalized process of participation and education, new environmental norms of environmental protection have been diffused, and participating states have been encouraged to endorse them and to apply them nationally.

Global environmental conferences have contributed to aggregate substantive changes in environmental governance. The Founex preparations for UNCHE contributed to transcending the environment/development dichotomy in the framing of international environmental policy. The focus of the environmental conferences has shifted from concern about resource scarcity and depletion to efforts to understand and protect ecosystem integrity. Scientific consensus has crystallized around comprehensive forms of ecological management doctrines such as Sustainable Development: and a new consensus was forged at the 1994 Population Conference in Cairo that population growth could not be considered in isolation from social issues shaping family planning choices, including women's roles in society. Jacques Fomerand (1996) in a comparative study of UN world conferences, concludes that Today it is recognized that population issues must be viewed within the framework of the close links between population, economic growth, sustainable development, and the promotion of women's condition in all its aspects as well as greater gender equality in general. (See also Sanwal, 1993.)

Later, UNCED's Agenda 21 was organized and designed around a matrix of issues so that policies would be developed to address the interconnections among human activities (i.e., industry, agriculture, styles of decision making, consumption patterns, and technology) and the environment, as well as amongst global ecosystems (e.g., the atmosphere, freshwater, oceans and land): with chapters of Agenda 21 designed to capture the intersections located in each cell of the matrix (UN, 1991). The earlier UNCHE framework had been organized around the more traditional tripartite administrative framework of environmental assessment (evaluation and review, research, monitoring, information exchange), environmental management (goal setting and planning, international consultation and agreements), and supporting measures (education and training, public information, organization, financing, technical cooperation) (UNEP, 1981). UNCHE had been organized around a conceptual framework of traditional administrative functions, whereas UNCED was set up to capture the newly appreciated analytic attributes of the issues to be addressed.

United Nations Convention to Combat Desertification (UNCCD)

Hama Arba Diallo
Secretariat of the Convention to Combat Desertification, Bonn, Germany

The issue of deserti cation was rst addressed by the international community at the multilateral level, as a follow up to one of the greatest environmental catastrophes of the past decades: the unprecedented African drought that struck the Soudano- Sahelian region from 1968 to 1973. Within that context, the General Assembly of the United Nations (UN) convened in Nairobi in 1977, the rst UN Conference on this issue which adopted the UN Plan of Action to Combat Deserti cation.

Fifteen years later, the UN Conference on Environment and Development, held in Rio de Janeiro, con rmed the urgent necessity to tackle this major environmental issue and recommended therefore, within Chapter 12 of Agenda 21, the elaboration of an International Convention to Combat Deserti cation.

The UNCCD (United Nations Convention to Combat Desertification) in those countries experiencing serious drought and/or desertification, particularly in Africa was adopted on 17th June 1994 in Paris, France. On that occasion, it was signed by 114 countries and the European Community. Resolutions on Urgent Action for Africa and on other activities to be undertaken in the interim period, before the Convention came into force, were also adopted.

June 17th was subsequently declared the World Day to Combat Desertification and Drought by the General Assembly of the UN (Decision GA 49/115).

The Convention entered into force on the 26th of December 1996, upon the deposit of the 50th instrument of ratification. As of June 2001, the Conventions had 174 Parties. It is legally binding to its members and represents a major follow-up to the 1992 UN Conference on Environment and Development, which called Parties to build upon the sustainable development paradigm and to provide a balanced legal framework for increased international cooperation in combating desertification.

KEY PRINCIPLES OF THE CONVENTION

According to the Convention, desertification means land degradation in arid, semi-arid and dry sub-humid areas resulting from various factors, including climatic variations and human activities (Article 1.a).

Desertification is recognized as a major global threat, which puts at risk the livelihoods of over one billion people in more than 110 countries, particularly in Africa. Causes include overcultivation, overgrazing, deforestation and poor irrigation practices.

Desertification does not affect developing countries alone. North America and European countries also suffer from it. Countries which are not directly affected also bear some of its consequences, for desertification contributes to poverty, food insecurity, political unrest and the resulting migrations.

In this framework, the Convention represents an innovative document with the following characteristics:

- it gives priority to Africa;
- it builds on a democratic, bottom-up approach, emphasizing popular participation and the creation, both nationally and internationally, of enabling environments for local populations to help themselves reverse land degradation;
- it takes a long-term approach that fully integrates the physical and biological dimensions of desertification with social and economic realities, while giving the latter full weight;
- it contains precise commitments, detailed in the regional implementation annexes, for the preparation by affected country Parties of National Action

Programs, fully integrated with national policies for sustainable development, as well as Sub-Regional Action Programs and Regional Action Programs;
- it provides for consultative processes leading to partnership agreements spelling out the contributions of both affected country Parties and the international community to these programs; in particular, developed-country Parties are called to actively support, individually or jointly, the efforts of affected developing-country Parties, particularly those in Africa and the least-developed countries;
- it gives an unprecedented role to non-governmental organizations in the preparation and implementation of Action Programs.

THE STRUCTURE OF THE CONVENTION

The objectives of the Convention are to combat desertification and mitigate the effects of drought, through effective actions at all levels, supported by international cooperation and partnership arrangements, in the framework of a full participatory and integrated approach which is consistent with Agenda 21, with a view to contributing to the achievements of sustainable development in affected areas.

The decision-making body of the Convention is the Conference of the Parties (COP), which shall keep under review and evaluate implementation of the Convention, harmonize policies, establish subsidiary bodies, and undertake additional actions. The COP met in Rome, Italy (October 1997), then in Dakar, Senegal (December 1998), Recife, Brazil (November 1999) in Bonn, Germany (December 2000) and will meet in Genera, Switzerland in its Fifth Session (October 2000).

The Permanent Secretariat of the UNCCD is established to serve the COP. The Secretariat also facilitates assistance to affected developing-country Parties in their consultative process and compilation of information required under the Convention, and promotes awareness raising on the issue of Desertification. It has been based in Bonn, Germany, since February 1999.

A Committee on Science and Technology (CST) appointed by the Parties was established under the Convention as a subsidiary body. The Committee provides the COP with information and advice on scientific and technological matters relating to combating desertification and the effects of drought and meets in conjunction with the ordinary sessions of the COP. The COP may, as necessary, appoint *ad hoc* panels to provide information and advice through the Committee on specific issues. The COP has established an *ad hoc* group on benchmarks and indicators, on traditional knowledge on early-warning systems and on survey and evaluation. It has also indicated that early warning systems in the broadest sense of the term are one of the issues for consideration of the CST.

The Convention contains four regional implementation Annexes – for Africa, Asia, Latin America and the Caribbean, and the Northern Mediterranean and a fifth annex has been adopted at COP4 to cover Central and Eastern Europe and should enter into force in September.

The African Annex is the most elaborate. It comprises 19 articles, and addresses a broad range of issues, including commitments and obligations of both African and developed-country Parties. Explicit reference is made with regard to technical assistance and cooperation to ensure that preference is given to the utilization of less costly local experts. Emphasis is placed on the need for increased coordination among the key players involved in desertification activities, including donors, national governments, non-governmental organizations and local populations. The annex also contains provisions for financial mechanisms and resources, and coordination, partnership and follow-up arrangements.

