Nile perch, introduced into Africa's Lake Victoria, severely altered the trophic structure of the lake by literally eating the species beneath it on the food chain, leading to the elimination of many of the lake's 500 endemic species of cichlid fishes. Other invasions alter the nutrient or water cycles, such as the nitrogen-fixing tree, *Myrica faya*, which invaded the Hawaiian islands and caused a 90-fold increase in nitrogen inputs. A number of tree species that have invaded the South African Cape Province fynbos ecosystem whose high rates of water extraction have strongly reduced, and in some cases even eliminated, river flow. Australian paperbark has invaded south Florida, covering nearly 200 000 acres, and promotes more intense fires, altering the natural disturbance cycle. Many other invasive species have similar effects, particularly grasses which can cause a buildup of dead flammable material, leading to fires that favor the expansion of the invading grass (D Antonio and Vitousek, 1992). Given their global extent and strong effects on ecosystems, biological invasions are a critical component of human caused global change (Mack *et al.*, 2000).

INTEGRATION

Most global change research addresses how one particular type of global change (rising carbon dioxide, nitrogen deposition, or invasion of a particular species) will affect

one (or a few) characteristics of a particular ecosystem. Yet, in reality, global changes are occurring together and they affect many (if not all) aspects of ecosystems, not just those of a particular researcher's specialty. It is thus critical to attempt more integrative assessments of responses to global change. For example, warming or nitrogen deposition can favor the success of an invasive plant that alters the fire cycle. Similarly, global warming or rising carbon dioxide can alter the export of DOC from terrestrial to freshwater ecosystems, fundamentally changing how these aquatic systems respond to enhanced UV-B radiation. Land-use changes can alter albedo and sensible heat flux, causing changes in climate. Elevated carbon dioxide, through a number of indirect pathways, can affect microbial processes in soil that produce other trace gases, including the greenhouse gases nitrous oxide and methane and the reactive gases nitric oxide and nitrogen dioxide. Global changes can thus interact in surprising ways: the response of a given ecosystem to one component of global change can affect its response to another, a neighboring ecosystem's responses, and even the extent of other global changes. Understanding these interactions is a formidable challenge.

CONCLUSIONS

Human activities are clearly changing Earth's terrestrial and freshwater ecosystems, changing both their structure and the processes they perform. No longer can one find pristine habitats free from human influence (Vitousek *et al.*, 1997): rising atmospheric carbon dioxide concentration is a global phenomenon, and pollutants are evident everywhere that researchers have looked, in the high arctic and in remote tropical islands, a clear example of humanity's global shadow.

Allometric

Allometric is a term most commonly used with reference to growth, usually of plants. *Allometric growth* describes a situation in which the rate of growth of one part of an organism is in a constant ratio with the rate of growth of another part. It may be expressed as the *allometric coefficient* (k), which is the ratio of relative growth rates: $k = (\mathrm{d}\ln x/\mathrm{dt})/(\mathrm{d}\ln y/\mathrm{dt})$. When $k = 1$ the growth of the two parts is said to be *isometric*; when $k > 1$ or $k < 1$ the situations are described as positive or negative allometry, respectively.

Allometric growth of plant organs or parts strongly suggests that correlative effects control one or the other part of the plant, or both. The nature of such effects is often unclear, but is usually internal (e.g., genetic or hormonal). However, environmental effects may affect or disrupt allometric growth. For example, under ideal growing conditions the root/shoot ratio of some plants is essentially constant over considerable periods of the plant's life. This is almost certainly an internal correlative effect that maintains the balance between root and shoot. Environmental factors that may disrupt this allometry include excess soil humidity, which tends to slow root growth, or reduced soil water content, which tends to stimulate it. An understanding of allometric growth may assist agricultural efforts to achieve maximum yield consistent with optimal growth of, for example, fruit or root crops.

Angiosperm/Gymnosperm

Higher plants, called *Spermatophytes* (seed bearing) are vascular plants characterized by the production of seeds. More primitive non-vascular plants such as fungi and mosses and vascular plants such as ferns reproduce by spores. Spermatophytes are divided into two classes: the *gymnosperms* (bearing naked seeds) and *angiosperms* (bearing enclosed seeds). The gymnosperms (*Pinophyta*), the more primitive group, are woody or perennial plants that are commonly evergreen; that is, they retain leaves (frequently needles) for two to several years so that the plant is leafy throughout the year. The angiosperms (*Magnoliophyta*) constitute the largest and most diverse group of plants, which has invaded and adapted to some of the world's most inhospitable habitats. Their habit of growth ranges from annual to perennial; many of the woody perennials are deciduous, losing all their leaves in winter or drought seasons.

Gymnosperms normally produce gametes in the axes of nodes clustered densely on a shoot with shortened internodes called a *strobilus* or *cone*. The gametes may be protected by bracts or scales, but the seeds (the female gametes or ovules) are not enclosed by the structure that bears them, nor in an ovary, and are therefore said to be naked even though they may be protected by the bracts of a cone. Angiosperms produce seeds that are normally born in structures called fruits, and the ovule is enclosed in an ovary; angiosperm seeds are therefore longer lasting after they have been shed. This evolutionary development appears to be largely responsible for the rapid and effective spread of angiosperms throughout the accessible habitats in the world. However, among woody plants, particularly trees, gymnosperms may better survive periods of extreme drought and cold (the most important consequence of intense cold is drought caused by freezing of available water) because of modifications that control water loss from their leaves.

Animal Physiology and Global Environmental Change

Karen Martin[1] and Ken Nagy[2]
[1]Pepperdine University, Malibu, CA, USA
[2]University of California, Los Angles, CA, USA

Animals accommodate to environmental change in several ways, depending on the time scale involved. Over short periods of time, such as hours or days, animals faced with an increase in environmental temperature may use behavioral means to escape into cooler local microhabitats. Alternatively, they may use physiological or morphological means, such as increased water evaporation or shunting circulating uids around the body to keep cool, or the formation of heat shock proteins to protect enzyme systems, but the animals retain their original thermal set points. Over longer periods, such as weeks or seasons, animals can acclimatize by changing their physiological attributes and set points, for example, increasing preferred body temperature by ectothermic animals such as reptiles and adjusting insulation (pelage or plumage or circulation to the skin) by endothermic animals (birds and mammals). Some animals may also use seasonal migration to nd equable thermal conditions. Over even longer periods, such as generations, such within-phenotype adjustments fade in signi cance, and genetic adjustments, that is, evolutionary changes, become important. For example, insects may have higher thermal tolerances after several generations of living in hot conditions. Finally, over centuries or millennia, changes in species' geographic ranges occur when animals are not able to evolve rapidly enough or thoroughly enough to adjust to the new climatic conditions in their original species range, and when adjacent habitats newly having the historically preferred conditions of the species become available.

Much is known about the physiological adjustments animals make on an hourly, daily, and seasonal basis to changes in ambient temperature and water availability. However, because global changes are expected to be rather slow and long-term events, the main concern is with the adaptive changes in physiology and associated attributes that occur over generations and centuries. Unfortunately, it has not been possible yet to measure the physiology of animals that are extinct (Martin and Nagy, 1997). Therefore, limited factual information is available about the evolution of physiological traits, so much of the following must be speculative.

We assume that global environmental change will take the form of gradual warming, which may also be accompanied by more frequent storms and higher variability in climate. Local climatic warming often is accompanied by increasing aridity in speci c terrestrial habitats, as in recent changes in the Sahel in northern Africa, but on a global scale, rainfall may actually increase as a result of global warming. Where warranted below, we discuss the connection between higher temperatures and water balance, and the additional challenges faced by terrestrial animals.

TERRESTRIAL SYSTEMS

In a terrestrial system, increased temperatures would have several effects on animals. Most directly, heat balance and water balance would be affected. Temperature in most terrestrial animals is regulated, either physiologically by endotherms such as mammals and birds, or behaviorally by ectotherms such as reptiles and amphibians. The activity temperature of many animals is only a few degrees below a critically high, lethal or damaging temperature for them. Animals are more sensitive to high temperatures than plants because of the presence of a nervous system. Lethal effects of high temperature are caused by dysfunction of the central nervous system, resulting in loss of coordination and physiological controls within the organism.

Animals could compensate for increased temperatures, in part, by increasing their evaporative cooling, such as by exposing more wet skin or selecting windier perches for most amphibians, or by panting, uttering the gular area of the throat or sweating as in birds and mammals. However, problems would occur if water were not available in sufficient quantity. As temperature increases, relative humidity decreases if water content in the atmosphere remains constant. Thus, animals would lose water by evaporation faster, and have increased water requirements. If increased environmental temperature were accompanied by more frequent droughts, this would further reduce habitat quality for animals. Decreased dry season mist, related to increased warming, is blamed for the extinction of 20 out of 50 species of frogs and toads in the Monteverde Cloud Forests of Costa Rica after a population crash in 1987 (Pounds *et al.*, 1999).

Alternatively, endotherms could evolve higher body temperature set points along with higher thermal optima for metabolic enzymes. Interestingly, there is little evidence that endotherms are able to accomplish this. There are differences in regulated body temperatures among endothermic taxa; birds average about 41 °C, placental mammals average about 38 °C, and marsupial mammals (with pouches) average about 36 °C (Willmer *et al.*, 2000). However, mammals that live in warm habitats do not have higher body temperatures than mammals that live in cold habitats.

Ectothermic animals, such as most amphibians and reptiles, as well as most invertebrates, have limited control over the body temperature and must rely on outside sources for heating and cooling. Many of these animals are able to be active only within a restricted range of temperatures found in their biogeographic range. These body temperatures are obtained by behavioral choices made by moving within microhabitats at appropriate times of day. With increased air temperatures, ectothermic animals living in historically warm habitats would be forced to spend more time in refugia against extremely high temperatures, for example, in burrows or other shaded areas. Excessively high temperatures over extended periods of time could prevent these animals from foraging or otherwise utilizing the habitat, for example, for seeking mates. Of 151 populations of Edith's checkerspot butter y studied, populations found in Mexico were four times more likely to have become extinct than populations in Canada (Parmesan, 1996). In Europe, 63% of 35 non-migratory butter y species have shown northward shifts in range over this past century, by as much as 35–240 km (Parmesan *et al.*, 1999). In extreme situations, as in some deserts, some amphibians and reptiles remain inactive in burrows for nine or more months of the year. During drought years, desert tortoises *Gopherus agassizii* in California reduce their activity, consume much less food and water over the year, and lose weight (Henen *et al.*, 1998). In historically cool habitats, such as at higher latitudes, ectotherms may enjoy increased opportunities for activity through the year, as a result of global warming. This would improve their food consumption, favoring more rapid growth and reproduction, provided that increased aridity did not accompany the warming trend. In Great Britain, the frog *Rana kl esculenta* and the newt *Triturus vulgaris* both spawn 9 10 days earlier today than 25 years ago, following a 1 °C increase in maximum temperature (Beebee, 1995). Among insects, in the Netherlands some Microlepidoptera reach their peak ight date 11.6 days earlier today than two decades ago (Ellis *et al.*, 1997) and ve species of aphids in England now reach their ight period three to six days earlier than 25 years ago (Fleming and Tatchell, 1995).

Increased ambient temperatures affect metabolic processes of ectotherms as well, since their enzyme systems are in uenced by body temperature. Thus, even while at rest, an increase in body temperature increases energy expenditure in an ectothermic animal and requires it to obtain additional food. If additional food is not available, the animal is forced to compensate in other ways, by limiting growth or restricting reproductive output. On the other hand, enzyme thermal optima apparently are evolutionarily exible, especially in ectotherms (Johnston and Bennett, 1996). There is a trend of gradual replacement of ectothermic animals eating a given diet, with endotherms eating the same diet as latitude increases from the equator to the poles. This is exempli ed by the competition between seed-eating ants and rodents in North America (Brown and Davidson, 1977), and it indicates that the nature of ectotherm physiology is competitively superior in warm climates to that of endotherms. This suggests that global warming will be detrimental to endotherms in general, from the perspective of competition with ectotherms for food. A further detriment is beginning to be seen in the form of expanded ranges for disease-bearing insects carrying malaria, dengue, and yellow fever (Epstein *et al.*, 1998) (*see* **Infectious Diseases**, Volume 2; **Malnutrition, Infectious Diseases and Global Environmental Change**, Volume 3).

Endotherms have greater internal control of body temperature, but species still have geographic distributions that are limited in part by ambient temperatures. Every endothermic animal has a range of temperatures, considered its thermoneutral zone, where basal metabolism is suf cient to maintain the body and no excess energy is necessary for heating or cooling. An animal s thermoneutral zone is affected by its size, insulation, and surrounding microhabitat. Endothermic animals in ambient temperatures above the thermoneutral zone must expend energy and effort to reduce the body temperature, in order to prevent body damage. Evaporative cooling, often in the form of panting or sweating, is the only way of getting rid of excess heat in a hot environment. Muscular activity generates heat, so endothermic animals are less able to be active when in high ambient temperatures, especially above the thermoneutral zone. Thus, with additional energy required for cooling, and decreased inclination and ability to be active in the heat, endotherms would be less able to actively forage. Therefore, population size would probably decrease in the short term, and in the long term, the population would have to migrate out of an area with unsuitably high temperatures or evolve greater thermal tolerance. Range expansions into higher latitudes and altitudes have been seen over the past 20 years in 59 species of British birds (Thomas and Lennon, 1999), in 14 of 24 species of birds in the western US (Johnson, 1994), and in 19 species of small mammals in the US (Davis and Callahan, 1992). Also, of 225 bird species examined in the UK from 1971 to 1995, 31% are laying eggs earlier, by an average of 8.8 days (Crick and Sparks, 1999).

MARINE SYSTEMS

In the oceans, temperatures uctuate much less than in air. The high heat capacity of water mitigates air temperature uctuations and insures that marine organisms are far less subject to daily, or even seasonal, changes in ambient temperature than are terrestrial animals in air.

The disadvantage of this is that many marine animals are restricted to a very narrow range of temperatures, and cannot tolerate changes of more than a few degrees Celsius. In addition, the stability of the ocean temperatures over vast distances makes the use of microhabitats as temperature refuges impossible. Thus, most ectothermic marine animals do not regulate their body temperature by behavioral choices within a habitat, but instead by the habitat preference itself.

A lack of options to avoid high temperatures in the ocean within a habitat implies that an animal's only option when temperature is intolerable (aside from death, which is hardly a strategy for survival) is migration out of the area. Thus, global warming effects could take longer to be perceived in the ocean, because of its thermal stability. However, once temperatures increase above tolerable limits, the resulting effects could be much more rapid and devastating than those in terrestrial systems, where animals may obtain some temporary relief from temperature stress at night or in shelters.

Effects of emigration could produce a shift of species to higher latitudes or greater depths in the ocean. In the English Channel, plankton abundance changes in response to sea surface temperatures and barnacle distributions have shifted up to 30 km (Southward *et al.*, 1995). Over the past century, intertidal invertebrates in California have shifted northward in their distributions, and southern species have become more numerous while northern species have declined (Barry *et al.*, 1995). However, range shifts are limited by the restriction of plant life to the photic zone at the surface of the ocean, which further restricts herbivorous animals and their predators to surface waters. Thus, migration to depth seems unlikely for these species. Therefore, surface migrations could leave tropical waters less populated and increase population pressures and competition at higher latitudes. From 1951 to 1993, the biomass of macrozooplankton in southern California waters decreased by 80% (Roemmich and McGowan, 1995). Temperate water fishes and invertebrates would be forced to ever higher latitudes as their temperature tolerances were exceeded, and entire food webs would be disrupted or destroyed. Over the past 25 years, species richness of reef fishes in California waters has declined by 15–25%, with more southern species dominant to the detriment of more northern types, which have declined in abundance (Holbrook *et al.*, 1997).

To some extent, a preview of global warming effects on the temperate ocean can be seen during El Nino–southern oscillation events in the eastern Pacific Ocean. At these times, ocean currents reverse and coastal waters that are usually cool become several degrees warmer, for several months or more. During these events, warm water fishes can be found at high latitudes but are not as common in their usual habitats. Marine animals along the coast, particularly intertidal animals, are severely depleted and also recruit poorly during these events. Schooling fishes such as anchovies and sardines move offshore to cooler waters, removing a critical link of the coastal food chain. Seals and sea lions are unable to forage adequately, resulting in numerous deaths of older individuals and pups. Ectothermic fishes not only cannot find enough food, but their need for food is increased as they also have increased metabolic demands because of increased ambient temperatures. A dramatic drop of 90% of the population of sooty shearwaters, the dominant seabird species off the coast of California, occurred between 1987 and 1994 (Veit *et al.*, 1997) in three different, widely separated transects.

Sessile marine organisms that live attached to the ocean oor are in even worse danger. Since they are unable to migrate out of a territory, rapid environmental change can lead to local extinction. Of great concern currently, coral reefs appear to be affected by increased ocean temperatures of only a few degrees Celsius. These reefs show signs of poor health and decreased growth and reproduction (Wilkinson *et al.*, 1999). Because coral reefs are tropical, one might consider the possibility that global warming could produce increased habitat for these living ecosystems. However, the length of time required to establish a healthy reef as a result of niche expansion may be longer than the period of time available if change is rapid (Hoegh-Guldberg, 1999). In addition, the requirements for a healthy reef include shallow, clear water with stable salinity, conditions that may not be readily available along most temperate coastlines.

Although oceans are very large, their high productivity is restricted to only a very small proportion of the available area. Plants only grow in the surface and shallow waters of the photic zone, where light can penetrate, and so the vast majority of the ocean is dependent upon its thin upper layers. In addition, the most productive areas of the ocean are in cooler water, which is enriched by upwelling nutrients along coasts. Increasing oceanic temperatures will likely reduce productivity of the oceans as a whole, not only of the plants but also of the fish, seabirds, whales, and other animals that depend directly or indirectly on marine plants. Warming in the Antarctic Ocean has reduced sea ice cover, which is correlated with an increased number of penguins (Fraser *et al.*, 1992) but decreased amounts of krill (Loeb *et al.*, 1997).

SUMMARY

In short, global warming is likely to have profound and far-reaching effects on animals. Warming should have direct effects on temperature regulation and water balance in terrestrial animals, probably increasing water requirements

and indirectly increasing food requirements, and probably decreasing population sizes. Species may extend ranges into higher latitudes or higher altitudes but may move away from traditional ranges, potentially leading to increased isolation, local extinctions, and decreased genetic diversity. Alternatively, species may evolve greater thermal tolerances if global warming occurs slowly enough. Changes in distribution of both plants and animals will undoubtedly lead to dietary shifts and changes in food web dynamics, with possible de-coupling of co-evolved species interactions (Hughes, 2000). In marine animals, global warming should lead to migration to higher latitudes in most cases, or to greater depths for cooler temperatures. Sessile animals unable to migrate may face local extinction and range contraction. Reproductive outputs may decline as coastal waters become less productive, and food webs will be altered by changes in latitudinal distributions according to temperature tolerances. Change in the oceans' productivity probably will reduce humans' ability to harvest food from the sea.

Anthropogenic Impacts on Atmospheric Oxygen

Ray Langenfelds[1,2]

[1] *CSIRO Atmospheric Research, Victoria, Australia*
[2] *University of Tasmania, Hobart, Australia*

Molecular oxygen (O_2) is the second most abundant gas in the Earth's atmosphere after nitrogen (N_2), with a mole fraction of almost 21%. It is biogeochemically active, most notably as a key agent of biological and combustion processes. Natural, biological cycling of O_2 involves respiratory consumption by animals and plants, combustion through biomass burning and replenishment of the atmosphere by photosynthetic production.

O_2 trends in the contemporary atmosphere are dominated by exchange with land biota and combustion of fossil fuels. These processes provide an intimate link with exchange of carbon dioxide (CO_2), the main contributor to anthropogenic forcing of the Earth's radiation budget. Because of this link, O_2 is emerging as a key tracer of the global carbon cycle. Human-induced changes in atmospheric O_2 levels represent just a tiny fraction of its vast atmospheric reservoir. No direct environmental consequences of these changes have yet been demonstrated. However, their precise quanti cation is helping to elucidate the roles of oceans and the land biosphere in slowing accumulation of CO_2 in the atmosphere. Improved understanding of the global carbon cycle is leading to better forecasts of future atmospheric CO_2 levels and of subsequent effects on Earth's climate.

It has long been suspected that atmospheric oxygen (O_2) levels are being altered by human activities. A declining trend is expected from the anthropogenic perturbation to rates of combustion of biogenic material. Fossil fuels (coal, oil, natural gas) have been the primary energy source over the period of industrialization. Rates of land clearing have increased in tandem with world population growth and expansion of agriculture. Earlier, though as yet unfounded, concerns existed over diminution of O_2 through other processes, such as a possible decline in phytoplankton stocks due to pollution of the oceans. A few decades ago, there was speculation that O_2 losses might be large enough to have detrimental environmental consequences. Extreme predictions warned of a catastrophic O_2 decline that could threaten the habitability of the planet. These fears were demonstrated to be unwarranted by theoretical calculations of oxygen cycle processes (Broecker, 1970) and subsequent measurement of actual changes in the atmosphere.

Before the 1980s, there were no ongoing O_2 monitoring programs. Measurements were sporadic and obtained by different researchers at various times and geographical locations. In a review of measurements reported to 1970, Machta and Hughes (1970) concluded that O_2 had been stable at 20.95% between 1910 and 1970, with any trend too small to be resolved by available data. Since then, advances in measurement technologies have achieved much higher precision, revealing small trends that would previously have escaped detection. Reported observations of O_2 trends from contemporary monitoring programs are listed in Table 1. Air is collected in glass asks from remote sites (usually in the marine boundary layer) and returned to a central laboratory for analysis. Other studies have extended records back as far as 1977 using air extracted from Antarctic firn (the

Table 1 Reported observations of trends in atmospheric O_2

				Oceans	Land biosphere
Keeling *et al.* (1996)	Flask sampling	-2.9 ± 0.4	1991–1994[c]	1.9 ± 0.5	1.8 ± 0.7
Battle *et al.* (2000)	Flask sampling	-3.4 ± 0.2	1991–1997	2.0 ± 0.6	1.4 ± 1.0
Battle *et al.* (1996)	South Pole firn	-3.6 ± 0.4[d]	1977–1985	3.0 ± 1.1	-0.4 ± 1.1
Langenfelds *et al.* (1999)	Cape Grim air archive	-3.5 ± 0.1	1978–1997	2.3 ± 0.7	0.2 ± 0.9

[a] O_2 changes are described here in terms of changes in atmospheric mole fraction in units of ppm; however, measurements are of O_2/N_2 ratio and are generally reported elsewhere as relative changes in this ratio, in units of per meg as $\delta(O_2/N_2) = [(O_2/N_2)_{sample}/(O_2/N_2)_{reference} - 1] \times 10^6$ where 1 per meg = 0.001‰ = 0.0001%. Assuming a mole fraction of 20.95% (Machta and Hughes, 1970), $\Delta O_2(ppm) = 0.2095 \times \Delta\delta(O_2/N_2)$ (per meg).
[b] Positive values indicate removal from the atmosphere.
[c] The results quoted here are obtained from measurements at three, globally distributed sites. The record at one of these sites (La Jolla, CA) extends back to 1989 and yields similar values to the global case for the O_2 trend and carbon fluxes.
[d] In this case, the atmospheric O_2 trend is not directly measured, but is inferred from measurements of the ratio-depth profile of O_2/N_2 in the firn. Measurements are corrected for modification of the O_2/N_2 ratio by diffusive, gravitational and bubble exclusion processes.

permeable upper layer of the ice sheet) and from archived air collected at the Cape Grim Baseline Air Pollution Station in Tasmania.

Results confirm that the rate of O_2 decline is minute by comparison to the vast amount of O_2 present in the atmosphere. Of considerable value, however, is the precise definition of these trends, which allows partitioning of fossil carbon dioxide (CO_2) uptake between oceans and the land biosphere, a subject of vigorous debate over recent decades. The value of O_2 measurements for this purpose stems from the fact that unlike CO_2, O_2 has low solubility in seawater. Although there are large seasonal, air-sea uxes of O_2 driven by cycling of marine biological production and ventilation of near-surface waters, there is generally assumed to be negligible change in the oceanic O_2 inventory on interannual time scales. Thus, trends in atmospheric O_2 can be attributed to two processes, fossil fuel combustion and exchange with the land biosphere. The global average stoichiometry of O_2/CO_2 exchange can be estimated for both processes, as can the rate of CO_2 emission from fossil fuel use. Thus, the O_2 trend directly constrains the rate of change of the size of the land biosphere. Together with the concurrent global trend in CO_2, the system can also be solved for the rate of oceanic CO_2 uptake.

Evaluation of global carbon budgets using measured O_2 trends suggests that before the early 1990s, the land biosphere was close to balanced. In other words, the total amount of carbon stored in terrestrial biomass and soils remained constant. The fact that it did so, despite ongoing deforestation, implies that loss of biomass through deforestation was compensated by growth of vegetation elsewhere. In the early 1990s the land biosphere became a net carbon sink, implying even faster growth. Increased terrestrial uptake may re ect either reforestation of previously cleared land or fertilization of existing plants by higher atmospheric CO_2 levels, higher rates of nitrogen deposition or climatic factors (Houghton *et al.*, 1998). The O_2-based budgets also indicate steady oceanic uptake of about $2\,\mathrm{PgC\,year^{-1}}$, in close agreement with predictions from ocean carbon cycle models.

The knowledge gained from recent decades can be used to model the change in O_2 over the period of industrialization (Figure 1). This calculation uses the land/ocean partitioning of CO_2 uptake determined by Trudinger *et al.* (1999) based on a deconvolution of the icecore/ rn CO_2 record from Law Dome, Antarctica (Etheridge *et al.*, 1996). They determine oceanic CO_2 uptake using a box-diffusion model, calibrated against ^{14}C and assessed against the Law Dome $\delta^{13}C$ record of Francey *et al.* (1999). The modeled rate of CO_2 uptake at the end of the record is in close agreement with budgets derived from measured O_2 trends. Records of fossil fuel use and land use change allow determination of net terrestrial exchange or, as displayed in Figure 1, exchange with land biota not including land use change. Corresponding changes in O_2 can be calculated for each of these terms. Depletion of the atmosphere by 151 parts per million (ppm) O_2 is implied for the period 1850 1990. Small, additional changes must also have been incurred before 1850, however early rates of land use change are not well known. An assumed history, involving linear extrapolation of the 1850 estimate back to $0.2\,\mathrm{PgC\,year^{-1}}$ at 1765, would imply pre-1850 O_2 loss of ≥ 12 ppm. Comparable depletion in earlier centuries is unlikely, as the Law Dome CO_2 record shows no signi cant trend between 1000 and 1800 with variations spanning a range of ± 5 ppm. Any CO_2 increase due to land use change is masked by natural variability, for example, as observed during the Little Ice Age (Etheridge *et al.*, 1996). Estimates of early fossil fuel use back to 1750 account for a further loss of 1 ppm. Recent observations indicate a trend of approximately $-3.5\,\mathrm{ppm\,year^{-1}}$ during the 1990s (Table 1). Not included in Figure 1 are effects of other processes that may have partially offset O_2 consumption. They include thermal expansion of oceans due to higher global temperatures, increased storage of organic carbon in oceans from input of anthropogenic nitrogen, and industrial reduction of metal oxide ores (Keeling, 1988). The estimated sum of their cumulative contributions carries large uncertainty, with a best estimate in the range 5 10 ppm.

Thus, by the end of the 20th century, atmospheric O_2 has fallen by an estimated 190 ppm. Over the same time, CO_2 has increased by some 90 ppm. The growth in CO_2 represents a large relative change in concentration of 30% compared to pre-industrial levels. This has signi cantly changed the radiative properties of the atmosphere and has major implications for Earth s climate. By contrast, the relative change in O_2 is just -0.1% of its atmospheric burden (approximately 209 500 ppm). A change as small as this is unlikely to be of any direct signi cance. No environmental impacts have yet been observed. To put the magnitude of this change in context, we may regularly encounter much larger variations as part of our daily lives. O_2 levels can be heavily modi ed on local scales, close to sources of fossil fuel combustion or respiration. Notable examples are urban areas that typically carry large volumes of vehicular traf c, indoors in the presence of people, or in forests where O_2 can be depleted by plant respiration, especially under stable, nocturnal boundary layer conditions.

It is pertinent to consider how O_2 levels may change in the future. Over coming years to decades, further O_2 decline is inevitable. Rates of both fossil fuel combustion and land clearing continue to increase and there is no indication that these trends will be reversed in the near future. Although the land biosphere has partly offset anthropogenic O_2 consumption in recent years, its capacity

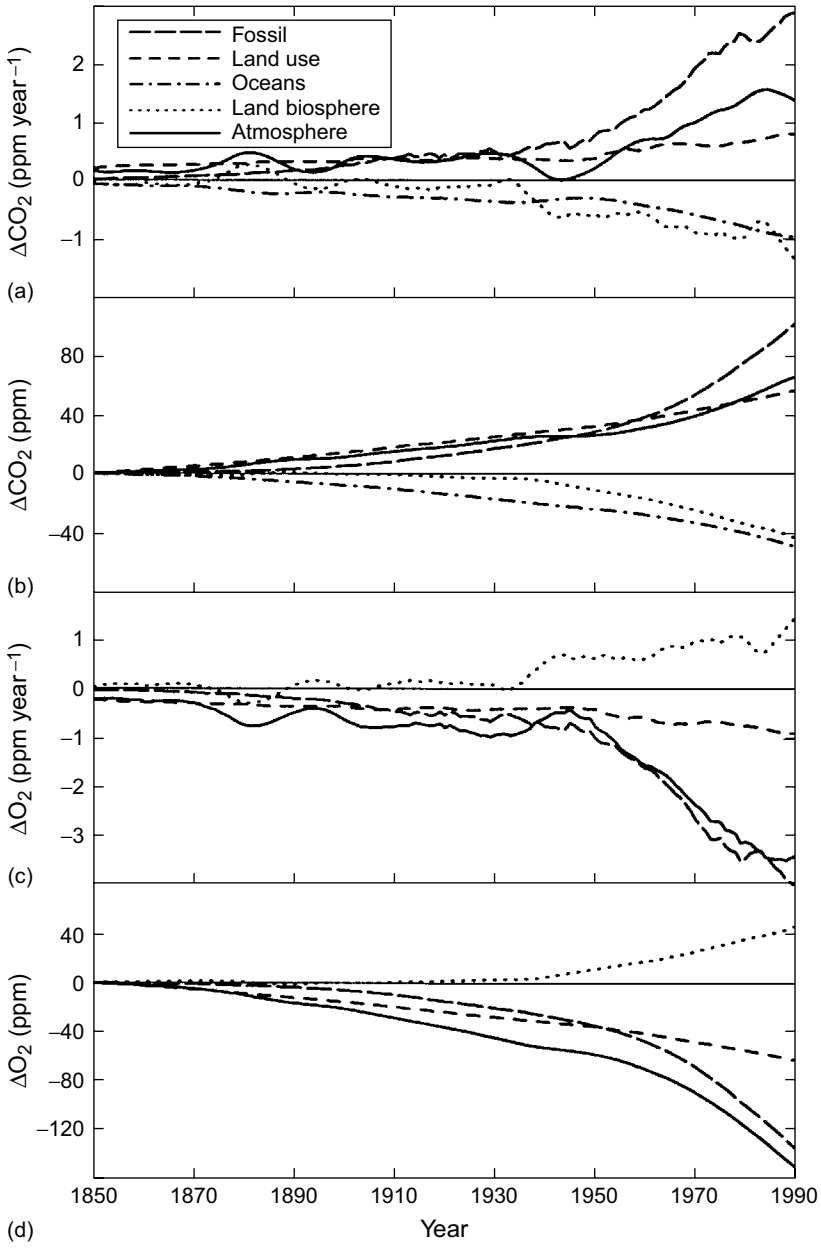

Figure 1 Changes in atmospheric CO_2 and O_2 over the period 1850–1990. CO_2 changes are described in terms of annual (a) and cumulative (b) fluxes. They represent observations of the atmospheric increase from air in Law Dome firn/ice, independent estimates of emissions due to fossil fuels and land use change, modeled oceanic CO_2 uptake and inferred land biospheric exchange not including land use change. Corresponding annual (c) and cumulative (d) O_2 fluxes are calculated assuming no change in oceanic O_2 inventory and known stoichiometric relationships of O_2/CO_2 exchange for terrestrial vegetation and for different fuel types (Keeling, 1988)

to sustain this growth is uncertain. A hypothetical calculation is possible of the maximum depletion that would result from oxidation of all accessible biogenic material. At the end of 1998, proven world fossil fuel reserves amounted to potential O_2 consumption of 600 ppm; however this figure will continue to grow as fuel reserves are boosted by future exploration. Estimates of total carbon stocks (biomass and soils) among four terrestrial biosphere models lie in the range 1150–2300 PgC (Kicklighter *et al.*, 1999), representing a further potential O_2 sink of 600–1200 ppm. If all of the material in both reservoirs were oxidized, atmospheric O_2 would be reduced by upwards of 1200 ppm. This is equivalent to reducing the atmospheric mole fraction from 20.95 to below 20.83%. However, the extent to which the potential loss is realized depends overwhelmingly on energy and land use practices of future generations.

Autotroph/Heterotroph

Autotrophs (literally self-nourishing) require only simple inorganic nutrients and manufacture their own basic food requirements using an external energy source. *Heterotrophs* (other, different or outside sources of nourishment) are unable to manufacture the organic molecules they need for energy and for making cellular components and must absorb them from their environment.

Autotrophic organisms may be classified as *photoautotrophs* or *chemoautotrophs*. Photoautotrophs, all photosynthetic plants and bacteria, derive their energy through the absorption of quanta of light. The energy so trapped is converted into chemical potential, which is available for manufacturing the organic nutrients required by the organism. Chemoautotrophs, mainly bacteria, derive their energy requirements from high energy or reduced inorganic chemicals in their environment that are not in themselves essential for the nourishment of the organism, but which are oxidized or otherwise chemically altered by the organism to a lower energy level. The energy so released is stored temporarily as chemical potential so that it may be used for the conversion of primary inorganic foodstuff (usually carbon dioxide) into the nutritional requirements of the organism. This group includes few species, but may be ecologically very important because of the large numbers of organisms and their often major impact on the environment, e.g., sulfur bacteria that oxidize hydrogen sulfide to elemental sulfur.

Heterotrophs, comprising non-photosynthetic plants and the majority of bacteria, are unable to acquire energy directly from such external sources but must absorb organic chemicals. These serve the double purpose of being substrates of respiration, which releases energy that is temporarily stored as chemical potential, and substrates for the synthesis of nutritionally required compounds and cellular materials using the stored chemical potential.

The term autotrophic may also be applied to an ecosystem in which the rate of photosynthesis exceeds that of respiration ($P > R$). Examples include communities that are heavily fertilized (e.g., agricultural or estuarine systems). In a heterotrophic ecosystem the rate of respiration exceeds that of photosynthesis ($P < R$), as may occur in areas of heavy pollution or high sewage deposition (e.g., swamps, cold or polluted streams). Where photosynthesis equals respiration, the ecosystem is said to be stabilized. Most ecosystems are stable (i.e., $P/R = 1$) regardless of their overall rates of photosynthetic production and respiration. A stable ecosystem may be autotrophic in summer and heterotrophic in winter, but the differences balance each other.

Benthic/Pelagic

The terms *benthic/pelagic* refer to organisms or situations that are located beyond the littoral or beach area of the sea or a lake. *Benthic organisms* are those that live on or close to the bottom of a lake or sea from the high water mark to the depths; *pelagic organisms* occupy the whole water column from the bottom to the top. Benthic organisms are frequently attached to the bottom (e.g., attached marine algae, mature shellfish), while pelagic organisms are free swimming (e.g., whales, fishes or marine unicellular plants). Pelagic animals are collectively called *nekton*, and pelagic plants (largely unicellular algae or dynoflagellates) are termed *plankton*.

R G S BIDWELL *Canada*

Biocenosis

Biocenosis is a community of interacting organisms (plants, animals, microorganisms, etc.) sharing the same habitat (terrestrial or aquatic). This term was invented by Möbius (1877), a German zoologist, for a community of organisms growing on an oyster reef. Biocenosis is formed as a result of intra- and inter-species competition and natural selection. It is shaped under certain average environmental conditions and any change in this average would lead to transformation of the biocenosis. In addition, the biocenosis would be changed if for some natural or anthropogenic reasons the number of individuals of particular species increased or diminished or one species disappeared, or a new species entered the community. The concept of biocenosis has been widely applied to various communities of living organisms co-existing in one place. The biocenosis is primary if it is formed without human influence (e.g., primary forest, natural grassland) or secondary if humans have altered it (e.g., regrowth after clear-cutting the forest, aquatic community living in artificially created water reservoir). Even an agricultural plantation can be considered as a special case of biocenosis even though it is fully managed by humans. The concept of biocenosis was expanded to biogeocenosis as an independently derived synonym for ecosystem by the Russian plant ecologist Sukachev (1945).

Biocomplexity

Biocomplexity is a term used to describe the dynamic web of often surprising interrelationships that arise when living things at all levels (from molecular structures to genes to ecosystems) interact with their environment.

The prefix bio refers to life. *The American Heritage Dictionary of the English Language* (1992) defines complex as "consisting of interconnected or interwoven parts". As most life scientists are used to looking at the small picture (cellular interactions, manipulation of a single variable in an experiment, behaviour of a particular species at one site) it may take perspectives from other disciplines, notably the earth sciences and the social sciences, to best explain these interrelationships. "At all scales, from microscopic to megascopic, from atoms to galaxies, natural processes are interconnected", wrote Palmer and Zen (2000). These connections are not necessarily straightforward and linear. Some of them are non-linear and chaotic: especially connections that are related directly to the activities of the human species. These ribbons of interconnections, some patterned, some not, some predictable, some not yet predictable, are the complexities we propose to study in this new century and that we could not study in the last century.

The definition of biocomplexity seems similar to that for ecology: "... the study of the relation of organisms or groups of organisms to their environment ..." (Odum, 1959, p. 4). The study of biocomplexity, however, is greater in scope than the study of ecology and ecosystems. It includes vertically integrated relationships, such as the relationship between the soil, bacteria, plants, herbivores, carnivores, societal systems, geological factors, and climate. Biocomplexity also includes relationships over time, such as events that recur on a regular or even irregular basis. It is a term that includes heretofore-undescribed (perhaps even heretofore-indescribable) relationships that we only now are beginning to have the tools to discover.

Biodiversity in Freshwaters

Christian Lévêque
CNRS-Programme Environment, Meudon, France

Inland water ecosystems are among the world's most fragile, scarce and threatened ecosystems. Probably more than any other area on the planet, inland waters are the focus of conflicting human uses and resultant pressures. Inland waters have been exposed to a variety of increasing stress such as water extraction for domestic, agricultural and industrial uses, pollution (organic and inorganic), fishing, introduction of alien species, habitat alterations in relation to water management, etc. Even in pristine lakes far from human influences, long-range atmospheric transport may sometimes cause deposition of acidic and potentially toxic substances, e.g., sulfates and polychlorinated biphenyls, respectively, into the lakes. This may cause a long-term decline in biodiversity. These stressors have affected, and continue to affect life in inland water ecosystems all over the world.

BROAD CHARACTERISTICS OF FRESHWATER BIODIVERSITY

Research on inland waters biodiversity offers special challenges:

1. River drainages or lake catchments have been compared to terrestrial islands isolated from one another. So for taxonomic groups unable to cross geographic terrestrial barriers such as fish, mollusc, macrocrustacea, etc., the distribution is patchy. Most inland water fish, for example, can only colonize adjacent basins episodically when climatic or geological conditions allow connections between tributaries. This has a number of implications:

    - inland water biodiversity is usually highly localized, with high levels of endemism, particularly evident in ancient lakes, which have been isolated for millions of years such as the great east African Lakes (Tanganyika, Malawi, Victoria), Lake Baikal, Lake Biwa, Lake Ohrid, etc., (Martens *et al.*, 1994);
    - this patchy distribution results in great genetic variability between isolated sub-populations;
    - many inland water species must survive *in situ* or will risk extinction when exposed to climatic and ecological changes, or when threatened by the impact of human activities. So they have to adapt to the changing environment by speciation and/or

physiological adaptation, or to move when possible to more suitable habitats or refuge zones, or to perish if there is no other possibility.

2. Inland waters contain a tremendous diversity of vertebrates, microorganisms, invertebrates and aquatic plants which are among the most poorly understood organisms on Earth and are now seriously threatened. There is little doubt that inland water fishes represent the most threatened set of vertebrates. Some 25–30% of all vertebrate diversity is concentrated into some 0.01% of the planet's water or about 1–2% of the land surface area. This includes the 10 000 identified species of freshwater fish (compared to 15 000 marine fish) (Nelson, 1994) and other vertebrates including many amphibians, reptiles, birds, mammals, etc., which closely rely on the existence of inland water habitats to implement their life cycle.
3. Freshwater habitats, and particularly shallow habitats, are widely considered to be transient in time and space. Climate and geomorphology determine the global distribution and diversity of freshwaters. The great majority of existing lakes, of which around 10 000 exceed 1 km^2 in extent, are geologically very young and occupy basins formed by ice masses or glacial erosion during recent ice ages (Gorthner, 1994). Many of them occur in the temperate zone of the Northern Hemisphere, and date from the retreat of continental ice-sheets some 10 000 years BP (before present). Only about 10 existing lakes are known to be much older which occupy large subsidence basins, such as Lake Baikal or lakes of the East African Rift. River systems can change course radically as a result of deposition and erosion of their channel, but large rivers rarely disappear.

The present biodiversity in freshwater ecosystems may be viewed dynamically as an heritage of the past climatic changes and evolution processes, in a water body constrained by present climate and geomorphology, and whose future rely on the impact of several natural or anthropogenic factors (Figure 1).

1. Inland water systems tend to be the first habitats to experience degradation since humans have historically congregated around water sources. As a consequence of this anthropogenic pressure, the habitats are subjected to a considerable range of stressors, including damming and canalization, reclamation of floodplains, water abstraction, pollution, loading with organic matter and detritus. In addition, activities pursued within the drainage basin (e.g., land use or deforestation) may have consequences on the aquatic ecosystem. It should also be noted that aquatic environments are recipients of virtually every form of human waste, resulting in rapid and continuous degradation. The increasing demand for inland water resources generated by population growth will most likely result in the further decline of inland water biota unless action is taken urgently.

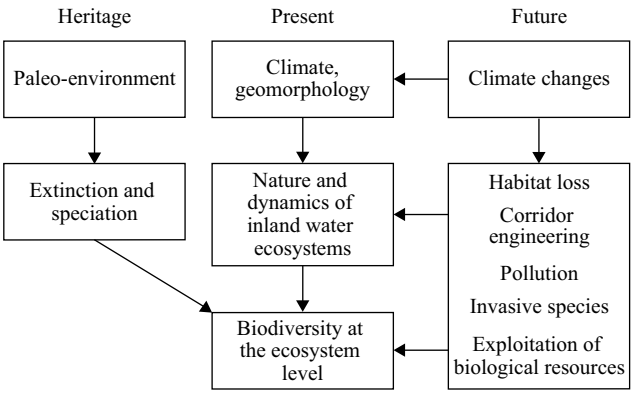

Figure 1 General factors in uencing the dynamics of freshwater diversity

INVENTORY OF FRESHWATER BIODIVERSITY

The global number of species-level biota, animals, plants and microorganisms that occur in fresh water is not precisely known. Knowledge is more complete for vertebrates than for invertebrates, while a few groups of invertebrates (molluscs, crustacea) have been more completely investigated than others. The knowledge is also more complete within the temperate zone than in the tropics.

About 100 000 species of organisms associated with freshwater sediments have been described (Table 1) but the true number is much higher than this (Palmer *et al.*, 1997). The number of species in most taxa can scarcely be estimated and global estimate of microbial diversity remains controversial. For example, some specialists estimate that there are hundred of thousands of aquatic nematodes and only a few percent of these have been described.

The best-known aquatic animals are fish. They exhibit enormous diversity in size, shape, and biology. There are descriptions of an estimated 24 600 valid species of fishes compared with 23 550 tetrapods and the eventual number of extant fish species may be close to 28 500 (Nelson, 1994). Presently, some 10 000 species of fish are found only in freshwaters, and a further more than 500 marine species also use freshwater. The freshwaters are therefore disproportionately rich in species of fish on the basis of volume and area when compared to oceans. That could be viewed as the result of the patchy nature of inland waters. Due partly to their behavior and partly to history, freshwater fishes tend to become isolated within drainage basins, resulting in distinctive populations and subspecies. This isolation

Table 1 Species richness of the freshwater sediment biota for several habitat types. Numbers are very approximate and derived from many sources. (Data collected by Palmer *et al.*, 1997)

Taxon	No species described	Probable number of species	Range of local species richness
Bacteria	>10 000	Unknown	>1000
Algae	14 000	>20 000	0- 1000
Fungi	600	1000- 10 000	0- 300
Protozoa	<10 000	10- 20 000	20- 800
Plants	1000	Unknown	0- 100
Invertebrates	70 000	>100 000	10- 1000
Aschelminthes	4000	>10 000	5- 500
Annelida	1000	>1500	2- 50
Mollusca	4000	5000	0- 50
Acarii	5000	>7500	0- 100
Crustacea	8000	>10 000	5- 300
Insecta	45 000	>50 000	0- 500
Others	1400	>2000	0- 100

favors genetic diversity; and the evolutionary potential of particular phylum such as cyprinodonts, cyprinids or cichlids also explains the high degree of endemicity observed in freshwater fishes.

In contrast with fish that are highly endemic, many flagellates, ciliates and rhizopods appear to be cosmopolitan, at least when considered at the morphospecies level. At higher trophic levels, macrozooplankton, especially many rotiferan and small cladoceran species, resemble phytoplankton in potentially occurring continentally or globally within bands of latitude (Green, 1994).

STATUS OF FRESHWATER BIODIVERSITY

Due to a general lack of data, it is difficult to assess the status of inland water biodiversity. However, evidence of biological impoverishment is pervasive in aquatic systems and when available, the data are very disturbing. For example, in the USA, where the status of aquatic biodiversity is well documented in comparison with other areas, 34% of fish, 65% of crayfishes and 75% of unionid mussels are classed rare to extinct (Master, 1990; Williams *et al.*, 1992). Of 214 stocks of Pacific salmon, 74% have a high or moderate risk of extinction (Nehlsen *et al.*, 1991). As a whole, the native fishes of North America are in serious decline and currently 364 taxa are listed by the American Fisheries Society as endangered, threatened or of special concern (Williams *et al.*, 1989). In California, Moyle (1995) reports a rising trend of extinction and endangerment in the region's native fishes from 24%, in 1988, to 43%, in 1992. Nearly half of Mexico is arid or semiarid with scarce waters. At least 92 springs and 2500 km of river have dried in this area. There are nearly 200 species of freshwater fishes, 120 under some threat, 15 extinct through human impact. As of 1985, an average of 68% of species was eradicated in local fish faunas (Contreras and Lozano, 1994).

Whatever the causes, inland water species are especially vulnerable to global changes since many of them are confined to individual watersheds and cannot readily disperse to undisturbed areas. Distinct species assemblages, highly adapted and specialized, have evolved in a wide array of habitats now threatened, and it has been estimated that 20% of the world's freshwater fish are either endangered or recently extinct (Moyle and Leidy, 1992).

MAJOR THREATS

The various anthropogenic factors that impact upon freshwater systems can be classified according to spatial scale and the location of effects (Boon, 1992) (Table 2). However in most cases, wherever impacts have been investigated and changes in biological diversity demonstrated, multiple factors are involved.

HABITAT ALTERATION

Habitat alteration is one of the major causes of loss of the diversity of aquatic life, and degradation or destruction of habitats is particularly threatening in rivers. Flow regulation occurs on almost every large river. Man-made lakes associated with hydroelectric dams or built for irrigation purposes prevent fish migrations, and alter the flow pattern downstream, one of the major consequences being the disappearance of floodplains and spawning grounds for different species. Canalization of the streambed reduces diversity of habitats. Catchment changes from large-scale land-use practices associated with deforestation, give rise to erosion, and increase of sediment load in river waters, as do

Table 2 Scale and source of factors impacting freshwater biodiversity in rivers (Boon, 1992)

Spatial scale	Source of impact
Supra catchment effects	Acid rain
	Inter-basin water transfers
Catchment land-use change	Deforestation, and afforestation
	Urbanization
	Agricultural development
	Land drainage
Corridor engineering	Flood protection
	Flow regulation; dams, weirs,
	Channelization
	Riparian vegetation removal
	Dredging, mining
Instream impacts	Organic and inorganic pollution
	Thermal pollution
	Abstraction
	Navigation
	Exploitation of native species
	Introduction of alien species

mining-related activities. In this context, fish communities are affected not only by events occurring in the channel, but also by several external influences occurring in the catchment.

Deforestation severely affects aquatic communities because massive quantities of sediment eroded from clear-cut watersheds are eventually discharged into freshwater systems, where they can be extremely destructive to aquatic organisms. Excess sediment loading in standing water bodies reduces light penetration and thereby photosynthetic rates, both planktonic and benthic. Herbivorous fish may be directly affected through reduced foraging efficiency, while zooplanktivores may also be indirectly affected by a decrease in the herbivorous zooplanktonic organisms on which they prey.

As an example, in Lake Tanganyika, 40–60% of the original woodland or forest land has been cleared in the central portions of the lake's drainage basins, and almost 100% around the northernmost portion of the lake. Steep slopes, heavy rainfall, generalized cultivation without protecting the land and slopes, and the abundance of torrential mountain streams are all factors generating rapid headwater erosion and stream incision which generate a massive increase of suspended sediment and sedimentation rates in the nearshore region of the lake. The rate of outbuilding of the Ruzizi River Delta, the major drainage pathway in the northern end of the lake, has probably increased by an order of magnitude in the past 20 years over its rate prior to deforestation. There are many fewer species of diatoms, ostracods and fish, in highly disturbed portions of Lake Tanganyika, than in moderately disturbed or undisturbed areas.

Water diversion may also be responsible for drastic changes in aquatic habitats. Among well-known examples is Lake Aral fed by the Amu Daria and Syr Daria rivers, which was the fourth largest inland body of water, just behind Lake Superior. To grow cotton, an immense irrigation system was built, diverting water from the rivers. The consequence is that the lake itself has shrunk to 25% of its 1960 volume, and its salinity is higher than the ocean leading to the extirpation of most of the 24 fish species (Létolle and Mainguet, 1993) (*see* **Aral Sea**, Volume 4).

INTRODUCTION OF EXOTIC SPECIES

Species introduction into aquatic systems have been, and are, commonplace. Welcomme (1988) listed 237 inland animal species which have been introduced into 140 countries worldwide, but the total number is much higher.

Many exotic species have been voluntarily or accidentally introduced in aquatic systems for a variety of purposes. The main goals of voluntary introductions, most usually decided by fishery officers, were initially to improve sport fisheries, artisanal fisheries and aquaculture, or to develop biological control of aquatic diseases, insects, and plants. More recently, transfers of ornamental plants and fish for the aquarium trade have also sharply increased as well as accidental introductions of these species into freshwater ecosystems.

Aquarium trade seems to be responsible for the introduction of many of the aquatic weeds in the world. In most tropical areas, *Eicchornia crassipes*, the water hyacinth native from South America, has been deliberately introduced in many countries as an ornamental plant for garden ponds. The species as well as the aquatic fern *Salvinia molesta*, also from South America, are now widely distributed through the tropical and subtropical regions of the globe where they are considered as major aquatic pests. Both are free floating plants with a high degree of morphological plasticity, competitive ability and tolerance of a wide range of environmental conditions. In temperate countries, the Canadian species *Elodea canadensis* has invaded canals in Europe and has had a significant effect on the aquatic ecosystems, preventing the full development of the native species.

Fish introductions are usually better documented than other aquatic taxa. The first introductions are believed to date from Roman times, and at least 260 species have been introduced in European waters since 1850 (Cowx, 1997). Approximately one-third of these species have been introduced in the 1960s and 1970s. In North America, the introduction of fish began in the late 1600s and the establishment of exotic species in US freshwaters is rising sharply: in 1920 only six species of exotic origin were established; by 1945, just three more have been added; the big boom of introductions occurred after 1950, and by 1980,

35 exotics had become established, and approximately 50 others had been recorded (Allan and Flecker, 1993). The future promises a continuing spread of exotic species, and managers of aquatic ecosystems will be confronted increasingly with a shifting mix of native and non-native species. Fish introductions are now an added route to invaders, and may be viewed against the background and concomitant increase of massive global changes in type and extent, and alteration in quality of freshwater habitats caused by human activities worldwide.

Invading species have been responsible for major ecological changes. These changes include extinction of native species which are more likely to occur when the successful invader is a top carnivore (Lévêque, 1997a). Direct competition for space or food with the indigenous fauna, as well as the impact of predation of introduced fish species, has been relatively well documented. Moyle *et al.* (1986) called it the Frankenstein effect because the impacts of introduced species on the native indigenous fauna tend to be negative in unpredictable ways. A well-known example is the introduction of *Lates niloticus* (the Nile perch) to lakes Victoria and Kyoga during the 1950s and early 1960s to improve the fisheries. The establishment of the Nile perch was initially supported by the large quantities of native haplochromines which were their main prey (Lévêque, 1997b). With the increasing *Lates* stock, the haplochromines declined rapidly and were drastically reduced.

Transport through ballast water is probably one the most important pathway for alien species invasions in several places, including the North American Great Lakes (Mills *et al.*, 1993). That is the case for the zebra mussel introduced into the Great Lakes, apparently in 1985 or 1986, which spread dramatically throughout the waterways of both Canada and the US with serious economical and ecological consequences. The recent finding of individual mitten crabs (*Eriocheir sinensis*) and the establishment of the alien gastropod *Potamopyrgus antipodarum* in Lake Ontario in 1995 demonstrate that the process of invasion is still going on at a fast rate.

One of the major problems in freshwater species introductions is their irreversibility, at least on scale of a human's lifetime. Once introduced and established, it is impossible, given current technology, to eradicate a fish, mollusc or plant species from a large natural water body. As a consequence, we are likely to see a continued reduction in native aquatic biodiversity and an increased homogenization of the world's freshwater biotas.

CONSEQUENCES OF CLIMATE WARMING FOR INLAND WATER ECOSYSTEMS

The Earth's average temperature will likely increase by 1–3 °C over the next century. Climate changes is likely to affect key processes (precipitation, evaporation, water vapor transport) that determine the amount and distribution of freshwater ecosystems. The information that is important to predicting future changes comes from the detailed study of climatic and biotic changes of the relatively recent past of the quaternary in which the geographical and biological setting is most closely similar to the present. Over the past 25 000 years, freshwater ecosystems have undergone massive changes in spatial extent correlated with trends in regional climate. Future climate change is likely to produce more or less comparable changes in the supply and distribution of freshwaters. However, while the climate has always been changing, current changes are unique in that they are superimposed upon a landscape, which has already been greatly altered by human activities. It is widely recognized that climate change will exert some additional stress on ecosystems that are already threatened by other human activities, such as increasing resource demands, unsustainable management practices and pollution.

The scientific review for the Intergovernmental Panel on Climate Change (IPCC) Second Assessment Report concluded that climate change will lead to an intensification of the global hydrological cycle. However, it is difficult to provide a general overview of how climate will change on a regional basis. We can expect:

- evaporation will lead to a drop in lake levels, and some wetlands will disappear while some of the smaller lakes may become wetlands;
- changes in the total amount, frequency and intensity of precipitation directly affecting the magnitude and timing of runoff, the intensity of floods and droughts, and the accumulation of nutrients and contaminants, etc.; prediction of variability is still more uncertain than predictions of mean values;
- increased runoff in high latitude regions due to increased precipitation, whereas runoff may decrease at lower latitudes due to the combined effects of increased evapotranspiration, and decreased precipitation;
- an increase in sediment runoff as a result of changes in the terrestrial ecosystems surrounding the rivers;
- an increase in the probability of dry days and the length of dry spells (consecutive days without precipitations) in some areas. Where mean precipitation decreases, the likelihood of drought increases.

Rivers will undergo changes in annual and seasonal runoff, and runoff variability. They may expand or contract. The Colorado river may see its water flow halved in the future and some rivers in Western Australia might have a 45% reduced flow, whereas the Ganges and Brahmaputra rivers in Bangladesh could increase by 50% or more. Changes in hydrological factors, such as increased or decreased frequency and magnitude, and changes in timing of high and low discharge events, will affect the ecology of streams and rivers in numerous ways. Current velocity

and turbidity of streams will change and if that leads to altered flow during spawning periods, spawning and nursery areas of migratory fishes may be unavailable. Warming may result also in faster drying out of temporary waters, increasing the challenge they present to aquatic life. With a water temperature increase, a decrease of dissolved oxygen content is expected, and this will have an immediate and direct effect on fish, particularly those living in shallow warm waters. In lakes, climate warming could result in higher surface temperature, longer ice-free periods, and an extended interval of thermal stratification.

In order to evaluate the anticipated effects of climate change on freshwater fish and their habitats, Regier and Meisner (1990) sketch out an iterative assessment process that uses water temperature, water quantity, and water quality variables. Temperature affects all vital processes, including activity, feeding, growth and reproduction. According to recent studies (Hill and Magnuson, 1990), growth of fish is expected to increase with climate warming if other factors now limiting growth also change with climate. But climate warming is also expected to increase productivity at all aquatic trophic levels by about 10–20% per 1 °C increase in temperature (Regier *et al.*, 1990). Another likely long-term consequence of global climate change is the modification of the genetic composition of populations and species. Selection for heat tolerance can quickly lead to the evolution of tolerant genotypes that may have altered life-history traits.

CONCLUSION

Research on the ecological aspects of global change should contribute to basic ecological understanding of processes regulating the Earth's biota. But the ultimate goal for ecologists is to be in a position to assist decision-makers in devising policies to anticipate, ameliorate or respond to global environmental change. Although much of the literature of aquatic ecology is relevant to global change, little work has focused explicitly on the consequences of global change for freshwater ecosystems (Carpenter *et al.*, 1992). Opinions regarding the necessary responses to global change range from those economists who think mankind should simply use his technology to adapt to changes as they occur to those who advocate the expensive option of reducing carbon dioxide (CO_2) emissions and thus preventing of further global change.

Actually, freshwater systems response to global change will depend on a complex array of physical and biological factors. These changes are likely to directly affect the survival, reproduction and growth of organisms, as well as the distribution, persistence and diversity of species:

- Global change may affect climate principally through temperature and precipitation regimes (amount, annual distribution, etc.). Both may have consequences on the overall distribution of freshwater biota (Tonn, 1990), as well as on the physiology and biology of individual species (Regier *et al.*, 1990).
- The conjunction between climate change and anthropogenic impacts could threaten more species than either factor alone. Habitat destruction and artificial barriers will obviously prevent many fish from colonizing new habitats when their native one is threatened. There is a general view that biological communities will change and shift in complex and unpredictable ways as the geographical distributions of species are altered individually rather than in community units. The rate of species invasion and extinction is likely to accelerate further, bringing about complex changes in species compositions and interactions.

Most of the concepts and strategies for biodiversity conservation were designed for terrestrial ecosystems and little has been done for the conservation of aquatic ecosystems. Rivers, particularly, raise specific problems due to their longitudinal structure and it is difficult to establish protected areas in a system for which the ultimate determinant of the quality and quantity of water is the catchment from which it originates. Habitat protection and restoration through a holistic ecosystem approach are the only major long-term means through which successful conservation of aquatic biodiversity will be achieved. Maintaining the integrity of aquatic systems contributes to providing harvestable fish populations, maintaining biological diversity, and helping to control the flux of nutrients from the land to lakes and seas. *See also* **Freshwater Fisheries**, Volume 2.

Biodiversity in Soils and Sediments: Potential Effects of Global Change

Gina A Adams and Diana H Wall
Colorado State University, Fort Collins, CO, USA

Activities of soil and sediment organisms, from their feeding on plant roots, their decomposition of plant and animal detritus and release of nutrients, and their movement through soil and sediment layers, regulate vital processes that yield goods and services (e.g., water purification, renewal of soil fertility) essential to the continued functioning of ecosystems and society. The biological diversity of the organisms in soils and sediments is estimated to be orders of magnitude greater than that above the surface, but is very poorly known. The significance of this vast below-surface biodiversity for ecosystem functioning is also unknown.

Recent assessments indicate that global change is reducing species biodiversity on landscape and global scales, and may cause the extinction of up to two-thirds of the world's species (Pimm and Brooks, 2000). In terrestrial and freshwater systems, habitat loss is the primary cause of these extinctions, but changing atmospheric composition and invasions of non-native species will become increasingly significant. However, most of these assessments are based on biodiversity above the surface of soils and sediments. If we are to accurately predict biodiversity change with global change and consequences for ecosystem functioning, we must rapidly increase our knowledge of distribution and functioning of species within soils and sediments.

Species richness is a surrogate measure of biodiversity that is commonly used for above-surface organisms. However, in below-surface habitats fewer studies have identified organisms to the species level, because of difficulties associated with their microscopic size and high abundance. Therefore, assessments of below-surface biodiversity consider additional measures, including diversity of functional groups (assemblages of species with similar ecological roles) and abundance of individuals (which influences genetic diversity).

This contribution outlines potential effects of global change on the species and functional group abundance and diversity of organisms that dwell in soils and freshwater sediments. It includes organisms that spend their entire life cycle below the surface and those that migrate out of soils or sediments to forage for food (e.g., ants) or as part of their life cycle (e.g., planktonic larval stages of freshwater bivalves). It reveals the significant gaps in our knowledge and offers some recommendations for research priorities.

BIODIVERSITY OF SOILS AND FRESHWATER SEDIMENTS

The dark and opaque domains of soils and freshwater sediments remain largely unexplored by science. While an estimated 13% of species across all habitats have been described (Hammond *et al.*, 1995), most of these are from above-surface domains. Although approximately 50% of larger soil invertebrates such as termites and ants have been described (Wall *et al.*, 2001) most smaller organisms remain undescribed. It is estimated that just 0.025–5% of nematode species have been described, and the majority of those are animal parasites, the relatively small proportion of nematode species that dwell above surface (Baldwin *et al.*, 2000). Similarly, although a single gram of soil may contain 20 000–40 000 bacterial species (Brussaard *et al.*, 1997) only approximately 13 000 bacterial species (Torsvik *et al.*, 1994) have been described, the majority of which are not soil or sediment dwelling. Table 1 shows the number of species described for some of the major phyla within soils and sediments.

Obtaining a clear picture of the diversity of organisms within soils and sediments is a daunting task. Each sample of soil or sediments collected can contain thousands of species of bacteria and fungi and hundreds of species of protozoa, and other small invertebrates (e.g., rotifers, tardigrades, nematodes) many of which are new, undescribed forms. However, new technologies, including molecular techniques and 3D imaging, are helping to advance our understanding by enabling increasingly rapid species identification.

Table 1 The approximate number of species described for some of the major taxonomic groups in soils and freshwater sediments (Palmer *et al.*, 1997; Wall *et al.*, 2001)

	Soils	Freshwater sediments
Bacteria		>10 000
by molecular analysis:	13 000	
by culture techniques:	1718	>10 000
Fungi	18 000- 35 000	600
Algae	Unknown	14 000
Protozoa	1500	10 000
Nematoda	5000	Unknown
Insecta	e.g., ants 8800 e.g., termites 2000	45 000
Annelida	e.g., earthworms 3600	1000
Mollusca	Unknown	4000

Table 2 Ecosystem services regulated by organisms within soil and sediments (modified from Daily, 1997)

- Removal of organic detritus through decomposition
- Release of nutrients for plants and maintenance of soil and sediment fertility through decomposition
- Detoxification of wastes and pollutants by microbes with specialized metabolisms
- Generation and maintenance of soil and sediment structure, e.g., by the burrowing activities of large invertebrates and particle-aggregating properties of microbes
- Filtration and cleansing of water by direct removal of particles (e.g., by filter feeders) and by maintaining the soil and sediment structure that filters water
- Modification of the hydrological cycle
- Erosion and sedimentation control
- Mitigation of floods and droughts
- Control of pests of agriculture and fisheries through predation and competition
- Regulation of concentrations of atmospheric gas (e.g., nitrogen, carbon dioxide, methane, oxygen) through consumption and production activities such as photosynthesis, aerobic and anaerobic respiration and specialized functions (e.g., nitrification and nitrogen fixation)
- Regulation of major biogeochemical cycles such as carbon and nitrogen cycles, through consumption and storage of organic matter and release of its inorganic constituents

ACTIVITIES OF SOIL AND SEDIMENT ORGANISMS IN ECOSYSTEMS

Differences in the types, rate and magnitude of the activities of organisms in soils and sediments contribute to the variety of processes that sustain ecosystems and will influence an ecosystem's response to global change (Table 2). Examining how individual species influence ecosystem functioning is a monumental challenge. One approach has been to reduce the diversity by grouping species with similar morphologies, physiologies and food sources into functional groups. This allows analysis of how biodiversity influences ecosystem functioning, but does not allow effects of individual species to be determined.

Evidence from a few studies indicates that species differences within functional groups can be important determinants of ecosystem processes and response to change. In a Puerto Rican stream, for example, Covich *et al.* (1999) found that two species of benthic macroinvertebrates (shrimp) have specific and complementary roles in the processing of organic matter, and that carbon retention in the headwater of streams is most efficient when both species are present. Where processes are thus regulated by specific species, loss of a single species may have a dramatic effect (e.g., formation of soil porosity by an earthworm species, certain transformations within the nitrogen cycle by a specialized bacterium). However, where numerous species serve identical functions in ecosystem processes, the loss of a species will have an undetectable effect on the process and there will be considerable species redundancy (e.g., formation of soil structure at the microscopic scale

by bacteria and fungi; microbial decomposition of common organic compounds). Improved knowledge of species-level effects on ecosystem processes is vital if we are to predict which ecosystems will be most vulnerable to reduced biodiversity associated with global change.

GLOBAL CHANGE AND SOIL AND SEDIMENT BIODIVERSITY

Drivers of global change (land use change, atmospheric change, climate change and biotic invasions) will influence the primary determinants of biodiversity within soils and sediments, namely:

1. physico-chemical properties (e.g., texture, salinity, pH);
2. resource supply (e.g., vegetation, organic matter and nutrients);
3. biotic interactions (e.g., herbivory, parasitism, predation);
4. microclimate (e.g., temperature, moisture) (Wall *et al.*, 2001);
5. disturbance regime (changes in rate and magnitude of disturbance that determine whether an ecosystem is in a non-equilibrium state populated by colonizing species, or in equilibrium populated by a climax community of species).

The performance of some species will be enhanced and others impaired and the overall response of species diversity will depend on the balance of the differential species responses.

Land use change has the most extensive and pernicious impacts on the determinants of biodiversity (Wall *et al.*, 2001). The impacts of atmospheric change (elevated carbon dioxide, nitrogen deposition, UV-B and ozone) and associated climate change are predicted to rise in the next 50–100 years. Biotic introductions of non-native species into novel habitats will also increase as exchange of materials increases with global travel and commerce.

The effect of the global change drivers on determinants of soil or sediment biodiversity will be direct and indirect (Table 3). Direct effects include altered soil structure through land use change (urbanization and cultivation), acidification and enhanced UV-B radiation through atmospheric change, altered temperature and moisture content of soils and sediments through climate change and altered biotic interactions such as predation and competition from species invasions. Indirect effects of global change drivers on soil and sediment biodiversity result from changes to above-surface vegetation and thus altered amount, quality, timing and diversity of plant inputs to soils and sediments and altered microclimate (through altered shading and precipitation interception). Currently the largest influence on vegetation is land use change, including deforestation, intensive agriculture and urbanization, but large effects as a result of altered atmospheric composition and climate are predicted.

The impact of global change drivers on soil and sediment biodiversity will vary according to biome type, geographical location, and spatial and temporal scales. Understanding and predicting this variability is a major research challenge, but some generalizations can be made:

- Species with short generation times such as microbes will adapt faster to change than longer-lived, larger organisms (macrofauna).
- Species that can migrate between moist and dry patches

Table 3 Direct and indirect mechanisms by which the major drivers of global change affect, or are predicted to affect in the future, biodiversity in soils and sediments

	Soils	Freshwater sediments
Land use change

Loss of habitat	+	+
Disturbance	+	+
Pollution	+	+
Indirect:		
Removal/alteration of plants and animals above-surface	+	+
Atmospheric change		
Direct:		
Acidi cation	+	+
UV-radiation	+	+
Indirect:		
Altered physiology of plant communities	+	+/?[a]
Altered composition of plant communities	+	+/?[a]
Climate change		
Direct:		
Loss of habitat (ooding of soils, drying of sediments)	+	+
Moisture	+	+
Temperature	+	+
Increased disturbance by extreme climatic events	+	+
Indirect:		
Altered physiology of plant communities	+	+/?[a]
Altered composition of plant communities	+	+
Invasive species		
Direct:		
Altered biotic interactions	+	+

[a] +/?, atmospheric change, including elevated CO_2 and nitrogen deposition, and climate change will alter the physiology and/or composition of vegetation in watersheds with consequences for freshwater sediment biota. However, studies have not examined whether the physiology and composition of submerged aquatic vegetation will be altered.

of soil will be less susceptible to soil drying with global warming.

- Species with large-scale migration or dispersal mechanisms will be better able to find new habitats in response to land use or climate change. Currently, our knowledge of soil and sediment biodiversity is confined to local or patch scales. Until knowledge of biogeographical distributions and migration abilities is increased, our ability to predict large-scale shifts in species distribution with global change will remain severely constrained.
- Currently, species may be most impacted in tropical regions where land use change is greater than temperate regions, but future global warming is predicted to be greatest at high latitudes.
- At the global scale, biodiversity will be reduced due to habitat loss and homogenization of landscapes. At the local patch scale, biodiversity responses will vary depending on site-specific conditions.

LAND USE CHANGE

Species diversity of all soil taxa decreases precipitously with land use change, as a result of altered soil texture, microclimate and timing and amount of vegetation inputs (Wall *et al.*, 2001). Organisms that tolerate a limited range of soil texture (e.g., termites, earthworms and enchytraeids), vegetation quality (e.g., species-specific herbivores or symbionts such as some mycorrhizae), or climate may be most affected, while those with broad tolerances (e.g., some bacteria) may be less affected.

In developing countries forest is rapidly being converted to agricultural land. Deforestation and replacement by pasture can reduce species diversity of soil macroinvertebrates by three-quarters. Conversion to agriculture can reduce soil biodiversity through reduced plant diversity, increased chemical inputs, increased pests and invasive species, depletion of soil organic content, soil compaction and erosion. The agricultural management practices used (e.g., slash and burn, rotations, conventional vs. no-till, minimal vs. high chemical inputs) strongly influence the impacts on soil biodiversity. For example, reduced tillage enhances soil fungal, microarthropod and earthworm populations compared with conventional tillage.

Freshwater sediment biota are also dramatically impacted by land use change. Humans currently appropriate 54% of the Earth's accessible freshwater runoff and this could reach 70% by 2025 (Lake *et al.*, 2000). As a result, the direction and amount of water flow is altered and freshwater habitats including their sediments, especially wetlands, are being rapidly lost.

Agriculture and urbanization practices in watersheds also impact sediment biota through sedimentation, acidification, salinization, contamination and altered timing, amount and quality of plant litter and dissolved organic carbon inputs. Watershed practices, such as clear-cutting, that alter the structure and composition of riparian plant communities, can have major consequences for sediment faunal composition. Reduced log and debris inputs to streams eliminate natural log dams that are a major site of invertebrate reproduction, reducing invertebrate populations and their processing of organic material with impacts on other decomposer species. Altered timing and amount of leaf inputs to streams alters the species composition of communities that shred leaf material in the first stages of decomposition.

Inefficient fertilizer application to agricultural lands decreases soil biodiversity and, through non-point source pollution and eutrophication, reduces biodiversity of freshwater sediments. Eutrophication increases phytoplankton density (but not diversity) and decomposition of this increased biomass consumes available oxygen, leading to anaerobic conditions. The diverse aerobic sediment fauna is replaced by a low diversity community consisting of anaerobic microbes and anoxia-tolerant macrofauna (Lake *et al.*, 2000).

Increased sedimentation, from soil erosion through agriculture, forestry, and urbanization reduces diversity and abundance of sediment biota, since it blocks the spaces between streambed particles that they inhabit (Lake *et al.*, 2000). It also blocks the transport of nutrients from groundwaters to sediments and transport of oxygenated water to the groundwater and hyporheic zone (sediments below running waters). The sediments of the hyporheic zone provide nursery beds for many insect and fish species and refugia for species following disturbance and its deoxygenation can severely reduce species abundance and diversity.

ATMOSPHERIC CHANGE

Direct effects of increasing atmospheric CO_2 concentrations on soil and sediment biodiversity are predicted to be small, because of the large concentrations already below-surface (Wolters *et al.*, 2000). However, indirect effects of increased atmospheric CO_2 concentrations on soil and sediment species may be large, as a result of plant responses to CO_2 enrichment. Elevated CO_2 concentrations can increase plant growth, carbon : nitrogen ratio, root : shoot ratio and water use efficiency. Differential responses of plant species and plant functional groups to elevated CO_2 are predicted to alter composition of plant communities. The altered plant physiology and community composition may affect soil and sediment species by altering organic resources, microclimate, habitat complexity and occurrence of plant host species. Data on the response of soil biota to altered plant community composition under elevated CO_2 are lacking, since most CO_2 enrichment studies are short-term and therefore

measure responses to altered plant physiology rather than community composition. However, there is strong circumstantial evidence for large effects on soil species. For example, plant species differ in their palatability to soil decomposer organisms; and relationships between soil symbiotic mutualists and their plant hosts can be highly specific.

The response of soil biota to elevated CO_2 has been generally considered for functional groups rather than species. Abundance of individuals within decomposer functional groups may increase or show no response to elevated CO_2 (Wall *et al.*, 2001). Fungal biomass can increase more than bacterial biomass, with corresponding increases in fungal-feeding microarthropods (Rillig *et al.*, 1999). Diversity of microbial communities has been altered under elevated CO_2 in some studies (e.g., beneath Mediterranean plant communities (Dhillion and Roy, 1997)) but not others (e.g., beneath grass (Hodge *et al.*, 1998)). The few studies that have examined species level responses of soil biota to elevated CO_2 provide evidence for differential species responses, e.g., with fungal and collembola (selective grazers on fungi) communities (Jones *et al.*, 1998).

Effects of elevated CO_2 on the biodiversity of freshwater sediments are as yet unknown. Altered physiology and composition of riparian and watershed vegetation may influence sediment biodiversity through similar mechanisms as for soil biodiversity. Submerged macrophytes may only show a response to elevated CO_2 in freshwaters where CO_2 is currently limited, such as soft waters.

Atmospheric sulfur, nitrogen and nitrous oxides from industry, agriculture and vehicles can acidify and leach cations (e.g., Mg^{2+}, Ca^{2+}) from soils and sediments. Diversity and composition of soil and sediment species is influenced by both the increased acidity and reduced cation availability. Aquatic organisms, including those that occupy the water film around soil particles and organisms that depend on calcium availability for shell development (e.g., crustaceans and mollusks) may be particularly affected. Following long-term acidification of the Tatra Mountains of the Slovak Republic, abundance and distribution of 'acidophilic' collembollan species increased, while some 'calciophilic' species disappeared. Across the landscape, collembolan species composition became more homogenous and less diverse (Rusek, 1993). Acidification can alter the dominance of foodwebs, for example, shifting the dominance of the soil microflora from bacterial to fungal and, correspondingly, reducing abundance and species diversity of omnivorous and predatory nematodes more than that of root-feeding and fungal-feeding nematodes. In acidified freshwaters, macrophytes are commonly lost and phytoplankton and zooplankton diversity is reduced. Impacts on plant-feeding and decomposer organisms within sediments are likely but have not been quantified.

Atmospheric nitrogen deposition also fertilizes ecosystems. The fertilization effect is modified by the production potential of the vegetation; in ecosystems adapted to low nitrogen availability, plant productivity is increased and plant diversity usually reduced and reductions in soil biodiversity may be expected. However, following long-term nitrogen deposition to the Tatra Mountains, sphagnum bogs adapted to extremely low nitrogen inputs were converted to more productive and species-rich grasslands, with a corresponding increase in abundance and species diversity of the soil collembolan community (J Rusek, personal communication).

Reduced concentrations of stratospheric ozone are increasing UV-B radiation to the Earth's surface. The effects of UV-B on soil and sediment biota are less studied than the effects of elevated CO_2, nitrogen deposition or acidification but enhanced UV-B radiation is likely to influence soil and sediment biodiversity indirectly through altered timing, quantity and quality of plant growth. UV-B radiation does not penetrate far into soils or sediments, so its greatest direct effects will be on those organisms that live at the surface. Enhanced UV-B radiation was shown to kill earthworm populations in approximately seven hours (Sicken *et al.*, 1999). In a freshwater lake, abundance of herbivorous invertebrate chironomid larvae declined under enhanced UV-B radiation (Bothwell *et al.*, 1994). Algae increased under the reduced grazing pressure with potential for effects along the food chain.

CLIMATE CHANGE

Predictions of future climate include a mean global warming of $1-3.5\,^{\circ}C$, increased precipitation with regional variation, and increased severity and frequency of catastrophic climatic events. Climate change will affect soil and sediment biota directly by influencing temperature, soil moisture, wet-drying and freeze-thawing cycles and disturbance regimes, and indirectly via altered vegetation. It is important to remember that the distribution of many soil and sediment species is limited by their cold tolerance and thus an increase in minimum temperatures, as well as maximum temperatures, may have strong effects.

Soil biota show considerable variability in their responses to warming, but less is known about the response of sediment species. In soils, the interaction between temperature and moisture, and the organisms' ability to withstand desiccation or flooding may be the key determinant of their response to warming. In Arctic regions where moisture was not limiting (tundra), collembola and oribatid mites were both resistant to warming of $2-5\,^{\circ}C$ over 3 years. However, where moisture was limiting (semipolar desert), the abundance of collembola, but not oribatid mites, declined under the elevated temperatures (Coulson *et al.*, 1996).

In the dry regions, species within these two groups also showed differential responses to warming. In another study, Briones (1997) showed that only the enchytraeid species that were able to migrate to moist patches or tolerate dry conditions withstood extreme summer temperature conditions at an artificially warmed site. These studies suggest that less mobile or less desiccation-tolerant taxa will be reduced or lost from soils that experience drying with global warming, affecting faunal composition and reducing diversity.

Migration and dispersal abilities will also influence the response of sediment species to warming on a landscape scale. In streams and rivers with intact north-south connectivity and unhindered migration paths, cold water species in high latitude and high altitude systems may be replaced by warm water species, resulting in new species assemblages. In streams and rivers with east-west drainage and in isolated ponds and lakes, thermal refuges may not be available and while some genetic adaptation may occur, there will be local extinction of species.

Increased severity and frequency of extreme climatic events, such as floods and droughts, will lead to localized extinctions of soil and sediment species. Droughts and floods comprise the disturbance regime in streams, rivers and floodplains; these control colonization by invaders and regulate nutrient and organic matter input. Increased flood severity can remove refuges that are vital for retaining reservoirs of species for recolonization. Increased flood frequency can impede successful recolonization. A study in a Californian stream demonstrated that reduced flooding can also reduce diversity (Power, 1995). When droughts reduced disturbance from flooding, grazing invertebrates persisted, suppressing spring algal blooms. As a result, a less complex foodweb was supported. Reduced waterflow in droughts also reduces hydrologic linkages between streams and groundwater zones, reducing nutrient and oxygen turnover and significantly stressing biota in groundwater and hyporheic zones. Droughts also reduce habitat area and fragment streams, which can impair migration and recolonization of species.

Climate change is predicted to alter physiology, composition and distribution of vegetation. Northward expansion of vegetation activity is occurring and may be accompanied by local extinctions of plant species at low latitudes. For plant species that cannot migrate, widespread extinctions will occur, as the fossil record shows occurred with global warming at the end of the Pleistocene. Migration and extinction of plant species with climate change may influence soil biodiversity in a number of ways. Differences in migratory rates of plants and soil biota, including plant symbionts (such as mycorrhizae, nitrogen-fixing bacteria and parasites) and free-living organisms, will disrupt biotic interactions such as herbivory, parasitisms, mutualisms, and decomposition. Whether or not this decoupling leads to extinction of soil and sediment species, or formation of new community assemblages will depend on the specificity of the relationship. Below-surface species that are closely co-evolved with above-surface species, e.g., some associations between plants, fungi and pathogenic nematodes and viruses may become locally extinct.

INVASIVE SPECIES

Animals, plants and microbes invading novel ecosystems have no natural competitors or predators and populations can explode, displacing native species and disrupting ecosystem functioning within soils and sediments. Plant invasions result from intentional planting in agriculture and horticulture, or through unintentional transport. Invasive soil species can be transported in soil attached to plants, animals or agricultural and construction machinery and through soil erosion with wind, irrigation and flooding. Invasive sediment species can be imported through flooding, in ballast water of ships or as parasites and gut inhabitants of species in aquaculture.

In the USA, invasion of the forest understory plant species *Berberis thunbergii* and *Microstegium viminium* altered soil organic and nutrient status, encouraging higher populations of earthworms (Kourtev *et al.*, 1998). Invasions of macrofauna (e.g., ants and earthworms) can alter soil organic matter, aeration, water infiltration and chemistry (Wall *et al.*, 2001) and reduce diversity of native invertebrates. The Argentine ant (*Linepithema humile*) is now invasive on all continents except Antarctica and eliminates native ant species and dramatically reduces diversity and alters composition of non-ant invertebrates (Wall *et al.*, 2001). In Northern Europe, invasions of Australasian planarian flatworms, *Artioposthia triangulata* are decimating earthworm populations on which they prey, with potentially devastating effects on soil porosity and hydrology (Boag *et al.*, 1997).

One of the most notorious invasive species is the zebra mussel *Dreissina polymorpha*, which has stripped phytoplankton from several North American lakes and rivers, disrupted foodwebs, and shifted the frequency and composition of algal blooms and nutrient cycling (Strayer *et al.*, 1999). Populations of native bivalves drop sharply following zebra mussel invasion but populations of other sediment invertebrates may increase as a result of more structurally complex habitat and increased organic matter deposition. Another invasive freshwater species, the crayfish *Orconectes rusticus* has reduced the diversity of sediment gastropods in Wisconsin lakes. It overgrazed macrophyte beds, removing this important refuge for gastropod species. Only gastropod species with thick shells or a burrowing ability to escape predators tended to survive (Covich *et al.*, 1999).