The other annexes are shorter and re ect the different priorities of the regions:

- The Asian annex is relatively general in scope. It foresees cooperation and coordination activities among country Parties, including networking on specific areas of interest such as the promotion of scientific, technical, technological and financial cooperation.
- The Latin American and Caribbean Annex mentions the important links between desertification and loss of biological diversity, as well as debt issues, unfavorable international economic trade practices, and other socio-economic factors. It also emphasizes traditional knowledge, know-how and practices.
- The Northern Mediterranean Annex is more scientifically oriented. It stresses urbanization and agricultural practices as economic causes of desertification and provides for collaboration with other regions in the preparation and implementation of action programs. It is also unique in that it clearly disqualifies the region from eligibility for funds raised through the Convention.

The Convention foresees the establishment of a Global Mechanism (GM) to promote actions leading to the mobilization and channeling of substantial financial resources, including money for the transfer of technology, to affected developing-country Parties.

On the occasion of the first COP, the Parties agreed to invite the International Fund for Agricultural Development to house the GM in Rome, Italy, and to cooperate with the World Bank and UN Development Program in this framework.

More information on the Convention can be obtained from the UNCCD web site at http://www.unccd.int.

United Nations Environment Programme (UNEP) Regional Seas Programme (RSP)

Stjepan Keckes
Borik, Rovinj, Croatia

The UNEP RSP, initiated in 1974, consists of a series of regional action plans adopted by high-level intergovernmental conferences. The action plans are designed to protect and develop the marine and coastal environment and their resources through coordinated joint efforts of the states participating in the plans. In a number of regions, the action plans are associated with regional conventions that provide their legal frameworks. Presently, the RSP is UNEP's major program for the implementation of Chapter 17 of Agenda 21 and other global programs and conventions relevant to the marine and coastal environment.

Nine action plans have been developed under UNEP's auspices and adopted, as part of the UNEP RSP, for the following geographic regions: the Mediterranean (1975), Persian/Arabian Gulf (1978), Wider Caribbean (1981), East Asian Seas (1981), West and Central Africa (1981), South-East Pacific (1982), South Pacific (1982), Eastern Africa (1985) and North-West Pacific (1994). The development of action plans for the North-East Pacific and the Upper South-West Atlantic is currently underway. Seven of these action plans are supported by legally binding regional conventions adopted in Barcelona (1976), Kuwait (1978), Abidjan (1981), Lima (1981), Cartagena (1983), Nairobi (1985) and Noumea (1986).

Regional programs adopted for the Red Sea and Gulf of Aden (1976), the Black Sea (1993) and the South Asian Seas (1995), or being developed for the Caspian Sea, albeit developed without major inputs from UNEP, are closely associated with and considered also as parts of the RSP.

All adopted conventions are in force. The conventions are of framework type and are supplemented by protocols dealing with specific issues, such as cooperation in cases of pollution emergency, control of pollution from dumping and land-based sources, protection of special geographic areas and biodiversity.

Most action plans are structured in a similar way, although the specific activities for a given region re ect the priorities and needs as defined by the governments of each region. Typically they are related to:

- environmental assessment, i.e., identification of the causes and sources of environmental problems, their magnitude and effects on the region;
- environmental management, focusing on integrated coastal zone management and control of land-based activities affecting the marine and coastal environment;
- environmental legislation through development of regional conventions and specific protocols, as well as development of national legislation in conformity with regionally and globally agreed norms;
- institutional arrangements for the coordination of activities agreed to be carried out under the action plans; and
- financial arrangements supporting the agreed activities; in most regions special trust funds are established to which governments make annual contributions.

Strengthening national institutional capabilities through training of national experts and technical cooperation, transfer of information and technologies and raising public awareness are important elements of all action plans.

While the focus of the first action plans was on the protection of the marine environment from pollution, the subsequently adopted action plans shifted their priorities to all issues relevant to the development and protection of the marine environments and their resources. The periodic

revisions of the action plans broadened their scope in order to emphasize issues related to integrated management and use of coastal and marine environment along the lines recommended by Agenda 21 adopted at the United Nations (UN) Conference on Environment and Development. In some regions, determined efforts are being made to pay more attention to the problems of small island states, to the management of the associated river basins and to the potential effects of climate change. Protection and management of fisheries resources is the only major issue not covered by most action plans in the framework of the RSP. A further positive development was the establishment, in one of the regions (Mediterranean), of a regional commission for sustainable development, as a subsidiary body of the contracting parties to the Barcelona Convention (*see* Blue Plan, Volume 4; Mediterranean Sea, Volume 4). The establishment of a similar body, as a joint subsidiary body of two African regional seas conventions, is under consideration.

The periodic meetings of the contracting parties to the regional seas conventions or, when action plans are not supported by such conventions, periodic high-level intergovernmental meetings, represent the highest authority guiding the action plans, determining the priorities that should be dealt with by the plans, and allocating the financial resources of the trust funds to these priorities.

UNEP provides the secretariat with six action plans and their respective legal instruments, either directly through its headquarters, or through semiautonomous regional coordinating units managed by UNEP. Three of the action plans have secretariats that are independent of UNEP.

More than 140 countries participate in the RSP through the involvement of about 400 national institutions and their experts. Active support to the implementation of the RSP is provided by a large number of international, intergovernmental and non-governmental organizations.

UNEP provided the funds needed to launch the action plans of the RSP, with the understanding that the governments will gradually assume the financial responsibility for their sustained implementation. However, the present straitened financial circumstances of most countries participating in the RSP are among the major impediments for a more vigorous progress in the development of the RSP.

Whenever appropriate, the RSP is used as the main mechanism to implement the various ocean-related activities of UNEP, such as the Global Plan of Action for the Protection of the Marine Environment from Land-Based Activities, and the Global International Waters Assessment, as well as the relevant parts of global conventions, such as the UN Convention on the Law of the Sea, and the Convention on Biological Diversity. UNEP's overall coordination of the RSP should ensure that such activities, although implemented regionally, remain essentially global in nature.

However, the horizontal cooperation between regional action plans and conventions that constitute parts of the RSP is relatively weak, although direct exchange of information, data, experience and expertise may be of mutual benefit to them. Likewise, there is little substantive cooperation between the RSP and the regional programs of similar nature, such as those carried out under the auspices of the Oslo/Paris Commission or the Helsinki Commission.

For further information on RSP, see http://www.unep.ch/seas/.

United Nations Environment Programme (UNEP) Saskawa Environment Prize

The *Sasakawa Environment Prize*, originally known as the Pahlavi Prize, was first awarded in 1976. The Prize was then funded by Iran and was administered by UNEP.

In 1982, the UNEP Governing Council accepted an endowment of US$1 million from the Japan Shipbuilding Industry Foundation to finance the Sasakawa International Environment Prize which would be administered by UNEP.

Now known as the UNEP Sasakawa Environment Prize, it is awarded annually to leading environmentalists and recognizes the work of these individuals at the global level.

Since its inception, interest in the award has increased significantly as attested by the growing number of nominations. After serious deliberations and in the light of the kinds of nominations received over the years, the Selection Committee decided to re-evaluate the process and has recommended that all nominations be considered on an annual basis and that the Prize be awarded to individuals who have made an outstanding global contribution to the management and protection of the environment . The Prize also aims to encourage environmental achievement in any field of the environment.

The annual award of $50 000 was increased to $200 000 in 1990.

Candidates to the Prize can be associated with any field of the environment. Those eligible to make nominations include, but are not limited to, specialists in environmental sciences, academies of science, engineering and research, members of the United Nations system, governments, intergovernmental organizations, trade unions and non-governmental organizations.

The Prize is named after Mr Ryoichi Sasakawa, who passed away in July 1995, and who was the founder and Chairman of the Sasakawa Foundation for more than three

decades. He donated more than US$400 million to social and public works projects both within and outside Japan.

The first Chairman of the Prize Selection Committee was His Excellency Dr Misael Pastrana Borrero, the late former President of the Republic of Colombia. For more than a decade Dr Pastrana Borrero led the committee with great commitment and dedication to the field of environment.

The inaugural UNEP Sasakawa Environment Prize was awarded posthumously to Dr Aurelio Peccei, who had died just two months before the Prize Selection Committee announced its decision to recognize the outstanding contribution that the former industrialist had made to defend the environment.

Nominations and curriculum vitae can be sent to: The Secretary, UNEP Sasakawa Environment Prize, United Nations Environment Programme, Information and Public Affairs Branch, PO Box 30552, Nairobi, Kenya. Tel.: +254-2-6-3401/62-3128; Fax: +254-62-3692/62-3927, E-mail: rajinder.sian@unep.org, elisabeth.guilbaud-cox@unep.org.

MOSTAFA K TOLBA *Egypt*

United Nations Framework Convention on Climate Change and Kyoto Protocol

Michael Zammit Cutajar
United Nations Framework Convention on Climate Change, Bonn, Germany

The United Nations Framework Convention on Climate Change (the Convention) is the centerpiece of intergovernmental action to combat the threat of human-induced climate change. Negotiations on the Convention were launched by the United Nations (UN) General Assembly in December 1990, in response to warnings from scientists over rising emissions of greenhouse gases from human sources, such as fossil fuel combustion and land clearance. Scientists warned that increased concentrations of greenhouse gases in the atmosphere could lead to irreversible climate change, with potentially dramatic negative impacts on human health, food security, economic activity and infrastructure.

The UN General Assembly established an Intergovernmental Negotiating Committee (INC) to conduct negotiations on the Convention, under the Chairmanship of Jean Ripert (France). After 15 months of negotiations, the Convention was adopted on 9 May 1992, and opened for signature that same year at the UN Conference on Environment and Development (the Earth Summit) in Rio de Janeiro. The Convention entered into force on 21 March 1994, after receiving the required 55 instruments of rati cation, acceptance, approval or accession. One hundred and eighty-three countries, plus the European Community, were Parties to the Convention (as of August 2000), so that it now enjoys virtually universal membership.

THE CONVENTION

Objective and Principles

The ultimate objective of the Convention is to stabilize atmospheric concentrations of greenhouse gases at a level that would prevent dangerous human interference with the climate system. The Convention does not specify what is meant by dangerous, but it does state that ecosystems should be allowed to adapt naturally, food production should not be threatened, and economic development should proceed in a sustainable manner.

The Convention defines a set of principles to guide Parties in their efforts to achieve this objective. A key principle is that of equity and common but differentiated responsibilities (*see* Common but Differentiated Responsibility Principle (Stockholm/Rio), Volume 4). This principle recognizes that all Parties share a common obligation to address climate change, but that developed countries bear a particular responsibility to take the lead in modifying longer-term emission trends. This is because developed countries have historically contributed the most to climate change, their *per capita* emissions remain above those of most developing countries, and they have greater financial and institutional resources to tackle the problem.

Commitments

For the purpose of assigning commitments, the Convention identifies two main groups of countries. Countries listed in its Annex I include those that were members of the Organisation for Economic Cooperation and Development (OECD) in 1992, the European Community, and countries with economies in transition (EITs) from the former Soviet Union and Eastern Europe (Box 1). All other Parties, basically, developing countries, are known as non-Annex I Parties.

General Commitments

All Parties, both Annex I and non-Annex I, are subject to general commitments to address climate change and adapt to its effects. These general commitments include:

- preparing national climate change programs, promoting the development and transfer of climate-friendly technologies;

Box 1 Countries listed in Annex I to the Convention

Australia	Liechtenstein*
Austria	Lithuania
Belarus	**Luxembourg**
Belgium	Monaco*
Bulgaria	**Netherlands**
Canada	**New Zealand**
Croatia*	**Norway**
Czech Republic*	Poland
Denmark	**Portugal**
Estonia	Romania
European Economic Community	Russian Federation
Finland	Slovakia*
France	Slovenia*
Germany	**Spain**
Greece	**Sweden**
Hungary	**Switzerland**
Iceland	Turkey (not yet a Party to the Convention)
Ireland	Ukraine
Italy	**UK**
Japan	**USA**
Latvia	

Notes: Bold indicates countries also listed in Annex II to the Convention. An asterix (*) indicates countries whose names were added to Annex I at COP 3.

- promoting sustainable forest management (forests act as *sinks*, absorbing carbon dioxide, the main greenhouse gas, from the atmosphere);
- preparing for adaptation to climate change (e.g., by developing coastal zone management plans);
- employing methods such as impact assessments to minimize any adverse effects (e.g., on the economy) of climate change mitigation or adaptation measures;
- cooperating in scientific research;
- promoting public awareness of climate change.

The Convention recognizes that certain groups of developing countries are especially vulnerable to the adverse effects of climate change (e.g., countries with low-lying coastal areas) and/or to the impact of the implementation of response measures (e.g., countries whose economies are highly dependent on fossil fuel imports). A process is currently underway to consider how best to address the specific needs and concerns of these Parties (see also the section on financial assistance).

Specific Commitments

In accordance with the principle of equity and common but differentiated responsibilities, only Annex I Parties were subject to the Convention's specific, but non-legally-binding aim to return greenhouse gas emissions to 1990 levels by 2000. The EITs (Economies in Transition) are allowed a certain degree of flexibility in this regard, due to the recent economic and political upheaval experienced by these countries. Several EITs have invoked this clause to take on a baseline other than 1990.

The most recent emissions data indicate that few individual Annex I Parties will meet this specific aim. Except for the EITs, whose emissions fell dramatically as a result of their economic collapse following the break-up of the Soviet Union, the emissions of most Annex I Parties may have continued to rise since the adoption of the Convention. As a group, however, the Annex I Parties may have indeed returned their collective emissions to 1990 levels by 2000, due principally to the falling emissions of the EITs and cuts achieved in Germany and the United Kingdom (emissions data for the year 2000 were not yet available at the time of writing).

Finance and Technology Transfer

In order to effectively address climate change and adapt to its effects, the Convention recognizes that developing countries will need access to financial resources and climate-friendly technologies. The OECD members of Annex I (who are also listed in the Convention's Annex II) are therefore committed to providing new and additional financial resources for this purpose. This includes a requirement to assist developing countries that are particularly vulnerable to the adverse effects of climate change in meeting the costs of adaptation. Financial assistance to developing countries is mostly channeled through the Convention's financial mechanism; currently operated by the Global Environment Facility (GEF) (see the following section). In addition, Annex II Parties are required to promote the transfer of climate-friendly technology to both developing countries and EITs, while greater emphasis is now being placed on the need for capacity-building in both these groups.