INTERACTIVE EFFECTS

Soil and sediment species will be exposed to multiple drivers of global change simultaneously, whose effects may be additive, synergistic or antagonistic. For practical reasons, most studies have examined single drivers but analysis of their interactions is an urgent research need, since multiple global change drivers can interact to alter the intensity of the change. For example, Gorham (1996) describes how acidification, climate change or removal of wetlands can reduce colored dissolved organic compounds in the water, increasing UV-B penetration to lake sediments. Studies need to be expanded to examine the effects of simultaneous global changes on the biota.

CONCLUSIONS

Global change will have varied effects on soil and sediment biota, but generally will result in reduced abundance and diversity. Differential responses of functional groups and their species will alter competitive relationships and will likely result in large shifts in community composition.

In general we cannot yet predict when and where global change will have minor vs. catastrophic impacts on soil and sediment biodiversity and ecosystem functioning. To advance this goal, research priorities should include:

- identifying those ecosystem processes that are performed by a few species and are thus most vulnerable to species loss;
- determining the rate, magnitude and variability of global change to which these keystone species or functional groups can adapt;
- routinely considering linkages between soils and sediments, since neither exists in isolation and indeed significant areas of the Earth's surface are an interface between the two;
- studying multiple effects of global change drivers to analyze how responses are modified by the presence of other species in a community;
- studying the interactive effects of different global change drivers.

Biodiversity: The UNEP De nition

Biodiversity is the variability among living organisms from all sources including, *inter alia*, terrestrial, marine and other aquatic ecosystems and the ecological complexes of which they are part; this includes diversity within species, between species and of ecosystems.

Biogeochemical Cycle

Biogeochemical cycle describes the cyclic passage through the biotic, atmospheric, aqueous and lithic (rock, soil) compartments of the environment of inorganic nutrient chemicals that enter and pass through the biotic component. Biogeochemical cycles are described as *gaseous* (i.e., carbon dioxide (CO_2), nitrogen) or *sedimentary* (i.e., nutrients that are largely present in rocks and soils). This distinction is not absolute: CO_2 has major lithic as well as gaseous components, and sulfur, primarily sedimentary, has minor gaseous forms. The cycling of water, the *hydrological cycle*, is usually considered independently from biogeochemical cycles.

Nutrient cycling is important for two main reasons: first, nutrients are important to organisms, their importance varying with their abundance, accessibility and the level of their requirement, and second, nutrients may have roles in ecosystem behavior quite unrelated to their obvious biological significance. For example, CO_2 is primarily important to the biotic component of an ecosystem as the substrate of photosynthesis, but it is also involved in environmental pH regulation, particularly in aquatic habitats. In addition, its role as a greenhouse gas may have major environmental and ecological consequences. These different roles interact to modify ecosystem behavior, and hence the behavior of the CO_2 cycle. The fact that major global environmental concerns (e.g., stratospheric ozone depletion, the greenhouse effect, acid rain, nitrogen and phosphorus overfertilization) are closely interrelated through the operation of biogeochemical cycles has greatly increased current interest in the behavior of these cycles.

Biogeochemical cycling of carbon involves its removal from the air or water by photosynthesis and its return by respiration/decomposition of plants, animals and bacteria. Carbon may be stored temporarily in soils or water, and more permanently in carbonaceous rocks such as limestone. Its transfer between water and air is complex because it is affected by many environmental factors (e.g., temperature, pH, water circulation and flow, winds and air movement). Large amounts of carbon are also transferred erratically to the air by fires and volcanism.

Nitrogen cycling is largely biological, involving the bacterial fixation of nitrogen gas, its conversion to organic (reduced) nitrogen in plants and thence animals, and its subsequent loss by bacterial decay to nitrates or nitrogen gas. Of growing concern is the increasing production of nitrogenous compounds to the atmosphere by automobiles, industrial pollution and power plants, and the large contribution to the environment from agricultural fertilizer and wastes. Additional nitrogen also enters the cycle from the production of nitrates or nitrites by lightning and volcanism.

The cycling of lithic nutrient chemicals is less complex, although the sequestering of sedimentary materials

(as well as nitrogen) in litter adds a highly variable biotic component. Cycles of sedimentary nutrients may also be affected by mass transfer throughout ocean ecosystems and their ability to be sequestered or released by lithic components (e.g., phosphorus in rocks, earth, marine deposits, bones, etc.).

Bioindicators

Lesley Hughes
Macquarie University, New South Wales, Australia

Hotter summers, heavier rain, and rising seas – just a few of the predictions as to how the world will change over the coming decades. Indeed, evidence is accumulating that global mean temperatures have already risen by over half a degree since 1860 and that the distribution of rain and snow is also changing. Shrinking sea ice, melting glaciers and warming oceans also provide evidence that steadily increasing concentrations of greenhouse gases are starting to have measurable impacts.

These atmospheric and climatic changes are expected to have profound effects on species and communities in the future. But has the modest warming recorded so far already had an impact on natural systems? Recent analyses of long-term datasets indicate that the answer to this question is a cautious yes. Although natural variation, or non-climatic factors, may be responsible for some of the published trends, the proposition that human-induced atmospheric change is the cause is convincing for some ecologists. The data come from such diverse sources as the isotope ratios of whale baleen, the emergence dates of butterflies, and sophisticated satellite imagery. Some examples are more convincing than others due to the quantity of data, strength of the trend, or a lack of more plausible explanations. No single study can be interpreted as unequivocal evidence for human-induced change, as none represents a controlled experiment and alternate hypotheses cannot be completely discounted. But what started as a trickle of published trends a decade ago has now built to a modest flood.

This article reviews evidence that some species are already responding to the anomalous climate of the last few decades. These responses range from changes in physiology and growth to movements of range boundaries and alterations in the timing of life cycles. A few species even appear to have undergone genetic adaptation as a response to the changing climate. The wait to assess the impact of the enhanced greenhouse effect may be over sooner than we thought.

WHAT DO WE EXPECT?

Ways in which enhanced greenhouse warming can affect the biosphere can be broadly summarized into four categories (Figure 1).

1. *Adaptation*: species with short generation times and rapid population growth rates may undergo micro-evolutionary change at a sufficient pace to keep up with climatic shifts.
2. *Effects on physiology*: changes in atmospheric carbon dioxide (CO_2) concentration, temperature, or precipitation will directly affect processes such as photosynthesis, respiration, growth and tissue composition in plants, and metabolic and developmental rates in many animals.
3. *Effects on distributions*: a 3 °C change in mean annual temperature corresponds to a shift in temperature zones of approximately 300–400 km in a north–south direction (in the temperate zone) or 500 m in elevation. Some species are therefore expected to move upward in elevation or toward the poles as the climate changes.
4. *Effects on phenology*: temperature frequently acts as a trigger for life cycle events such as flowering and fruiting in plants, and hatching in insects and birds. Warmer spring temperatures, in particular, may result in some events occurring earlier in the season.

Any of the above changes to an individual species will inevitably alter its interactions with other species (Figure 1) and eventually lead to changes in the composition and structure of communities. It seems likely that at least some species will become extinct, either as a direct result of physiological stress, or via interactions with other species.

EVIDENCE FOR MICRO-EVOLUTIONARY CHANGE

The anticipated rate of climate change over the next few decades is far greater than any observed in the past. While laboratory experiments have shown that some bacteria populations rapidly adapt to changes in temperature by selection on new mutations, it seems unlikely that most higher eukaryotes, with smaller population sizes and longer generation times, can evolve rapidly enough to track climate change. There is evidence, however, that at least two insect species may have already undergone micro-evolutionary

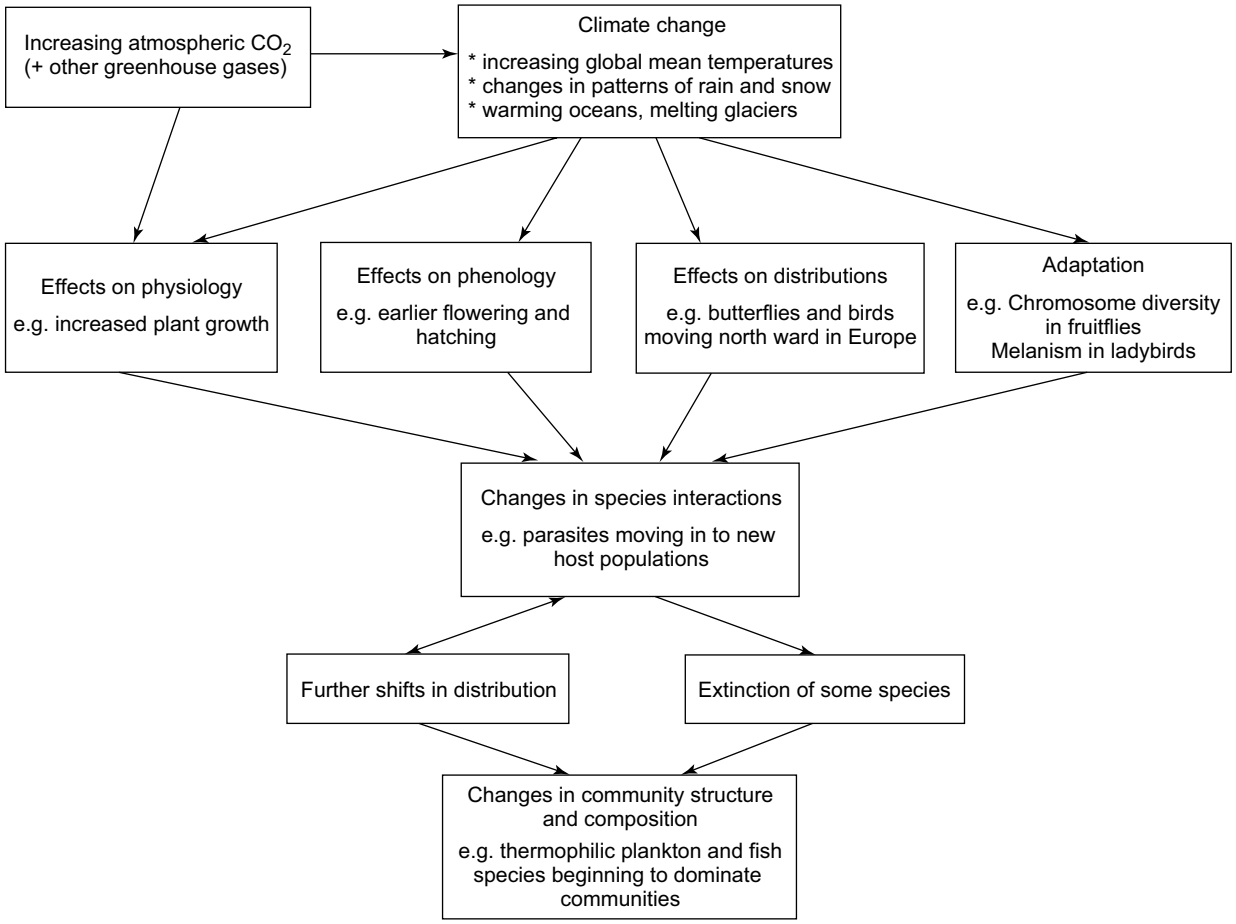

Figure 1 Potential consequences of the enhanced greenhouse effect for species and communities. (Reproduced from Hughes, 2000)

adaptation to the relatively modest warming experienced so far.

The fruitfly, *Drosophila subobscura*, has been sampled over a 16-year period (1976–1980 and 1988–1991) (>80 generations) at a site in Spain that has experienced sustained warming since the mid 1970s. Of particular interest is the *O* chromosome of these flies, which has been linked to thermo-tolerance related traits, and contains a gene family that exhibits direct responses to selection on heat tolerance in the laboratory. A significant reduction (18.3%) in chromosomal diversity in the flies has been detected over the sampling period, with particularly rapid changes in several chromosome inversion polymorphisms. These results are in accord with what would be expected from known latitudinal and seasonal variation in these genetic components (Rodríguez-Trelles and Rodríguez, 1998).

The two-spot ladybird *Adalia bipunctata* has several color morphs that can be broadly classified as predominantly red with black spots (melanics) and predominantly black with red spots (non-melanics). Laboratory experiments show that the melanic forms have a thermal advantage over non-melanics at low temperatures. Over the last two decades there has been a decline in the frequencies of the melanic form in ladybird populations across the Netherlands associated with warmer spring temperatures (de Jong and Brakefield, 1998).

EVIDENCE FOR CHANGES IN PHYSIOLOGY, PRODUCTIVITY AND GROWTH

Both temperature and atmospheric CO_2 concentration directly affect photosynthesis, and hence plant growth and productivity. Plant growth in the Northern Hemisphere has apparently responded to recent trends in warming and CO_2, although it is difficult to separate the relative contributions of the two factors.

Atmospheric CO_2 concentration has been increasing since the mid-1800s. CO_2 concentration rises in winter and declines in summer in response to the seasonal growth of terrestrial vegetation. Since the early 1960s,

the amplitude of this oscillation has increased by 20% in Hawaii and by 40% in the Arctic (Keeling *et al.*, 1996). Increasing assimilation of CO_2 by land plants is one explanation for this trend, and this idea is supported by satellite data showing increased plant growth and a lengthening of the active growing season (1981–1991) in the Northern Hemisphere between 45–70 °N (Myneni *et al.*, 1997). Further support that CO_2-fertilization has already affected tree growth comes from studies of tree-rings at sites in both hemispheres. Increasing CO_2 levels may also have affected the anatomy of leaves. Several studies have shown that the densities of stomates in plants collected recently are significantly lower than in herbarium specimens of the same species collected 70–200 years ago. These trends are consistent with experimental studies using pre-industrial CO_2 concentrations, and with the fossil record.

Some of the recent changes in terrestrial vegetation have important implications for the rate of future atmospheric and climate changes. For example, atmospheric changes and warming are thought to be responsible for the increasing yields of conifer plantations recorded since the mid-1800s in parts of Europe, and for the acceleration of turnover rates and biomass of tropical trees since the 1950s. If CO_2 fertilization is already promoting forest growth, which in turn is sequestering carbon, future climate change might be partially mitigated. A recent report however, that the tundra may have recently changed from being a net carbon sink to a source, is a potential countertrend that may accelerate future change (Serreze *et al.*, 2000).

Recent climate changes may also be affecting productivity in the oceans. Large changes in phytoplankton abundance have been recorded since the late 1940s in the northeast Atlantic and North Sea. Phytoplankton season length and abundance south of 59 °N have increased, while the opposite trend is seen to the north of this latitude. The northern decline may be a result of unusually cold waters spreading from the Arctic where increased freshwater export from melting ice and permafrost is occurring. Further evidence for a decline in phytoplankton productivity at far north latitudes comes from carbon isotope ratios in the baleen plates of bowhead whales in the Bering Sea. Isotope ratios in the zooplankton on which the whales feed, and, by extension, the phytoplankton, are incorporated into keratin deposited into the growing baleen plate. Baleen plates from whales harvested by Alaskan Inupiats from 1947–1997 indicate that seasonal productivity has been declining since the 1970s, with average $\delta^{13}C$ ratios decreasing by over 2.7%, inferring a drop in seasonal carbon fixation of ~30–40% (Schell, 2000). This implies that the carrying capacity of these oceans has been progressively declining, a trend correlated with declines in the top consumers of the region such as sea birds, fur seals and harbor seals.

EVIDENCE FOR CHANGES IN SPECIES DISTRIBUTION AND ABUNDANCE

Human activity over the last millennium has altered the distributions and/or abundance of most species, with most changes being attributed to habitat loss or alteration. Some recent shifts in species distribution toward the poles, or upward in elevation, however, are more convincingly explained by recent climatic trends. Not surprisingly, most of these examples come from species such as alpine and arctic plants whose distributions are most obviously limited by climate, and from organisms that are highly mobile at some stage of their life cycle such as flying insects, birds, and marine invertebrates.

Arctic and Alpine Plants

A substantial warming trend in Antarctica since the 1960s has been associated with dramatic increases in abundance of the only two native vascular plants in the region, *Colobanthus quitensis* (Antarctic pearlwort) and *Deschampsia antarctica* (Antarctic hair grass). At Galindez Island, for example, *D antarctica* increased from 500 individuals in 1964, to 12 030 in 1990 as a result of increased seed germination and successful establishment of seedlings. Similar patterns for these species have been recorded at many other sites (Smith, 1994).

Alpine plants appear to be moving upward, with young trees establishing at elevations or latitudes beyond the current treeline in many regions. Most locations in western North America, for example, show an upward expansion of the forest margin after 1890. Upward colonization of a range of alpine species in the European Alps also appears responsible for increasing plant species richness measured in the early 1990s, compared with historical records.

Invertebrates

Butterflies in both Europe and North America are apparently expanding their ranges northward. In Europe, these expansions range from 35–240 km. For many species, the southern boundaries of the distribution have remained stable, resulting in an overall range expansion. In North America, a survey of over 150 previously recorded populations of Edith's checkerspot butterfly, *Euphydryas editha*, found that locations where the butterflies had successfully persisted were, on average, 2° farther north or at higher elevations than those where populations had become extinct (Parmesan, 1996).

Recent range shifts in other arthropods have serious implications for human health. Increases in mosquito-borne

diseases have been reported in the highlands of Asia, Central Africa and Latin America. Dengue fever, previously limited to about 1000 m in elevation in the tropics, has appeared at 1700 m in Mexico, and *Aedes aegypti*, a vector of dengue fever and yellow fever viruses, has recently been reported at 2200 m in Colombia. *Plasmodium falciparum* malaria is a growing public health threat in the New Guinea highlands, and in 1997 malaria was reported for the first time up to 2100 m in the highlands of Irian Jaya and Papua New Guinea, with similar changes reported from Tanzania and Kenya (Epstein *et al.*, 1998) (*see* **Infectious Diseases**, Volume 2; **Viral Diseases and the Influence of Climate Change**, Volume 3).

Shifts in the distribution of disease and parasites are not limited to the tropics. The northern distribution of the European tick *Ixodes ricinus* has apparently shifted northward in Sweden between the early 1980s and 1990s in response to milder winters (Lindgren *et al.*, 2000).

Marine Species

The rapid, and sometimes dramatic, responses of marine species to the short-term sea surface temperature changes accompanying El Niño/Southern Oscillation (ENSO) events indicate that these organisms respond sensitively to ocean warming. During the past 5000 years, El Niño events have typically occurred at a frequency of one to two per decade but, since the mid-1970s, have occurred more often, been more intense, and persisted longer. The impact of these climate events on marine species is clearly evident among corals, which are known to bleach (by expelling symbiotic algae) in response to a range of environmental stresses. The highest sea surface temperatures associated with an ENSO event ever recorded in the tropics occurred in 1998, topping a 50-year trend for some tropical oceans. This event was associated with the most geographically extensive and severe coral bleaching in recorded history, causing significant mortality worldwide. The coral community in Belize in the Caribbean, for example, collapsed completely. Cores extracted from the Belizean reefs showed that these events were unprecedented over at least the past 3000 years (Aronson *et al.*, 2000) (*see* **Coral Reefs: an Ecosystem Subject to Multiple Environmental Threats**, Volume 2).

The almost 25-year trend of warming winter temperatures on the east coast of the US may also have facilitated the spread of two oyster diseases caused by the protozoan parasite *Perkinsus marinus*. Warmer winters appear to have reduced parasite mortality, favoring the northward expansion of *P marinus* into new, susceptible host populations (Harvell *et al.*, 1999).

Changes in the distribution and abundance of several taxa off the coast of California have been particularly well documented over the past few decades. The surface waters of the California current warmed 1.2–1.6 °C between 1951 and 1993. Data from the Californian Cooperative Oceanic Fisheries Investigations indicate that this warming was accompanied by a 70% decline in zooplankton abundance, possibly because increased surface temperatures have reduced the upwelling of cold, nutrient-rich waters to the surface. One of the top predators in this system, the sooty shearwater *Puffinus griseus*, suffered a 90% decline in abundance off western North America between 1987 and 1994 with a nine month lag in response time to changing surface temperatures (Veit *et al.*, 1997). Whilst other influences, such as gill-net mortality and pollution, cannot be discounted, the coincidence in space and time of an oceanic temperature increase and the decrease in zooplankton abundance suggest a direct causal relationship.

Two further studies of marine organisms associated with the Californian coast also provide evidence of recent climate-induced changes in community composition. Two surveys of invertebrates at the same intertidal site conducted 60 years apart documented that of the 45 species first surveyed in 1931–1933, eight out of nine southern species had increased, while five out of eight northern species had declined, with no trend being evident for cosmopolitan species. Over the same period, annual mean shoreline ocean temperatures increased by 0.75 °C and mean summer maximum temperatures by 2.2 °C (Barry *et al.*, 1995). Analogous changes in community composition have occurred in a Californian reef fish assemblage surveyed over a 20 year period (1974–1993) where the proportion of northern, colder affinity species declined from approximately 50% to about 33%, and the proportion of warmer affinity, southern species increased from about 25 to 35%. These changes were accompanied by substantial (up to 92%) declines in the abundance of most species, with the northern species suffering the greatest reductions (Holbrook *et al.*, 1997). Concurrent declines of a similar magnitude were observed for several trophic levels of the benthic ecosystem farther north, with biomass of understory macroalgae decreasing by about 80%.

Warming oceans may also be responsible for observed changes to the species composition of fish and plankton communities at northern high latitudes. Since the beginning of the 20th century, 16 non-indigenous plankton species have become an integral part of the pelagic system of the North Sea. Ten of these species are classified as *thermophilic*, i.e., species usually found in more southerly and warmer regions, and all were recorded for the first time during the last decade (Nehring, 1998). Similar northward range expansions of warm water species of fish and benthic organisms have been observed in the Adriatic, Mediterranean and the English Channel over the last two to three decades.

Terrestrial Vertebrates

Marine organisms may not be the only species affected by ocean warming. Enhanced evaporation from warm surface waters releases large amounts of water vapor. The latent heat released as this moisture condenses accelerates atmospheric warming and does so proportionately more at higher elevations. In the cloudforests of Monteverde, Costa Rica, this process appears to have resulted in a lifting cloud base and a decline in the frequency of mist days. These trends have been strongly associated with synchronous population declines of birds, reptiles and amphibians on plots at 1540 m. Accompanying the declines has been an increase in colonization of cloud–forest intolerant bird species from lower altitudes (Pounds *et al.*, 1999).

Poleward range expansions have been reported for birds in both Europe and the US. The northern margins of 59 bird species with distributions in the south of Britain, for example, have moved farther north by an average of nearly 19 km over a 20-year period (1988–1991 compared to 1968–1972) (Thomas and Lennon, 1999). A survey of small mammals in the southwest US reported similar northward range expansions for 19 species from a variety of habitats (Davis and Callahan, 1992).

EVIDENCE FOR CHANGES IN TIMING OF LIFE CYCLES

The life cycles of many organisms are strongly influenced by temperature and precipitation (*see* **Phenology**, Volume 2). Warmer conditions in the future are generally expected to advance events such as flowering and fruiting in plants, and to hasten development time in some species. Monitoring of seasonal plant and animal activity (phenology) has a long tradition in some countries, particularly in Europe. Many of the long-term datasets compiled by enthusiastic naturalists are now providing some of the most compelling evidence yet for the impact of human-induced climate change.

Analyses of phenological records of events such as flowering, fruiting and leaf unfolding in Northern Hemisphere plants all point to the same conclusions: spring is getting earlier, and the main growing season is lengthening. Data gathered since the late 1950s from the International Phenological Gardens, a Europe-wide network covering a large latitudinal (42–69 °N) and longitudinal (10 °W–27 °E) range that has genetically identical clones of trees and shrubs, show that spring events such as leaf unfolding have advanced by six days, whereas autumn events such as leaf coloring, have been delayed by nearly five days. This means that the average growing season has lengthened by nearly 11 days over the last four decades (Menzel and Fabian, 1999).

The phenological trends in Europe are mirrored by similar ones in the US and Canada. In central and eastern US, for example, first leaf spring index dates became earlier at a rate of about one day per year from 1978–1990. In Edmonton, Canada, there has been a general advance in the timing of spring by eight days over the last six decades. Over a longer period, between 1936 and 1990, the data of first bloom of 10 spring flower species recorded by the Leopold family on a farm in Wisconsin, became earlier by an average of 13 days (Bradley *et al.*, 1999). These reported changes in phenology were accompanied by increases in temperature during March–May of approximately 1–2 °C across central, southern and western Europe and similar or larger rises in temperature during December–February in the central and eastern US. For some individual species, the phenological advances have been dramatic. In Estonia, for example, the pollination of hazel has advanced by 20 days over the last 48 years while in Canada, there has been a 26 day shift to earlier blooming in *Populus tremuloides* over the last century (1900–1997) (Beaubien and Freeland, 2000).

Evidence that recent warming is affecting animal life cycles comes mainly from insects and birds. Butterflies and moths monitored over the last few decades in Britain (since the mid 1970s) and Europe (since the mid 1950s) appear to be emerging as adults earlier. In the Netherlands, for example, the date of flight peak of over 100 species advanced by an average of 12 days between 1975 and 1994 (Ellis *et al.*, 1997). Similar, but less dramatic trends have been found in the dates of aphid flights with five species recorded by a suction trap network across the UK showing an advance of three to six days over the past 25 years (Fleming and Tatchell, 1995).

The enthusiasm of amateur bird watchers for recording their observations has provided a goldmine of data, showing how warming has affected various aspects of bird ecology. Earlier egg-laying, larger clutch sizes and more rapid chick development have been recorded for many British, European and North American birds, and these trends are strongly associated with increases in spring temperatures over the last few decades. For example, an analysis of the laying dates of 65 British bird species surveyed from 1971–1995 showed significant trends toward earlier egg laying in 20 species (31%), with only one species laying significantly later. The shift toward earlier laying averaged 8.8 days over the 24-year period (range 4–17 days). A subsequent, more extensive analysis of the annual median laying date of 36 British bird species over 57 years (1939–1995) found that 19 (53%) species show long-term trends with laying dates becoming later in the 1960s and 1970s, and then earlier in the 1980s and 1990s (Crick and Sparks, 1999). In the US, the date of first nest in the Mexican jay in southeastern Arizona has advanced by nearly 11 days and mean date of first clutch by 10 days

from 1971–1998 (Brown *et al.*, 1999) and the laying date recorded for North American tree swallows advanced by up to nine days from 1959 to 1991 (Dunn and Winkler, 1999). Parallel trends in earlier reproduction have been reported for several British amphibians over the period 1978–1994, with every 1 °C increase in maximum temperatures corresponding to an advance in spawning date of nine to ten days (Beebee, 1995).

For many species, advances in one stage of the life cycle may result in a lack of synchronization with the availability of important resources. The apparent growing disjunction between low- and high-altitude phenology in the Rocky Mountains provides an example. American robins are arriving 14 days earlier at the Rocky Mountains Biological Station than in 1981, apparently in response to warmer air temperatures at lower altitudes where the spring migration is initiated. But at the higher altitudes where the robins arrive to feed, the timing of snowmelt has not changed and as a consequence, the interval between the birds' arrival and the first date of bare ground has lengthened by 18 days. The birds have therefore faced increasingly longer periods of snow-covered ground before the summer growing season begins. Yellow-bellied marmots in the same area may also have experienced similar problems. These mammals are emerging from hibernation 38 days earlier than 23 years ago (Inouye *et al.*, 2000).

WHAT NEXT?

Many of the trends reviewed here show accelerated rates of change over the last two to three decades and if these studies are indeed early indicators of future change, we will expect to see the following situations becoming increasingly apparent:

- Extensions of species' geographic range boundaries toward the poles or to higher elevations by progressive establishment of new local populations with concomitant extinctions of populations along boundaries at lower latitudes or elevations.
- Increasing invasion by opportunistic, weedy, mobile and/or thermophilic species, especially into sites where local populations of existing species are declining.
- Progressive mismatching of established species interactions (e.g., plants and pollinators, parasites and hosts) due to lack of synchronization between life cycles.

Altogether, such changes at the level of individual species will inevitably, and irrevocably, alter the structure and composition of whole communities. In several decades, some of the trends reviewed here may be reinterpreted as simply due to natural variation. But even if only a fraction are indeed attributable to the influence of humans on the atmosphere, we are left with the sobering thought that they have occurred in response to a warming that is probably only a fifth of that expected over the century ahead.

Biome

Widely separated geographic regions with similar environmental conditions typically contain similar types of biota. This feature allows the partitioning of the biosphere into very large regions, called *biomes*, in which similar geology and climate are home to species with similar adaptations and life history strategies. Biomes are often named after their dominant kind of vegetation (e.g., grassland or shrubland) and, as the geographically largest biotic units, they include all ecosystems and successional stages of ecosystems located within their borders.

The boreal forest is an example of a terrestrial biome. It occurs in Asia, Europe, and North America where the climate and geology combine to produce suitable environmental conditions. The boreal forest biome has the same general kinds of ecosystems everywhere, but the individual constituent species differ from one boreal forest region to another (partly because these regions differ in their ecological, geological, and climatic histories). Nonetheless, the different boreal forests contain organisms that are ecologically similar, i.e., the species differ but they correspond in the sense that they have adapted to similar environments and have developed similar life cycles.

Biome Models

Wolfgang Cramer

Potsdam Institute for Climate Impact Research, Potsdam, Germany

Biomes may be defined as "... the world's major (plant and animal) communities, classified according to the predominant vegetation and characterized by adaptations of organisms to that particular environment" (Campbell, 1996). A synonym for biome is major life zone. Typical biomes are, e.g., coniferous forest (taiga), desert, grassland, Mediterranean shrubland, rain forest, savanna, temperate forest, tundra, coastal waters, coral reef, freshwater, and open

ocean; but the number of subdivisions in any biome list is arbitrary and depends on the list's specific purpose. Due to their broad geographic extent, often covering broad continent spanning zones, biomes normally consist of multiple types of ecosystems, which reflect local environmental gradients and interactions. For example, the same taiga biome contains wet oceanic cold rain forests and cold adapted continental deciduous conifer forests.

On land, biomes are usually characterized by their dominant vegetation expressed in broad categories. Just like in the more narrowly defined ecosystems, animals and soil biota are equally important elements in their function and therefore also for their structure. Biome definitions usually do not relate to the kind of human land use that takes place within their boundaries. Biomes may, however, be considered as indicators for the agricultural or forest practice that can be carried out potentially in a given region.

CLIMATIC FACTORS THAT DETERMINE BIOME DISTRIBUTIONS

Biomes are well determined by macroclimatic and soil characteristics. Indeed, before the advent of large-scale climate maps based on weather stations, both geographers and climatologists have often considered biomes as indicators for climate in areas with insufficient weather stations (Köppen, 1884; Cramer and Leemans, 1993). Climatic factors may be used to identify environmental correlates or even causes for the distributional limits of either biomes or species. Classically, the factors used were easily accessible longer-term averages of standard variables, such as annual or monthly averages of temperature and precipitation. By visual map comparison, coinciding climatic and biome limits could be used to further characterize the biome and its typical environment.

Increasingly, so-called *bioclimatic* indicators are being developed from climatic boundaries that are based on specific processes of plant growth or survival. Ultimately, the goal of such indicators is to be able to predict the location, and the possible change, of biome distribution limits in response to past or future climate change. Examples are growing degree days or heat sums (i.e., the sum of all temperatures above a certain threshold), absolute cold tolerance limits or estimates of typical maximum drought stress based on a simple water balance calculation. The life zone classification by Holdridge (1947, 1967) was the first attempt to provide a complete biome (life zone) system defined by only two such bioclimatic variables (*see* **Holdridge Life Zone Classification**, Volume 2). The Holdridge system could be applied globally and thereby provided a first simple global biome model that could be used to assess the sensitivity of global vegetation distribution to climate change (Emanuel *et al.*, 1985).

BIOME MODELING APPROACHES

The arrival of digital computers with sufficient capacity to store and manipulate large global climatic databases, as well as maps of other environmental variables, triggered the development of more elaborate mathematical models of global biome distribution. Such models are global in the sense of being applicable at any (ice-free) land surface, if given a description of environmental conditions at this location. The models have no implicit spatial resolution, and there is no lateral interaction between neighboring locations.

Depending on their purpose, biome models have been developed for the characterization of biome distributions as a function of climate and soils. Some related models have also been used to assess the dynamics of carbon and water fluxes, using a map of biome types. A third, more recent group of models combines these two aspects. The most recently developed class of models adds transient dynamics of vegetation structure and carbon pools to the picture. All four classes of models are briefly discussed in the following subsections.

Equilibrium Models of Biome Distribution

For the first generation of the biome models, biome distribution is assumed to be in equilibrium with climate. Box (1981) developed such a model, combining the concepts of life form (Raunkiær, 1907) and life zone (Holdridge, 1967). To capture the essential life forms of all higher plants, Box defined 90 different plant types, as well as bioclimatic envelopes (lower and upper boundaries) for eight variables (listed in Table 1), which all could be mapped on the basis of available climatic normals. Woodward (1987) was the first to show that a more appropriate analysis of biome distribution required the representation of the physiological processes that control survival and performance of plants in a given ecosystem. His analysis and the resulting model focussed primarily upon cold tolerance and the water

Table 1 Bioclimatic indices used by the Box model

T_{max}	Mean temperature of the warmest month (°C)
T_{min}	Mean temperature of the coldest month (°C)
D_T	Range between T_{min} and T_{max} (°C)
P	Mean total annual precipitation (mm)
MI	Moisture index, de ned as the ratio between P and annual potential evapotranspiration (Thornthwaite and Mather, 1957)
P_{max}	Mean total precipitation of the wettest month (mm)
P_{min}	Mean total precipitation of the driest month (mm)
$P_{T_{max}}$	Mean total precipitation of the warmest month (mm)

Source: Box, 1981.

needs of plants, both of which could not easily be derived from existing climate data sets.

The development of a biome distribution model to be applied under different climate regimes (such as those of earlier periods in geological history, or for scenarios of future developments) required the incorporation of mechanistic formulations for all critical processes that could limit plant distributions, as well as the development of suitable data sets for model application worldwide. For the parameterization of process formulations, it was found necessary to group plant species into so called functional groups. Each functional group describes plant types with similar behavior for a given process. A widely used model of this type is the BIOME model (Prentice *et al.*, 1992). It involves four major bioclimatic tolerance/requirement factors (Table 2) which are characterized independently for 13 plant functional types (PFTs). Several PFTs may co-occur at any location (Table 3). Since precipitation provides no direct indication of moisture stress, a process-based water balance model (Cramer and Prentice, 1988; Prentice *et al.*, 1993) is used to assess regions with significant differences between actual and potential evapotranspiration. The development of BIOME was possible since the climatic limitations could be mapped more precisely than earlier using a topography-sensitive global climate data base developed for this purpose (Leemans and Cramer, 1991). A significantly updated version of this data base is available free of charge from http://www.pik-potsdam.de/~cramer/climate.htm.

Applications of BIOME cover a broad range of questions. Since the model gives an appropriate characterization of broad land surface types (in the absence of direct human impact), it has been found to be a suitable replacement for land cover maps that are used in atmospheric general circulation models. Asynchronously coupled to the atmosphere (i.e., with permitted change in biome distribution only every five years or so), the model has allowed one to address critical issues in atmosphere/biosphere stability on the paleoecological time scale (Claussen, 1994, 1996).

Equilibrium Models of Biogeochemical Fluxes

The necessity to better quantify the role of the land biosphere for the overall balance of carbon fluxes was recognized many years ago (Bolin, 1977). As a result of the International Biological Programme (IBP), Lieth (1975) quantified the relationship between net primary productivity (NPP) and climate (temperature, precipitation) in a regression model consisting of one globally applicable equation. The model was revolutionary for its time, but the limitations of this regression for the assessment of future fluxes are nevertheless significant. Most fundamentally, inspection of the Earth's vegetation shows that a single monotonous equation is likely to fail near the boundaries of major biomes, such as forest–tundra boundaries, where the presence of a major life form affects both the local environment and thereby also productivity.

Moreover, the observations naturally cover only the recent range of atmospheric carbon dioxide concentrations, while it is likely that higher carbon dioxide concentrations will cause changes in plant productivity. Finally, NPP is not the variable of direct interest for assessments of global change impacts; net biome production (NBP), i.e., the remaining net flux after deducting all losses due to respiration and disturbance, is more important and only weakly related to NPP (IGBP Terrestrial Carbon Working Group, 1998).

To overcome these limitations, several groups have developed process-oriented biogeochemical models, e.g., TEM (Raich *et al.*, 1991), CARAIB (Nemry *et al.*, 1996) and FBM (Lüdeke *et al.*, 1994). A detailed review of the state of the art for these models may be found in Cramer *et al.* (1999). Most of these models share the biome concept

Table 2 Derivation of bioclimatic indices from interpolated climatic data in the BIOME model

Tolerance/requirement	Ecophysiological mechanism	Bioclimatic index	Climatic variable (monthly means)
Cold tolerance	Killing temperature during coldest period of the year	T_{min} (temperature of the coldest month, lower limit)	Temperature
Chilling requirement	Winter chilling period required for budburst of woody plants	T_{min} (temperature of the coldest month, upper limit)	Temperature
Heat requirement	Annual growth respiration requirement	GDD (growing degree days above 0 °C and 5 °C)	Temperature
Moisture requirement/drought tolerance	Soil moisture availability	AET/PET (annual actual evapotranspiration/ annual potential evapotranspiration)	Temperature, precipitation, cloudiness

Source: Prentice *et al.*, 1992.

Table 3 Environmental constraints for each PFT in the BIOME model

PFT		T_{min} min	T_{min} max	GDD_0 min	GDD_5 min	T_{max} min	AET/PET min	AET/PET max
Trees	Tropical evergreen	15.5					0.80	
	Tropical raingreen	15.5					0.45	0.95
	Warm temperate evergreen	5.0					0.65	
	Temperate summergreen	−15.0	15.5		1200		0.65	
	Cool temperate conifer	−19.0	5.0		900		0.65	
	Boreal evergreen conifer	−35.0	−2.0		350		0.75	
	Boreal summergreen		5.0		350		0.65	
Non-trees	Sclerophyll/succulent	5.0					0.28	
	Warm grass/shrub					22.0	0.18	
	Cool grass/shrub				500		0.33	
	Cold grass/shrub			100			0.33	
	Hot desert shrub					22.0		
	Cold desert shrub			100

as a central feature, which is implemented in a static way, i.e., either by using a global vegetation map or by using BIOME as input. Mechanistic formulations of photosynthesis, plant and soil respiration and other processes are parameterized for each biome, and the resulting pools and fluxes of carbon are a function of both biome distribution and climate. Biogeochemical models that make use of remote sensing data are not included here, since these models are not capable of forward-looking simulations and therefore are outside the scope of biome models *per se*.

Coupled Biome Distribution/Biogeochemistry Models

Some equilibrium biome models simulate biogeochemical processes (fluxes) and pattern (vegetation type and structure) simultaneously. Usually, the determination of the vegetation types follows process-optimization rules, e.g., by maximization of NPP according to soils and climate, or by maximization of the leaf area index (LAI) to satisfy the annual moisture and carbon balances. Examples are DOLY (Woodward *et al.*, 1995) and BIOME3 (Haxeltine and Prentice, 1996). In both models, the distribution of PFT (Plant Functional Type), and hence the resulting biomes, is a function of climate and soils, but (different from BIOME) this function is contained in modules that describe both biogeochemical fluxes and resulting pool sizes quantitatively within the basic bioclimatic limits for PFT survival. Photosynthesis, respiration and water use are simulated depending on climate, as well as on atmospheric carbon dioxide concentration, using process descriptions from field and laboratory studies. This allows one to expect a greater degree of realism even for extrapolations into future conditions, as opposed to regression type approaches.

The most recent model of this class is BIOME4 (Kaplan, personal communication). BIOME4 was developed from BIOME3 with the aim of better covering the diversity of biome types by adding additional PFT and updating some process formulations and parameters. It is based on 13 PFTs, each of which has assigned bioclimatic limits that determine whether or not NPP is calculated for a given location. A coupled carbon and water flux scheme is used to determine the LAI that maximizes NPP for each PFT. The PFT with the highest NPP is chosen to represent vegetation for the biogeochemical fluxes and pools. For savanna vegetation, where the interaction between trees and grasses is particularly important, separate rules are defined to estimate the combined effect of co-existing PFTs.

Dynamic Global Vegetation Models

Interest in biome models comes to a large extent from the need to estimate likely changes in carbon stores in the terrestrial biosphere, as a consequence of atmospheric carbon dioxide increase and the associated changing climate. In periods with rapidly changing climate, the equilibrium assumption in classical biome models is invalid, since vegetation structure and carbon stores in above- and below-ground biomass often change only over decades to centuries, except for disturbance type events such as fires. To realistically simulate NBP, growth of PFTs needs to be considered as well as the major processes affecting soil carbon pools.