Some financial support is also available for eligible developing countries to enable them to attend sessions of the Convention bodies (see the following section). This support is funded by voluntary contributions from Parties, and is channeled through a special trust fund under the Convention. Approximately $1.8 million a year was earmarked for this purpose in 2000 and 2001.

Reporting and Review

All Parties are required to report on the action they are taking to implement the Convention. The level of detail required, however, is greater for Annex I Parties, and the time frame for submitting their reports, known as *national communications*, is tighter. Most Annex I Parties have now submitted two national communications, and their third was due on 30 November 2001. These national communications must include information on the climate change policies that

Annex I Parties have implemented, along with the projected effects on their emissions. Annex II Parties must also report on the financial assistance they have provided to developing countries and on their technology transfer initiatives. The national communications of Annex I Parties are subject to an individual in-depth review by a team of experts, whose reports are made publicly available. In addition, Annex I Parties must submit annual inventories of their greenhouse gas emissions. These are subject to a technical review for a trial period starting in 2000.

The information required in national communications from non-Annex I Parties is less specific, in line with the more general commitments of these Parties under the Convention. The Convention allows more time to non-Annex I Parties to prepare their national communications, including their emission inventories, and the time frame is also contingent on the receipt of financial resources from the GEF. For this reason, non-Annex I Parties have only recently begun to submit their initial national communications. As of August 2000, 27 had been received. Non-Annex I Party national communications are not subject to individual in-depth review.

Institutions

Conference of the Parties

The supreme decision-making body of the Convention is the Conference of the Parties (COP) (Figure 1). The COP, which brings together all Parties to the Convention, usually meets on an annual basis. It has now met six times in cities around the world; its latest session at the time of writing, COP 6, was held in The Hague (Netherlands) in November 2000.

The COP has responsibility for reviewing the Convention's implementation and for assessing the progress made by Parties in meeting their commitments. At each of its sessions, the COP takes decisions aimed at promoting the effective implementation of the Convention. For example, at its second session (Geneva, 1996), the COP adopted revised guidelines to be used by Annex I Parties to prepare their national communications. It further updated these guidelines at its fifth session (Bonn, 1999). Also at its fifth session, the COP established a consultative group of experts on non-Annex I Party national communications. At its fourth session (Buenos Aires, 1998), the COP launched a technology transfer consultative process aimed at giving new impetus to efforts to promote climate-friendly technology transfer. Decisions taken by the COP, around 20 at each session, make up a detailed rulebook for the implementation of the Convention.

The proceedings of the COP, and those of the subsidiary bodies discussed below, are governed by written rules of procedure. Although Parties have not yet formally adopted these rules, due to disagreements over the voting majority needed to take decisions, the draft rules of procedure are applied at each session of the COP, except for the rule on voting. As there is no agreed voting rule, almost all decisions under the Convention must be taken by consensus, which is taken to mean that there is no stated objection to a decision. Amendments to the Convention and its Annexes, however, may be adopted by a three-quarters majority vote, because the Convention itself specifies this voting rule. No amendments have yet been adopted to the Convention itself, although its Annex I was amended at COP 3 (see Box 1).

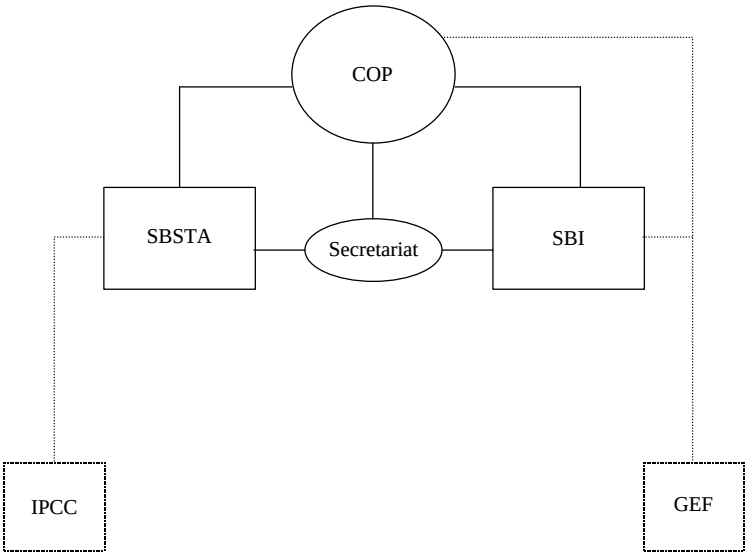

Figure 1 Convention bodies. Note: The GEF formally reports to the COP, hence the direct link shown in this figure. COP is the Conference of Parties; SBSTA is the Subsidiary Body for Scientific and Technological Advice, and SBI is the Subsidiary Body for Implementation

Observer organizations, such as representatives of UN bodies, inter-governmental organizations (IGOs) or non-governmental organizations (NGOs) (e.g., business and industry groups, environmental NGOs, local authorities), are allowed to attend meetings of the COP and the subsidiary bodies, unless at least one-third of Parties object. There has been considerable interest in the Convention on the part of observer organizations, and their representatives routinely outnumber Party delegates at sessions of the Convention bodies. Almost 400 NGOs and approximately 35 IGOs are currently accredited to the Convention process.

Subsidiary Bodies

The Convention also established two permanent subsidiary bodies, the Subsidiary Body for Scientific and Technological Advice (SBSTA) and the Subsidiary Body for Implementation (SBI) (see Figure 1). Both bodies meet at least twice a year to carry out preparatory work for the COP. They are open ended, which means that any Party can participate in their sessions.

The SBSTA has responsibility for providing advice to the COP on scientific and technological matters. This includes, for example, work on suitable methodologies for compiling emission inventories or on how best to promote the transfer of climate-friendly technologies. The SBSTA also serves as the link between information provided by scientific bodies outside the climate change regime, such as the Intergovernmental Panel on Climate Change (IPCC), and the policy needs of the COP.

The SBI advises the COP on issues related to the implementation of the Convention, in particular on the review of national communications. It also has specific responsibility for liaison with the GEF, as well as for financial and administrative matters, including consideration of the proposed program budget (see the section on the secretariat).

Financial Mechanism: the Global Environment Facility (GEF)

The Convention established a financial mechanism to channel financial assistance to developing countries and entrusted its operation to the GEF on an interim basis. A memorandum of understanding with the GEF was adopted at COP 2, and COP 4 confirmed that the GEF would continue to operate the financial mechanism, subject to review every four years. The GEF is accountable to the COP for its climate change activities, and the COP provides it with regular policy guidance.

The GEF, a joint initiative of the UN Development Programme, the United Nations Environment Programme (UNEP) and the World Bank, was launched in 1991 (initially as a pilot program) to fund developing country projects resulting in global environmental benefits (the GEF also funds projects on ozone protection, international waters and biodiversity). Since its establishment, the GEF has allocated a total of US$5.7 billion to climate change activities.

IPCC

Although the IPCC is not an institution of the Convention, it has played a crucial role in its development. The IPCC was established in 1988 by UNEP and the World Meteorological Organization to provide policy-makers with authoritative and up-to-date information on climate change science. The First Assessment Report of the IPCC, published in 1990, confirmed that climate change was indeed a threat and recommended the launch of negotiations on a treaty to address the problem. The IPCC's Second Assessment Report (SAR), finalized in 1995, presented the landmark conclusion that the balance of evidence suggests that there is a discernible human in uence on global climate . The SAR estimated that global average temperatures would increase by 1–3•5 °C by 2100, the fastest rate of change since the end of the last ice age, while sea levels would rise by 15–95 cm over the same time period. The SAR's conclusions were critical in accelerating the momentum of negotiations on what was to become the Kyoto Protocol. The Third Assessment Report was released in 2001.