Dynamic global vegetation models (DGVMs) are specifically developed for the assessment of transient changes in vegetation structure as well as NBP, driven by climate change. Their development is based on the advances made in equilibrium biome models, as well as in forest succession models. DGVMs, such as HYBRID (Friend *et al.*, 1997) or

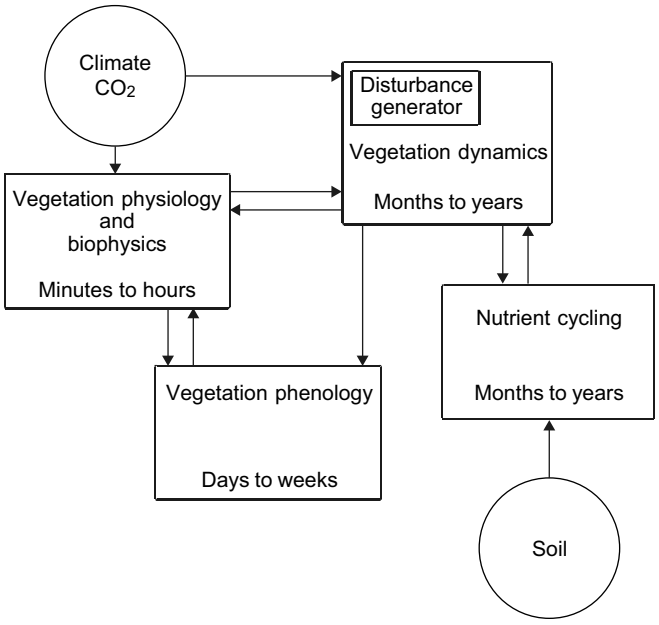

Figure 1 Basic structural elements of a DGVM and their associated time scales (Cramer *et al.*, 2001)

LPJ (Sitch, 2000) contain dynamic formulations for slow and fast processes of carbon and water fluxes (Figure 1), and they maintain the principal pools of carbon over long time scales. A more detailed description of current DGVMs, and an application are to be found in Cramer *et al.* (2001).

Ultimately, the quantitative and transient analysis of biospheric structure, as made in DGVMs, abandons the biome concept for all but the diagnostic description. All PFTs have more or less smooth responses to environmental gradients and they do not usually react abruptly, except for the case of rapidly deteriorating conditions. Most biomes have broad transition zones between each other. Environmental changes, such as those that occurred after the deglaciation of Northern Europe, usually led to smooth transitions from a biome dominated by some species into one dominated by another. It is nevertheless useful for analysis and communication, if the resulting distribution of PFTs is shown as a distinct biome map. Otherwise, the reader would have difficulty grasping the distribution of multiple plant types across the globe, using a single map.

BIOMES AS PART OF THE FULL EARTH SYSTEM

Plant types, ecosystems and biomes are not only distributed as a function of climate, they also influence atmospheric processes in a way that differs between biome types. Important characteristics for this influence are the roughness of the canopy (which influences the characteristics of the surface boundary layer), its albedo (which affects the energy balance) and its LAI (which affects carbon and water fluxes). These effects have long been known at the local scale (Köppen and Geiger, 1936), but were studied at the global scale only much later (Dickinson, 1983). Now, many model experiments have shown that large-scale changes of biome distribution, e.g., due to human land use, affect atmospheric circulation (Salati, 1986). Inevitably, these effects produce feedbacks between atmosphere and biosphere which may even lead to multiple stable states of the coupled system (Claussen, 1998).

The consequence of the notion of bi-directional feedbacks between atmosphere and biosphere (expressed as biomes) is that all assessments of future conditions of the system depend on understanding all of the major elements of the Earth System, which is currently destabilized primarily by human disruption of the carbon balance. What we need to know is whether the Earth's vegetation might amplify or dampen the impacts of this disruption. Present estimates seem to indicate that physiological processes in some major biomes (e.g., the boreal forest) lead to increased uptake and storage of carbon by ecosystems, due to the increased carbon dioxide concentration in the atmosphere (Cramer *et al.*, 2001). However, the resulting changes in temperature may well lead to increased drought and fire risk in some areas, notably the drier variants of forested biomes (White *et al.*, 2000). This would in turn influence the atmosphere due to the resulting release of carbon from dying forests and mineralized soil carbon.

We cannot presently determine the exact trajectory of these changes. But model results are sufficiently plausible to raise concern over the stability of the overall system. Some biomes, such as tropical forests, have also been identified as being crucial for a sustainable Earth from other perspectives, such as the maintenance of biodiversity.

Biome- BGC Ecosystem Model

Lars Pierce

California State University, Monterey Bay, CA, USA

As human population increases, so do the influences that we as humans have on the biosphere. Human-induced disturbances such as land use change and environmental pollution all impact the Earth system yet our understanding of how ecosystems will respond to these disturbances is limited. We rely upon both field measurements and computer

modeling to describe the response of ecosystems to global environmental changes. Computer models that describe the flow of energy and matter through ecosystems are referred to as ecosystem models. Ecosystem models allow us to explore the potential interactions between environmental disturbance and ecosystem structure and function.

Biome-BGC is an ecosystem model that was first developed in the coniferous forests of the western US, and has since been adapted to simulate the biogeochemical cycling (BGC) of most terrestrial ecosystems. Biome-BGC is designed to simulate the fluxes of carbon (C), nitrogen (N), and water through plants and soils over space and time (Running and Hunt, 1993). The model has been utilized to simulate ecosystem processes from the plot scale up to the global scale (Hunt et al.*, 1996). Biome-BGC is similar in concept and design to several other ecosystem models (VEMAP Members, 1995). In terms of complexity, these models occupy a middle ground by choosing to represent only those ecosystem processes critical for making regional-scale predictions across a range of ecosystems and climates. These models generally do not simulate processes at sub-daily resolutions, and instead operate from daily to monthly timescales. These models differ, however, in their conceptual representation of ecosystem water, carbon, and nitrogen cycling which somewhat reflects the type of ecosystem for which they were initially developed.*

MODEL STRUCTURE AND COMPUTATIONS

Biome-BGC has retained much of the same structure of its predecessor Forest-BGC (Running and Coughlan, 1988), and includes one canopy layer, one soil layer, five vegetation carbon and nitrogen pools, and two soil carbon and nitrogen pools. The model is driven by routinely available daily climate data (air temperature, solar radiation, humidity and precipitation) and the definition of several key state variables; vegetation, soil, and site conditions (Figure 1). Biome-BGC is a big-leaf model; the plant canopy is represented as a single layer whose thickness is defined by the leaf area index (LAI) of the ecosystem. Leaf-level water and carbon fluxes are scaled to the canopy according to LAI, a key variable describing ecosystem structure, which can be obtained at regional scales from satellite imagery (Pierce *et al.*, 1993).

The Biome-BGC model simulates ecosystem processes in both plants and soils across a range of timescales (Figure 1). Processes in the plant compartment occur at shorter timescales (i.e., daily), whereas processes in the soil compartment occur at longer timescales (i.e., monthly to yearly). Within the plant compartment, daily precipitation (PPT) is intercepted by the canopy. Throughfall (T_f) is routed to soil water (H_2O) storage, the capacity of which is a function of plant rooting depth and soil texture. Any water in excess of the soil water-holding

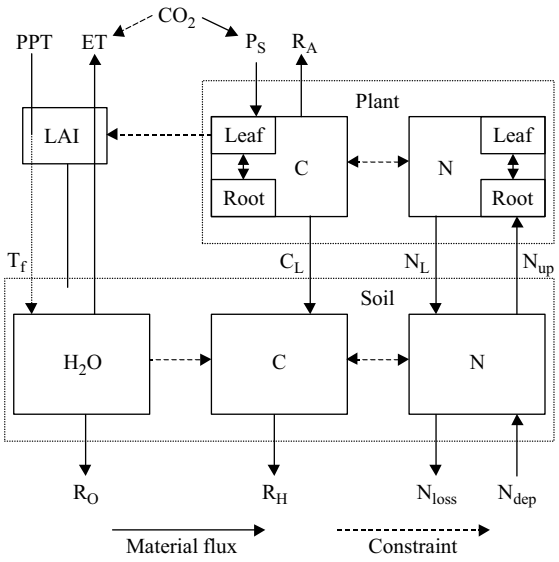

Figure 1 Schematic owchart of the BIOME-BGC Ecosystem Model. Abbreviations and coef cients are de ned in the text

capacity is assumed to leave the ecosystem as runoff (R_O). Soil moisture controls soil evaporation (E) and leaf-level transpiration (T), which are calculated using the Penman-Montieth equation. Photosynthesis (P_S) is calculated using a formulation of the Farquhar model (Hunt *et al.*, 1996). Plant maintenance respiration (R_A) is calculated as a function of biomass, tissue nitrogen concentration, and temperature. Nitrogen (N) is taken up by the plant, (N_{up}), from the soil mineral nitrogen pool at a rate proportional to root biomass, soil temperature, and soil moisture. Carbon and nitrogen are then allocated to leaf and root based upon the relative balance between photosynthesis and nitrogen uptake. Excess carbon uptake via leaves relative to nitrogen uptake via roots favors allocation of resources to acquiring more nitrogen through additional root growth. Excess nitrogen uptake relative to carbon favors allocation of resources to acquiring more carbon through additional leaf growth. Allocation to woody biomass (stem and coarse root) is a function of leaf allocation. Growth respiration is calculated as a constant proportion of allocated carbon.

Within the soil compartment, turnover of live plant carbon and nitrogen is controlled by a balance between maintenance respiration and photosynthetic carbon uptake (Mooney and Gulmon, 1982), such that allocation cannot occur until maintenance respiration requirements have first been met. If maintenance respiration requirements are not satisfied, then live tissue carbon and nitrogen must turn over from plants until plant maintenance respiration requirements are met by carbon uptake. Litterfall (C_L, N_L) is routed to the litter and soil organic pools, where carbon is released through heterotrophic

respiration (R_H) and nitrogen is mineralized into the soil mineral nitrogen pool at a rate controlled by the litter carbon–nitrogen ratio, and soil temperature and water constraints. Nitrogen inputs through atmospheric nitrogen deposition (N_{dep}) and nitrogen losses (N_{loss}) through leaching are also calculated.

Within Biome-BGC, soil moisture and photosynthesis calculations in the plant compartment control processes in the soil compartment. Temperature and water controls, as well as plant production, are calculated in the plant compartment and passed to the soil compartment where this information is used to control litter and soil turnover. Changes in decomposition and nitrogen availability calculated in the soil compartment feed back to control carbon and nitrogen uptake and water use in the plant compartment. In this way, the plant and soil compartments influence one another, and overall model behavior. One of the key feedbacks in Biome-BGC is the influence of soil decomposition processes and nitrogen availability on leaf nitrogen and photosynthesis.

ECOSYSTEM RESPONSES TO ELEVATED ATMOSPHERIC CARBON DIOXIDE

As an example of how an ecosystem model can be used to examine the response of ecosystems to disturbance, such as increases in atmospheric carbon dioxide (CO_2) concentration, we provide an example from the Jasper Ridge CO_2 Experiment (Field *et al.*, 1996). The Biome-BGC ecosystem model is used to simulate the response of a Mediterranean annual grassland community to elevated atmospheric CO_2 under three different rainfall regimes (Field *et al.*, 1997). The results of the simulations can then be compared to measured data to determine the utility of the ecosystem model in estimating the response of an ecosystem to changes in atmospheric CO_2. The grassland community was grown during the winter and spring of 1994–1995 in open-top chambers at the Jasper Ridge Biological Reserve on the Stanford University campus in central coastal California. To closely represent natural environmental conditions, each open-top chamber is exposed to ambient temperature and sunlight. Precipitation inputs to the chambers were controlled to represent dry, average, and wet years at Jasper Ridge. Natural sandstone soil profiles were reconstructed within the chambers, and the chambers were seeded to mimic the species composition and structure of the local annual grassland community. One half of the open-top chambers received ambient CO_2 (350 ppmv), while the other half of the open-top chambers received double-ambient CO_2 (700 ppmv). Total above-ground biomass was then harvested and recorded for each of the six treatments (two CO_2 treatments × three rainfall treatments) at the end of the growing season.

The Biome-BGC ecosystem model was then run to simulate total above-ground biomass for each of the six water and CO_2 treatments. Plant physiological parameters within the model were defined for a Californian annual grassland, according to Jackson *et al.* (1994), who measured a 45% reduction in leaf conductance under doubled atmospheric CO_2. Soil texture and nitrogen content were set according to Field *et al.* (1996). The daily rainfall data collected at Jasper Ridge for the 1994–1995 growing season was modified to include water manipulations representing the dry, average, and wet rainfall treatments. Each of the three water treatments was then simulated using Biome-BGC for ambient and twice-ambient atmospheric CO_2 concentrations. Total above-ground biomass harvested at the end of the growing season (Thayer and Field, unpublished data) was used for comparison to simulated total above-ground biomass production through the same date (Figure 2). Simulated biomass compared favorably with measured biomass across the wide range in rainfall and atmospheric CO_2 ($y = 1.13x - 82.27$, $r^2 = 0.95$). Within Biome-BGC, increases in atmospheric CO_2 enhance leaf-level carbon uptake and reduce stomatal conductance and leaf-level transpiration. More carbon is therefore taken up by the leaf, and less water is used, such that increased atmospheric CO_2 tends to enhance water availability in an annual grassland. Increases in productivity under elevated CO_2 can occur both because of increases in carbon uptake, as well as increases in plant water-use efficiency.

As part of the CO_2 Model-Experiment Activity for improved Links (CMEAL), we have used a suite of ecosystem models, including Biome-BGC, to examine the short- and long-term responses of ecosystems to elevated atmospheric CO_2. Simulations utilizing Biome-BGC (as well as the other ecosystem models) suggest that the response of ecosystem net primary production (NPP) to an instantaneous doubling

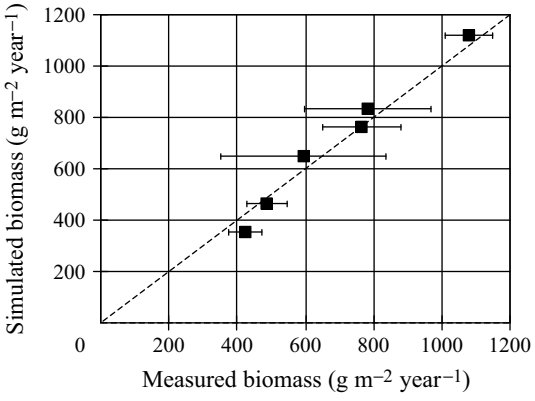

Figure 2 Measured above-ground biomass compared to the above-ground biomass simulated using BIOME-BGC for the water × CO_2 experiment in the Jasper Ridge CO_2 Experiment (Field *et al.*, 1997)

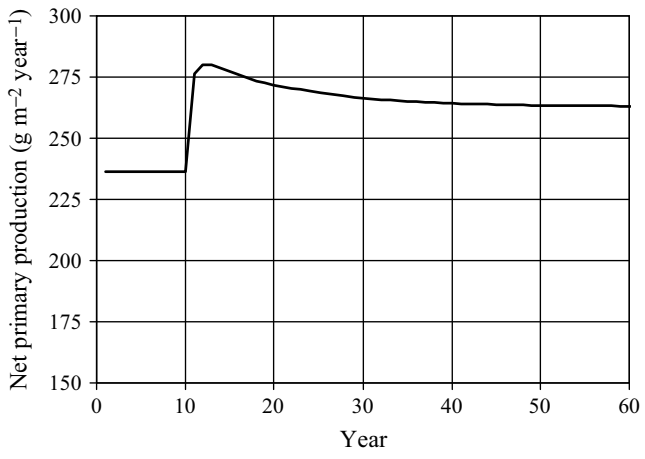

Figure 3 The response of annual NPP for the Jasper Ridge annual grassland to a step increase in atmospheric CO_2 (in year 10). Climate data for 1993 were used repetitively to drive the 60 year simulation

in atmospheric CO_2 is controlled by resource availability at a variety of timescales (Figure 3). Following a step increase in atmospheric CO_2 within the models, short-term increases in NPP (one to three years) are controlled primarily by physiological increases in carbon uptake due to increased atmospheric CO_2. At intermediate timescales (3–20 years), NPP often peaks and then declines. Intermediate timescale changes in NPP are controlled by soil nitrogen availability (plant uptake vs. decomposition) and the plasticity of plant carbon–nitrogen ratios. At longer timescales (>20 years), NPP usually reaches a new equilibrium as soil nitrogen availability comes into balance with plant demand for nitrogen. Long-term NPP responses are controlled by the net amount of nitrogen added (via atmospheric deposition) or removed (via leaching) from the ecosystem.

The CMEAL model intercomparison shows that increased ecosystem nitrogen use efficiency, either through, (a) increases in plant or soil carbon–nitrogen ratios or, (b) increased partitioning of nitrogen from soils to plants, is predicted to be an important mechanism for controlling the response of ecosystem productivity to elevated CO_2. The utility of ecosystem models is that they allow us to test a variety of hypotheses regarding the response of ecosystems to changes in the environment, as well as to extend the results of short-term experiments to the longer-term. An understanding of these interactions has helped experimentalists to identify specific, shorter-term, field measurements that can indicate the longer-term response of ecosystems to change. New measurements, in turn, help to improve the models, and it is this cyclic exchange of information between measurements and models that increases our understanding of how ecosystems respond to global environmental change.

Biosphere

The *biosphere* is the life-supporting layer surrounding the Earth's surface. This layer extends from the biologically active depths of the soil on land, and from the deep sea vents in the oceans, to a few kilometers into the atmosphere.

The biosphere constitutes the global ecosystem, including all life and the inert materials which provide the nutrition

and energy necessary to sustain life. This global ecosystem is largely powered by solar energy which drives the constant, characteristic cycling of matter that supports the self-reproduction of various large molecules and cells. Water is the key predisposing material for all life on Earth. In addition, various chemical elements (e.g., carbon, hydrogen, nitrogen, oxygen, phosphorus, and sulfur) combine into complex organic molecules during their cycles and these provide the fuel and building blocks to sustain populations of living organisms.

Human impact on the biosphere has increased enormously over the last 10 000 years. Through the development and global spread of animal husbandry and agriculture, humans now control about 40% of all solar energy captured by terrestrial organisms. In addition, the world's human population is growing at about 80 million per year and may reach 10 billion during the 21st century. In the context of simultaneous, global, economic growth, the increasing human populations threaten ever greater impacts on the biosphere in the future. Perhaps the most serious of these impacts is the release of greenhouse gases (including carbon dioxide, methane, and chlorofluorocarbons) into the atmosphere.

Biosphere Enhancement Ratio (BER)

Biosphere enhancement ratio (BER) is the biomass of a vegetative cover at a given elevated carbon dioxide (CO_2) concentration, divided by the biomass at some control (e.g., present day) level of CO_2 (g per g) (*see* **Plant Growth at Elevated CO_2**, Volume 2).

Biosphere Reserves

Jeffrey A McNeely
The World Conservation Union, Gland, Switzerland

Biosphere Reserves are areas of terrestrial and coastal/marine ecosystems, which are internationally recognized under United Nations Economic and Social Cooperation Organisation's (UNESCO's) Man and the Biosphere (MAB) Programme. They are designed to promote and demonstrate a balanced relationship between people and nature. They are nominated by national governments and remain under the sovereign jurisdiction of the states where they are located. As of 1999, 88 countries had established a total of 357 biosphere reserves. Several countries have extensive networks of Biosphere Reserves, such as the USA (29), Russia (19), Bulgaria (17), Spain (15), China (14), the UK (13), and Australia (12); but more than half of the participating countries have only one or two Biosphere Reserves. Emerging from UNESCO's MAB Programme as a concept in 1967, the first Biosphere Reserves were formally designated in 1976 (Batisse, 1997).

Biosphere Reserves must meet agreed criteria and adhere to a minimum set of management agreements before being admitted to the worldwide network. Each Biosphere Reserve is expected to perform three complementary functions.

- A biodiversity conservation function (with a focus on conserving a representative sample of major types of ecosystems).
- A development function (with a focus on humans in the biosphere, emphasizing an integrative role for local communities).
- A logistical function (combining conservation, research, education, training and monitoring).

The United Nations Environment and Social Cooperation Organisation (UNESCO) promotes Biosphere Reserves as illustrations of an open system that is able to interact with the surrounding landscapes much more extensively than can traditional protected areas with distinct boundaries. By their very nature as legally established units of land management, conventional protected areas have boundaries. Yet nature knows no boundaries, and recent advances in conservation biology are showing that most protected areas are too small to effectively conserve the large mammals or trees that they are designed to preserve. The boundary is too often also a psychological boundary, suggesting that since nature is taken care of by the protected area, people can abuse the surrounding lands, isolating the protected area as an island

of habitat which is subject to the usual increased threats that go with insularity.

Not only are the boundaries of protected areas difficult to defend even when they are well demarcated, but they also make it very difficult to adapt to change. Recent scientific conclusions about climate change make it very apparent that the distribution of biological systems are virtually certain to change as temperature, rainfall, and seasonality change in the coming years. Protected areas with hard boundaries are going to find it difficult to adapt to these changes.

The multiple-zone approach taken by Biosphere Reserves, on the other hand, is far more flexible and it should be reasonably easy to adjust the relatively soft boundaries between the core, buffer, and transition zones. Thus biosphere reserves may find it far easier to adapt to changing climatic (and other) conditions than will protected areas without buffers and with less flexible approaches to boundaries.

As designed by UNESCO, Biosphere Reserves are a special kind of conservation area with a nested set of zones having different management objectives. These include one or more core areas where human interventions are minimal, a surrounding buffer zone, and a flexible transition area, with the latter two designed to include people within the overall conservation framework.

The core area is devoted to long term protection, non-destructive research, and low-impact uses (such as education and some tourism), while resource management activities compatible with the conservation objectives are permitted in the buffer zone. In the transition zone, such management activities are promoted and developed with the active participation of local communities, management agencies, scientists, non-governmental organizations, cultural groups, economic interests and other stakeholders. Originally envisaged as a series of concentric rings, the three zones have been implemented in many different ways to respond to local needs and conditions.

The Biosphere Reserve approach has generated several variations, including *cluster reserves* (where several non-contiguous protected areas are linked in a network of collaboration on research and management, with the objective of fostering better conservation throughout the entire region). There are also transboundary protected areas (where adjoining protected areas from two or three countries are linked through various forms of cooperation on resource management, tourism, research, and public information) (Fall, 1999).

A few countries have enacted legislation specifically to establish Biosphere Reserves, but in most countries, the core areas and buffer zones typically are designated as part of other types of protected areas under national law, such as national parks. These core and buffer areas typically are public land while the transition area often is under private or communal forms of ownership.

Biosphere Reserves are designed explicitly to support social and economic development in the surrounding lands. Such benefits can include some access to wild plant resources, improved flow of water, and improved tourism. In many cases, local communities are also enabled to participate in decision making about the Biosphere Reserve. However, many of these benefits take time to develop, and Biosphere Reserves are perhaps best seen as the beginning of a socio-economic experiment that is designed to build trust and commitment between conservation managers and local human populations. While biodiversity conservation is a central feature of Biosphere Reserves, conservation is not necessarily a function of all Biosphere Reserve zones; conservation may be absent as an objective within the transition zone where the emphasis may be on the sustainable use of biological resources.

In 1983, the first International Biosphere Reserve Congress was held in Minsk (Bylorus, but then in the Soviet Union), which gave rise to an action plan for Biosphere Reserves that laid out a framework for action under a series of objectives. The action plan provided fairly broad guidance rather than detailed advice. A second International Biosphere Reserves Congress was held in Seville, Spain, in 1995. This event resulted in the Seville Strategy for Biosphere Reserves, and a Statutory Framework of the World Network of Biosphere Reserves (UNESCO, 1996). The statutory framework was formulated with the objectives of enhancing the effectiveness of individual Biosphere Reserves and strengthening common understanding, communication and cooperation at regional and international levels. It sets out clear criteria for qualifying as a Biosphere Reserve as well as a procedure for designating these areas by the International Coordinating Council of UNESCO's MAB Programme.

The statutory framework states that in order to qualify for designation as a Biosphere Reserve, an area should:

1. encompass a mosaic of ecological systems representative of major biogeographic regions, including a gradation of human interventions;
2. be of significance for biological diversity conservation;
3. provide an opportunity to explore and demonstrate approaches to sustainable development on a regional scale;
4. have an appropriate size to serve the three functions of Biosphere Reserves through appropriate zonation that includes a core area, a buffer zone, and an outer transition area.

In addition, organizational arrangements should be provided for participation of a suitable range of groups interested in the design and carrying out of the Biosphere Reserve, including public authorities, local communities, and private interests. In managing the Biosphere Reserve, provisions should be made for managing human use in the buffer zone; a management policy or plan for the area as a

Biosphere Reserve; a designated authority or mechanism to implement the management plan for the site; and programs for research, monitoring, education and training.

The statutory framework also called for the status of each Biosphere Reserve to be reviewed every 10 years, to ensure that it still meets the criteria for participating in this international program.

UNESCO expects Biosphere Reserves in the 21st century to be living examples of sustainable development, incorporating care of the environment and greater social equity, including respect for rural communities and their accumulated wisdom. They remain based on solid science, with research guiding management and feedback from monitoring systems helping to ensure that Biosphere Reserves are able to adapt to changing conditions. Ideally, Biosphere Reserves should be a means for the people who live and work within and around them to live in a balanced relationship with the natural world, while also contributing to the needs of society as a whole by demonstrating the way to a more sustainable future.

Boreal Ecosystem-Atmosphere Study (BOREAS)

Ray Desjardins

Agriculture and Agri-Food Canada, Ottawa, Canada

BOREAS was a joint international experiment which took place from 1994 to 1996. It was undertaken to clarify the potential impact of the boreal forest on the concentration of greenhouse gases in the atmosphere and to determine how this ecosystem would respond to climate change. This study, which was carried out in Northern Canada, covered an area 1000 × 1000 km. It involved 75 scientific teams from university, government and industry. They quantified the fluxes of sensible and latent heat as well as carbon dioxide, methane and other important trace gases over a wide range of scales with the best technology available. The results are now published in scientific journals and most of the data collected are available on CD. More details on BOREAS are also available on the internet.

The boreal forest, which is located north of 48 °latitude, occupies 21% of the world's forested land surface. It contains about one-sixth of the carbon in the terrestrial biosphere. It has the potential to be an important sink for the carbon dioxide (CO_2) produced from the use of fossil fuel. One of the predictions of the new dynamic global vegetation models is that by 2100, boreal forests will occupy a substantial portion of the land that is now covered by tundra vegetation (Melillo, 1999). This northward extension of boreal forest is expected to cause an additional warming of approximately 4 °C in spring and about 1 °C in the other seasons (Foley *et al.*, 1994). Understanding the potential impacts of climate change for natural ecosystems is essential if we are going to manage our environment to minimize the negative consequences of climate change and maximize the opportunities that it may offer (Melillo, 1999). BOREAS was undertaken to clarify the role of this ecosystem with respect to global environmental changes (Sellers *et al.*, 1997). BOREAS was a joint international experiment, sponsored primarily by groups from the United States and Canada with the involvement of scientists from Britain, France, Japan and Russia. The region selected for BOREAS covered an area of 1000 × 1000 km in Manitoba and Saskatchewan Canada, and fieldwork took place between the years 1994 and 1996. The project involved 75 science teams from universities, governments, and industry. These teams were grouped into six disciplines: airborne flux and meteorology, tower flux, terrestrial ecology, hydrology, trace gas biogeochemistry, and remote sensing science.

To study differences in temperature and moisture, two areas, located 500 km apart, were selected within the BOREAS study region, each measuring approximately 50 × 50 km. The northern study area (NSA) was located near Thompson, Manitoba, and the southern study area (SSA) was located near Prince Albert, Saskatchewan. Flux towers were used for stand-scale measurements within each study area (five in the NSA, and six in the SSA). The tower flux data, which rely on the eddy covariance technique, provided a complete picture of the fluxes of water vapor, heat, CO_2 over days, seasons and even longer, for some of

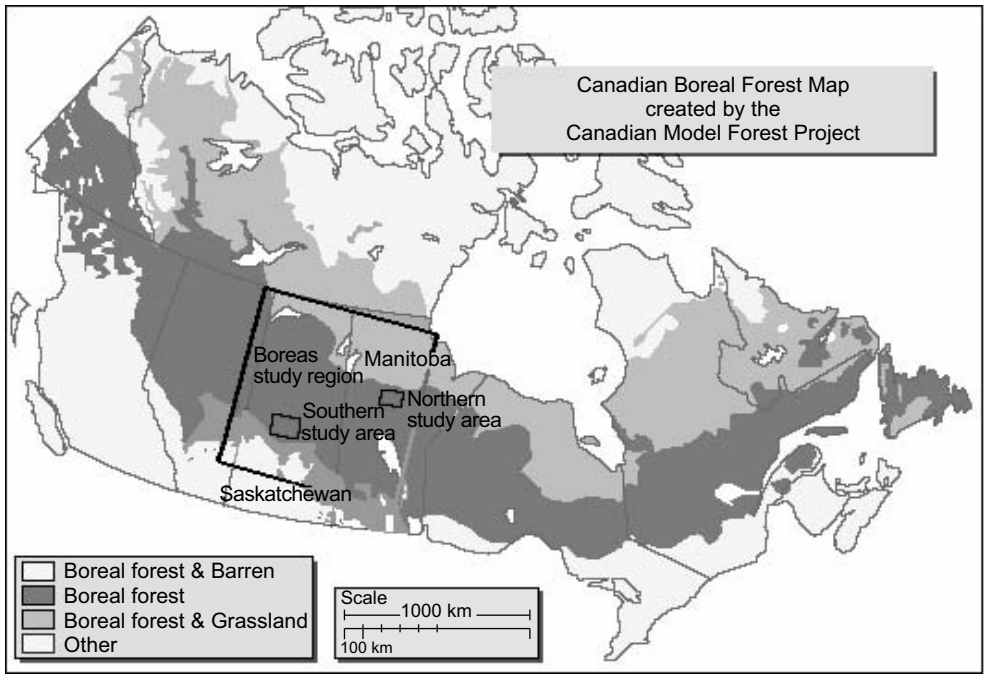

Figure 1 Map showing the BOREAS study region as well as the southern and northern study areas

the major species (Black *et al.*, 1996). Aircraft data were used to supplement and expand the data collected from the tower-based systems (Desjardins *et al.*, 1997). Transects and grid patterns were flown over both study areas (Figure 1). Satellite observations of reflected and emitted radiation were used to expand the sampling area to the entire BOREAS study region. These measurements were collected in conjunction with various ecological, meteorological and soil variables. These data are now being used to improve and validate models for obtaining regional flux estimates (Frolking, 1997).

BOREAS revealed several important features about the relationship between the boreal forest and the atmosphere. Firstly, it was not possible to measure the CO_2 flux over the entire boreal forest accurately enough to determine whether or not the boreal forest is the missing carbon sink in the global carbon cycle (Sellers *et al.*, 1997). Secondly, the atmosphere above the boreal forest is similar to that above a desert; it contains a deep planetary boundary layer and very dry air. Only small amounts of water enter the atmosphere from the boreal forest due to the low evapotranspiration rates of boreal conifers, and the presence of cold, large lakes that act as heat sinks rather than water evaporators (Sellers *et al.*, 1997). Thirdly, results from BOREAS are providing basic information to improve weather forecasts. For example, by providing a more realistic estimate of the albedo, in the presence of snow, BOREAS data allowed the European Center for Medium Range Forecasts to correct a bias in their surface temperature forecast over the boreal forest by up to 10 °C (Viterbo and Betts, 1999).

More details on these results can be found in the special issue of the *Journal of Geophysical Research*, Vol. 102, December 1997. Further information on BOREAS can be found on the Internet at http://boreas.gsfc.nasa.gov/BOREAS/BOREAS_home.html.

Boreal Forest

E H (Ted) Hogg
Canadian Forest Service, Edmonton, Alberta, Canada

The boreal forest, or taiga, is one of the world's most extensive ecosystems, occupying vast areas of the northern landscape in North America and Eurasia. Natural disturbances such as fire and insect outbreaks, in combination with variation in climate, topography and soils, have led to a diverse patchwork of forest types, often interspersed with numerous lakes and wetlands.

Winter snow cover typically lasts for six months or more, and average year round temperatures are near or below freezing, resulting in widespread permafrost in the coldest portions of the boreal forest.

Although the boreal forest has been inhabited by indigenous peoples for thousands of years, the impact of human activity on the landscape has been minimal until relatively recently. Major human-induced changes began with intensive agricultural land use along the southern edge of the boreal forest, and then expanded into more remote areas with resource development for forestry, oil and gas, mining, and hydroelectric power during the latter half of the 20th century.

The influence of industrial activity has been significant in some areas, but global climate change could lead to more dramatic future changes in the boreal forest, where the climate has already been warming at a much faster rate than in most other parts of the world. Some of the changes noted to date include extensive thawing of permafrost and an increase in forest fire during the 1980s and 1990s, when temperatures were warmer than those recorded in any previous decades.

These changes are expected to accelerate during the 21st century, as levels of carbon dioxide (CO_2) in the atmosphere continue to rise. In certain areas of the boreal forest, where moisture and soil nutrients are in abundant supply, tree growth might increase in response to longer growing seasons and the effects of higher CO_2 levels. However, if the warming leads to drier climatic conditions, the combined effects of drought, fire and insect outbreaks could lead to losses of forest cover, especially in the southern boreal forest.

The results of large international experiments and computer modeling have begun to demonstrate the importance of the boreal forest to global cycles of carbon, water and energy. It has been shown, for example, that carbon uptake by the boreal forest caused a significant slowing of the rate of increase in atmospheric CO_2 levels over the past century, thus indirectly acting to slow the rate of global warming. However, scientists are divided as to whether northern forests will continue in this role as the climate warms: there are already indications that large areas of boreal forest have become sources of CO_2 release to the atmosphere, largely because of recent increases in fire and other disturbances. (See also ***Boreal Forest Carbon Flux and it's Role in the Implementation of the Kyoto Protocol Under a Warming Climate***, *Volume 4.)*

The boreal forest occupies a total area of about 12 million km^2, or about 8% of the earth's land surface. Its distribution extends around the North Pole, across 20 time zones and a distance of more than 15 000 km. Viewed from space, the overall shape of the boreal forest resembles a somewhat jagged doughnut, broken into two pieces. The largest piece is dominated by the boreal forests of Russia, including Siberia, as well as Finland, northern Sweden and Norway. The second piece includes the boreal forests of Canada and Alaska, and also takes in the northern part of Minnesota in the continental US (Figure 1).

The immense size of the boreal forest is partly an accident of geography. The zone of latitudes between 50–70 °North, where the boreal forest is located, has more than twice its share of land when compared to the earth as a whole. In contrast, the latitudinal zone between 50–70 °South is almost exclusively dominated by ocean, so that nearly all of the world's cold-climate forests are located in the northern hemisphere.

The name *boreal forest* comes from Boreas, the ancient Greek personification of the north wind. The Russian word taiga is sometimes also used as a synonym for boreal forest, but more commonly, *taiga* refers specifically to the more northerly portions of the boreal forest that are dominated by slow-growing, coniferous trees. The boreal forest is bounded to the north by subarctic woodlands and arctic tundra, and to the south by temperate forests and grasslands.

More than anywhere else in the world, the boreal forest is a land of extreme seasonal changes. Summers are short, but in combination with the long days, warmth and moisture are sufficient to allow tree growth. Winters are long and cold, with snow on the ground for four to eight months each year, and at the latitudes north of the Arctic Circle, include a mid-winter period of continuous night. A comparison of the climates of three representative locations in the boreal forest shows that Siberia has, by far, the coldest winters – the

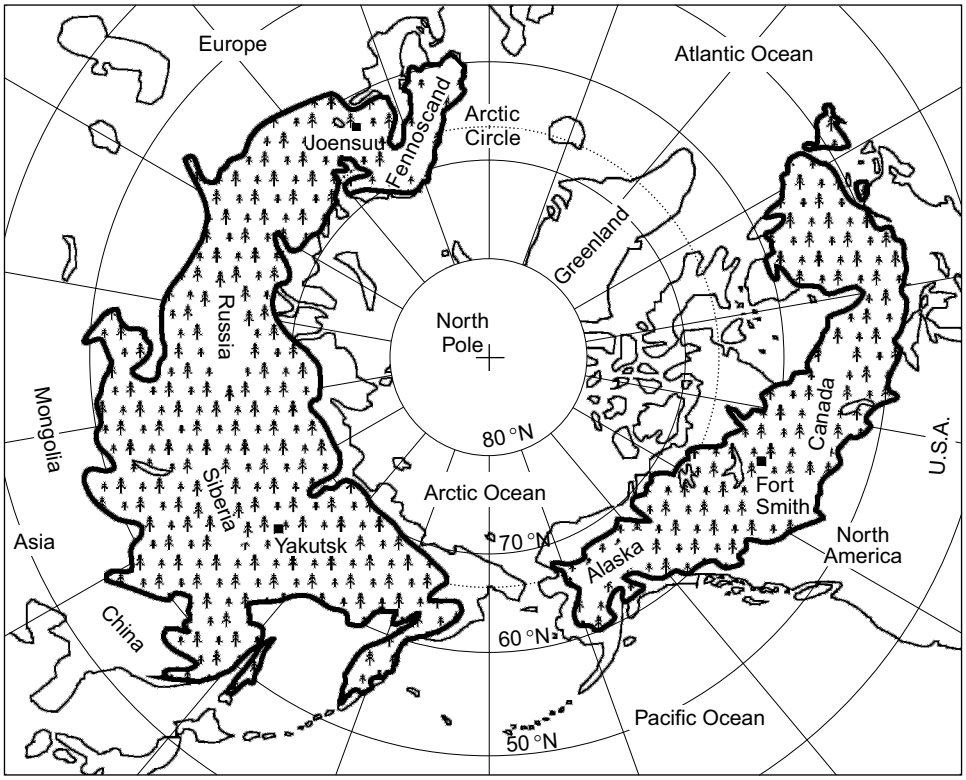

Figure 1 Global distribution of the boreal forest

average temperature in January at Yakutsk is −43 °C, and the lowest recorded temperature in the Siberian boreal forest (−68 °C) is colder than that recorded anywhere else in the world except Antarctica. Winters in the North American boreal forest are generally milder than in eastern Siberia; the average January temperature at Fort Smith, Canada (−25 °C) is typical across much of the region. Northern Europe is balmy in comparison, with an average January temperature of −12 °C at Joensuu, Finland (Figure 2).

Throughout the boreal forest, average annual temperatures range from about +3 °C to −10 °C. Deep layers of soil situated beneath insulating surface layers of moss and lichens are very slow in responding to summer warmth. Thus, they remain permanently frozen in areas where the year-round average temperature is less than 1–2 degrees below freezing. The continuously frozen moisture in the soil is referred to as *permafrost*, while the depth of soil near the surface that thaws each summer is called the *active layer*, where the roots of trees and other plants can obtain liquid moisture and nutrients. Moving north from the southern edge of the boreal forest, permafrost becomes increasingly common – first as isolated patches, but eventually forming a nearly continuous frozen layer of soil in the coldest regions of boreal forest (*see also* **Permafrost**, Volume 1).

Permafrost has profound effects on northern landscapes, as well as posing a major engineering challenge for construction and development. Houses in the most northerly areas of boreal forest are often perched above the ground on poles to prevent their heat from melting the underlying layers of permafrost that support them. In natural ecosystems, the presence of permafrost normally inhibits tree growth, because roots cannot penetrate very far into the soil for water and nutrients. On flat, waterlogged landscapes, however, trees are restricted to growing on patches of ground that are slightly elevated and supported above the water by the underlying permafrost. In these situations, thawing of permafrost can result in a drunken forest – where trees start leaning and eventually fall over into pools formed as the melting mixture of ice and soil collapses.

The boreal forest is dominated by evergreen coniferous trees, primarily spruce, pine and fir. However, deciduous forests of aspen or birch predominate over large areas of the southern boreal forest, both in North America and Eurasia. Another notable exception is in the extreme environment of northeastern Siberia, where the forests consist almost exclusively of larch. Larch is a cone bearing, needle-leaved tree like spruce and pine, but its needles fall off each autumn. Despite the immense area of the boreal forest, there are only 14 boreal tree species in Eurasia and a similar number in North America – none of these trees occurs naturally on both continents. Most regions within the boreal forest have only a few tree species.