The IPCC also prepares more concise Special Reports and Technical Papers on specific issues, usually at the request of the SBSTA. For example, it recently finalized Special Reports on aviation and the global atmosphere, technology transfer and land-use, land-use change and forestry. This latter Special Report will be particularly helpful to Parties as they consider how to treat carbon sinks under the Kyoto Protocol (see the section on specific commitments under the Kyoto Protocol) (*see* Intergovernmental Panel on Climate Change (IPCC): an Historical Review, Volume 4).

Secretariat

The COP and its subsidiary bodies are serviced by a secretariat, currently staffed by some 100 international civil servants. The main functions of the secretariat are to make practical arrangements for sessions of the Convention bodies, provide support for on-going negotiations (e.g., by drafting background documents), circulate information submitted to it by Parties, and ensure the necessary cooperation with secretariats of other bodies, such as the GEF and the IPCC.

The secretariat operates autonomously within the administrative framework of the UN. It is headed by an executive secretary, at the level of assistant-secretary-general of the UN, who is accountable to the COP and to the secretary-general of the UN. The current executive secretary, Michael Zammit Cutajar (Malta), has headed the secretariat since it was set up in 1991. Since August 1996, the secretariat has been located in Bonn (Germany), having moved there from its previous location in Geneva, following an offer from Germany to host the secretariat. The offer was accepted at COP 1.

The secretariat works according to a biennial program budget, which is proposed every two years by the executive secretary. The current program budget for the biennium 2000–2001 amounts to around $12 million per year. It is funded by contributions from Parties, with their shares calculated according to the UN scale of assessment.

THE KYOTO PROTOCOL

When governments adopted the Convention, they knew that its commitments would not be sufficient to achieve its ultimate objective. They therefore included provisions to ensure the review of the Convention at regular intervals, with the aim of strengthening their commitments as scientific evidence of climate change hardened and political will increased. The first review of the Convention took place at COP 1 (Berlin, 1995) where, in a decision known as the Berlin Mandate, Parties agreed to launch negotiations to strengthen commitments for Annex I Parties through the adoption of a protocol or another legal instrument. The Berlin Mandate specified that this round of negotiations should not set any new commitments for developing countries. Negotiations took place in the specially convened Ad Hoc Group on the Berlin Mandate (AGBM), under the Chairmanship of Ambassador Raúl Estrada-Oyuela of Argentina. The AGBM met eight times over a period of 31 months, before forwarding the results of its work to COP 3 (Kyoto, 1997), the deadline for concluding negotiations set by COP 1. Intense negotiations continued at COP 3 before the Kyoto Protocol was eventually adopted on 11 December 1997.

The Protocol will enter into force when it has received instruments of ratification, acceptance, approval or accession, from 55 Parties to the Convention, including Annex I Parties accounting for 55% of the 1990 carbon dioxide emissions of that group. As of August 2000, 22 Parties had ratified the Protocol, all of them developing countries. However, almost all Annex I Parties were among the 84 Parties who signed the Protocol during the one-year period when it was open for signature, thus indicating their intent to ratify in the future.

The Kyoto Protocol shares the objective and principles of the Convention. It will also make use of the Convention's institutions, such as the subsidiary bodies, secretariat and financial mechanism, while the COP to the Convention will serve as the meeting of the Parties to the Protocol (the COP/Meeting of the Parties, MOP).

Emission Commitments

The cornerstone of the Kyoto Protocol is its emission targets for Annex I Parties, which, in a significant step forwards from the Convention, are legally binding. The emission targets for individual Annex I Parties are listed in the Protocol's Annex B (see Box 2). Together, they add up to a total reduction in Annex I Party emissions of around 5.2% from 1990 levels. However, because the emissions of most Annex I Parties have increased since 1990, this collective target amounts to a real reduction of over 20% from business-as-usual projections. If this target is met, it will at last reverse the upward trend in greenhouse gas emissions that has prevailed in the industrialized world over the past two centuries.

Box 2 Individual emission targets under the Kyoto Protocol

Party	Percentage change	Party	Percentage change
Australia	+8	Liechtenstein	−8
Austria	−8	Lithuania	−8
Belgium	−8	Luxembourg	−8
Bulgaria	−8	Monaco	−8
Canada	−6	Netherlands	−8
Croatia	−5	New Zealand	0
Czech Republic	−8	Norway	+1
Denmark	−8	Poland	−6
Estonia	−8	Portugal	−8
European Community	−8	Romania	−8
Finland	−8	Russian Federation	0
France	−8	Slovakia	−8
Germany	−8	Slovenia	−8
Greece	−8	Spain	−8
Hungary	−6	Sweden	−8
Iceland	+10	Switzerland	−8
Ireland	−8	Ukraine	0
Italy	−8	UK	−8
Japan	−6	USA	−7
Latvia	−8		

Notes: Belarus and Turkey, while both included in Annex I to the Convention, were not assigned emission targets under the Kyoto Protocol and therefore not included in Annex B, as they were not Parties to the Convention when the Protocol was adopted.

The individual targets of Annex I Parties range from −8% for the 15 members of the European Union, Switzerland and several EITs, to an increase of +10% allowed to Iceland. Under the terms of the Protocol, the EU is permitted to redistribute its target among its 15 member States, so long as the overall −8% reduction is achieved. The EU has already reached agreement on how it will do this.

The emission targets cover the six main greenhouse gases (see Box 3) taken together as a basket, and are calculated against a baseline of 1990 (except for the EITs, who may request a different baseline). However, an alternative baseline of 1995 may be chosen for HFCs, PFCs and sulfur hexa uoride (SF_6). This is because, in some Parties, emissions of these gases increased considerably in the early

Box 3 Greenhouse gases covered by the Kyoto Protocol

Carbon dioxide (CO_2)
Methane (CH_4)
Nitrous oxide (N_2O)
Hydrofluorocarbons (HFCs)
Perfluorocarbons (PFCs)
Sulfur hexafluoride (SF_6)

1990s, as they were used as substitutes for ozone-depleting substances being phased out under the 1987 Montreal Protocol on Substances that Deplete the Ozone Layer. Certain activities that enhance carbon sinks, notably afforestation, reforestation and tackling deforestation, may be used to offset emission targets, although the uncertainty and complexity surrounding carbon sinks means that the details of these provisions remain to be worked out (*see also* Boreal Forest Carbon Flux and it s Role in the Implementation of the Kyoto Protocol Under a Warming Climate, Volume 4). Annex I Parties must meet their emission targets by the commitment period of 2008–2012. A target period was chosen rather than a single year to smooth out annual uctuations in greenhouse gases. The maximum amount of greenhouse gas emissions that an Annex I Party may emit over this five-year commitment period is known as its *assigned amount*.

In addition to these emission commitments for Annex I Parties, all Parties (including non-Annex I Parties) are subject to a set of general commitments that reaffirm the general commitments in the Convention and seek to advance their implementation, in order to achieve sustainable development. These general commitments cover the preparation of greenhouse gas inventories and national climate change programs; the development and transfer of technology; scientific research; education, training and public awareness on climate change; and reporting. Regarding national climate change programs, the Protocol specifies that these would include consideration of the energy, transport and industry sectors, as well as agriculture, forestry and waste management.