Due to the low diversity of trees in the boreal forest, insect and disease outbreaks can produce dramatic changes

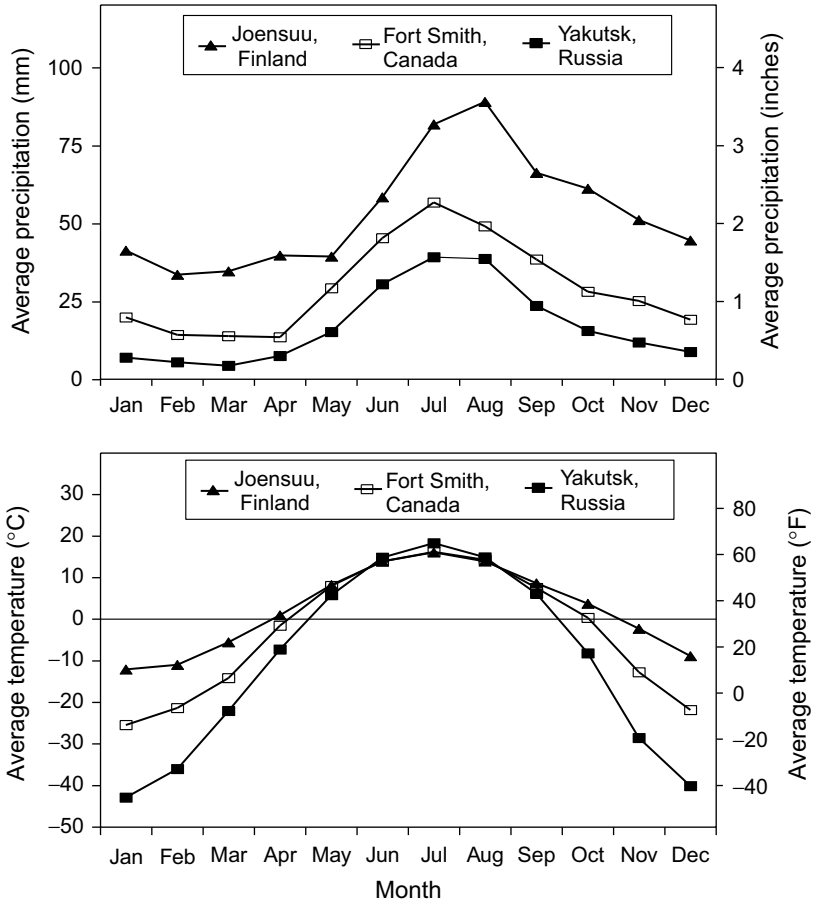

Figure 2 Average monthly climate for three representative climate stations in the boreal forest

on the landscape – even if only a single tree species is affected. In western Canada, for example, periodic population explosions of forest tent caterpillars feed voraciously on the leaves of aspen-dominated forests across areas as large as several million hectares, although the trees usually recover after the outbreak collapses. Coniferous evergreens, on the other hand, are often killed during major insect outbreaks. Examples include the spruce budworm in eastern and central Canada, spruce bark beetle in Alaska, and silkworms in Siberia; each of these insects has caused widespread death of trees over vast areas.

Fire is also an integral part of the boreal forest ecosystem. In remote areas, most forest fires are ignited by lightning and spread rapidly during periods of drought – not uncommonly, a single fire burns more than 100 000 hectares. In the Canadian boreal forest, there are an average of nearly 10 000 fires each year, burning a total of between one and eight million hectares annually. Over the centuries, fire has left its legacy on the boreal landscape in the form of a rich mosaic of boreal forest communities of different ages – mainly determined by the time that has elapsed since the last fire. Even with the recent expansion of the forest industry, fire continues to burn a much larger proportion of the Canadian boreal forest than that harvested by humans.

Another distinctive feature of the boreal forest is the abundance of peatlands, including bogs and fens, where peat has accumulated over thousands of years in waterlogged areas. Peat is formed by the deposition of moss and other carbon-rich plant material below the water table, where the low oxygen levels and cold temperatures greatly reduce their subsequent decay. Peatlands may be either treeless or support a stunted growth of spruce, pine or larch. Altogether, they occupy about 20% of the area of the boreal forest and are estimated to contain 450 billion tons of carbon. This represents about one-fifth of the total carbon stored in the world's vegetation and soils, and is nearly twice as much carbon as the total amount released to the atmosphere by human fossil fuel use since the industrial revolution.

Until recently, most of the boreal forest was a pristine, natural ecosystem that was sparsely populated by indigenous people who lived off the land. Although large areas remain as remote wilderness, significant changes in the landscape have occurred in response to human industrial activity. These include, for example, large reservoirs

created for hydroelectric power, roads, pipelines, and seismic lines that were cut through the forest for oil and gas exploration. Emissions of heavy metals and other pollutants from smelters have led to localized devastation of boreal forest, especially in Russia.

Acid rain, as well as acidic snowfall, dry particles, and deposition of gases occur even in remote areas, as pollutants such as sulfur dioxide and nitrous oxides can be carried long distances by the wind. Acid rain can have major impacts; for example, it has been implicated in the disappearance of peat-forming mosses in some parts of Europe. Paradoxically, however, acid rain may also act as a nitrogen fertilizer that can stimulate forest growth in areas where soil nitrogen concentrations are naturally low. The impacts are greatest on the Precambrian shield, where the soils are naturally acidic.

Global climate change could become the greatest single environmental threat to the boreal forest during the 21st century. Computer models of the earth's climate system indicate that a future doubling of CO_2 in the atmosphere over the next 100 years could lead to an average global warming in the range of 1.5–5 °C. However, the rate of warming is expected to be much greater, 3–8 °C, in the northern continental areas that include much of the world's boreal forest.

Although many uncertainties in these predictions remain, the climate record shows that large areas of the boreal forest have already experienced a warming of about 1.5 °C over the past century. Most of this temperature increase has been attributed to human activities, especially the global emissions of CO_2 from burning fossil fuels – coal, oil and natural gas. The warming has already caused the thawing of permafrost over extensive areas in the boreal forest; it is especially evident along the valleys of northern rivers, where the frozen slopes are transformed into mud, producing massive landslides.

Since the 1970s, the average area burned by forest fires has doubled, when compared to the previous 50 years, despite improvements in technology for fire detection and suppression. Because of the vast size of the boreal forest, natural forces – especially lightning and hot, dry weather – tend to dictate the number and size of the largest fires. The effectiveness of human efforts to stop fire in the boreal forest will continue to be limited, except in small, intensively managed areas. Therefore, it is likely that fire will continue to increase under the warmer and drier climate that has been predicted for many areas of the boreal forest.

Because the climate of the boreal forest is characteristically cold, it might be expected that warming would be beneficial to the growth of trees and other vegetation in the boreal forest. Global warming would lead to a lengthening of the summer growing season as well as warmer soils, where more nutrients are made available by the increased rate of soil decomposition. These positive effects on tree growth are likely to be greatest in the coldest parts of the boreal forest. Warming could also trigger the gradual colonization of the arctic tundra by boreal tree species; there is some evidence that this is already occurring in some areas. Another potential benefit of global change for the growth of trees and other vegetation includes the fertilizing effect of increasing CO_2 levels on photosynthesis – the process by which plants capture the sun's energy to produce the sugars needed for growth. There is considerable controversy, however, as to whether these benefits will be significant, especially in forested areas where growth is currently limited by moisture and nutrients.

From a human perspective, future changes in the southernmost regions in the boreal forest can be expected to have an especially major impact. These regions are most heavily utilized by people, for a wide range of forest-based activities, including forestry and recreation. Based on most model predictions, future changes in the southern boreal forest can be expected to differ dramatically from one region to another.

The boreal forest in eastern North America and Europe is climatically moist, and is bounded to the south by another forest type – the temperate forest. These forests are usually dominated by a high diversity of deciduous hardwoods, especially in North America where they consist of more than 50 tree species. It is thought that many of these hardwood trees are absent from the boreal forest because they are not adapted to survive temperatures lower than about −40 °C. Therefore, many of these species might be capable of colonizing the southern boreal forest as the winters become milder. The result could be a curious mixture of temperate and boreal organisms with some unexpected consequences for ecosystem functioning, although growth and diversity of trees might be expected to increase.

In western Canada and Siberia, the situation is very different. The climate is drier, so that the boreal forest is bounded to the south by grasslands: the Great Plains of North America and the steppes of central Asia. The forest–grassland boundary marks a dramatic change in both the appearance and ecosystem functioning of the landscape. This change is linked, both directly and indirectly, to moisture. In the boreal forest, the amount of rain and melting snow is usually more than enough to recharge the soil with moisture. The excess water drains off the land as runoff that maintains streams and rivers, thus ensuring that water levels in the numerous lakes remain relatively constant from year to year. The moist climate also allows the formation of peatlands, including bogs and fens. Peatlands depend on a constant water level in the soil close to the surface to maintain the oxygen-free conditions that severely retard the breakdown of organic matter. In the grasslands, virtually all aspects of the ecosystem are changed because of the dry climate. There is little surplus moisture, so that

there are very few streams, while lakes are often saline and intermittent – they dry up completely during periods of drought. Peatlands are generally absent. If wetlands are present, they are usually marshes, where little organic matter accumulates because it is repeatedly exposed to oxygen as water levels drop. Coniferous trees are also absent, probably because the establishment of seedlings requires a sustained period when soils are moist – a rare occurrence in the arid grasslands. In western Canada, stunted patches of aspen occur in the heavily cultivated, northern part of the prairies in a vegetation zone called the aspen parkland. They persist in this dry climate because they have the ability to sprout from their roots after drought or grass fires kill the aboveground stems.

If the future climate in boreal regions becomes drier, as predicted by some of the models, the impacts could be severe. For example, drought, in combination with outbreaks of insects or fungal pathogens, could lead to large-scale forest dieback. Forest cover might eventually be eliminated from some areas, as drought not only leads to more fire, but also prevents conifers from regenerating. Adopting innovative management practices could reduce adverse effects on forestry, but it could become increasingly difficult to maintain healthy forests in a natural state within parks and other protected areas.

We are now learning that changes in the earth's ecosystems can have a major effect on the amount of CO_2 in the atmosphere. Only about half of the extra CO_2 released by fossil fuel burning and land use changes can be accounted for by the observed rate of increase in atmospheric CO_2 concentration. This means that over the past century, the earth's oceans and vegetation must have been absorbing CO_2 at a faster than normal rate. Other studies point to northern forests as being important in slowing the rate of CO_2 increase. Potentially, this could be explained by increases in growth rates of these forests, but it is difficult to demonstrate that this has occurred. Another explanation that has emerged from Canadian research is that during the period between 1920 and 1970, the boreal forest experienced relatively little disturbance by fire and insects, which caused an increase in carbon storage in the trees and soil. The research indicates, however, that because of recent increases in disturbance, mainly fire and insects, the Canadian boreal forest may have already become an overall source of CO_2 to the atmosphere. Furthermore, there is concern that under a warmer and drier future climate, lowered water tables in peatlands could lead to much greater releases of CO_2: the peat would decompose more quickly, and the risk of deep-burning peat fires could increase dramatically.

The results of large international field experiments, together with computer simulation models, are beginning to show that the boreal forest has other, more direct effects on the earth's atmosphere and climate patterns. In one of these experiments, the boreal ecosystem–atmosphere study (BOREAS) (*see* **Boreal Ecosystem–Atmosphere Study (BOREAS)**, Volume 2), instruments mounted on towers (Figure 3), aircraft and satellites were used to measure the exchange of CO_2, water vapor and energy between the forest and the atmosphere. The information gained from this study provided insights into the ways that the boreal forest may be influencing its own climate. For example, measurements showed that spruce and pine forests produce a dark landscape that absorbs most of the incoming energy from the sun, even when snow is on the ground. The solar energy absorbed by the trees heats the air, which results in a climate that is warmer than it would be without the trees, because open landscapes reflect more of the sunlight back into space, especially when snow is on the ground.

The boreal forest also plays a role in returning moisture to the atmosphere, mainly through the process of water uptake

Figure 3 Tower in a black spruce (*Picea mariana*) stand in western Canada, used to measure the exchange of carbon dioxide, water vapor and energy between the boreal forest and the atmosphere

by roots and its release as water vapor from the leaves (transpiration). Such recycling of moisture could be important in stimulating summer rainfall across the boreal forest, most of which occupies continental areas where mountain ranges block the supply of moisture from the oceans. Even the type of forest could have a significant influence on regional weather and climate patterns: measurements from BOREAS showed that when green leaves are present, the release of water vapor from aspen forests is nearly twice as great as from nutrient-poor coniferous forests.

Ecologists and meteorologists alike have begun to recognize that the interaction between vegetation and climate is a two-way street: Not only does climate change affect vegetation, but large-scale changes in vegetation can also cause significant feedbacks on regional climate. Thus, the ability to forecast future global climate change and its impacts could ultimately depend on the depth of our understanding of these feedbacks, especially over large continental areas such as the boreal forest.

Buffering Capacity

Buffers are mechanisms in natural systems that serve to maintain stability (or resistance) against external physical or chemical stresses that would otherwise cause damage or malfunction. There are many buffering mechanisms in the environment. From a chemical viewpoint, one of the most important is the inherent capacity in soils to stabilize the pH of water filtering through it, thus protecting terrestrial and aquatic flora and fauna from large fluctuations in acidity.

Soils containing aluminosilicate clays play a vital role in neutralizing acidic inputs, particularly in areas subjected to high levels of acid rain. Clay soil particles contain negative charges on their surfaces to which base cations are electrostatically attracted. There are four common environmental base cations: sodium (Na^+), potassium (K^+), magnesium (Mg^{2+}), and calcium (Ca^{2+}). The neutralization reaction involves an exchange on the clay surface of a base cation by hydrogen ion (H^+):

$$\text{clay}\}\text{-}Na^+ + H^+(\text{soil solution}) \longrightarrow \text{clay}\}\text{-}H^+ + Na^+(\text{soil solution})$$

Thus, H^+ is removed from the soil solution and replaced by Na^+. Plants that take up soil water, and lakes receiving

drainage from the soils, are spared from acidification. The total H^+ that can be neutralized by a clay soil depends upon the density of negative charges on the clay surface and the availability of base cations. Together they define the soil's buffering capacity, which can be expressed in units of $kg\,H^+\,ha^{-1}$.

At the peak intensity of acid rain in Central Europe in 1980, deposition of H^+ on forest soils averaged about $3\,kg\,ha^{-1}\,year^{-1}$. The soils receiving this input had a buffering capacity of around $100\,kg\,H^+\,ha^{-1}$. If the acid rain had persisted at the 1980 levels in the succeeding decades, the soil's buffering capacity would have been exhausted in about 33 years.

When buffering in a clay soil is depleted, the pH of the soil solution rapidly descends below $pH = 4.2$. At the lower pH, aluminum, a highly toxic metal, is mobilized via dissolution in the soil solution. Aluminum mobilization in areas strongly affected by acid rain has been implicated in forest dieback and fish extinctions in lakes receiving the aluminum-contaminated waters. Thus, maintaining the buffering capacity in soils should be a high priority in environmental management of soils. This is an example of a chemical time bomb (*see* **Contaminated Lands and Sediments: Chemical Time Bombs?**, Volume 3).

C_3 and C_4 Photosynthesis

James R Ehleringer and Thure E Cerling
University of Utah, Salt Lake City, UT, USA

Atmospheric carbon dioxide is reduced to organic forms through photosynthesis. Among terrestrial and aquatic autotrophs, there are three photosynthetic pathways. Here we discuss the ecological and evolutionary aspects of C_3 and C_4 photosynthesis, the two most widely distributed pathways.

Three photosynthetic pathways exist among terrestrial plants: C_3, C_4, and *crassulacean acid metabolism* (CAM) photosynthesis. C_3 photosynthesis is the ancestral pathway for carbon fixation and occurs in all taxonomic plant groups. The term C_3 photosynthesis is based on the observation that the first product of photosynthesis is a 3-carbon molecule. In C_4 photosynthesis, the initial photosynthetic product is a 4-carbon molecule. C_4 photosynthesis occurs in the more advanced plant taxa and is especially common among monocots, such as grasses and sedges, but not very common among dicots (most trees and shrubs). CAM photosynthesis, in honor of the plant family in which this pathway was first documented, occurs in many epiphytes and succulents from very arid regions. However, CAM photosynthesis is sufficiently limited in distribution that CAM plants are not an appreciable component of the global carbon cycle. This section focuses on the factors influencing the dynamics of C_3 and C_4 dominated ecosystems.

C_3 and C_4 photosynthesis are relevant to global change studies. These two photosynthetic pathways respond quite differently to changes in atmospheric carbon dioxide (CO_2) concentration and to changes in temperature. From a global change perspective, the kind of photosynthetic pathway present influences the magnitude of carbon fixation by the ecosystem, the quality of the plant food resource available to animals, and the isotopic composition of CO_2 released to the atmosphere.

C_3 photosynthesis is a multi-step process in which the carbon from CO_2 is fixed into stable organic products; it occurs in virtually all leaf mesophyll cells (Figure 1). In the first step, ribulose bisphosphate (RuBP) carboxylase-oxygenase (Rubisco) combines RuBP (a 5C molecule) with CO_2 to form two molecules of phosphoglycerate (3C molecule). However, Rubisco is an enzyme capable of catalyzing two distinct reactions: one leading to the formation of two molecules of phosphoglycerate when CO_2 is the substrate and the other resulting in one molecule each of phosphoglycerate and phosphoglycolate (2C molecule) when oxygen (O_2) is the substrate. The latter oxygenase reaction results in less net carbon fixation and eventually leads to the production of CO_2 in a process known as *photorespiration*.

The proportion of the time that Rubisco catalyzes CO_2 versus O_2 is dependent on the $[CO_2]/[O_2]$ ratio; the reaction is also temperature dependent, with oxygenase activity increasing with temperature. This dependence of Rubisco on the $[CO_2]/[O_2]$ ratio establishes a firm link between current atmospheric conditions and photosynthetic activity. As a consequence of Rubisco sensitivity to O_2, the efficiency of the C_3 pathway decreases as atmospheric CO_2 decreases.

C_4 photosynthesis represents a biochemical and morphological modification of C_3 photosynthesis to reduce Rubisco oxygenase activity and thereby increase photosynthetic rate in low CO_2 environments such as we have today (Figure 3). In C_4 plants, the C_3 cycle of the photosynthetic pathway is restricted to interior cells within the leaf (usually the bundle sheath cells). Surrounding the bundle sheath cells are mesophyll cells in which a much more active enzyme, phosphoenolpyruvate (PEP) carboxylase, fixes CO_2 (but as HCO_3) into oxaloacetate, a C_4 acid. The C_4 acid diffuses to the bundle sheath cell, where it is decarboxylated and refixed in the normal C_3 pathway. As a result of the higher activity of PEP carboxylase, CO_2 is effectively concentrated in the regions where Rubisco is located and this results in a high CO_2/O_2 ratio and limited photorespiratory activity. The additional cost of C_4 photosynthesis is the adenosine triphosphate (ATP) requirement associated with the regeneration of PEP from pyruvate.

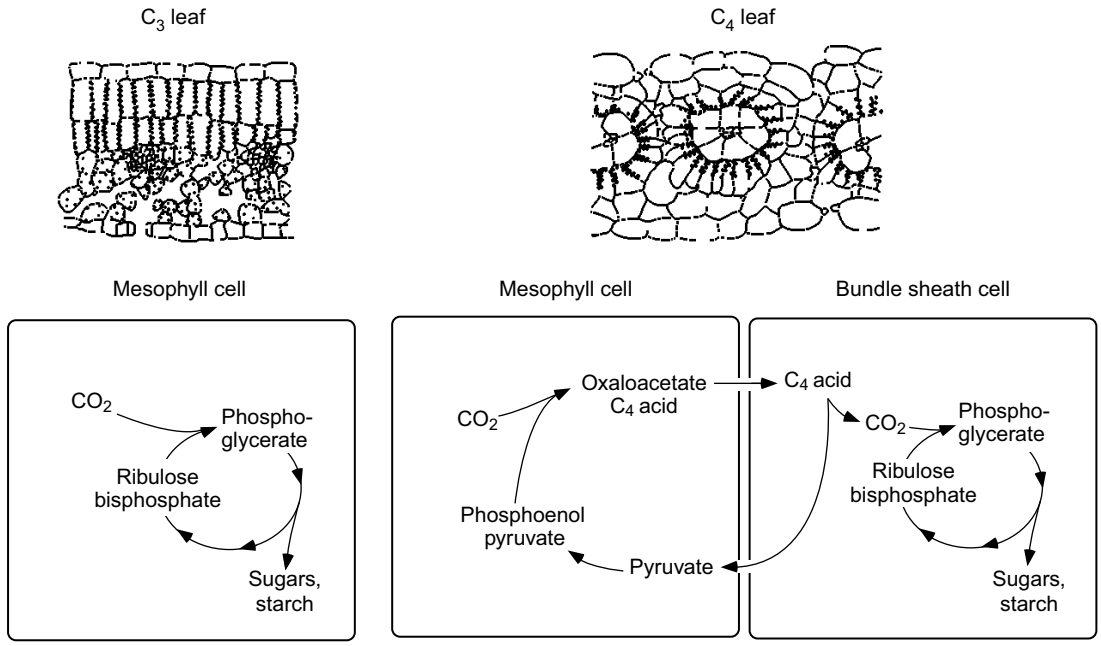

Figure 1 Leaf anatomy and basic photosynthetic biochemistry of C_3 and C_4 photosynthesis

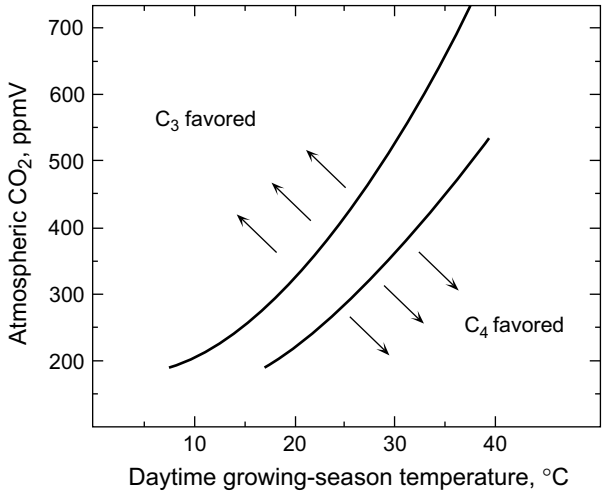

Figure 2 Modeled crossover temperatures of the photosynthetic light-use ef ciency (quantum yield) for C_3 and C_4 plants as a function of atmospheric CO_2 concentrations. The crossover-temperature is de ned as the temperature (for a particular atmospheric CO_2 concentration, in parts per million by volume, ppmV) at which the photosynthetic light-use ef ciencies are equivalent for both the C_3 and the C_4 plant. (Figure is modi ed from Ehleringer *et al.*, 1997)

C_4 photosynthesis is advantageous under low atmospheric CO_2 and/or high temperatures. The advantages of C_4 photosynthesis occur in lower CO_2 environments and/or high temperature environments, where photorespiration rates are relatively high in C_3 plants. Under these conditions, the efficiency of C_4 photosynthesis is greater than that of C_3 photosynthesis. However, under elevated CO_2 environments or at cool temperatures, the efficiency of photosynthesis is greater in C_3 photosynthesis because photorespiration is reduced and the additional ATP cost of C_4 photosynthesis makes it less efficient. We present these trade-offs graphically in Figure 2. From these light-use efficiency model predictions, it is clear that C_4 plants are not expected in environments where atmospheric CO_2 is greater than ≈600 parts per million (ppm). As atmospheric CO_2 decreases, C_4 plants should become most common first in the warmest environments, than in progressively cooler environments as CO_2 levels then continue to decrease.

The recent history of Earth has been one of decreasing atmospheric CO_2 levels. The atmospheric CO_2 levels are thought to have been higher in the Cretaceous than today (Figure 3). Some time following the Cretaceous (perhaps during the late Miocene), CO_2 levels decreased to about 500 ppm. During recent glacial–interglacial cycles, atmospheric CO_2 has fluctuated between 180 and 280 ppm. Since the dawn of the Industrial Revolution, atmospheric CO_2 levels have risen and these increases have been most dramatic since the 1950s (Figure 3).

C_4 photosynthesis occurs primarily within monocotyledonous plants. The flowering plants are classified as monocotyledons or dicotyledons. Approximately 6000 of the 15 000 monocotyledonous plants (primarily grasses and sedges) possess C_4 photosynthesis. In contrast, only about 1600 of the 300 000 dicotyledonous plants possess C_4 photosynthesis. In terms of taxonomic diversity, C_4 photosynthesis occurs in 401 monocotyledonous genera and 86 dicotyledonous genera.

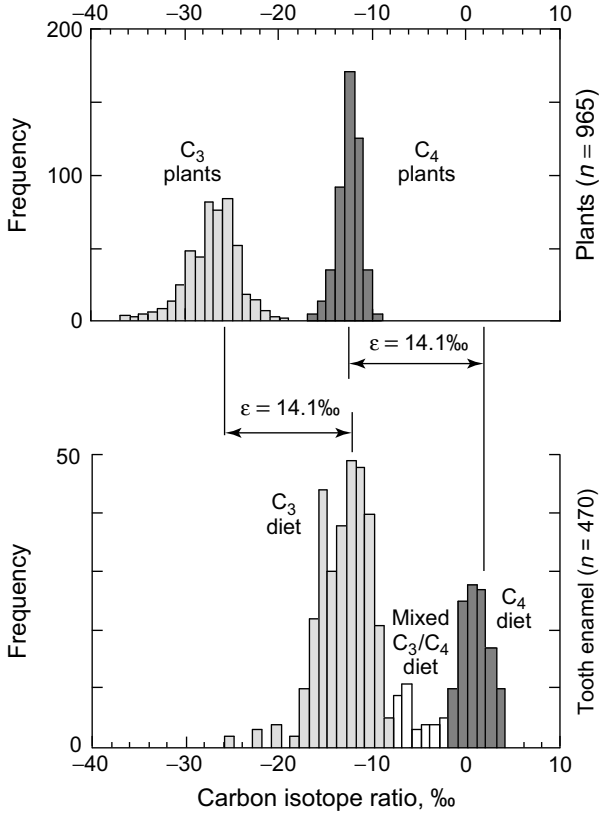

Figure 4 Histograms of the carbon isotope ratios of modern grasses and modern tooth enamel; (adapted from Cerling *et al.*, 1997)

C_4 grasslands emerged globally as an important ecosystem 6–8 Ma ago. Carbon isotope ratios are distinct and different between C_3 and C_4 plants (Figure 4). Variations in the carbon isotope ratios within a pathway reflect changes in environmental conditions and genetic differences among plants within a pathway type. The diet of animals (tissues in extant animals and tooth enamel in fossils) is reflected in their carbon isotopic composition. The offset of 14‰ between carbonate in tooth enamel and the C_3/C_4 food diet as shown in Figure 4 reflects a fractionation associated with apatite (calcium phosphate carbonate) formation in the tooth. Since animal fossils, such as teeth, are much more common in semi-arid and arid ecosystems, we can use the carbon isotopes in tooth enamel to reconstruct the presence of C_4-dominated ecosystems through time.

Between 8 and 6 Ma there was a global expansion of C_4 ecosystems (Figure 5). There is no conclusive evidence for the presence of C_4 biomass in the diets of mammals before 8 Ma, although the presence of small amounts of C_4 biomass is not excluded because of the uncertainty in the $\delta^{13}C$ end member for C_3 plants. By 6 Ma there is abundant evidence for significant C_4 biomass in Asia, Africa, North America, and South America, but not in Europe. Figure 5 documents several different ecosystem-type changes as recorded in mammalian tooth enamel. While each of these regions appears to have been dominated by C_3 ecosystems earlier in the Miocene, the C_3 Pakistani ecosystem was almost completely replaced by a C_4 ecosystem; African, North American, and South American ecosystems retained both C_3 and C_4 components. European and northern portions of North American ecosystems did not show any change in the fraction of C_3 biomass, remaining at virtually 100% C_3 ecosystems. The mixture of both C_3 and C_4 components within a grazing ecosystem can be achieved in one of two ways: a temporal separation with C_3 grasses active in winter–spring and C_4 grasses active in

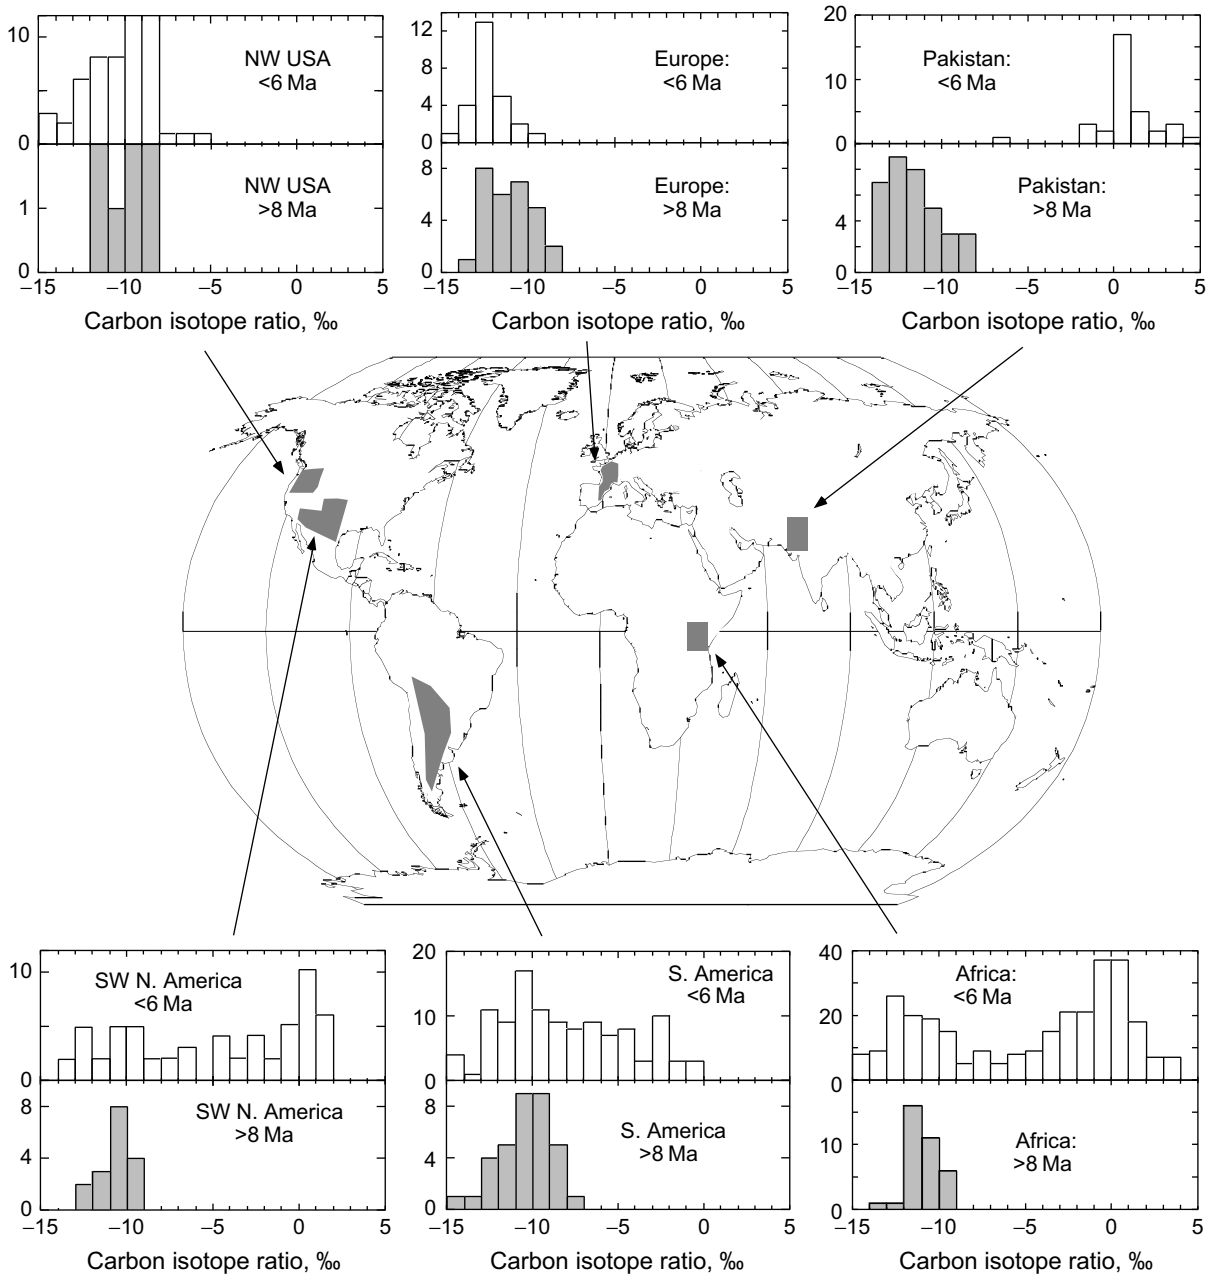

Figure 5 Histograms comparing the carbon isotope ratio values for fossil tooth enamel older than 8 Ma (lower charts) with those that are younger than 6 Ma for six regions of Earth; (adapted from Cerling *et al.*, 1998)

summer or by a monsoonal system with C_4 grasses and C_3 woody vegetation.

The isotopic evidence in tooth enamel indicates clearly that the expansion of C_4 ecosystems was a global phenomenon, persisting until today. The C_3/C_4 changes were accompanied by significant faunal changes in many parts of the world. It is unlikely that the global expansion of C_4 biomass in the late Miocene was due solely to higher temperatures or to the development of arid regions. There have always been regions of Earth with hot, dry climates. To explain the simultaneous global expansion of C_4 plants requires a global process. The light-use efficiency model (Figure 2) suggests that changes in atmospheric CO_2 are a strong possibility for this global mechanism. The supporting evidence indicates that the global expansion of C_4 ecosystems appears to have originated in warmer, equatorial regions and then spread to cooler regions, consistent with the temperature sensitivity predictions of the quantum yield model. Cerling *et al.* (1997) documented that within both modern and fossil horses (equids), the distributions

of isotope ratios strongly support a decrease in abundance of C_4 photosynthesis in moving from warm equatorial to cooler temperate latitudes.

C_4 grasslands are thought to have a wider distribution during glacial periods than they do today. The model in Figure 2 predicts greater global proportions of C_4 biomass during Pleistocene glacial, than interglacial periods. The published literature of organic $\delta^{13}C$ values in peat bogs and lakes from Central and Eastern Africa in regions (areas currently dominated by rain forest ecosystems) strongly suggest extensive C_4 expansion during the last full glacial period. Within western portions of North American, soil carbonate data also indicate that C_4 ecosystems were more extensive during the last glacial period than they are today. The model in Figure 2 suggests that mechanistically C_4 grasses were much more common during the glacial period when C_3 vegetation would have been CO_2 starved. Following deglaciation, the decline in C_4 abundances appears to be correlated with increases in atmospheric CO_2 levels.

What of the future? It is anticipated that atmospheric CO_2 levels will be double the current values by the end of this century. Until mankind's thirst for fossil fuels is quenched, it is likely that atmospheric CO_2 will continue to rise beyond levels experienced in the recent history of this planet. The quantum yield model predicts that as CO_2 levels rise, the atmosphere concentrations will once again cross the CO_2-threshold where C_4 plants do not have a competitive advantage over C_3 plants from the standpoint of reduced photorespiration and enhanced light-use efficiency. Will C_4 plants disappear in the future? That answer is unclear, but it appears that they will not have a competitive advantage. Certainly humans will continue to plant C_4 crops since many of today's most prominent crops are C_4 plants (e.g., corn and sorghum). Regardless of whether or not C_4 plants are as common among subtropical and tropical ecosystems, changes in atmospheric CO_2 will have continued impacts on the distributions of C_4 taxa.

Carbon and Energy: Terrestrial Stores and Fluxes

Dennis Baldocchi

University of California, Berkeley, CA, USA

The exchanges of solar energy, carbon dioxide, and water vapor between vegetation and the atmosphere are tightly coupled. Vegetation must attain energy to sustain the work that is needed to assimilate carbon dioxide, for biosynthesis, to evaporate water, and to transport nutrients from the soil to the plant. Concurrently, these activities require flows of substrate material, which are obtained from the atmosphere and soil. In this article, the physical, biological and chemical principles that govern carbon, water and energy exchange between the terrestrial biosphere and atmosphere are described for leaf, canopy, biome and global scales.

A cycle of birth, life, death and decay is sustained on Earth by the cycling of carbon and energy between the atmosphere, biosphere and geosphere. Carbon plays a major role in the formation of living matter because of its unique chemical property. Carbon has four electrons in its outer atomic shell. This property facilitates covalent bonding, thereby enabling carbon to form a myriad of long chain macromolecules. Examples of carbon-containing building blocks in living organisms include lignin, cellulose, and nucleic acid.

The cycle of carbon and energy begins with plants. They harvest solar energy through their ability to perform photosynthesis. In doing so, they assimilate CO_2 from the atmosphere and reduce it into a storable and useable chemical energy form. The subsequent respiration (oxidation) of high-energy carbon compounds, by plants, their consumers and the consumers of their consumers, taps this energy for work. Without chemical energy, originating from photosynthesis, living organisms would not be able to maintain their metabolism, build and repair their structure, and reproduce.

This essay discusses fluxes and stores of carbon and energy in the terrestrial biosphere. With regard to contemporary environmental issues, an understanding of this topic is needed to quantify: (1) how on-going perturbations in the Earth's climate and the chemical composition of its atmosphere will impact on the functioning of the biosphere; and (2) how potential changes in the functioning of the biosphere may feedback on the atmosphere and its climate system. The nature of this topic is complicated by the numerous biological, physical and chemical processes, which operate at length scales spanning from cells to the globe, on time scales from fractions of seconds to centuries and have non-linear responses to biotic and abiotic forcings.

CARBON BALANCE CONCEPTS

Carbon dioxide is the most common form of carbon in the atmosphere, and it is the primary source of carbon in organic matter. The mean mole fraction of CO_2 in the contemporary atmosphere (*circa* 1999) is near 365 parts per million. However, this value is increasing at a rate of about 2.4% per year, due to fossil fuel combustion, cement production and deforestation. Carbon dioxide ranks fifth in order of abundance in the atmosphere, after nitrogen (N_2), oxygen (O_2), argon (Ar) and water vapor (H_2O).

Natural fluxes of carbon into and out of the atmosphere cause the CO_2 concentration in the atmosphere to vary on diurnal and annual time scales. The daily variation is the greatest. Daytime photosynthesis depletes atmospheric CO_2 and nighttime respiration supplies it. The daily growth and descent of the planetary boundary layer affects the size of the atmospheric reservoir that is coupled with the surface. Minimum values of CO_2 concentration occur after midday when photosynthesis is greatest and the planetary boundary layer is fully grown and well mixed. At night, CO_2 concentrations become significantly elevated with respect to the global mean concentration. Nocturnal CO_2 concentrations are elevated because the boundary layer is quite shallow (a few hundred meters) and the ecosystem is respiring. It is quite common to observe CO_2 concentrations exceeding 500 ppm a few meters above the ground.

The annual cycle of atmospheric CO_2 results from net carbon assimilation during the growing season and net ecosystem respiration during the dormant period. The amplitude of the annual variation of CO_2 is more conservative than the daily cycle. At specific terrestrial sites, the annual variation is on the order of about 10–15 ppm. In contrast, the mean annual meridional difference in atmospheric CO_2 concentration between North and South Pole is about 4 ppm. The mixing of the atmosphere through its global circulation reduces meridional differences.

The major carbon pools in the terrestrial biosphere are generally differentiated as stores in the leaves, stems, and roots of plants, plant detritus and the soil. The amount of carbon stored in each biosphere pool depends on the difference between the rate at which carbon enters and leaves the biosphere. At steady state (or at equilibrium), the flows of carbon into and out of a specific carbon pool are equal and the amount of carbon in the pool remains unchanged.

The rate that carbon is assimilated by the biosphere is called *gross primary productivity* (GPP). In principle, the assimilation of CO_2 is a consequence of a balance between a leaf's demand and the atmosphere's supply of CO_2. Environmental factors that affect a leaf's demand for CO_2 include sunlight, temperature, humidity, soil moisture and available soil nutrients, such as nitrate and ammonium. Biotic factors affecting photosynthesis include growth form (herbaceous or woody, evergreen or deciduous), leaf type (broad-leaved or needle-leaved, dicot or monocot), photosynthetic pathway (C_3, C_4, Crassulacean acid metabolism (CAM)) and longevity (annual or perennial). The supply of CO_2 to a leaf is determined by the concentration of CO_2 in the atmosphere and by the rate of diffusion through the leaf boundary layer and stomatal pores.

Plants cannot acquire carbon without an expense. This expenditure comes in the form of respiration. Autotrophic respiration is the oxidation of organic compounds to CO_2 and water. Autotrophic respiration is responsible for producing biochemical energy compounds called adenosine triphosphate (ATP) and the reduced from of nicotinamide adenine dinucleotide phosphate (NADPH). These compounds are the biochemical equivalents to currency in an economy. Sustainable autotrophic respiration is constrained by the rate of photosynthesis. On a whole plant

basis, autotrophic respiration is generally 40–60% of gross photosynthesis.

The difference between gross photosynthesis and autotropic respiration of plants is called *net primary productivity* (NPP). The net annual production or expansion of leaves, stems, twigs, branches and roots is a result of NPP. To a first degree, NPP scales with available solar energy. The efficiency of this conversion is rather low for several reasons. The spectral range of photosynthetically active radiation (sunlight with wavelengths in the range between 0.4 and 0.7 μm) spans half of the solar spectrum. Between 5 and 10% of this radiation is reflected by leaves. Once a leaf absorbs a photon, chemical limitations and thermodynamic inefficiencies restrict the direct correlation between absorbed photons and molecules of carbon dioxide that are fixed. In the laboratory, eight photons are required for photosynthesis to fix one molecule of CO_2, whereas 12–20 photons are needed to fix a molecule of CO_2 in the field. Together, these factors yield a 2–3% conversion efficiency of solar radiation to photosynthesis. This conversion efficiency is even lower when plants are subject to soil moisture deficits, high vapor pressure deficits and extremely low or high air temperatures.