Implementation Mechanisms

The Kyoto Protocol does not specify how Annex I Parties should implement their emission targets. It does, however, include a list of possible policies and measures that Parties could adopt, including enhancing energy efficiency, developing new and renewable forms of energy, and phasing out market imperfections (such as subsidies and tax exemptions) that go against the objective of the Convention. The Protocol also requires Annex I Parties to strive to minimize the adverse effects of their climate change mitigation policies on other Parties, especially developing countries. Fossil fuel exporters, for example, are particularly concerned about knock-on effects on their economies that may arise from measures implemented by Annex I Parties to reduce their greenhouse gas emissions from fossil fuel consumption.

The Kyoto Protocol also includes three innovative mechanisms that Annex I Parties may use to help them meet their emission targets as cost-effectively as possible.

1. Under Article 6 of the Protocol, Annex I Parties may invest in emission reducing (or sink enhancing) projects in other Annex I Parties, and credit the resulting emission reduction units to their own assigned amounts. A corresponding debit is made from the assigned amount of the host country of the project. This mechanism is often known as *joint implementation* (*see* Joint Implementation, Volume 4). It is expected that joint implementation will mostly be carried out through investments by the OECD members of Annex I in the EITs, where climate change mitigation options are often cheaper and more plentiful.
2. Article 12 of the Protocol defines a *clean development mechanism* (CDM) (*see also* Clean Development Mechanism, Volume 4), whose purpose is not only to help Annex I Parties meet their emission targets, but also to assist non-Annex I Parties in achieving sustainable development. Under the CDM, Annex I Parties may use certified emission reductions achieved through climate change mitigation projects in non-Annex I Parties to offset their own emission targets. Because non-Annex I Parties do not have emission targets or baselines of their own, it is particularly important to ensure that emission reductions achieved through CDM projects are additional to what would otherwise have occurred in the absence of the project. With this aim in mind, emission reductions must be certified by separate operational entities, and also be subject to independent auditing and verification. The CDM will be supervised by an executive board. Developing countries that are particularly vulnerable to the adverse effects of climate change will gain added benefit from the CDM, as a share of the funds generated by the mechanism will be diverted to help these countries meet adaptation costs. The Kyoto Protocol envisages that participation in joint implementation and the CDM will prove attractive not only to governments, but also to private entities, such as businesses. Both mechanisms certainly hold considerable potential to harness private sector investment for climate-friendly projects in EITs and developing countries, thus increasing the ow of much-needed financial resources to these countries, while promoting the transfer of environmentally friendly technologies. Joint implementation and the CDM could thus create unprecedented opportunities to tackle climate change

in an economically effective way, while also promoting sustainable development.

3. The third Protocol mechanism, outlined in Article 17, is *emissions trading* (*see also* Emissions Trading, Volume 4). Emissions trading allows an Annex I Party that finds it relatively easy to achieve its emissions target to transfer parts of its assigned amount that it may not need to another Annex I Party that is experiencing greater difficulty in meeting its commitments. Article 17 states, however, that use of emissions trading by Annex I Parties to meet their targets must be supplemental to domestic climate change mitigation action. Although the Protocol does not mention the private sector, many Parties see opportunities for emissions trading, both domestically and internationally, as an important incentive for engaging private businesses in climate change mitigation efforts.

Credibility Mechanisms

The legally binding nature of the Protocol's emission targets places a premium on accurate emission inventories, rigorous reporting by Parties and thorough review of both inventories and reports, to ensure that compliance can be authoritatively assessed and cases of non-compliance identified. The Protocol therefore provides for more stringent guidelines for the preparation of both annual emission inventories and national communications, and for a more rigorous in-depth review process than that under the Convention. These provisions can be understood as the Protocol's credibility mechanisms, which seek to uphold its environmental effectiveness.

Key to securing the Protocol's environmental credibility is the compliance provisions outlined in Article 18. These call on the COP/MOP, at its first session after entry into force, to approve procedures and mechanisms to determine and address cases of non-compliance with the Protocol. However, any non-compliance procedures and mechanisms that entail binding consequences can only be adopted by amending the Protocol.

Unfinished Business

When Parties adopted the Kyoto Protocol at COP 3, they left a large burden of unfinished business to be worked out in subsequent negotiations. In particular, the details of how joint implementation, the CDM and emissions trading would operate in practice remain unresolved. In addition, more technical work is needed to iron out provisions on carbon sinks and to draw up guidelines for the Protocol's credibility mechanisms, especially the all-important compliance procedures. A further outstanding issue is how to minimize adverse effects, of both climate change and mitigation action, on developing countries.

The Kyoto Protocol cannot enter into force while so much unfinished business is still pending; Annex I Parties need to have a clearer idea of the shape of their commitments under the Protocol before ratifying it. Recognizing this, at COP 4, Parties adopted the so-called Buenos Aires Plan of Action for finalizing the Protocol's unfinished business, and set COP 6 (The Hague, November 2000) as a deadline for adopting decisions on it. (The Plan of Action also covered important on-going Convention issues, notably the financial mechanism and technology transfer.)

Since COP 4, work on the Protocol's unfinished business has proceeded at an intensive pace in both the SBSTA and the SBI, and also in a Joint Working Group established by COP 4 to negotiate the Protocol's compliance procedures. Numerous workshops and informal meetings have also been held in between sessions.

Concluding Remarks

The Kyoto Protocol has already promoted much greater awareness of climate change among businesses and the public worldwide. Its adoption sent a clear signal that governments take the threat of climate change seriously, and are committed to tackling it. This signal has triggered a noticeable response; many businesses are already implementing energy efficiency measures, increasing their investments in renewable energy, accelerating the development of low-carbon fuel cells or exploring emissions trading opportunities. Even in developing countries, which have no formal emission targets, there is strong evidence that environmentally friendly policies are slowing the growth in greenhouse gas emissions. These policies are usually implemented for reasons other than climate change, demonstrating that tackling climate change can also bring economic and social side-benefits.

Despite these encouraging signs, much more aggressive action is needed to move emission trends onto a downward path and avoid the worst effects of climate change. Combating climate change is a long-term task; a new round of negotiations to determine the next set of commitments post-2012 is due to start no later than 2005, and may be launched earlier. Targets for Annex I Parties will need to be tightened and, eventually, commitments must be extended to a wider group of countries. For now, however, the next crucial step is entry into force and implementation of the Kyoto Protocol. The Convention and Protocol have laid the foundations for an effective response to climate change; it is now up to the Parties to implement their provisions and finally mark an end to the business-as-usual trends that threaten the world's climate.

UNSCEAR (United Nations Scientific Committee on the Effects of Atomic Radiation)

The UNSCEAR is a Committee of the General Assembly of the United Nations. The Committee was established in 1955 in response to widespread concerns regarding the effects of radiation on human health and the environment. At that time, nuclear weapons were being tested in the atmosphere, and radioactive debris was dispersing throughout the environment, reaching the human body through the intake of air, water and food. Treaties now ban atmospheric tests, but many other exposures to radiation occur from other sources, both natural and man-made.