The net loss of carbon from the biosphere is a function of the amount of carbon stored in the system (C) and the average turnover time (τ). Two turnover times are considered when quantifying respiratory losses of carbon. One turnover time (τ_r) is associated with heterotrophic respiration (R_h), the respiration by fungi, bacteria and soil fauna and flora. The difference between NPP and heterotrophic respiration is called net ecosystem production (NEP):

$$\mathrm{NEP} = \mathrm{NPP} - \frac{C}{\tau_r} \tag{1}$$

NEP represents the net carbon flux between plants and the soil. The rate that carbon is lost from the soil system is accelerated as a soil warms and is restricted when a soil is too dry or wet.

The other carbon turnover time of interest is related to the frequency of disturbance, as in the cases of fire, harvesting, erosion or insect/pathogen infestation (τ_f). Net biosphere production (NBP) is defined as the difference between NEP and losses of carbon compounds from the biosphere via disturbance:

$$\mathrm{NBP} = \mathrm{NPP} - \frac{C}{\tau_r} - \frac{C}{\tau_f} \tag{2}$$

NBP is a process that occurs on time scales of decades to centuries in natural ecosystems, as most fields and forests do not burn or die from insect or pathogen infestation every year.

The time rate of change of carbon in a given pool, dC_i/dt, is a function of the fraction of net primary productivity that is allocated to each pool, a_i, and τ_i is the turnover time of each pool.

$$\frac{dC_i}{dt} = a_i\mathrm{NPP} - \frac{C_i}{\tau_i} \tag{3}$$

The carbon content in individual pools scales with available nitrogen. In general, ratios between carbon and nitrogen vary 5 : 1 and 10 : 1 for soil microbes and between 10 : 1 and 20 : 1 for leaves and roots. The carbon–nitrogen ratio for tree trunks is on the order of about 500 : 1. Fine roots possess the fastest turnover time, which is less than 1 year. Leaves possess turnover times on the scale of 1–3 years. Typical turnover times for stems, boles and soil organic matter can range from decades to centuries.

Soil is a medium for the anchorage of roots and the venue from where plants obtain water and nutrients. The soil is a reservoir of carbon that is continually undergoing losses as roots respire and microbes decompose litter, fine roots and fallen stems. The decomposition of soil organic matter is a function of temperature, soil moisture and litter amount and quality. Ecological data suggest that soil respiration and net primary productivity are positively correlated with one another. High net primary productivity produces more litter. More litter encourages higher decomposition, via soil respiration. This sequence of events promotes mineralization, which produces more nitrogen for plant growth. Because soil respiration involves enzymatic processes, it is highly dependent upon temperature, provided ample moisture is available. Respiration rates from moist but unsaturated soils double with every 10 °C increase in temperature.

The carbon cycle affects the formation and physical and chemical properties of soil in two ways. The dissolution of carbon dioxide in water forms carbonic acid, a weak acid with a pH near 5.6. Weathering of rock is caused by a geochemical reaction between mineral rock and carbonic acid. On annual time scales, the input of plant detritus (leaves and roots) into the soil leads to an accumulation of organic matter and nitrogen, thereby affecting the texture and chemical composition of soil.

ENERGY BALANCE CONCEPTS

The ultimate source of energy for photosynthesis, evaporation and warmth is the sun. With a radiant temperature of about 6000 K, the sun emits most of its radiation in the ultraviolet, visible and near infrared wavebands (0.35–2.7 μm), in accordance with Planck's Law. The Earth's atmosphere is mostly opaque to high-energy ultraviolet radiation, but it is highly transparent to visible and near infrared radiation. On a clear day about 70–80% of shortwave radiation that is incident at the top of the atmosphere is transmitted to the surface.

Atmospheric CO_2 affects energy exchange and life in many direct and indirect ways. Carbon dioxide is a greenhouse gas. It absorbs infrared radiation in the 2.67, 2.77, 4.25 and 15 μm wave bands. CO_2 absorbs and re-radiates infrared energy to the Earth's surface allowing the Earth's mean surface temperature to remain 15 °C above freezing (288 K). The maintenance of liquid water is crucial for the existence and functioning of life. Liquid water is a constituent of photosynthesis, it hydrates cells, and it is the medium by which nutrients are dissolved and exchanged between organs and storage pools. Water vapor is also a greenhouse gas. Together with CO_2 and other greenhouse gases, our atmosphere remains, on average, 51 K warmer than the temperature that the planet would have without an atmosphere.

The net radiation balance at the Earth's surface (R_n) is a function of the flux densities of incoming solar (R_g) and terrestrial radiation ($L\downarrow$) and the surface's albedo (α) and temperature (T_s):

$$R_n = (1-\alpha)R_g + (1-\varepsilon)L\downarrow - \sigma\varepsilon T_s^4 \quad (4)$$

The albedo of the surface defines what portion of incoming solar radiation is reflected. The albedos of conifer and broad-leaved forests, crops and snow are about 0.10, 0.15, 0.20 and 0.7, respectively. The Earth emits infrared radiation in proportion to the fourth power of its surface temperature. The other terms in Equation (4) represent the Stefan–Boltzmann constant (σ) and the surface emissivity (ε), which is near one for a black body radiator.

The net radiation balance at the Earth's surface is used to drive photosynthesis (P); evaporate water, and melt snow and ice (lambda E), heat the air (convection) (H); and heat the soil (G) and plants (S) (conduction);

$$R_n = H + \lambda E + G + S + P \quad (5)$$

In Equation (5), λ is the latent heat of evaporation and fusion and E is the flux density of evaporation.

There is a close linkage between a plant stand's carbon and energy fluxes through the canopy's ability to intercept solar radiation, its net primary productivity, its site water balance and the amount of leaf area the stand can sustain (Figure 1).

The amount of leaf area a landscape can support is related to its water balance, the difference between the precipitation and evaporation. Plant stands, which form closed canopies (whose leaf area index exceeds three), exist where the water balance is positive (precipitation exceeds evaporation). Plant stands with sparse vegetation inhabit regions with a negative water balance.

A dense, closed canopy will intercept most incident sunlight. Hence, it will experience relatively high rates of photosynthesis and a high surface conductance. This occurrence will translate into relatively higher rates of evaporation and relatively low rates of sensible heat transfer.

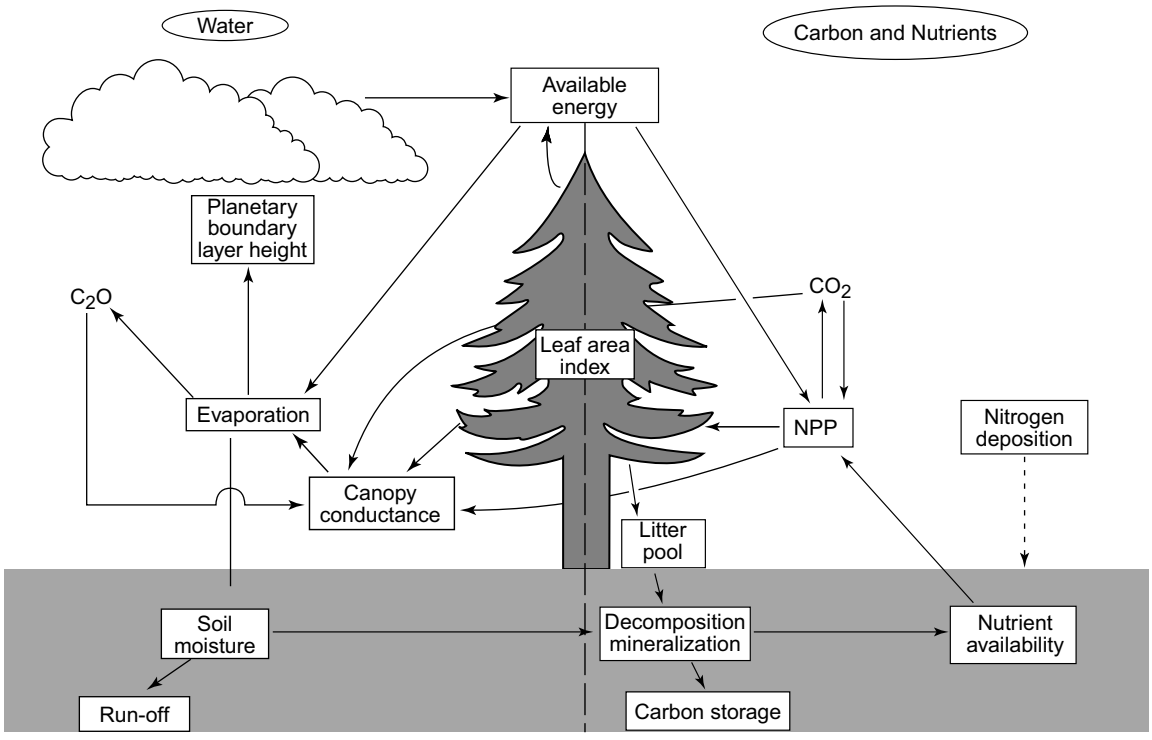

Figure 1 Diagram showing the feedbacks between energy, carbon, water and nutrient fluxes between a plant canopy and the atmosphere

These linkages can limit the height to which the planetary boundary layer develops over the course of a day. A shallow planetary boundary layer is moister than a deep boundary layer. Humidification of the boundary layer also imposes a negative feedback on further evaporation over the course of a day by reducing the atmosphere's vapor pressure deficit. On an annual time scale, a dense canopy is able to provide greater inputs of biomass and nutrients into the soil system. This effect will promote decomposition and mineralization and supply enough nutrients to support high rates of net primary productivity that sustain the leaf area of the closed canopy.

At the opposite extreme, an ecosystem that maintains a low leaf area index (less than three) will intercept less sunlight than a dense stand. Hence, it will experience relatively low rates of photosynthesis per unit ground area, it will possess a low canopy conductance and it will experience relatively low rates of evaporation and high rates of sensible heat transfer. A deeper and drier planetary boundary layer will develop over a sparse, unproductive region than would otherwise occur over a moister and more productive region. On yearly time scales, a sparse canopy provides low inputs of biomass and nutrients to the soil system and its soil is more likely to become dry. These effects will ultimately set limits on decomposition, net primary productivity, leaf area and evaporation.

CO_2 AND WATER VAPOR EXCHANGE AT VARIOUS SPATIAL SCALES

The net exchange of carbon and energy between the biosphere and atmosphere is associated with processes that operate across a spectrum of scales. In this section we discuss CO_2 and water vapor exchange at the cellular, leaf, plant, landscape and global scales.

The Cell

The chloroplast, a cell organelle, is the fundamental scale at which carbon exchange occurs. This is the venue where the suite of biochemical reactions associated with photosynthesis proceeds. A leaf is the fundamental scale at which photosynthesis is sustained as an integral process. The structure of a leaf is needed to support the array of chloroplasts, which harvest sunlight. A leaf also houses stomata, which regulate the diffusion of CO_2 between the atmosphere and the mesophyll cells in the leaf interior, and supports the veins that are tied to the plant's central plumbing, the xylem and phloem.

Leaf photosynthesis involves two separate sets of chemical reactions. One set occurs in sunlight and the other occurs in the dark. The light reactions involve the harvesting of sunlight by chlorophyll and the transfer of electrons to the produce of biochemical energy compounds ATP and NADPH via the process called photophosphorylation. The energy contained in molecules of ATP and NADPH is subsequently used in the dark reactions to drive the photosynthetic carbon reduction cycle, or Calvin Cycle. The functional relationship between leaf photosynthesis and sunlight can be quantified with a rectangular hyperbola, a diminishing returns function.

Three metabolic pathways are possible for the reduction of CO_2. These include the C_3 and C_4 photosynthetic pathways and the CAM (*see* **Photosynthesis**, Volume 2). The C_3 photosynthetic pathway is associated with 95% of plants. In this pathway, a three-carbon compound (phosphoglyceric acid) by a reaction between ribulose bisphosphate (RuBP, a five-carbon compound) and atmospheric CO_2. The C_3 pathway is less efficient than the C_4 pathway because the enzyme, Rubisco (ribulose bisphosphate carboxylase/oxygenase), has a dual and competing affinity with divalent oxygen and CO_2. The competitive reaction between O_2 and Rubisco initiates a biochemical cycle called photorespiration. This auxiliary cycle causes a fraction of CO_2, which is initially assimilated, to be lost. Photorespiration is a function of temperature, oxygen and CO_2 concentrations. The rate of photorespiration diminishes with lower O_2, higher CO_2 and lower temperature.

The C_4 pathway is used by many warm season grasses. The carboxylation of CO_2, by the C_4 photosynthetic pathway, begins with a reaction that is catalyzed by the enzyme PEP carboxylase. It forms an intermediate, four-carbon compound, malate. A key feature of C_4 photosynthesis is its association with a special leaf anatomy, called bundle sheaths. Once formed, the four-carbon compound, malate, diffuses deep within the interior of the leaf, where oxygen is nil. At this locale, malate is decarboxylated. CO_2 that is released by the reaction is, thereby, re-carboxylated via the C_3 pathway (photosynthetic carbon reduction reactions). The combination of the C_4 leaf's unique morphology and this suite of reactions causes this photosynthetic pathway to bypass photorespiration. Furthermore, C_4 plants have a greater quantum yield and higher water use efficiency than C_3 plants and are better adapted to warmer climates.

The CAM pathway is used by cacti and succulent plants in desert and arid regions. These plants keep their stomata closed during the day, but are able to harvest light energy. Then at night, they open their stomata, when compensatory water loss is less, and assimilate CO_2.

Dark respiration produces energy and substrate, in the form of ATP and carbon skeletons, respectively, that are used by growth and maintenance respiration. Dark respiration involves four linked processes. These processes are glycolysis, the oxidative pentose phosphate cycle, the tricarboxylic acid (or Krebs) cycle and oxidative phosphorylation. To produce ATP, these processes transfer electrons, with oxygen being the terminal electron acceptor. From a

stochiometric viewpoint, the respiration of glucose yields six CO_2 molecules, six oxygen molecules and 32 units of ATP. Basal rates of leaf respiration scale positively with leaf nitrogen content and negatively with leaf longevity. Short-term rates are an exponential function of temperature. Typically, respiration rates double with a 10 °C increase in temperature.

The Leaf

The diffusion of CO_2 into a leaf and the transpiration of water vapor from a leaf are regulated by stomata. Stomata are active pores in the epidermis of leaves that occupy less than 5% of a leaf's surface area. Pairs of specialized guard cells characterize stomata. Their opening and closing depends on changes in turgor pressure. Stomatal opening correlates positively with photosynthesis and sunlight. Increasing atmospheric humidity deficits, soil moisture deficits and CO_2 concentration induce declines in stomatal conductance. In general, stomata will open or close in response to environmental perturbations to keep the intercellular CO_2 concentration (C_i) at a relatively constant fraction of the atmospheric concentration (C_a). Typically, C_i/C_a is on the order of 0.7 for C_3 plants and 0.4 for C_4 plants. Theoreticians argue that stomata evolved this behavior to optimize the gain of CO_2 with respect to the loss of water.

Stomatal limitations upon photosynthesis also restrict transpiration since water and carbon dioxide molecules must diffuse through stomata. One consequence of a reduction in transpiration is an increase in sensible heat transfer and leaf temperature. This change forces a negative feedback upon net photosynthesis, as respiration increases exponentially in response to rising leaf temperatures.

Plant Canopy

At the plant canopy scale, the spatial distribution and orientation of leaves affect the performance of the canopy. In general, a plant canopy consists of an assemblage of plants, whose leaves and plants may be arrayed in a random, clumped or regular pattern and whose leaf angles may be erect, flat, or aligned in conjunction with the surface of a sphere. Inside a plant canopy some leaves are fully sunlit, others are exposed to a fluctuating regions of sunflecks, and the remainder exist in deep, but punctuated, shade. The age and the vertical and horizontal position of leaves, their angular relationship to earth–sun geometry, their exposure to current environmental conditions and the availability of soil moisture and nutrients affect how well leaves assimilate and respire carbon dioxide.

Leaves in full sunlight, and normal to the sun's beam, generally have higher photosynthetic capacities than shaded leaves. However, these leaves often experience saturated rates of photosynthesis, as biochemical constraints, such as high temperature and CO_2, limiting their ability to utilize the available solar energy. Furthermore, sunlit leaves are often warmer than air temperature. This situation promotes dark respiration, decreases the solubility of CO_2 relative to O_2 and decreases the Rubisco specificity factor, thereby restraining the maximal rate of photosynthesis attained by sunlit leaves.

The photosynthetic response to light of leaves in sunflecks is not the same as encountered by those exposed to steady light conditions. The history of the preceding sunflecks and the duration and intensity of the current sunflecks affect how the photosynthetic apparatus responds to changes in available light energy. As the light exposure of a leaf changes from dark to bright conditions, a dynamic response, known as induction, occurs if the previous dark exposure period was prolonged and de-activated the enzyme Rubisco. The consequence of this enzymatic de-activation is a delay in the attainment and a reduction in the magnitude of the next steady-state level of photosynthesis experienced by the leaf. The duration of this delayed response can exceed 20 min, but this time response is diminished if the leaf is exposed to repeated light flecks. Post-illumination carbon fixation is another important dynamic response experienced by leaves in fluctuating light. When the view of the sun is eclipsed by an upper leaf, rates of carbon fixation can be sustained for a spell as accumulated pools of metabolites are consumed. In fluctuating light environments, the occurrence of post-illumination photosynthesis enhances assimilation rates in comparison to rates that would occur otherwise under steady conditions with the same mean level of light exposure.

Leaves deep in a canopy adapt to shade. They have lower photosynthetic capacities than leaves positioned at the top of the canopy since less Rubisco, a nitrogen-rich compound, is allocated to them. This effect causes their photosynthesis rates to saturate at lower light levels. Furthermore, the photosynthesis system of these leaves tends to operate at a non-induced level since sunflecks are infrequent.

The functional relationship between light and photosynthesis at the canopy scale is a stark contrast with the behavior exhibited at the leaf scale. Canopy CO_2 flux densities over closed crops are a quasi-linear function of available photon flux density (Q_p), while over forests and sparse vegetation, non-linear response between canopy CO_2 uptake and absorbed photosynthetically active sunlight is observed. The relationship between canopy photosynthesis and available sunlight is affected by whether the sky is clear or cloudy. Rates of net ecosystem CO_2 exchange during clear conditions are diminished by more than half when compared with those observed under cloudy skies and similar photon flux densities. The effect is manifested

through the effect of sky conditions on the distribution of light through the canopy and on the energy budget of leaves. Under cloudy skies, incoming sunlight is more isotropic. The process allows more light to reach deeper into the canopy and illuminate typically sunlight-deficient leaves. On sunny days, the photosynthetic rates of upper sunlit leaves tend to be light-saturated. They also experience a higher heat load, which enhances respiration, so it lowers net photosynthesis.

The light-saturated response of canopy photosynthesis to changes in temperature is very plastic and parabolic. The temperature optimum for canopy CO_2 exchange rates of crops and forests, growing in temperate continental climates, is on the order of $20-30\,^{\circ}C$. The temperature optimum, however, can vary with species, ecotype, site and time of year. A diminution in leaf photosynthesis occurs at supra-optimal temperatures ($T_a > 35\,^{\circ}C$). This reduction occurs from a decrease in the relative solubility of CO_2 compared with O_2, a decrease in the specificity factor of Rubisco, an exponential increase in dark respiration rates and an accumulation of carbohydrates. Soil respiration rates increase exponentially with soil temperature and offset canopy photosynthesis rates.

There are coordinated, whole-plant responses to the environment that also affect photosynthesis. These include a response to temperature, nitrogen availability and soil moisture. Freezing and chilling injury are temperature-related phenomena that affect canopy photosynthesis in a negative manner. Chilling can cause membrane damage, while freezing can burst cells, causing mechanical damage, or dehydrate them. Low soil temperatures can also reduce photosynthesis through effects on water balance and stomatal conductance.

Leaf photosynthetic capacity increases with leaf nitrogen content, as nitrogen is a major component of Rubisco. Native plant stands tend to distribute leaf nitrogen in an optimal or coordinated manner through the canopy in proportion to the extinction of mean absorbed sunlight. Leaf nitrogen content will also vary during the growing season, thereby causing photosynthetic capacity to change.

Soil moisture deficits and high temperature stress have several negative impacts on physiological processes of plants. Soil moisture deficits can cause reductions of cell expansion, leaf area development, photosynthesis and transpiration. Non-stomatal and stomatal factors can limit carbon assimilation when soil moisture is lacking. Non-stomatal limitations of photosynthesis occur when photochemical conversion efficiency or the mesophyll conductance to CO_2 diffusion decreases.

With regard to stomatal limitations, there is ample evidence that a hormonal signal (abscisic acid, ABA) sent from the roots can induce stomatal closure. When ABA signals spawn stomatal closure, CO_2 concentration at the chloroplast is drawn down. Stomatal-induced reductions in chloroplast CO_2 concentration reduce carboxylation rates and alter the kinetic properties of the enzyme, Rubisco. An increase in the rate of photorespiration (relative to carboxylation) and a lowering of the optimum temperature for photosynthesis are two outcomes of changing Rubisco properties.

Canopy respiration involves two activities, growth and maintenance respiration. Canopy respiration is a relatively conservative fraction of canopy photosynthesis. A growing body of empirical evidence shows that this ratio is on the order of 40% and it is independent of temperature and plant life form.

BIOME CARBON AND ENERGY FLUXES AND CARBON STORES

Net CO_2 exchange and carbon content varies by biome (Table 1) due to climatic and genetic factors. Colder climates (e.g., boreal evergreen conifer forests and wetlands) and grasslands tend to store more carbon in the soil and warmer climates tend to store more carbon in above-ground biomass, as is evident in tropical forests and the great redwoods of the Pacific Northwest.

The carbon exchange rates of the world's biomes will vary markedly with time as photosynthetic capacity, the availability of solar radiation and soil moisture, and air and soil temperature vary over the course of the growing season. With regard to forests, deciduous forests lose carbon during the dormant period and gain carbon during the growing season between the period of moderate leaf expansion and leaf senescence. Evergreen forests (conifers and broad-leaved) are capable of acquiring carbon year round, as long as temperature exceeds freezing. Year to year changes on net carbon uptake of broad-leaf and conifer forests are affected markedly by the length of the growing season. Drier systems, like grasslands, savannas and boreal forests, experience numerous days during the heart of the growing season when they lose carbon to the atmosphere.

Several methods exist for measuring and evaluating biosphere–atmosphere carbon fluxes. At the global scale, the model inversion technique is used. This method treats the Earth as a giant cuvette. It combines wind information, from general circulation models, and CO_2 concentration data, from a global flask sampling network, to infer regional sources and sinks of carbon dioxide. The spatial resolution of this method is poor due to the mathematics of the inversion method and the poor resolution of the flask sampling network. Finer resolution information can be deduced by combining satellite imagery with ecosystem models. These carbon flux estimates, however, are discontinuous in time as they depend on images obtained during relatively cloud free conditions. At the stand-level, micrometeorological methods provide a direct and quasi-continuous measure of

Table 1 Estimates of net primary productivity, heterotrophic respiration and net ecosystem CO_2 exchange by plant functional type (Hunt *et al.*, 1996)

Land cover type	Land area (10^6 km^2)	NPP (10^{15} gC year^{-1})	R_h (10^{15} gC year^{-1})	NEE (10^{15} gC year^{-1})
Carbon fluxes				
C_3 grassland	34	9.6	10.7	−1.1
C_4 grassland	20	8.0	11.9	−3.9
Evergreen needle leaf	12	6.6	5.8	0.8
Deciduous needle leaf	2.5	0.5	0.3	0.2
Evergreen broad leaf	17	17.5	22.4	−4.9
Deciduous broad leaf	14	4.6	5.8	−1.2
Shrubland	18	5.2	8.7	−3.4
Total	117	52.0	65.7	−13.6
		Leaf C (10^{15} gC)	Stem C (10^{15} gC)	Soil C (10^{15} gC)
Carbon pools				
C_3 grassland		2.5	0	351
C_4 grassland		1.3	0	159
Evergreen needle leaf		4.3	102	190
Deciduous needle leaf		0.25	10.1	32
Evergreen broad leaf		4.3	224	169
Deciduous broad leaf		1.5	111	167
Shrubland		1.7	10.9	130
Total		15.9	458	1198

canopy–atmosphere CO_2 exchange. In practice, the method is restricted to relatively flat terrain. On the other hand, it gives good information on processes and controls of canopy carbon exchange. Biomass and soil sampling surveys can give long-term integrated measures of carbon fluxes. Yet, long intervals (years to decades) are needed between samples to resolve differences in growth or carbon accumulation in the soil. So this method is unable to provide much information on processes.

GLOBAL CARBON BALANCE

On the global scale, NEP is close to zero and its sign is uncertain (±2 Gt). In contrast, its constituent fluxes are quite large. GPP is about 100 Gt C year^{-1}, while autotrophic and heterotrophic respiration account for about 50 Gt C year^{-1}, each. Year to year variations in the global carbon balance can arise from an array of sources. Potential explanations include land use change (deforestation and burning), a response in biospheric respiration and photosynthesis due to changes in temperature and soil moisture during El Niño periods and a fertilization effect due to rising CO_2 concentration and nutrient deposition.

The major pools of carbon in the Earth's system include the atmosphere, plants, soil and oceans. On land, soil is the largest store of carbon. Although plants and trees are highly visible, more carbon is stored in the transparent atmosphere than in vegetation (Table 2).

Table 2 Carbon stores (Schimel, 1995)

Pool	Gt C
Atmosphere	750
Vegetation	610
Soil and detritus	2190
Surface ocean	1020
Deep ocean	38 100
Marine biota	3
Dissolved organic C	<700
Sediments	150

Carbon Cycle

L Danny Harvey
University of Toronto, Toronto, Canada

The term carbon cycle refers to the flow or cycling of carbon from various compartments or components in the climate system to other compartments and eventually back to the original compartment. The atmosphere is one of many compartments in which carbon can occur, primarily as CO_2 and CH_4 – both of which are greenhouse gases. The carbon cycle is critically important to climate because it regulates the amount of these two important greenhouse gases in the atmosphere. The carbon cycle can be represented by a series of carbon storehouses or reservoirs that are interconnected by carbon flows or fluxes. Unlike the amount of water vapour in the atmosphere, which is directly and instantly driven by changes in the climate, the CO_2 concentration in the atmosphere responds to changes in the climate on time scales ranging from a few months to thousands of years.

Figure 1 shows the major carbon reservoirs. The number in each box is the estimated amount of carbon in the reservoir in units of gigatons (Gt, or billions of tonnes) prior to human disturbance. Carbon occurs in the atmosphere primarily as CO_2 and to a much smaller extent as CH_4; in the living biota and soils as organic matter; and in the oceans primarily as dissolved CO_2, HCO_3^- (bicarbonate ion), and CO_3^{2-} (carbonate ion). The CO_2, HCO_3^-, and CO_3^{2-} are collectively referred to as *dissolved inorganic carbon* (DIC). The ocean can be divided into a surface layer and the remaining subsurface water. The surface layer is referred to as the mixed layer because it is well mixed by winds and the effects of winter cooling. Water parcels in the mixed layer are frequently brought to the ocean–air interface and can exchange CO_2 with the atmosphere.

From Figure 1 it can be seen that: (1) the amount of carbon in the land biota is roughly comparable with the amount of carbon in the atmosphere; (2) the amount of soil carbon and detritus is about two times the amount in either the atmosphere or above-ground land biota; (3) the amount of carbon in the ocean mixed layer, which interacts directly with the atmosphere, is comparable with the amount of carbon in the atmosphere itself; and (4) the overwhelming majority of the total carbon in the biosphere + atmosphere + ocean system is in the deep ocean. The ocean can be thought of as a giant flywheel in the carbon cycle, while the atmosphere contains a comparatively small amount of carbon. Thus, a small percentage loss of carbon from the ocean to the atmosphere would translate into a large increase in the amount of carbon in the atmosphere.

Also shown in Figure 1, as numbers next to the arrows between the boxes, are the carbon fluxes in units of Gt year^{-1}. Carbon dioxide is incorporated into living plant material through photosynthesis and released to the atmosphere through respiration (the process by which organic matter is burned to provide energy, either by the plant itself, or by organisms that consume and thereby decompose organic litter). Some of the biospheric carbon is returned to the atmosphere as CH_4 rather than CO_2. This is represented by the flux of methane (M) in Figure 1, which is probably on the order of 0.2 Gt C year^{-1}. This flux is broken down into various biospheric sources in Table 1, where it is seen that the major sources are emissions from wetlands and termites. The CH_4 is largely oxidized to CO_2 within the atmosphere after about 10 years on average. Some of the biospheric carbon is also delivered to the oceans by

Table 1 Estimated emissions of methane from the terrestrial biosphere and oceans (natural emissions), taken from Lelieveld *et al.* (1998)

Source	Emission (Tg year^{-1})
Wetlands	145 ± 30
Termites	20 ± 20
Oceans	10 ± 5
Wild ruminants	5 ± 5
Freshwater	5 ± 5
CH_4 from sediments	5 ± 5
Total natural	190 ± 70

rivers (the riverine flux (R) in Figure 1), where it is either oxidized and returned to the atmosphere as CO_2, or sinks into the deep ocean. This flux is estimated to be on the order of 0.5 Gt C year^{-1}. Carbon is transferred between the atmosphere and the ocean mixed layer through diffusion of gaseous CO_2 across the air–sea interface. When the carbon cycle is in a balanced state, the total flux into each reservoir will equal the total flux out of the reservoir. Photosynthesis, respiration, and related processes also occur in the ocean. There is a small net flux into the deep ocean that, for a balanced system, will be equal to the rate of burial of carbon. Over geological time scales, the burial flux will be balanced by a variety of processes, including volcanic out-gassing of CO_2. These processes are not shown in Figure 1.

ATMOSPHERE-OCEAN MIXED LAYER-DEEP OCEAN EXCHANGE PROCESSES

When CO_2 enters sea water, the following chemical reactions take place

$$\underset{\text{(gas)}}{CO_2} + \underset{\text{(liquid)}}{H_2O} \longrightarrow \underset{\text{(aq) (carbonic acid)}}{H_2CO_3} \quad (1)$$

$$H_2CO_3 \longrightarrow H^+ + HCO_3^- \quad (2)$$

$$CO_3^{2-} + H^+ \longrightarrow HCO_3^- \quad (3)$$

giving the net reaction

$$H_2O + CO_2 + CO_3^{2-} \longrightarrow 2HCO_3^- \quad (4)$$

About 90% of the inorganic carbon in the oceans is in the form of HCO_3^-, about 10% is in the form of CO_3^{2-}, and less than 1% is in the form of CO_2. The transfer of CO_2 between the atmosphere and ocean is driven by the difference in CO_2 partial pressures (pCO_2). If, for example, the pCO_2 in the atmosphere is greater than that of the ocean surface, there will be a net flow of CO_2 into the ocean. The fact that only 1% of oceanic carbon is in the form of CO_2 means that the pCO_2 in the surface water is much smaller than it would be otherwise. This in turn allows the ocean to hold a large amount of carbon without creating a large back pressure that would drive CO_2 back into the atmosphere.

In the surface layer of the ocean, two biologically driven processes of importance occur: the construction of soft organic tissues by photosynthesis, which can be represented by the reaction

$$CO_2 + H_2O \longrightarrow CH_2O + O_2 \quad (5)$$

and the construction of calcareous skeletons, through the net reaction

$$Ca^{2+} + 2HCO^{-3} \longrightarrow CaCO_3 + H_2O + CO_2 \quad (6)$$

Photosynthesis in the oceans is estimated to take up about 50 Gt C year^{-1}. Most of this goes into short lived microorganisms, and is rapidly returned to ocean surface water when these organisms die or are eaten and burned by larger organisms. However, some of the soft tissue and skeletal material produced in the mixed layer ends up in the deep ocean through sinking dead microorganisms. The combined flux is crudely estimated to be about 10 Gt C year^{-1}, and is referred to as the biological pump. About 60–80% of this flux is due to falling soft tissue, and the remainder due to falling $CaCO_3$ particles. Most of the organic tissue decomposes in the upper 1 km of the ocean, while most of $CaCO_3$ dissolves below a depth of 3–4 km. The net result is to deplete the surface water in nutrients (primarily phosphate and nitrate) and DIC, to create maximum nutrient concentrations around a depth of 1 km, and to create a maximum DIC concentration at a somewhat greater depth in the ocean. Because of the sharp increase in the DIC concentration with increasing depth in the upper ocean, turbulent mixing (diffusion) tends to transfer DIC (and nutrients) upward. This is the main process that balances the downward transfer of DIC by the biological pump.

There are thus two reasons why the atmospheric CO_2 concentration is so low, and why most of the carbon is in the oceans: The first reason is the fact that most of the oceanic carbon does not occur as dissolved CO_2, due to the chemistry of DIC. The second reason is because the DIC concentration is comparatively low in the surface mixed layer but high in the deeper ocean, combined with the fact that the atmosphere is in direct contact only with the mixed layer but is largely isolated from the deep ocean. The mixing processes within the mixed layer are quite intense, but the mixing or exchange of DIC between the mixed layer and the deeper water is much slower. This is why the biological pump is able to maintain a low DIC concentration in the mixed layer in spite of 10% greater concentrations immediately below. The low DIC concentration in the surface water combined with the chemistry of DIC results in a low pCO_2 of surface water, and since the atmospheric pCO_2 tends to adjust to the pCO_2 of the water with which it is in contact, the atmospheric pCO_2 is also low.

WEATHERING AND FORMATION OF CARBONATE SEDIMENTS

The weathering of rocks on land removes carbon dioxide from the atmosphere. Rocks can be divided into two broad categories based on chemical composition: silicates, which contain minerals built around the elements silicon (Si) and oxygen (O), and carbonates, which contain minerals that are built around CO_3^{2-}. Most chemical weathering at the Earth's surface occurs through reaction with carbonic acid (H_2CO_3), which forms when CO_2 dissolves in H_2O. The net weathering reactions can be represented schematically as

$$CaCO_3 + H_2O + CO_2 \longrightarrow Ca_2^{+} + 2HCO^{3-} \qquad (7)$$

for carbonate rocks, and

$$CaSiO_3 + 2CO_2 + H_2O \longrightarrow Ca^{2+} + 2HCO^{3-} + SiO_2 \qquad (8)$$

for silicate rocks. Two CO_2 molecules are removed from the atmosphere for each Ca^{2+} released by the weathering of silicates, and one CO_2 is removed for each Ca^{2+} released by the weathering of carbonates. All of the Ca^{2+} delivered to the oceans, whether from the weathering of carbonates or silicates, is available to form $CaCO_3$ through the reverse of reaction Equation (7). This reaction adds only one CO_2 to the atmosphere + ocean system for each Ca^{2+} that is precipitated. If the Ca^{2+} came from the weathering of a carbonate rock, then the permanent burial of $CaCO_3$ has no net effect on the amount of carbon in the atmosphere + ocean system. When weathering of silicate rocks is followed by the burial of $CaCO_3$, there has been a net conversion from silicate to carbonate rocks and a net removal of CO_2 from the atmosphere + ocean system. However, as ocean sediments enter subduction zones through plate tectonic movements, $CaCO_3$ sediments are transformed back to silicate rocks and the missing CO_2 is produced. This CO_2 eventually finds its way back to the atmosphere through volcanic eruptions and hydrothermal vents (e.g., geysers), which are often collectively referred to as the volcanic source. Since the weathering and volcanic degassing fluxes are about $0.2\,\mathrm{Gt\,C\,year^{-1}}$, the removal of CO_2 by weathering + $CaCO_3$ sedimentation, and its restoration from volcanic degassing, completely replaces the atmospheric CO_2 content once every 3000 years or so.

The solubility of sea water with respect to $CaCO_3$ increases with increasing pressure and hence depth. As a result, the deepest ocean (below a depth of 1–4 km, depending on location) is unsaturated with respect to calcite (the most common form of $CaCO_3$), and $CaCO_3$ sediments are restricted to the ocean floor shallower than this depth.

RESPONSE TIME SCALES

Considerable insight into the behaviour of the carbon cycle can be gained by looking at the ratio of the size of a given reservoir to the total rate of flow of carbon into or out of the reservoir. This ratio is called the residence time (τ). It is the average length of time that a carbon atom spends in a reservoir before being transferred to another reservoir; it is also the length of time required, on average, to completely replace all the carbon atoms in a given reservoir. From Figure 1 it is seen that, based on the fluxes between the atmosphere, land biota, and soil carbon and detritus, the atmospheric reservoir of carbon is completely replaced about once every 5 years on average ($\tau_{atm} = 5$ years). The fluxes between the atmosphere and ocean mixed layer are also sufficient to completely replace the atmospheric CO_2 once every 5 years. Photosynthesis is sufficient to completely replace the land biota once every 6 years on average, giving $\tau_{biota} = 6$ years. About 60 Gt carbon enter and leave the soil and detritus pool every year, and since its size is about 1200 Gt, the mean residence time for this reservoir, τ_{soil}, is about 20 years. The oceanic mixed layer exchanges carbon with both the atmosphere and deep ocean; exchange with the atmosphere is sufficient to completely replace the surface layer carbon about once every 6 years, whereas exchange with the deep ocean is sufficient to completely replace surface layer carbon about once every 50 years. On the other hand, the deep ocean carbon is completely replaced only once every 3000 years or so.

The residence time also gives the characteristic time scale with which the carbon content of a given reservoir will adjust to a change in any of the fluxes between the reservoirs. Based on the residence times estimated above, we see that the carbon content of the biota, atmosphere, ocean, mixed layer, and – to a lessor extent – soils, will respond rather quickly to changes in the inter-box fluxes, but that the carbon content of the deep ocean is much slower to fully adjust. The atmosphere + biota + soils + mixed layer components thus form a tightly coupled subsystem which slowly exchanges carbon with the deep ocean.

When fossil fuel carbon is added to the atmosphere, the relevant response time scale is not given by the residence time of atmospheric carbon based on the exchange with the other reservoirs with which the atmosphere rapidly interacts. Rather, the response to fossil fuel carbon is given by the residence time of carbon in the coupled atmosphere–biosphere–mixed layer subsystem. This is because the rapid transfer of carbon from the atmosphere to the biota or mixed layer is quickly followed by a return flow to the atmosphere. The residence time of coupled atmosphere + biota + soils + mixed layer subsystem is given by the total mass of carbon in the subsystem (about 3100 Gt) divided by the rate of exchange with the deep ocean (about 10 Gt C but

highly uncertain). The result is a residence time of about 300 years. This is a very crude representation of highly complex processes, which are outlined in more detail below, but serves to illustrate in an intuitively simple manner how two very different response time scales for atmospheric CO_2 (5–6 years and 300 years) can arise and how we can get a feeling for what the magnitude of the response time scales should be.

STEPS IN THE RESPONSE OF THE CARBON CYCLE TO ANTHROPOGENIC EMISSIONS OF CO_2

The direct effect of an increase in atmospheric concentration is to stimulate photosynthesis by plants on land, and to induce a flow of carbon from the atmosphere to the ocean. Both responses are discussed in considerable detail by Harvey (2000), but are outlined here.

The products of increased terrestrial photosynthesis – more plant matter and litter – will eventually decompose, causing the carbon to return to the atmosphere. If the products of the increased photosynthesis make their way into long-lived soil components, then it will take longer for the return flow of carbon by respiration to balance the increased photosynthesis, and there will be a larger net storage of carbon on land. Climatic change, if it induces a greater incidence of forest dieback and forest fires, could eventually undo some or much of the initial carbon storage.

Although the flow of carbon into the ocean leads to an increase in the concentration of CO_2 dissolved in sea water, there is almost no stimulatory effect on marine photosynthesis – in contrast to the response on land. Recall that, today, less than 1% of DIC is in the form of CO_2. As CO_2 enters the ocean, reaction (4) proceeds to the right. However, once a new chemical equilibrium is achieved, the carbon does not distribute itself among CO_2, HCO_3^-, and CO_3^{2-} in the same proportions as existed before. Rather, the new carbon remains disproportionately in the form of CO_2, such that the increase in the CO_2 concentration is about ten times faster than the increase in DIC concentration (this factor of ten is referred to as the *buffer factor*, and will slowly increase as more CO_2 enters the ocean).

Since the oceanic pCO_2 is directly tied to the increase in CO_2 alone, this causes the back-pressure of oceanic CO_2 on the atmosphere to increase ten times faster than the relative increase in DIC as CO_2 enters the oceanic mixed layer, thereby limiting the ability of the mixed layer to absorb CO_2. On the other hand, the uptake of CO_2 by the mixed layer is much larger than if there were no chemical reactions at all (Harvey, 2000). One might expect, based on Figure 1 and our discussion of response times above, that the mixed layer would adjust to a pulse of CO_2 into the atmosphere on a time scale of 6 years. However, because of the buffer factor, the *turnover time* does not equal the *adjustment time* of the mixed layer to a perturbation. Rather, the mixed layer adjustment time is given by the turnover time divided by the buffer factor. Thus, the adjustment time is less than 1 year.

As DIC accumulates in the mixed layer and the oceanic pCO_2 increases, subsequent uptake of atmospheric CO_2 is tied to the slow downward mixing (diffusion) of DIC into the deeper ocean. In most of the ocean, the time scale to mix down to the 500 m depth is on the order of 100 years. Because this is much slower than the response of the mixed layer to changes in atmospheric CO_2 (about 1 year), downward diffusion serves as a bottleneck on the oceanic uptake of anthropogenic CO_2. Complete mixing of the CO_2 that would be released from combustion of a large part of the recoverable fossil fuel resource (which is estimated to be around 4000 Gt C) through the entire volume of the ocean would dilute the surface DIC concentration enough to allow the oceans to absorb about 75–80% of the carbon added to the atmosphere. However, on the order of 1000 years would be required for most of the absorption to occur.

Reaction (4) implies that, as ocean water absorbs CO_2, the concentration of CO_3^{2-} will decrease. This decreases the degree of supersaturation of water in the upper ocean with respect to $CaCO_3$. As CO_3^{2-}-depleted water penetrates into the deep ocean, the boundary between supersaturated and unsaturated water will rise, allowing the deepest $CaCO_3$ sediments to begin dissolving. As $CaCO_3$ dissolves, CO_3^{2-} is restored to the surrounding water. As this water mixes back up to the surface, the ocean can absorb more CO_2 from the atmosphere. The amount of $CaCO_3$ sediment that can dissolve is limited by the fact that, as dissolution occurs, the non-carbonate sediment is left behind, and this sediment eventually forms a capping layer thick enough to prevent further dissolution of carbonate sediments. Nevertheless, it is expected that enough carbonate sediment can dissolve to allow the oceans to absorb about half of the remaining 20–25% of anthropogenic CO_2, so that the oceans ultimately absorb 85–90% of CO_2 emitted into the atmosphere. However, several thousand years will be required for this to happen. Enhanced chemical weathering on land would take up the remaining 10–15%, but over a time period of about 200 000 years (Archer *et al.*, 1997).

THE CURRENT CARBON BUDGET

The natural carbon cycle, shown in Figure 1, was close to perfectly balanced over time periods of a decade or longer. Humans have upset this balance by adding new emission sources (fossil fuel combustion and deforestation), and the carbon cycle has responded with the oceans and terrestrial biosphere absorbing some of the remaining carbon (the added carbon (as explained above), creating carbon sinks). The difference between sources and sinks has accumulated in the atmosphere. Table 2 summarizes the current carbon

Table 2 The estimated current carbon budget, based on information in Harvey (2000). 1 Gt = 1 gigatonne = 1 billion metric tonnes

Term	Magnitude (Gt C year^{-1})
Emissions	
Fossil fuel emission	5.5 ± 0.5
Tropical deforestation	1.6 ± 1.0
Regrowth of temperate forests	$-0.5 \pm$
Net anthropogenic emission	6.6 ± 2.0
Sinks or accumulation in atmosphere	
Oceanic sink	2.0 ± 1.0
Terrestrial biosphere sink	1.5 ± 1.0
Accumulation in atmosphere	3.3 ± 0.2

budget. There is considerable uncertainty associated with the size of the source due to deforestation, in the partitioning of the total sink between the oceans and the terrestrial biosphere, and in the geographical distribution of the terrestrial biosphere sink.

Carnegie-Ames-Stanford Approach (CASA)

James T Randerson

California Institute of Technology, Pasadena, CA, USA

The Carnegie–Ames–Stanford Approach (CASA) terrestrial biogeochemical model was specifically designed to take advantage of global satellite observations. In applications over the last decade, the CASA modeling framework has provided several insights about changes in ecosystem function at the scale of biomes and continents.

STRUCTURE

CASA calculates the net carbon balance of an ecosystem as the difference between plant growth (or net primary production (NPP)) and microbial decay (or heterotrophic respiration) (Potter *et al.*, 1993). NPP is estimated at each model time interval, t, and grid cell, x, as the product of absorbed photosynthetically active radiation (APAR; with units of MJ per unit time) and a light use efficiency that reflects the capability of plants to convert light energy into carbon compounds for growth and reproduction (ε; with units of g C/MJ):

$$\mathrm{NPP}(x, t) = \mathrm{APAR}(x, t) \times \varepsilon(x, t) \quad (1)$$

where APAR is derived from satellite observations of *normalized difference vegetation index* (NDVI) (*see* **Remote Sensing**, Volume 2), which is constructed from reflected visible and near infra-red light, and surface radiation in the visible part of the spectrum (specifically known as *photosynthetically active radiation* or PAR, *see* **PAR (Photosynthetically Active Radiation)**, Volume 2). Multiple National Aeronautics and Space Administration (NASA) and National Oceanic and Atmospheric Administration satellites in polar earth orbits provide continuous global coverage of NDVI. NDVI captures seasonal and interannual variation in canopy development and thus the fraction of PAR (FPAR; unitless) absorbed by plants. To obtain APAR, FPAR is multiplied in CASA by estimates of PAR at the top of the canopy. PAR is obtained from a separate set of satellite-derived cloud and aerosol measurements that are used to attenuate incoming solar radiation and thus calculate the light reaching the surface of the Earth. While most spatial and temporal variation in CASA NPP arises from light availability (PAR) and canopy development (FPAR), a small amount of additional variation is introduced by the light-use efficiency term (ε) that responds to locally varying soil moisture and temperature stress.

The simplicity and success of Equation (1) is based on the principle that plant investment in light harvesting (and thus satellite-detectable APAR) is optimized so that all other resources (e.g., below-ground levels of soil nitrogen and phosphorous) are equally limiting to growth (Field *et al.*, 1995).

NPP in CASA is allocated to leaves, wood, and fine roots following an allocation scheme that is sensitive to light limitation, atmospheric carbon dioxide (CO_2), and water stress. The lifetime of leaves, wood, and fine roots are

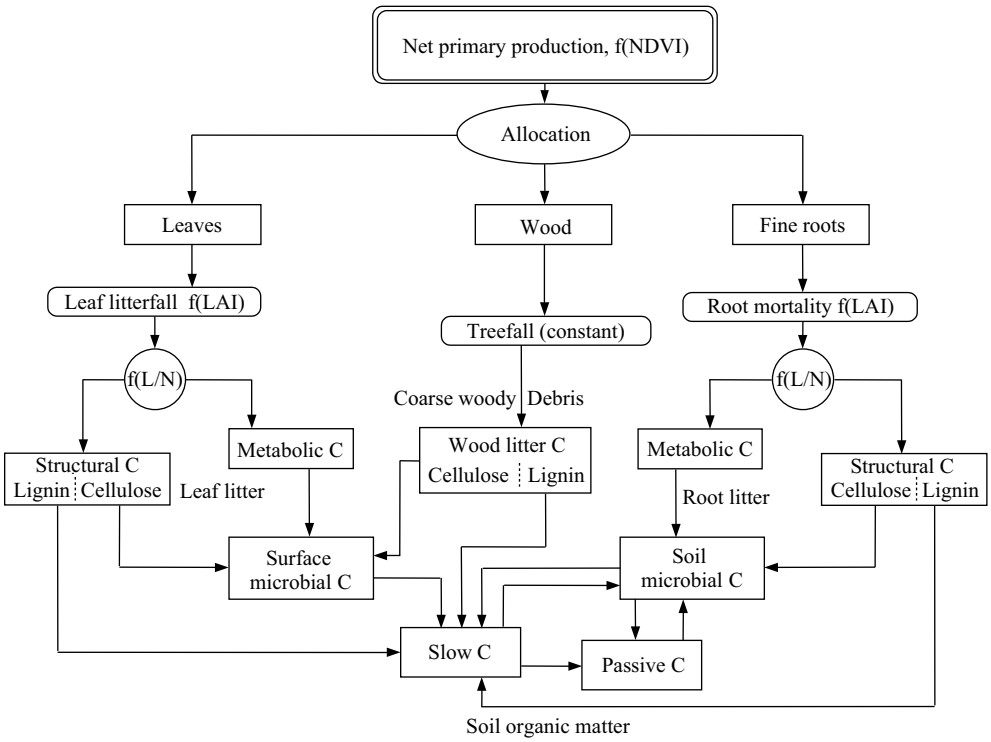

Figure 1 NPP in the CASA terrestrial biogeochemical model is driven by satellite NDVI observations. Carbon transfers in the model follow the arrows during each time interval. Each transfer from litter and soil organic matter pools is microbially-mediated and involves a heterotrophic respiration ux to the atmosphere. At the global scale, the model typically operates with $1 \times 1^{\circ}$ grid cells and a monthly timestep

prescribed as a function of biome type. The mortality (or shedding) of leaves and fine roots and subsequent access by the heterotrophic community is based on satellite-derived changes in leaf area (again derived from NDVI). Decomposition of plant litter and the turnover of soil organic matter depend on soil moisture, temperatures, and the chemical composition (the carbon to nitrogen ratio and lignin content) of incoming plant litter and coarse woody debris following the structure of the CENTURY biogeochemical model (Figure 1) (*see* **CENTURY Ecosystem Model**, Volume 2). The heterotrophic respiration flux (R_h) associated with decomposition has a positive non-linear response to monthly air temperature (described by a Q10 value of 1.5 in the following equation):

$$R_h(x,t,i) = k(x,t,i) \times C(x,t,i) \times \mathrm{Q10}^{(T-30)/10} \quad (2)$$

where $k(x,t,i)$ is the rate constant for decomposition of carbon in pool $C(x,t,i) \cdot k(x,t,i)$ which is a function of the lignin-to-nitrogen ratio of incoming plant litter and the local soil moisture.

CASA model development occurred during the 1990s under the auspices of a NASA Earth Observing System Interdisciplinary Science team led by P J Sellers, H A Mooney, and I Y Fung.

THE WORLD ACCORDING TO CASA

A primary achievement of the terrestrial biogeochemical modeling community during the 1990s was in exploring and defining the boundaries of perturbations to the contemporary carbon cycle arising from elevated levels of atmospheric CO_2, nitrogen deposition, variability in climate, and land use. CASA was able to contribute to advances in our understanding on many of these fronts, with its simplicity in design and dependence on satellite data sometimes serving as an asset and at other times serving as a limitation.

Applications of the CASA model included the analysis of interannual variation in NPP (Malmstrom *et al.*, 1997), spatial and temporal patterns of nitrogen trace gas emission (Potter *et al.*, 1995), the sensitivity of carbon storage to changes in plant litter quality and plant allocation (Potter and Klooster, 1997), and changes in NPP driven by changes in land use (DeFries *et al.*, 1999).

CASA has also guided the interpretation of atmospheric CO_2 data in several ways, including providing seasonally varying (but annually balanced) carbon fluxes required for assessments of the spatial distribution of land and ocean carbon sinks (Fan *et al.*, 1998). Specifically, fluxes from the terrestrial biosphere may co-vary on

seasonal timescales with vertical and horizontal changes in atmospheric circulation, leading to a mean annual build-up of atmospheric CO_2 over the surface of continents, even though the mean annual biosphere flux is zero. This effect is of critical interest, as it must be estimated and removed from the CO_2 observations prior to an inversion calculation of regional sources and sinks. CASA also has been used to estimate the $\delta^{13}C$ of respiration, and the isotopic $\delta^{13}C$ disequilibria of terrestrial vegetation (Fung *et al.*, 1997). The $\delta^{13}C$ disequilibrium is critical for another type of atmospheric inversion that simultaneously uses rates of change in atmospheric CO_2 and $\delta^{13}C$ to partition land and ocean fluxes.

Listed below are a few specific examples of insight into global ecosystem function that may or may not have been gained by the analysis of satellite data and CO_2 observations with CASA.

Northern ecosystem carbon uptake increased during spring months in recent decades. By measuring atmospheric CO_2 from Point Barrow, AK, and Mauna Loa, HI, C D Keeling at Scripps Institution of Oceanography was able show that, in recent decades, the seasonal amplitude of atmospheric CO_2 increased in the Northern Hemisphere and that the phase progressed (Keeling *et al.*, 1996). With a combination of CASA and the Goddard Institute for Space Studies (GISS) atmosphere model, it was possible to demonstrate that the observed changes in the seasonal cycle of atmospheric CO_2 were not consistent with the hypothesis that NPP increases evenly across the growing season. Rather, increased NPP and ecosystem uptake during spring and early summer provide the best fit with the atmospheric data. This is evidence for the existence of a class of mechanisms that would alter the seasonal distribution of NPP (including shifts in the growing season or a changing disturbance regime). Other mechanisms that may have less impact on the seasonal distribution of NPP, such NPP increases from nitrogen deposition or CO_2 fertilization, are less consistent with the atmospheric observations. In additional analyses involving CASA, the spatial pattern of CASA NPP was used to calculate a biosphere-weighted monthly temperature for high northern latitudes. A strong interannual correlation between the biosphere-weighted spring temperatures and ecosystem carbon uptake inferred from atmospheric CO_2 measurements may further implicate a short-term photosynthetic response to temperature.

The potential of an ecosystem to sequester atmospheric CO_2 depends equally on NPP and the distribution of carbon turnover times in plant, litter, and soil pools. Thompson *et al.* (1996) demonstrated that the potential of an ecosystem to serve as a source or sink of atmospheric CO_2 depends on the product of the initial NPP (NPP_0), the initial distribution of carbon turnover times in the ecosystem (τ_0), and the rate at which either NPP or the distribution of turnover times is perturbed (r).

$$\frac{dC}{dt} = NPP_0 \tau_0 r \tag{3}$$

Using CASA to examine spatial patterns of this sink potential has provided evidence that boreal forests and tropical forests have the highest intrinsic potential to alter atmospheric CO_2 levels. Tropical forests have high levels of NPP, and allocation to woody biomass ensures large carbon residence times even though temperatures and soil moisture are favorable to decomposition. In contrast, in boreal forests, NPP is much lower, but in Equation (2), this is compensated for by allocation to wood, chemical recalcitrance of leaf litter, and climate conditions that are unfavorable for decomposition during fall, winter, and spring.

Stimulation of NPP from elevated levels of atmospheric CO_2 may contribute only marginally to the contemporary terrestrial carbon sink. The perturbation to NPP from elevated levels of atmospheric CO_2 (r in Equation 2) is relatively well known. Specifically, the trajectory of CO_2 increase over the last several centuries from industrial activities is relatively well characterized from ice core measurements. Additional information on the response on NPP to levels of CO_2 comes from a number of free air CO_2 enrichment (FACE) studies, in which natural and managed ecosystems were exposed to elevated levels of CO_2 for a period of months to years. With r constrained from the information described above, several global assessments were made using CASA of the magnitude of the carbon sink driven by elevated levels of CO_2. The initial distribution of NPP (NPP_0) was obtained by using the contemporary spatial distribution obtained from satellite data (Equation 1), and scaling it back to a pre-industrial level using a uniformly applied relationship between CO_2 level and NPP obtained from the FACE studies. The other unknown in Equation (2), the distribution of carbon residence times (τ_0), was automatically determined by the structure and parameters of the CASA model. In these simulations, the magnitude of the terrestrial carbon sink is only one-third to one-half of contemporary estimates based on isotopes and oxygen data. This is because CASA estimates of carbon turnover are rapid as compared with other biogeochemical models. Some of the most sensitive parameters in CASA that affect the turnover time of carbon in ecosystems include allocation of NPP to wood, fine roots and leaves, and biome-prescribed turnover times of living vegetation (Figure 1). At the global scale, the spatial co-variation of NPP and carbon turnover emerges as another critical factor in regulating the response of the biosphere to changes in NPP. These model simulations highlight that our greatest limitation in predicting ecosystem carbon sequestration over the next century comes from uncertainties in our knowledge of turnover, carbon

stocks, and allocation, and not NPP or the response of NPP to external forcing from elevated CO_2 or some other factor.

A single light use efficiency (ε) captures global patterns of NPP. Variability in observed NPP across biomes (from Arctic tundra to broadleaf tropical rainforest in the Amazon Basin) can be successfully represented with a single plant light use efficiency (ε) that is not biome-dependent, but responds to local changes in soil moisture and temperature. With high resolution maps of satellite NDVI and PAR that became available in the early 1990s, it was also possible to show with CASA that a maximum (unstressed) ε of $0.4-0.5\,\mathrm{g\,C\,MJ^{-1}}$ PAR was all that was required to explain variability in the global distribution of NPP. This ε for unmanaged ecosystems is several-fold lower than the mean of observations obtained from fertilized and irrigated agricultural systems.

Tropical savanna fluxes are more seasonal than boreal forest fluxes. The largest *growing season net flux* (GSNF) occurs in tropical savannas and not in northern boreal forests. GSNF is defined as the integral of carbon uptake by an ecosystem over the growing season, and is approximately balanced by respiration releases (and fire) outside of the growing season in most areas. Seasonal APAR distributions from CASA provide strong evidence that NPP in tropical savannas is concentrated during the wet season whereas heterotrophic respiration occurs more evenly throughout the year, albeit at much lower rates when soil moisture is limiting. While boreal forests show a similar offset from heterotrophic respiration continuing under snow during fall, winter, and spring months, the total magnitude of the gross one-way flux (i.e., NPP) in boreal systems is only about one-third (on a per area basis) of what occurs in fast growing C_4 savannas across Africa, South America, and Southeast Asia. Boreal and tundra ecosystems, however, can induce large seasonal oscillations in atmospheric CO_2 because in high latitude regions atmospheric convection is small and so seasonal variations in carbon fluxes are trapped near the surface where they have a relatively large impact. In contrast, strong vertical convection in equatorial regions erases the large seasonal variation in fluxes imposed by tropical ecosystems.

Changes in tropical NPP are difficult to detect. It follows from the second point above that even very large changes in tropical NPP will leave almost no trace on the seasonal phase or amplitude of atmospheric CO_2 at pole-ward surface observation stations because of strong vertical mixing. This result, demonstrated by coupling CASA to the GISS atmospheric tracer model (Randerson *et al.*, 1997), provides an excellent example of the challenges involved with assessing changes in tropical ecosystem carbon balance using just surface CO_2 observations.

FUTURE DIRECTIONS

CASA is currently being modified to take advantage of new satellite-derived fire and land use products. The new model structure will include a distribution of plant functional types and vegetation ages within each grid cell. These modifications will provide a critical framework for assessing the impacts of human- and climate-induced changes in disturbance regime on the carbon balance of the terrestrial biosphere.

CENTURY Ecosystem Model

William Parton
Colorado State University, Fort Collins, CO, USA

The CENTURY generalized ecosystem model simulates the dynamics of carbon (C), nitrogen (N), phosphorus (P), and sulfur (S) for plant-soil systems. The model is being used extensively to simulate the impact of climatic and land use changes on natural and managed ecosystems at the site, regional, and global level.

GENERAL DESCRIPTION OF THE MODEL

The model represents plant growth, nutrient cycling, and soil organic matter (SOM) dynamics for grassland, agricultural, forest, and savanna systems. The savanna system simulates the growth of trees and grasses (crop growth can also be represented) separately and includes competition for light, nutrients and water. The grass/crop and forest systems have different plant production submodels that are linked to common soil organic and nutrient cycling submodels. The model was developed with the bias that growth of cropland, grassland and forest systems can be increased by adding soil nutrients (Owensby *et al.*, 1970; Lauenroth *et al.*, 1978). The model structure reflects this bias with the soil nutrient cycling and SOM dynamics been represented in great detail, while plant growth is represented using relatively simple submodels.

The SOM and nutrient submodels represent the flow of C, N, P and S in plant litter and different organic and inorganic soil pools, with mineralization of soil nutrients primarily resulting from turnover of SOM pools. The plant production model calculates plant production and allocation of nutrients to above-ground and below-ground compartments (living) as a function of climatic factors and available soil nutrients. The model uses a monthly time step, while the major input variables include monthly precipitation, monthly average maximum and minimum air temperature, soil texture, lignin (L), N, S, and P content of plant material and soil and atmospheric N inputs. This article presents a description of the model, the method used to test and validate the model, and a summary of the application of the model for environmental impact assessment.

Figure 1 shows that the major structural components of the CENTURY model are the plant production, SOM, and the soil water and temperature submodels. The plant production submodel calculates potential plant production and nutrient demand as a function of monthly average soil temperature (STEMP) and precipitation, reduces plant production based on available soil nutrients and allocates new C, N, and P to the different live plant compartments. The monthly soil water flow model calculates water balance, soil water storage, soil water drainage and stream flow, while monthly average STEMP is calculated as a function of above ground plant biomass. Monthly precipitation, stored soil water and STEMP control the rate of decomposition of the SOM pools and release of nutrients from the SOM pools. The SOM submodel simulates the dynamics of C and soil nutrients for the different SOM pools. Decomposition of the SOM pools results in the release of soil nutrients from the SOM pools, which is then available for plant uptake. Dead plant material from the plant production submodel flows into the surface and below-ground litter pools, which are inputs into the SOM model.

Soil Organic Matter (SOM) Model

The SOM model simulates SOM dynamics for soil active, slow and passive pools, while dead litter material is represented using above-ground and below-ground structural and metabolic pools (Figure 1). The active pool (approximately 2% of the total SOM pool) includes soil microbes and microbial products with short turnover times (1–3 months). The slow SOM pool (45–60% of total SOM)

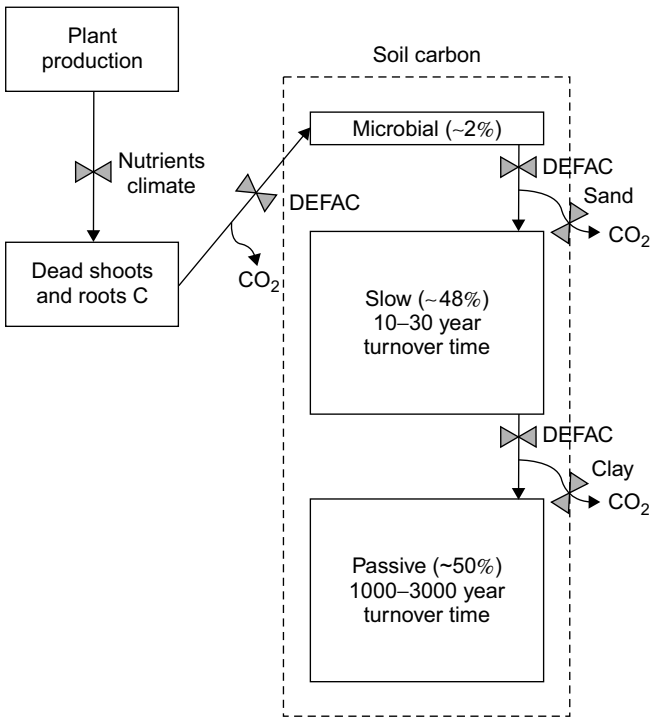

Figure 1 Major structural components of the CENTURY ecosystem model (following Parton *et al.*, 1987). DEFAC, abiotic decomposition factor

includes resistant plant material derived from structural plant material and soil stabilized soil microbial products that have turnover times ranging from 10 to 50 years depending on the climate. The passive pool (45 to 60% of total SOM) includes physically and chemically stabilized SOM that is very resistant to decomposition (turnover times from 400 to 4000 years). The structural material includes the cellulose, hemi-cellulose and lignin fraction of plant material (resistant to decomposition), while the metabolic material is readily decomposable. Plant litter material is split into structural and metabolic material as a function of the lignin to nitrogen ratio (L : N) of the litter (more structural with higher L : N ratio).

The CENTURY model assumes that decomposition of plant residues and the SOM pools are microbially-mediated with an associated microbial respiration carbon dioxide (CO_2) loss. Microbial respiration losses from decomposition of active SOM increase with the soil sand content (from 30 to 80% as sand content increases to 90%), while microbial respiration losses are approximately 50% for decomposition of all of the other litter and SOM pools. The litter and SOM pools have pool specific maximum decomposition rates with the maximum rate being reduced by an abiotic soil decomposition factor that is controlled by the soil moisture and STEMP. The STEMP function increases exponentially with increasing temperature, while the soil moisture function increases as the ratio of stored water plus current rainfall to potential evapotranspiration (PET) increases (the curve is most sensitive to changes in the ratio below 0.6). The decomposition rate of structural litter is also a function of the fraction of the structural material that is lignin (lower for higher fractions) and the lignin fraction of plant material is assumed to flow directly to slow SOM as plant structural material decomposes. The model also assumes that the fraction of the passive pool formed during decomposition of active and slow SOM increases with clay content. The net effect of the soil-texture controls on decomposition of active and slow SOM is to increase soil C stabilization for soils with low sand content and high clay content. A thorough description of the CENTURY SOM model and justification for the approach used in the model are presented by Parton *et al.* (1994).

The CENTURY model has N, P, and S pools that are analogous to all of the soil C pools. The amount of N, P, and S flowing out of a particular pool is equal to the product of the C flow out of the pool times the C-to-element ratio of the pool. A similar approach is used to calculate the flow of different elements into a specific pool but the C-to-element ratio of the receiving pool is a function of the labile inorganic mineral nutrient concentration. Low levels of available nutrients result in high C-to-element ratios for the different pools. Each pool has an allowable C-to-element ratio based on a conceptual model presented by McGill and Cole (1981). The C : N ratios of the SOM pool are narrow (5–20) compared to the C : P and C : S ratios (100 to 400). Mineralization (release of nutrients from SOM) or immobilization of N, P and S (uptake of nutrients by SOM) occurs as a result of decomposition of dead plant material and the SOM fractions. Immobilization of nutrients into SOM generally occurs during the decomposition of structural plant material (high C-to-element ratio material), while mineralization of nutrients occurs as result of decomposition of active and slow SOM (low C-to-element ratio material). The nutrient content of structural material is quite low and nutrients are immobilized into microbial biomass during decomposition of structural material, while slow and active SOM have high nutrient contents and release nutrients (mineralize) while they are being decomposed. A complete description of the soil nutrient model is presented by Parton *et al.* (1988).

Soil Water and Temperature Model

The CENTURY model uses a simplified water budget model to calculate monthly bare-soil evaporation, interception and transpiration water loss, stored soil water, snow water content, stream flow and saturated water flow between soil layers. Interception and bare-soil water loss are calculated as fractions of the monthly precipitation and are subtracted from monthly precipitation before the water is added to the soil. Because each CENTURY simulation is completed for a single cell assumed to have flat topography, the water budget does not take into account precipitation redistribution on uneven terrain by overland flow. Bare-soil water loss is a function of above-ground biomass (decreasing with increasing biomass), while interception water loss increases with increasing above-ground biomass. Transpiration water increases as a function of live leaf biomass. Water loss occurs first as interception followed by bare-soil water loss and transpiration with the sum not exceeding the PET water loss (PET is calculated as a function of maximum and minimum air temperature). Precipitation in excess of PET is stored in soil water layers by adding the water to the top layer. If average air temperature is less than 0 °C then monthly precipitation occurs as snow. Sublimation from snow pack occurs at the PET rate (corrected for the heat of fusion) while snow melt is a linear function of the average air temperature for temperatures > -6 °C.

Near-surface average STEMP is used to calculate the abiotic decomposition rate and the temperature effect on plant growth. STEMP is calculated using equations where the maximum STEMP is a function of maximum air temperature and the canopy biomass (lower for high biomass) and the minimum STEMP is a function of minimum air temperature and canopy biomass (higher for high biomass). It

is important to note that both the soil water balance and STEMP models include the effect of simulated live and dead above-ground plant biomass on STEMP and soil water balance.

Plant Production and Management Model

The CENTURY model is set up to simulate the dynamics of forests, grasslands, agricultural crops and savanna systems. The grassland/crop submodel simulates growth of different crops (corn, wheat, potatoes, sugarcane, etc.) natural plant communities (temperate warm and cool season grasslands, tropical grasslands, etc.), and managed grassland systems (alfalfa, clover, and improved grasslands). The forest submodel simulates the growth of evergreen (pine and fir systems and evergreen tropical systems), temperate deciduous, and drought deciduous systems. The savanna system simulates a tree-grass system by simultaneously running the tree and grassland/crop submodels with the submodels interacting through shading effects and N competition. Both submodels assume that monthly maximum production is controlled by soil moisture and temperature with maximum rates decreased if the soil nutrients supply is insufficient (the most limiting nutrient controls production). The grassland/crop model also includes the effect of shading by standing dead vegetation, while the forest model includes the effect of live leaf area on plant production. Potential production is a function of the maximum growth rate for each grassland/crop or forest system and reduced by 0–1 scalars depending on the factors that limit production. Plant nutrient uptake is a function of living root biomass with uptake increasing as living root biomass increases up to 0.3 $g\,m^{-2}$. As mentioned earlier, in most forest and grassland/crop systems, plant production will increase with the addition of nutrients.

The forest and grassland/crop models are generic plant growth models that can be parameterized to represent a large variety of crop, grassland, and forest systems by altering crop and forest specific parameters. The grassland/crop model includes living shoots and roots, and standing dead plant parts, while the forest system includes living shoots and fine roots, large wood, fine branches and coarse roots. The effect of grazing and fire on the grassland/crop system is represented in the model with the major effect of fire being the increase in root-to-shoot ratio, increase in the C : N ratio of roots and shoots, removal of vegetation and return of nutrients from the fire. Grazing removes live and dead vegetation, alters the root-to-shoot ratio, increases the N content of live shoots and roots and returns nutrient to the soil. All of the natural fire effects and standard forest management practices can be represented by the model (selective logging, clear cutting, etc.). A complete description of the parameterization of the model for different plant systems and the use of the different management options is presented in the CENTURY user manual (Metherell *et al.*, 1993).

Use and Testing of the CENTURY model

Extensive data sets from long-term agricultural experiments and grasslands have been used to test the CENTURY model. We used the observed data to test the model and as a tool for integrating and interpreting the data sets. Plant production and soils data from extensive tropical and temperate grassland around the world (Parton *et al.*, 1993) show that the model correctly simulates the effects of burning, irrigation, fertilization, and grazing on plant production and the seasonal patterns for live and dead biomass. The model has been used to simulate the long-term (30–60 years) dynamics of SOM and plant production for corn, and winter and spring wheat systems. The model was used to correctly simulate the impact of adding different amounts and types of organic matter (pea vine, sawdust, straw, green manure and manure), straw burning, the use of different fertilizer levels, different tillage practices (stubble mulch, conventional plow, and no-till) and wheat pasture rotations on STEMP, soil water dynamics, soil C and N levels, plant production, soil NO_3 leaching and soil N mineralization (Paustian *et al.*, 1992, Probert *et al.*, 1995). The forest model has been evaluated for tropical, temperate and boreal systems and used to simulate the response of forests to different natural disturbances and management practices (Peng *et al.*, 1998).

The CENTURY model has been used extensively to simulate the effect of environmental changes and management practices on natural and managed ecosystems at the site, regional and global level. The grassland model has been used to simulate the impact of climate change and increased atmospheric CO_2 levels on grasslands around the world (e.g., Parton *et al.*, 1995) with a detailed analysis for the US Great Plains region (Schimel *et al.*, 1990). The combined effect of future environmental change and improved land use practices on soil C storage and plant production has been evaluated for the US Corn Belt (Donigian *et al.*, 1995), while Paustian *et al.* (1996) have used CENTURY to evaluate the soil C storage in the US resulting from the conservation reserve program. The Vegetation/Ecosystem Modeling and Assessment program (VEMAP) (VEMAP, 1995) has used the CENTURY model to evaluate the impact of climate change and increased CO_2 levels on the natural ecosystems in the US using a $0.5 \times 0.5^{\circ}$ resolution and has compared model results with two other biogeochemistry models. The model has also been used to simulate ecosystem dynamics at the $0.5 \times 0.5^{\circ}$ scale for global ecosystems (Schimel *et al.*, 1997). We are currently developing a daily version of the model (Kelly *et al.*, 2000) which simulates all of the ecosystem dynamics using more mechanistic soil water and temperature submodels and

also simulates daily trace gas fluxes (N_2O, N_2, NO_x and CH_4).

Chaos and Cycles

Bruce E Kendall

University of California, Santa Barbara, CA, USA

Regular fluctuations in population density, both periodic and chaotic, are found in a variety of species in nature, including boreal mammals, insect herbivores, grouse and partridge, and salmon. Although the exact causes of these cycles remain undetermined for most species, they generally involve strongly nonlinear trophic and competitive interactions among a small number of species. Because of these nonlinearities, it is difficult to extrapolate the effects of global environmental change on the dynamics of any particular population. However, if communities become less diverse and conditions change so as to increase many

species' intrinsic growth rates, then cyclic and chaotic population dynamics may become more common.

INTRODUCTION

The study of complex population dynamics is nearly as old as population ecology. In the 1920s, Alfred Lotka and Vito Volterra independently developed a simple model of interacting species that still bears their joint names. The predator–prey version of this linear model displayed neutrally stable cycles. Experimentalists such as G F Gause and A J Nicholson produced cyclic dynamics in laboratory populations of protozoa and insects (Figure 1). In the meantime, Charles Elton had become fascinated by cyclic fluctuations in field populations of voles (small rodents; Figure 2) and in the numbers of furs of Canadian lynx and other large mammals traded by the Hudson's Bay Company. Foresters have long been dismayed by the periodic outbreaks of certain leaf-feeding insects (Figure 2), which can completely defoliate a forest when at peak density. However, it was not until Michael Rosenzweig, as a graduate student with Robert MacArthur in the 1960s, added density dependence and predator behavior to the Lotka–Volterra equations that an ecological model capable of displaying true nonlinear limit cycles was developed.

In the early and mid 1970s, physicist Robert May took theoretical ecology by storm with a series of papers demonstrating that complex dynamics (cycles and chaos) could be generated by the simplest ecological models (e.g., May, 1976), including the logistic map, an extremely simple model of density-dependent population growth with discrete generations:

$$N(t+1) = rN(t)\left[\frac{1-N(t)}{K}\right] \qquad (1)$$

The dynamics of this model are described in **Non-linear Systems**, Volume 2. Theoreticians rapidly embraced the new science of nonlinear dynamics, hoping that chaos could explain some of the erratic fluctuations that were hitherto called noise. Empirical ecologists were rather more skeptical, and never embraced the claims that chaos was important in the real world; but they gradually accepted the idea that nonlinear dynamics in general were important. This acceptance was indicated by a 1990 symposium sponsored by the Ecological Society of America entitled "The Shift from an Equilibrium to a Non-Equilibrium Paradigm in Ecology".

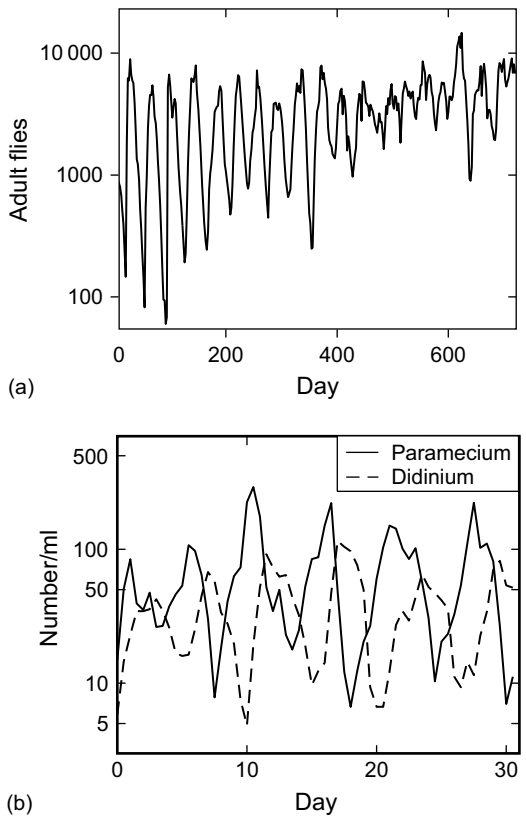

Figure 1 Examples of nonlinear dynamics in laboratory populations. (a) Blow ies (*Lucilia cuprina*). The insects were provided a limited supply of protein, which they require to produce eggs; all other food was *ad lib*, so the cycles were caused by density-dependent fecundity. By the end of the experiment the ies had evolved an increased ability to reproduce at high density, at the expense of their formerly high fecundity at low densities; there were about two generations per cycle. Although the dynamics shift abruptly, the fecundity parameters appear to have been changing continuously, suggesting that the ies evolved through a bifurcation. (b) The protozoa *Didinium nasutum* (predator) and *Paramecium aurelia* (prey). These are pure predator- prey cycles, as the food supply for *Paramecium*, along with all other environmental conditions, was constant. (Redrawn from Nicholson, 1957 and Luckinbill, 1973)

MATHEMATICAL BACKGROUND

Chaos was first knowingly observed in a mathematical model by meteorologist Edward Lorenz in the early 1960s. Not only did he observe deterministic aperiodic fluctuations, but he also discovered sensitive dependence on initial conditions: restarting a simulation model without bothering to copy all of the significant digits, Lorenz observed a sequence of numbers that soon started to diverge from the original simulation. Within the context of turbulence studies, the mathematical and computational strands of chaos were woven together in the 1970s and 1980s. In 1971 mathematicians David Ruelle and Floris Takens coined an evocative term *strange attractor* to describe the complex structures of chaos.

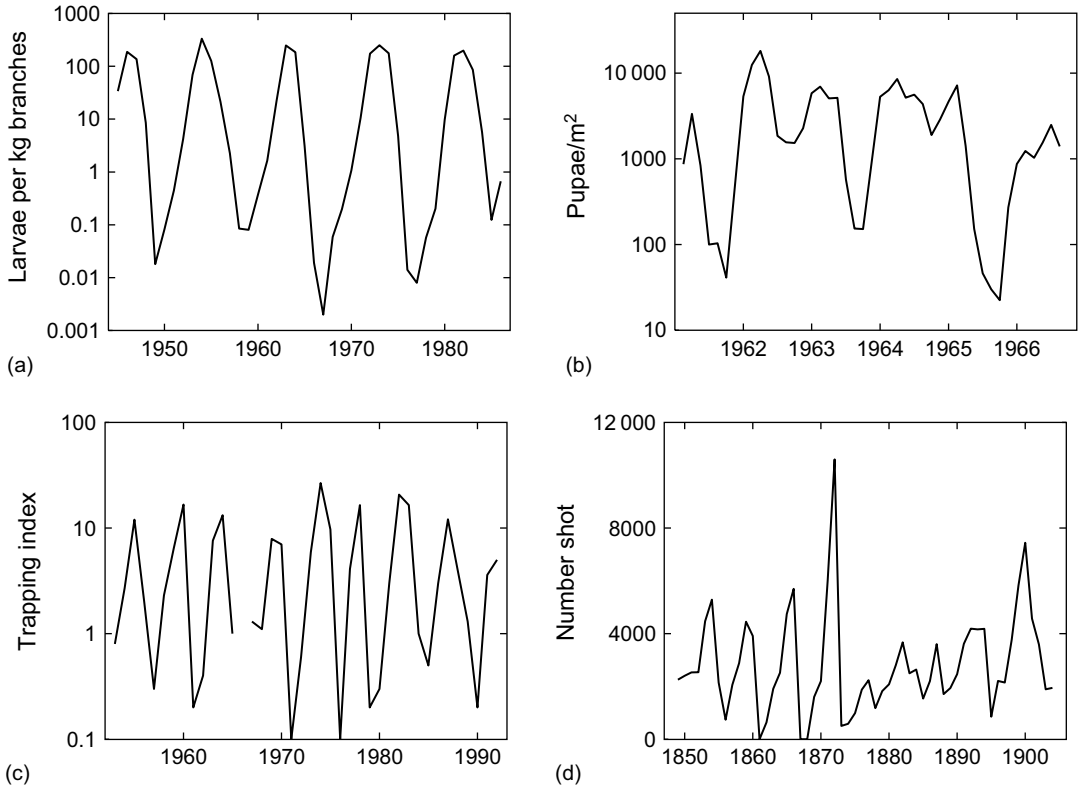

Figure 2 Examples of nonlinear dynamics in eld populations. (a) Larch budmoth (*Zeiraphera diniana*) in Switzerland. These cycles are probably caused by interactions with parasitoids, although there may also be feedback through changes in nutritional quality of the larch needles. Tree-ring data indicate that this extraordinarily regular cycle has persisted for at least 150 years. (b) Coffee leaf-miners (*Leucoptera* spp.) in Tanzania. This also appears to be a host- parasitoid system, coupled with seasonal variation in growth rates (there are eight generations per year). (c) Voles (*Microtus* and *Clethrionomys*) in Finland. This is probably driven by predation by least weasels and stoats, which specialize on small rodents. (d) Red Grouse (*Lagopus lagopus scotius*) in Scotland. Both intraspeci c competition and interactions with an internal parasite have been proposed as mechanisms for these cycles. (Redrawn from Baltensweiler and Fischlin, 1988; Bigger, 1973; Hanski *et al.*, 1993; Middleton, 1934)

The mathematics of deterministic dynamical systems is well understood (*see* **Non-linear Systems**, Volume 2). Four qualitative types of dynamic attractors are observed: *equilibrium*, *periodic* cycles (also called limit cycles), *quasiperiodic* cycles, and *chaos* (Figure 3). Chaos is characterized by a positive *Lyapunov exponent*, which can be thought of as a measure of the long-term unpredictability of the system (see Box 1); equilibrium and periodic attractors have a negative exponent, whereas a quasiperiodic attractor has an exponent of zero. As the system's parameters are changed, the dynamics may undergo an abrupt, qualitative change, known as a *bifurcation* (*see* **Non-linear Systems**, Volume 2).

Environmental Variability and Nonlinear Dynamics

Dynamical systems theory was developed in the context of controlled physical experiments. In ecology, the assumption of a constant, noise-free environment is untenable, and we have to ask whether any of the results for deterministic systems carry over. There are two important ways that these assumptions could be violated: periodic variation in parameter values (e.g., seasonality) or noise (random perturbations to the parameters or state variables due to environmental variability).