The Committee collects and assesses global data on the sources and effects of ionizing radiation. Detailed reports to the General Assembly are produced every few years and are made widely available as United Nations sales publications. The latest editions were 1988, 1993, 1994, 1996 and 2000. The reports review exposures from natural radiation sources, from man-made practices and events such as nuclear power production, nuclear tests, Chernobyl and other accidents, from medical radiation uses and occupational radiation exposures. Methods of exposure evaluation and extensive data compilations are included. The reports also review results of epidemiological, radiobiological and genetic effect studies in order to estimate risks of exposures. Other biological topics are addressed to improve understanding of mechanisms involved in radiation effects and to interpret modified features of exposures, e.g., dose rate, age/tissue sensitivities, adaptive responses, interactions with other agents. The assessments are recognized to be scientifically accurate and authoritative, and they serve as the basis for national and international standards for radiation protection.

The Committee is comprised of 21 member countries. Its Secretariat is located at the Vienna International Center, P.O. Box 500, A-1400 Vienna, Austria.

Use of Epidemiological Data to Develop Air Quality Standards for Short-term and Long-term Environmental Health Benefits

Jeffrey R Brook[1], Richard T Burnett[2], and Marjorie Shepherd[1]

[1] *Meteorological Service of Canada, Toronto, Canada*
[2] *Health Canada, Ottawa, Canada*

Air pollutant emissions need to be managed and ideally reduced to avoid environmental and human health problems. This can be achieved by setting and enforcing ambient air quality standards as part of a program of long-term national and international environmental policies. Standards must be based upon science before they are accepted by the public and industry. Epidemiological studies, which include the analysis of how the health within a population responds to environmental hazards, such as air pollution, are a useful tool for developing air quality standards. To demonstrate why and how information from epidemiological analyses can be applied, a case study based on a recently developed Canadian air quality standard will be discussed.

Table 1 Common air pollutants associated with urban smog

Direct products of combustion *Primary Pollutants*	Products of atmospheric chemical reactions *Secondary Pollutants*	Other
Carbon monoxide	Ground level ozone	Particles[a] (e.g., re-suspended dust)
Nitrogen oxides		Volatile organic compounds (e.g., unburned fuel, solvent escape)
Particles[a] (PM_{10}, $PM_{2.5}$)		
Sulfur oxides	Particles[a] (PM_{10}, $PM_{2.5}$)	

[a] Particles or suspended particulate matter (PM) are tiny solid/liquid particles, which are made up of a range of chemical compounds, many of which are produced during combustion. Particle concentrations, as well as gaseous pollutant concentrations, are often measured as a mass per cubic meter of air. The size of the particle included in a measurement should also be specified, where particle diameter (d) in micrometers is indicated after the abbreviation; PM_d (e.g., $PM_{2.5}$ means all suspended particulate matter below 2.5 μm in diameter). Sulfate, nitrate, ammonium and organic carbon are the most prevalent chemical compounds in $PM_{2.5}$ while larger particles will contain more soil-based compounds like silicon, aluminum and calcium.

THE NEED FOR AIR QUALITY STANDARDS

Air pollution or smog is an urban and regional-scale problem with the air pollutants having their greatest impact on people and the environment in the source area (i.e., an urban setting) and up to at least 500 km downwind (regional scale). Inhalation of the common pollutants associated with urban smog, which are listed in Table 1, can lead to a range of cardio-respiratory effects from exacerbation of asthma in children to premature mortality of people with severe, but not necessarily untreatable, pre-existing diseases. The amount of research documenting these effects has increased significantly during the past 10 years. In particular, several epidemiological studies of populations in different cities found associations between daily mortality rates and day-to-day variations in fine particle concentrations at levels below current ambient air quality standards. This consistency among studies lends strength to the case for more stringent standards for fine particles. The fact that acute effects other than mortality, such as increases in hospital admissions, emergency department visits, asthma symptoms, changes in heart rate variability, and changes in blood composition, have been found, as well as evidence of chronic effects, strengthens the scientific rationale for a new fine particle standard (i.e., coherence among effects). However, particles are not the only pollutant of concern. There continues to be strong evidence that ozone has a significant impact on public health, including mortality. Nitrogen dioxide, carbon monoxide and ultra fine particles ($PM_{0.1}$) have also been implicated in recent studies. Thus, many pollutants in the smog mixture are of concern and their combined effect on public health is greater than the effect of any individual pollutant (see Figure 1).

The pollutants in smog should be managed in a coordinated fashion, optimizing the benefits to public health, especially given their common link to fossil fuel combustion and their interactions in the atmosphere. For example, lowering greenhouse gas emissions would lead to direct decreases in air pollutants. There is also the potential for indirect benefits if changes in global climate and subsequent changes in prevailing regional weather patterns, which could cause more smog episodes and/or overall increases in pollutant levels, are avoided.

Figure 1 The Toronto skyline: (a) obscured by the fine particles found in urban smog and; (b) a relatively particle-free day. The CN Tower, which is ≈5 km away, and the other buildings are much less visible due to high particle levels. The hourly average $PM_{2.5}$ concentrations in (a) and (b) were 40 and 6 μg m^{-3}, respectively. Hourly concentrations of 50–100 μg m^{-3} are not uncommon in many of the world's major cities. The annual average 24 h $PM_{2.5}$ concentration in Toronto is about 16 μg m^{-3}, just above the new US Environmental Protection Agency annual standard

Management of air pollutants is achieved through *source-based* (*emission controls*) and *receptor-based* (*air quality standards*) strategies. Ideally, only a source-based approach should be needed, requiring emissions to be kept at an absolute minimum. This is not achievable due to technological limits and economic constraints. Even if every source was optimally controlled, an ever-increasing number of sources would still lead to increasing smog. Thus, air quality standards are needed to ensure that when there are too many sources or emissions are too large, there are mechanisms prohibiting smog levels from getting too high. Standards or knowledge of safe levels are also important because as global emissions increase, which is likely as developing countries increase their energy consumption and economic growth continues worldwide, the area affected by air pollution can be expected to increase.

Air quality standards are management targets to reduce impacts on health and the environment to acceptable levels. They have been established in many countries and guidelines have been recommended by the World Health Organization (WHO). Although the standards, objectives or guidelines (hereafter referred to as standards) are similar among countries, and human health protection typically serves as the rationale, there are differences regarding enforcement and compliance. If data exist, then environmental protection, particularly for crops, forests and aquatic ecosystems, may also provide rationale and useful information for establishing standards. Most jurisdictions review standards on a regular basis ensuring that they re ect current knowledge of health and environmental effects, so that they continue to be effective in promoting progress towards cleaner air.

USE OF EPIDEMIOLOGICAL DATA FOR HEALTH-BASED STANDARDS

Setting the level and the form (e.g., hourly average, 24 h average, annual average, etc.) for a standard is not straightforward. The health effects data may be inconsistent due to variations in study design and type and geographic location. Several approaches to studying effects exist, but the three basic approaches for obtaining data for setting a standard are animal toxicology, controlled human exposure studies, and epidemiological studies (observational). Each of these is necessary to demonstrate the biological plausibility of an effect and to build a solid scientific case for new standards. However, observational epidemiological studies involving the population at large are particularly useful for standard setting because:

- they provide a basis for determining exposure and concentration response functions (CRFs). For examples of CRFs see Figure 2(a);
- they are the most direct way of assessing the health outcomes of real-world mixtures of pollutants to which people are exposed;
- they are the only way to determine or predict health effect responses among a human population because, unlike laboratory animals, populations are heterogeneous, containing individuals with varying susceptibilities, disease status and exposures. A population-based response cannot be predicted from animal toxicology and all the necessary information is not likely available from controlled human exposure studies due to ethical reasons;
- they are based on large administrative databases and thus demonstrate the impacts on public health and even enable estimates of the costs to society;
- they are the only direct source of information on long-term cumulative effects.