Seasonal variation can induce complex dynamics in systems that would be stable in a constant environment. For example, one of the standard epidemiological models of childhood infectious disease has a stable equilibrium in a constant environment. Allowing the contact rate parameter to fluctuate through the year (to simulate the effect of school terms) induces, not surprisingly, a limit cycle with a one-year period. However, further increases in the magnitude of seasonality lead to a periodic or chaotic modulation of the basic annual cycle.

A small amount of noise merely blurs the attractor. The fractal structure of a chaotic attractor is destroyed, but the basic dynamical characteristics of the attractors, such as

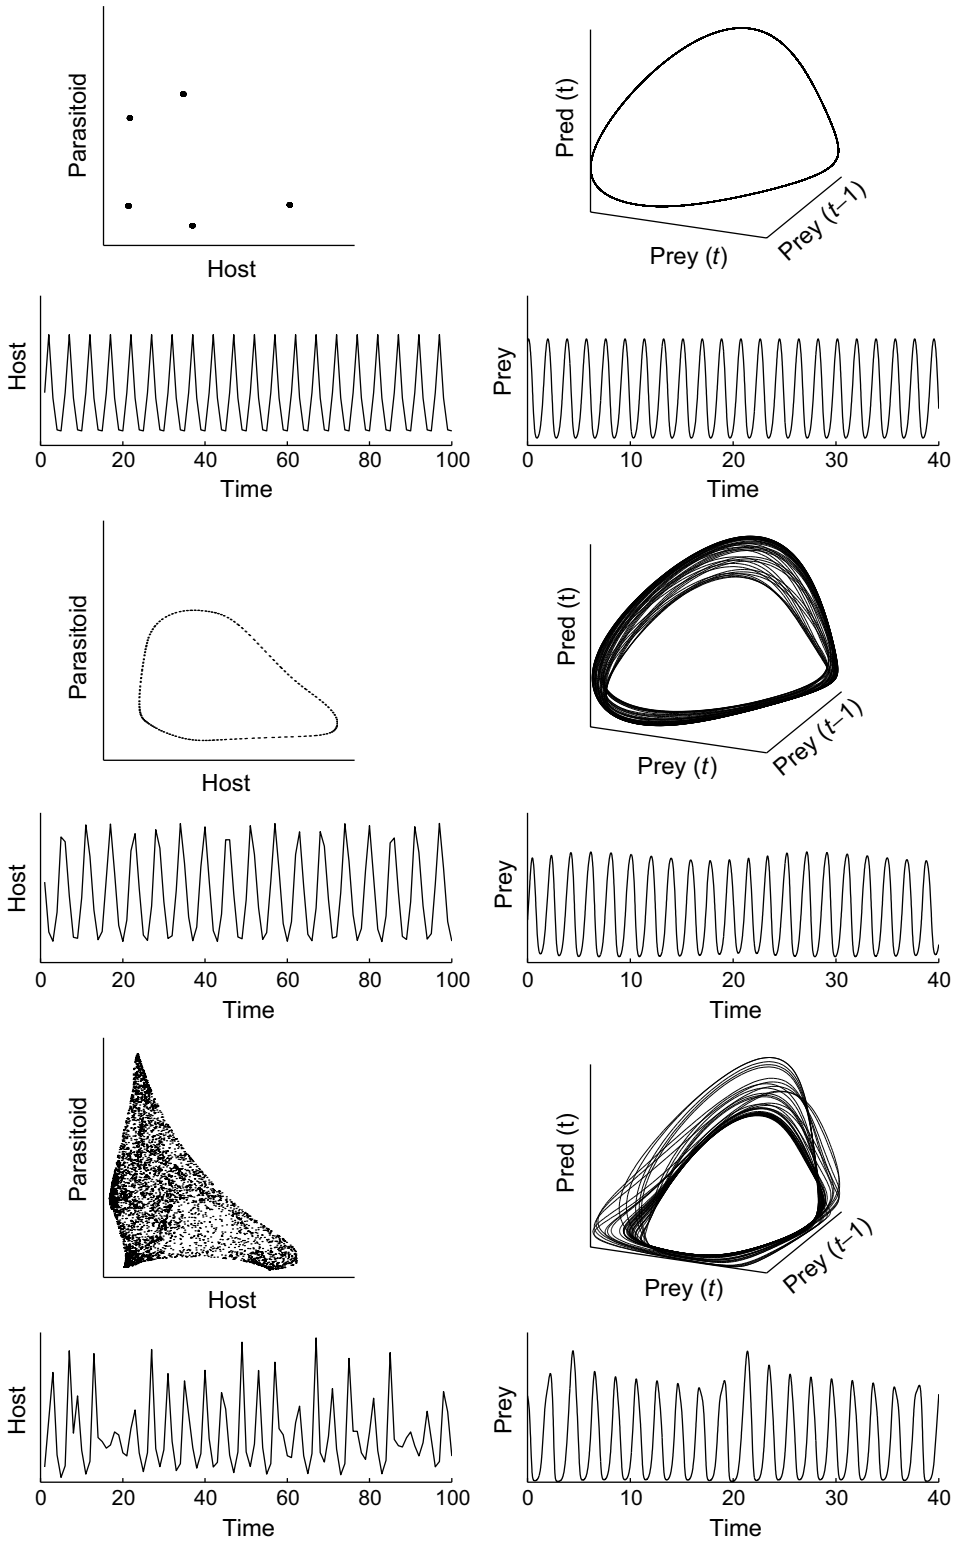

Figure 3 Time series and phase space representations of a discrete-time host- parasitoid model (left panes) and a continuous-time predator- prey model with seasonal variation in the prey carrying capacity (right panes). Top rows: limit cycles. Middle rows: quasiperiodic cycles. Bottom rows: chaos. For the host- parasitoid model the parasitoid attack rate increases from top to bottom. For the predator- prey model the strength of seasonality increases from top to bottom (there is no seasonality in the top pane); notice that the period of the predominant oscillation remains longer than one year. (Models originally published in Beddington, 1976; Rinaldi *et al.*, 1993)

Box 1 Lyapunov exponents

Lyapunov exponents are properties of attractors, and quantify an important aspect of the dynamics associated with the attractors described above: if a system is perturbed slightly, will it return to the trajectory it would have followed in the absence of the perturbation, or will the effect of the perturbation grow through time? If the largest Lyapunov exponent is negative, then the effects of the perturbation will die out; this is associated with stable equilibria and limit cycles. If the largest Lyapunov exponent is positive, then perturbations will tend to grow; this is a property of chaotic attractors. Quasiperiodic attractors have a largest Lyapunov exponent of exactly zero: perturbations neither grow nor decay.

the Lyapunov exponent, are unchanged. In contrast, a large noise variance can have surprising effects on the dynamics. If there are multiple coexisting attractors in the system, then the noise can bounce the trajectory among them, leading to episodes of qualitatively different dynamics. In addition, many systems contain complex transient dynamics as the trajectory returns to the attractor from a distant part of the state space, even when the attractor is a limit cycle or equilibrium. A trajectory following such transients can have all the characteristics of chaos – indeed, the transients are often the ghosts of chaotic attractors from other parameter values. If large perturbations are frequent enough, then the trajectory will spend more time on the transients than on the deterministic attractor.

CHAOS AND CYCLES IN ECOLOGICAL DYNAMICS

Empirical investigations of nonlinear population dynamics have generally proceeded along three directions: statistical analysis of time series data, experimental manipulations of whole populations, and mechanistic models built on known processes.

Time Series Analysis

Spectral analysis is a statistical technique that identifies periodicity by decomposing the time series into sinusoidal components, and asking whether the most important component is larger than would be expected by chance if the fluctuations were random. Even chaotic time series have a strong spectral peak. A recent analysis of 700 long population time series revealed that fully 30% of them displayed statistically significant periodicity (Kendall *et al.*, 1998).

Early approaches for estimating the Lyapunov exponent and the attractor dimension were developed by physicists for use on long (hundreds of points), noise-free time series. Olsen and Schaffer (1990) applied these techniques to data on childhood diseases, and concluded that the chickenpox data displayed noisy periodicity whereas measles epidemics were chaotic. However, these techniques are unsuited to the short, noisy time series that characterize most ecological systems.

Modern techniques for estimating the Lyapunov exponent fit a statistical time series model to the data and then analyze the model directly. A difficult problem that remains unsolved is how to select the best model that fully captures the underlying dynamics without fitting the noise. Ellner and Turchin (1995), using a selection scheme that was biased towards simpler dynamics, analyzed a variety of laboratory and field population time series, and found evidence for chaos in a few, but not many, of the populations. Thus, the answer to the question: "Is Mother Nature a strange attractor?" (Hastings *et al.*, 1993) seems to be occasionally, but not often.

Experiments

There have been numerous laboratory populations raised with the intent of reproducing the predator–prey cycles predicted by the Lotka–Volterra model. Most of these experiments were performed with interacting species (predators and prey) of protozoa or mites (Figure 1b). Along with blowfly populations raised by A J Nicholson (Figure 1a), they demonstrated that population fluctuations could occur even in a constant environment.

A powerful tool for uncovering mechanisms is to modify demographic parameters or interaction rates and observe the resulting changes in dynamics. For example, Constantino *et al.* (1995) induced transitions between equilibrium and cyclic dynamics in laboratory populations of the flour beetle (*Tribolium castaneum*) by artificially increasing the adult mortality rate. In contrast, Nicholson stabilized the blowfly cycles by increasing the juvenile death rate. In the field, Krebs *et al.* (1995) added food and reduced predation on snowshoe hares in 1 km^2 enclosures during the course of a cycle; each manipulation increased the peak density (and delayed the peak). Density manipulations have been used to prolong the cycle peak of Red Grouse (Moss *et al.*, 1996). The results of these manipulations are often initially counter-intuitive, as most of us have intuition based on linear situations. Thus, these results can be best understood by making analogous manipulations to a nonlinear model.

Mechanistic Models

Time series analysis does not provide any information about the processes that govern nonlinear dynamics. Using verbal models to generate predictions leaves the results of experimental manipulations less than sharp. Both of these empirical approaches greatly benefit from the thoughtful use of mechanistic models. For example, the conclusions about smallpox and measles were strengthened by the analysis

of a nonlinear epidemiological model that supported the time-series analysis: with parameters appropriate to smallpox, the model produces stable limit cycles, whereas with measles parameters, it produces chaos (Olsen and Schaffer, 1990). Kendall *et al.* (1999) demonstrated techniques whereby alternative mechanistic models could be fit to a time series, and then time-series analysis could be used to discriminate which model better reproduced the patterns in the data. The *Tribolium* study used a mechanistic model to make predictions (which were sometimes confirmed) about the qualitative changes in dynamics as the mortality rate was varied (Constantino *et al.*, 1995).

The ideal study to uncover the underlying causes of nonlinear dynamics in a population would start with a set of mechanisms that are consistent with the existing data, in the sense of reproducing the dynamic patterns when entered into models. It would then use these models to find the critical experiments that would conclusively distinguish among the competing mechanisms. Finally, the outcomes of these experiments would be analyzed rigorously using time-series statistics. Such an ideal study has never been performed, so we still lack rigorously defensible explanations for the causes of cycles in any field population.

GLOBAL CHANGE AND POPULATION DYNAMICS

Only one experiment has been performed to examine the effects of global environmental change on population fluctuations, but it is possible to make some speculations based on both model behavior and the biology of cyclic populations. A feature common to most population models is that an increase in the intrinsic growth rate of the population makes cycles and chaos more likely. Thus, changing environmental conditions may induce cycles in some populations that do not currently exhibit these dynamics. For example, increased temperature may reduce the generation time in multivoltine insects (such as aphids), allowing their population growth to outstrip the factors that currently regulate their density. Bazzaz *et al.* (1992) demonstrated experimentally that raising the carbon dioxide (CO_2) concentration to 700 $\mu l\, l^{-1}$ increased the fecundity of the annual plant *Abutilon theophrasti* to the point that the plant would exhibit chaotic fluctuations in abundance due to overcompensating density dependence. These oscillations might not be observed in the field (*Abutilon* is an early successional species and persists only for a few years at a given site), but this experiment suggests that cycles in plants (which are presently rare) may become more common with rising CO_2.

Most of the cyclic herbivorous insect species are associated with plant stands that are either naturally or artificially low in diversity (e.g., pine plantations, alpine larch forests). The herbivores are often specialists, and have specialist parasitoids. As plantations replace diverse tropical forests, the potential for such cyclic insect outbreaks increases. There are very few long-term datasets on tropical insect populations, but a study of leaf-miners infesting coffee plantations in Tanzania shows a prominent two-year cycle (Figure 2b).

In temperate forests, many of the cyclic insect herbivores rely on young foliage to meet their nutritional needs for rapid growth. Thus, a key feature of the population dynamics depends on the synchrony between bud burst and hatching of the larvae. If these two processes rely on different environmental cues (as seems likely, for the synchrony often breaks down in years with unusual weather), then changes in temperature and rainfall regimes may break the synchrony and reduce the prevalence of such cycles, at least until the insects can evolve new emergence cues.

One of the hypotheses for the pronounced cycles in boreal mammals is that the simpler communities, and especially the absence of the generalist predators that live farther south, allow classic predator–prey cycles to arise. If this is true, and if there is warming of these environments, then invasion by generalist predators (and their alternative prey) from farther south may lead to these cycles disappearing.

The bifurcation diagrams suggest that we might see abrupt changes in population dynamics as the environment changes. However, the noise that characterizes ecological systems will smooth these transitions. Indeed, these shifts may be accompanied by transient dynamics that mimic the old attractor, so that it may be years or decades before the new attractor is revealed.

and out-compete potentially invading species in the climax environment. Over long time scales, however, environmental shifts due to climatic change or ecological and evolutionary processes produce changes in the species composition of the climax stage.

In environments with relatively low frequencies of major disturbance, succession has enough time between disturbances to run its course and reach the climax stage. This usually produces a stable assemblage of species dominated by a few prominent ones. Where major disturbances are frequent, succession may never reach the climax stage, resulting in diverse mixes of species with no consistently dominant species.

Global environmental change is likely to reduce the occurrence of climax vegetation in two ways. First, in a lot of areas, disturbances are likely to occur more frequently so succession may no longer have enough time between disturbances to reach its climax. Consequently, climax vegetation and climax species assemblages are expected to become less common. Secondly, the unidirectional nature of much of global environmental change is likely to alter the species composition of the climax vegetation. Where the environment changes relatively quickly compared to the time it takes the species composition of the climax stage to evolve to new environments, the species composition of this climax vegetation may itself be constantly changing. In this sense, true climax vegetation may be unrealizable in these places until the environment there has stabilized (*see also* **Disturbance**, Volume 2; **Succession**, Volume 2).

Climax Vegetation

Climax vegetation is the vegetation present at the ultimate stage (climax) of the ecological succession of a species assemblage under the predominant physical environmental conditions occurring on a given site. Left undisturbed, the species composition of the climax remains relatively stable because these species successfully reproduce themselves

CO_2 Enrichment: Effects on Ecosystems

Ch Körner
University of Basel, Basel, Switzerland

We live in a carbon world, which means that almost half of all dried organismic tissue consists of the element carbon, C. If organismic tissue or debris is oxidized (decomposed), carbon is emitted as carbon dioxide, CO_2. Although CO_2 is called a trace gas, because only ca. 360–370 ppm of

the atmosphere is currently represented by CO_2, it is the major substrate which green plants absorb by photosynthesis. Photosynthesis, in essence, reduces CO_2 to sugar, utilizing solar energy (release of oxygen, O_2). Non-green living parts of plants, green parts at night, all animals and nearly all microbes obtain their energy requirements from re-oxidizing carbon compounds (respiration), and thus consume oxygen and emit CO_2. Photosynthetic binding of CO_2 and respiratory release of CO_2 are the two major components of the biological carbon cycle of the globe, which turns over approximately 100 Gt (i.e., billions of tons) of carbon year^{-1}.

Whenever the magnitude of the two processes is unequal, carbon either accumulates in the atmosphere or in the biosphere (including the pedosphere, i.e., the soil humus, and organic ocean sediments). Net biospheric carbon accumulation during the last 0.5 billion years has created enormous fossil carbon reservoirs below the ground, a large part of which mankind is releasing within ca. 300 years, starting around the year 1800, with dramatic increases of emission in recent decades, further enhanced by deforestation (the release of current biosphere carbon). This is why the atmospheric CO_2 concentration is increasing so rapidly and thereby is changing the biosphere's diet at an unprecedented speed. Atmospheric CO_2 is plant food, but at the same time, it absorbs long wave (infra-red) radiation and, together with other gases, contributes to an enhancement of the global greenhouse effect. The latter phenomenon may create a warmer climate, for which the greenhouse gas CO_2 is best known, but this synthesis aims at explaining the direct biological consequences of CO_2 enrichment, irrespective of any indirect influences on organisms via climatic change. Elevated CO_2 contributes to the biodiversity crises in a slow, invisible manner. It is one of the prime needs of global change science to visualize such possible effects.

ARE CURRENT ATMOSPHERIC CARBON DIOXIDE (CO_2) CONCENTRATIONS UNUSUAL FOR PLANTS?

There is no doubt that human activities are responsible for the current increment of atmospheric CO_2 concentration, which is unusual indeed. Ice cores sampled from the Antarctic ice shield permit a reconstruction of atmospheric CO_2 concentrations over the last 0.4 million years (Figure 1). Air bubbles trapped in fossil ice tell us that CO_2 concentrations oscillated between 180 and 290 ppm over this period of several ice ages and interglacial warm periods such as the current one. Nearly all plant species existing today lived and survived these long periods of low CO_2 concentrations (during peak glaciation, as low as half the current concentration). The mean ambient atmospheric CO_2 concentrations are currently close to 370 ppm (http://cdiac.esd.ornl.gov/ftp/ndp001/maunaloa.co2), nearly one-third above the recorded interglacial maxima, and this has occurred in only about the last 250 years. This is a rapid, very unusual change of the life conditions for plants.

The best evidence that atmospheric CO_2 enrichment is man-made and reflects burning of biotic (both recent and fossil) carbon (C), comes from studies of stable carbon isotopes in the atmosphere. CO_2 containing the heavier ^{13}C isotope (ca. 1.1% of all carbon on the globe) is slightly discriminated by plants during photosynthesis as compared with $^{12}CO_2$. Consequently, all carbon compounds of biological origin, including fossil ones, contain less ^{13}C; and emissions of CO_2 from biotic carbon sources (lighter carbon) will always dilute the ^{13}C concentration in the atmosphere, exactly what records show (Figure 2). Over nearly four decades biologists explored the influences of CO_2 enrichment on plants, and research during the last two decades have produced about 3000 publications on this topic (Saxe *et al.*, 1998; Körner, 2000).

WHY DOES CO_2 ENRICHMENT INFLUENCE PLANT LIFE DIRECTLY?

Just like any other chemical reaction, the enzymatic binding of CO_2 in the chloroplasts of photosynthesizing organs depends on substrate concentration (in this case CO_2 concentration). CO_2 must enter the leaf interior through tiny, but variable pores (the stomata) through which plants also lose water vapor. The more these pores are closed, the more is the uptake of CO_2 restricted. When soil and atmospheric moisture are high, these pores are wide open and thus allow CO_2 concentrations beneath the pores (in the intercellular air spaces of photosynthesizing tissue) to be maintained at 70–80% of that outside the leaf, while photosynthesis inside the leaf consumes CO_2. When stomata are closed during the daytime (e.g., because of drought), the internal CO_2 concentration can fall to less than 10% of that outside the leaf. CO_2 concentration is a rate-limiting factor for photosynthesis.

Although specialized to utilize very low concentrations of CO_2, the photosynthetic machinery, in essence the CO_2-binding enzyme called RubisCO, is able to process CO_2 at much faster rates if concentrations at the reaction sites are increased up to the point where the process becomes substrate saturated (commonly around three times current ambient concentrations). Such non-linear responses to environmental changes can be found for almost any plant trait, but are particularly obvious for the leaf photosynthetic response to CO_2, a curve which is the basis of almost all predictive models, even if not explicitly stated. During geological periods when CO_2 concentrations became very low for the first time (during the Cretaceous period) a number of plant families evolved species which adopt a trick to rate-saturate RubisCO naturally, by actively pumping

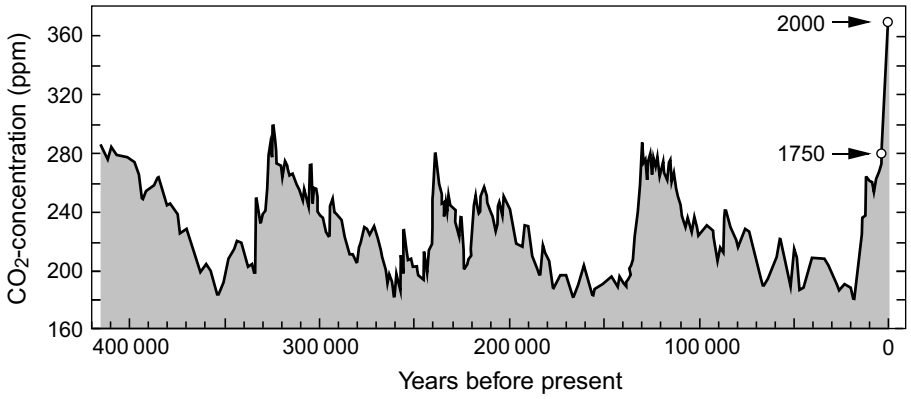

Figure 1 A 420 000 years record of CO_2 concentration in air bubbles trapped in the Antarctic ice indicates that the biosphere operated between 180 and 290 ppm during this period, except for the most recent time, when CO_2 rose to the current mean of ca. 368 ppm (Petit *et al.*, 1999)

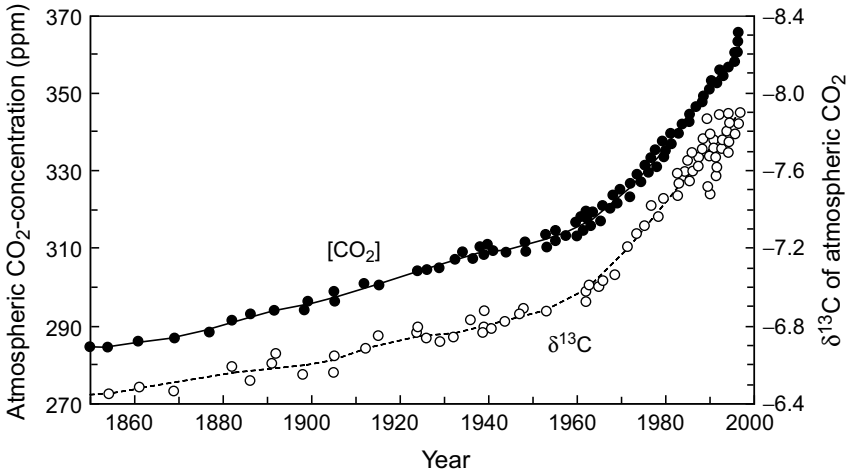

Figure 2 Atmospheric CO_2 enrichment and $^{13}CO_2$ depletion go hand in hand, which underlines the anthropogenic cause of both, namely biogenic carbon release (Joos *et al.*, 1999)

CO_2 to the reaction sites using an enzyme called phosphoenalpyruvat (PEP) carboxylase and a special anatomical arrangement of cells (called kranz anatomy). The first intermediate product of this process is a compound with four carbon atoms, the reason why these specialists are called C4 plants (in contrast to the majority of species which operate without this expensive pump, the so-called C3 species). *See* **C_3 and C_4 Photosynthesis**, Volume 2. The C4 pathway has been and still is very successful in periodically dry and hot environments, where plants need to save water and thus, need to restrict vapor loss, which at the same time restricts CO_2 diffusion into the leaf (among crop plants, maize, sorghum and sugar cane belong to this group of species). It is obvious that photosynthesis of C4 and C3 plant species will not be equally sensitive to atmospheric CO_2 enrichment (Figure 3). Under high soil moisture, C3 plants have been found to be much more responsive. In summary, there are good biochemical reasons why higher atmospheric CO_2 concentrations will influence plants.

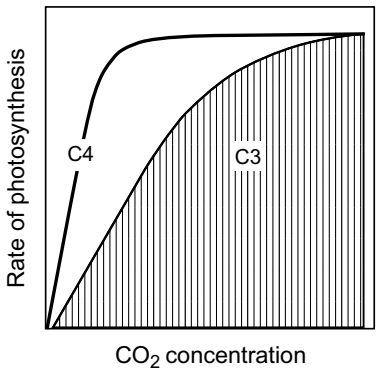

Figure 3 The instantaneous response of photosynthesis to increasing CO_2 concentrations on a unit leaf area basis for C3 and C4 plant species (schematic)

HOW WILL PLANTS RESPOND TO A NEW CARBON DIET?

The principles of photosynthetic responses to environmental changes, including CO_2 enrichment, are well understood and documented. Other responses such as those of growth and development of plants are much more difficult to understand and predict, because these depend on many internal and external drivers in addition to those influencing photosynthesis directly. In many cases it is not even clear whether CO_2 supply represents the bottleneck for biomass production. One can compare the significance of these other determinants of biomass production with the conditions which control automobile speed in a metropolitan area, which rarely depends on fuel availability or the power of the engine. The most important of these external factors for plant growth responses to CO_2 enrichment are mineral nutrient availability, water, light and disturbance (e.g., browsing animals). However, this is not a classical minimum factor limitation situation, because CO_2 enrichment alters the relative demand of these resources, and the sensitivity to these other growth determinants. Commonly, plants can cope with less nutrients, water and light if provided with more CO_2 (Drake *et al.*, 1997). The situation becomes more complex if one wishes to account for interactions between plants (e.g., competition for resources under an altered CO_2 supply) and between plants and other organisms (herbivores, symbionts, soil microorganisms). It becomes impossible to predict plant growth responses to CO_2 enrichment from first principles only (the photosynthetic response), when effects of plant age and plant development in general (including reproduction) come into play. These are the fields where empirical work has improved our capability to develop likelihood scenarios. Experimental sciences (together with mathematical simulation) are now able to provide projections of what is likely and what is less likely to occur, but the long-term adjustment of the whole biosphere to a doubled CO_2 world cannot be predicted with engineering certainty, something decision makers need to bear in mind. What follows here, is a brief account of what is most likely to happen as CO_2 concentration continues to increase, and how observational data must be weighted in order to arrive at a realistic picture.

THE FOUR MOST IMPORTANT CRITERIA FOR UNDERSTANDING PLANT AND ECOSYSTEM RESPONSES TO ELEVATED CO_2

Firstly, it is important that *absolute* (e.g., increment in grams) and *relative responses* (% change) are distinguished. Very poor growth conditions including those at the edge of survival, may in fact facilitate substantial relative responses to elevated CO_2 at otherwise negligible absolute gains. For plants in the deepest shade of a forest, for instance, CO_2 enrichment may permit net carbon gains to increase from zero to a minute positive value, which mathematically counts as an infinite relative stimulation (e.g., Figure 3). Ecologically such relative responses may be very important, but they would not permit much additional carbon binding. On the other hand, a sustained absolute annual increase of the current net carbon stock in the biomass of the forests of the world, of the size of only *ca.* 6 Gt C or ca. 1% of the current global biomass C-pool (ca. 10–15% of annual terrestrial net primary production not becoming recycled by respiration) would remove nearly all annually emitted fossil carbon from the atmosphere/ocean system. To put this number in perspective, one needs to bear in mind that a forest with a 100-year rotation has a mean net carbon fixation of 1% of its final carbon stock per year, hence one additional percent per year means doubling its growth rate or halving its rotation time (see the second criteria below). When CO_2 responses reported in the literature are compared, this distinction between absolute and relative responses is essential. Relative responses are often more relevant in an ecological context (e.g., for biodiversity); absolute responses are of greater interest when carbon binding is discussed.

Secondly, another important distinction is the one between *fluxes* and *pools* of carbon. A growth rate indicates a flux of carbon from the atmosphere to a plant or to the whole ecosystem per unit of time (often termed *productivity*). Live and dead plant mass and soil humus represent the biological carbon inventory per unit land area, a carbon pool of a certain, but limited lifetime. Growth rates and carbon stocks commonly are not coupled, in fact, their interrelationship often is an inverse one. The greatest carbon stocks are found in old forests which have little annual growth (little annual net carbon uptake), whereas highly productive plantations commonly represent much smaller carbon pools but grow quickly. What matters in terms of biospheric carbon binding is the amount of carbon per unit of land area, and not the rate of carbon cycling through these terrestrial pools. Hence, a stimulation of growth represents net carbon binding only if it is not balanced by plant death, burning etc. elsewhere. Since all organisms ultimately die, it is a matter of their age demography whether their populations fix net amounts of carbon. If life cycles are artificially synchronized (e.g., in a forest plantation) a carbon release wave is exported into the future, when these plants reach their life span or harvest size. Hence, a short-term growth stimulation at one time and one place must not be confused with carbon sequestration (IGBP Terrestrial Carbon Working Group, 1998). However, such transitory carbon binding may be seen as a means of buying time, i.e., postponing the atmospheric CO_2 enrichment by a few years, at least partly, at the price of burdening the distant future with carbon recycling. From this it is obvious that the most effective long term management option for biological carbon binding is

to increase the aerial extent of carbon-rich forests and preserve the old ones still existing (cf. IGBP Terrestrial Carbon Working Group, 1998). A second option is to increase the total amount of forest products used in construction. A very effective fossil carbon saving strategy and the only sustainable biological measure to mitigate CO_2 accumulation in the atmosphere, is the substitution of fossil carbon by bio-carbon (Marland and Schlamadinger, 1997).

Thirdly, CO_2 enrichment causes non linear responses and responses change with the duration of exposure and plant age. This makes it extremely difficult to project experimental findings derived from exposing young plants to a step change in CO_2 concentration into the future. As can be seen from Figure 3, the relative response of photosynthesis gets smaller as CO_2 concentration rises, a dampening phenomenon, which becomes enhanced if photosynthetic acclimation takes place. It is plausible to assume that biomass responses to each ppm of atmospheric CO_2 enrichment were greatest when CO_2 concentrations started to rise 250 years ago, are smaller today, and may already (or soon) approach zero in some natural ecosystems (ecosystem CO_2 saturation). Furthermore, a step increase of CO_2 often causes a strong initial stimulation of growth (for a couple of years) which gradually declines with time and/or plant age, so that the duration of the actual observation/treatment period becomes a codeterminant of results (Figure 4). There are possibly not more than five published studies worldwide which extended over more than five years of experimental CO_2 enrichment, and so far none of these included trees, which are responsible for nearly 90% of all biomass carbon on the globe. The only long-term observation suggesting that such age dependency may in fact exist, comes from trees growing around natural (geological) CO_2 springs (Figure 4).

The fourth criterion to be considered is that soil quality determines plant responses to CO_2. One of the lessons of a large number of CO_2 enrichment experiments is that there is no common response, but one which depends on experimental conditions. When amply supplied with essential resources other than CO_2, CO_2 enrichment can greatly enhance plant growth, both in relative but even more so, in absolute terms. Under such conditions the mean seasonal stimulation of biomass accumulation in the temperate zone by a doubling of CO_2 supply is around 30%. This is why CO_2 enrichment became economically important in greenhouse agronomy (Wittwer, 1984). Under less optimal growth conditions, responses depend on the relative abundance of soil resources. In many cases little stimulation of growth has been seen under more natural growth conditions. Most remarkably, but hardly investigated, is the fact that plants can even respond in opposite directions to CO_2 enrichment, when grown in communities under close to natural conditions, but on two different soil types (Figure 5). Another example is given by legumes such as

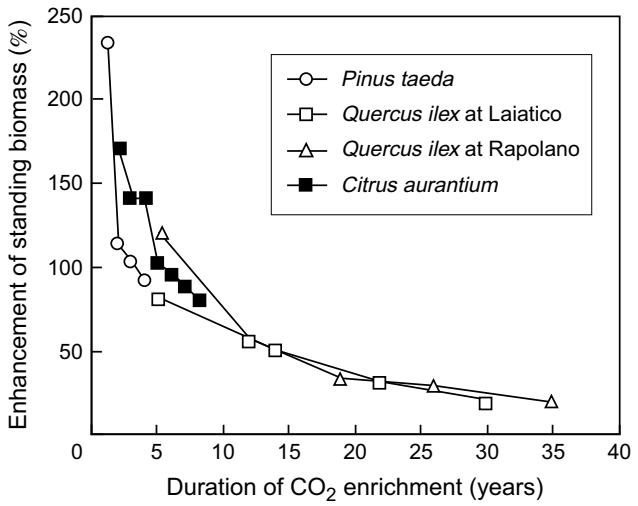

Figure 4 The percent enhancement of standing tree biomass produced by a sustained ca. 300 ppm increase in atmospheric CO_2 concentration for three tree species versus the duration of exposure (Idso, 1999 and references therein)

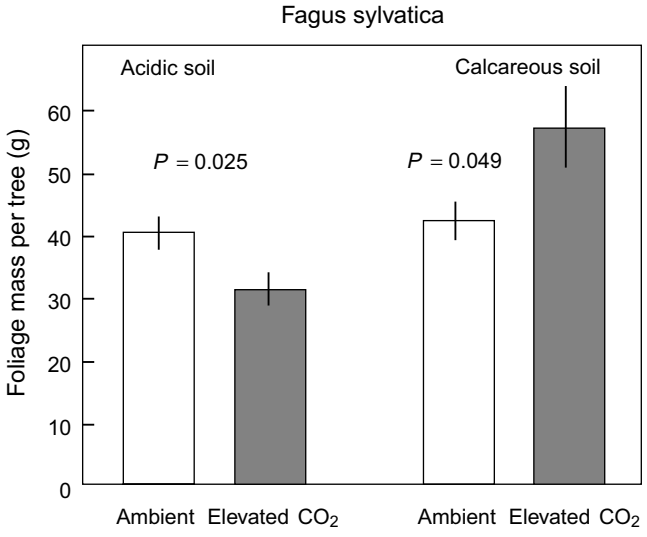

Figure 5 European beech, grown in 600 instead of 360 ppm CO_2 on forest soil in a mixed model community with spruce and understorey plants, either gains or losses in elevated CO_2 in terms of leaf production, when tested on calcareous or on acidic soil (after Egli *et al.*, in Körner, 2000)

clover which live in symbiosis with N_2-fixing bacteria. N_2 fixation is a costly process and can be expected to profit from CO_2 enrichment. This is indeed the case, but only under conditions of adequate phosphate availability, not a situation very common in nature.

All reports on responses of plants and vegetation to atmospheric CO_2 enrichment must be viewed with these four key criteria in mind.

GROWTH AND PRIMARY PRODUCTION

Given that most of the experimental data available today are for a step change of CO_2 (doubling) and for growth conditions under which CO_2 may indeed be *the* limiting resource (e.g., isolated, young, well fertilized plants), it is very difficult to estimate how natural vegetation might respond to the gradual enhancement of CO_2 over the long run. There is no safe way to distill such projections from statistical treatments of published data, because these would always reflect the frequency distribution of experimental conditions, despite attempts to categorize them. Mathematical models are limited to the extent that their parameterization depends on experimental data, and those which start from physiological first principles are likely to come up with overestimates of carbon binding. Approaches assuming stoichiometric proportionality, i.e., the need for certain amounts of nitrogen (N) and phosphate (P) for the biological fixation of one unit of carbon, are more promising, but the central question, whether soils will release the needed amounts of nitrogen and phosphate, and the consequences of atmospheric nitrogen deposition for the carbon cycle, as discussed by Nadelhoffer *et al.* (1999), are still controversial (error terms as big as the current missing carbon of ca. 1.5 Gt C year^{-1}). The nitrogen cycle (and often linked to it, the phosphate cycle) is most likely driving both, the terrestrial as well as the oceanic biotic carbon cycle (for oceans see Falkowski *et al.*, 1998).

A reasonable estimate of the long-term upper limit of CO_2 responsiveness of seasonal biomass production based on a handful of field data obtained under as natural as possible experimental growth conditions may be a 5–15% enhancement, by the time that atmospheric CO_2 concentration will have doubled (second half of 21st century), compared with pre-industrial concentrations. As mentioned above, such seasonal growth stimulations must not be confused with the size of carbon stocks, which also depend on concurrent or follow-up biomass breakdown, mortality and disturbance. In woody plants, such seasonal gains can accumulate and may accelerate forest turnover. If such carbon gains would translate into greater soil humus stocks, the transfer of biomass carbon (C/N ratio 40–80) into humus carbon (C/N ratio 10–20) would almost quadruple nitrogen demand – an unlikely sustainable and unwanted effect, given that it would reduce nutrient availability for plant growth. Due to these constraints, long-term net carbon binding (net ecosystem productivity, NEP) is unlikely to be of the magnitude to keep the global carbon budget in balance (ca. 4–5 Gt C year^{-1}, in addition to the current amount). Currently a biospheric net carbon fixation of around 1.5 Gt C year^{-1} is assumed, a number not derived from biological carbon accounting, but obtained by default from comparing anthropogenic carbon release data with the atmospheric and dissolved surface ocean pools. Carbon release by forest destruction, losses of carbon from soil humus due to intense agriculture or by erosion and carbon release from polar carbon stocks because of the current thawing of the permafrost in arctic ecosystems, all together are likely to balance or exceed CO_2-induced carbon binding (CO_2 fertilization) on a global scale.

Other, more indirect effects of atmospheric CO_2 enrichment on ecosystems, seem to be at least as, if not more influential, than CO_2-induced carbon binding as such. Three of such interactions are of particular interest:

- CO_2 enrichment and water;
- CO_2 enrichment and plant quality;
- CO_2 enrichment and biodiversity.

CO_2 AND WATER RELATIONS

Because plants tend to optimize the CO_2 uptake/water vapor-loss ratio by stomatal adjustments, higher concentrations of CO_2 around a leaf commonly cause a reduction of the stomatal pore width (a reduction of stomatal diffusive conductance). In cases where this happens, this has a multitude of consequences: At given ambient air humidity, leaf transpiration will be reduced. This in turn will cause leaf temperature to slightly increase (reduced evaporative cooling). Reduced transpiration will also cause less humidification of surrounding air which, together with leaf warming, will steepen the leaf–air vapor gradient, which will reduce the net CO_2 effect on transpiration, and make it hard to predict. The effect is further dampened by aerodynamic constraints to gas diffusion, which are not influenced by stomata, but are resistors in series with the stomatal one. The few field data on evapotranspiration of grassland under >500 ppm CO_2 suggest an instantaneous net reduction of only a few percent. However, such small but continuous water savings may accumulate into significant changes of the hydrological balance: during rainless periods, soil water will be less rapidly depleted, drought will be delayed and nutrient availability will be enhanced. In contrast, during more humid periods, runoff and nutrient losses will be enhanced, because soils will remain near full moisture storage capacity for longer periods of time. Several years of experimental field trials indicate that these indirect, moisture-driven effects of CO_2 enrichment are likely to be more significant for growth than direct CO_2 effects (Figure 6). This also explains the puzzling observation that growth of C4-plants is stimulated by CO_2 enrichment (not to be expected from Figure 3). Just like C3 plants, they profit primarily from a moister rhizosphere as a result of stomatal responses to CO_2. Stomatal responses to elevated CO_2 were found to be species specific, hence savings by one species may also be beneficial to neighboring species,

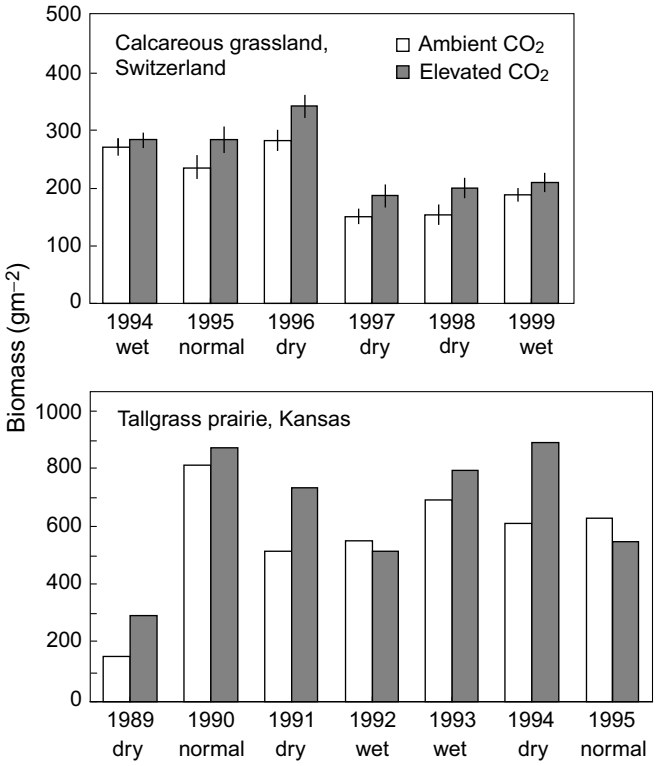

Figure 6 Due to CO_2-driven soil moisture savings, CO_2 effects on biomass production are commonly more pronounced in dry seasons as compared with very wet seasons (examples from Kansas, Owensby *et al.*, 1997, and from Switzerland by P Niklaus and Ch