Observational epidemiological studies build a link directly between air quality monitoring site data, which are ultimately used to evaluate implementation programs, and health impacts. When such links are detected, as has been demonstrated for many air pollutants in smog, it is important only to know that there is a correlation between the ambient monitor concentrations and the personal exposure to pollutants of outdoor origin.

There are some difficulties with relying on epidemiological data to establish CRFs for individual air pollutants. There are significant potential confounders to the interpretation of the epidemiological studies, including weather, co-varying air pollutants and possibly indoor air exposure. Most recent studies have used techniques which reduce confounding, but it is not possible to completely eliminate this concern. Nonetheless, given the variety of locales, pollutant mixtures and exposure levels in the epidemiological studies and the growing body of evidence from other types of studies, it is clear that confounding does not negate the association observed between ambient concentrations and impacts.

Another difficulty is limited information on the mode of action; and causal mechanisms are only now being elucidated, especially in the case of particles. Consequently, objective assessment of the coherence and consistency of the body of evidence, as was discussed above for the case of particles, is an important step that must be undertaken before accepting and applying the epidemiological data.

DEVELOPMENT OF CONCENTRATION-RESPONSE FUNCTIONS AND THEIR APPLICATION IN SETTING A STANDARD

Achieving an air quality standard has traditionally implied that there will be no adverse health effects if concentrations are kept below that level. Recent epidemiological analyses

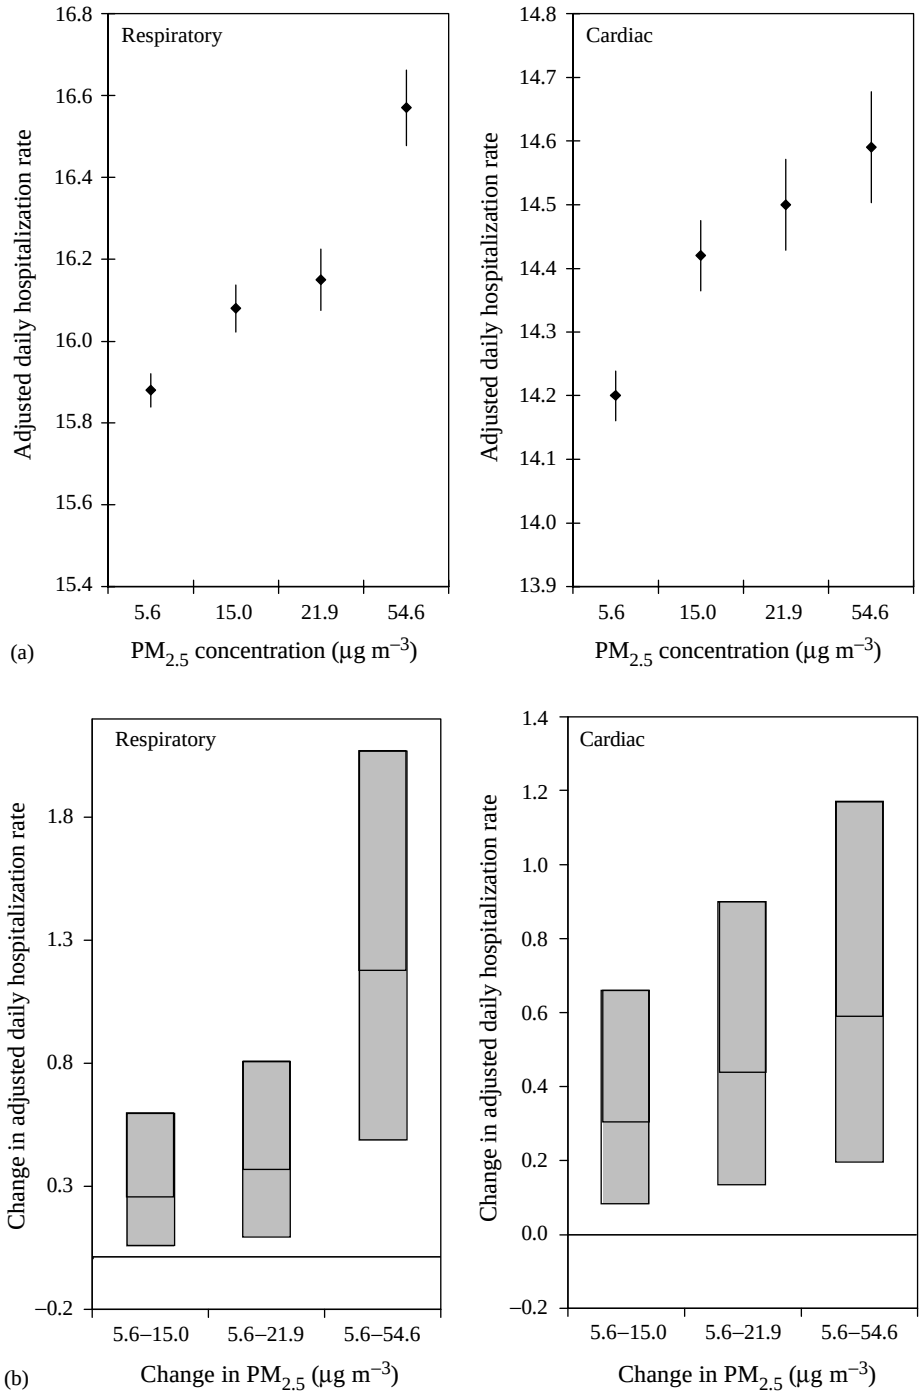

Figure 2 (a) Relationship between the mean adjusted respiratory and cardiac hospitalization rates (±1 standard error) and ambient $PM_{2\cdot5}$ concentrations in southern Ontario, Canada. The four groups represent observations within the lower two quartiles (mean $PM_{2\cdot5}$ of 5.6 μg m^{-3}), the third quartile (mean $PM_{2\cdot5}$ of 15.0 μg m^{-3}), the 75th to 90th percentile (mean $PM_{2\cdot5}$ of 21.9 μg m^{-3}) and the 90th to 100th percentile (mean $PM_{2\cdot5}$ of 54.6 μg m^{-3}). (b) Statistical significance of the increases in the mean adjusted respiratory and cardiac hospitalization rates associated with an increase in the ambient $PM_{2\cdot5}$ concentration. Solid bar shows the mean value of the increase in rate and shaded areas above and below the bar indicate ±2 standard errors (≈95% confidence interval). An overlap with the zero line indicates a non-significant change. The lowest concentration at which a significant change was detected was for an increase from 5.6 to 15.0 μg m^{-3}

focusing on ozone, particles (PM) and carbon monoxide, however, have not found conclusive evidence of a threshold below which there are no effects. The CRFs from studies involving relatively large populations have mostly been found to be linear or near linear throughout the range of ambient air concentrations (FPWG, 1999).
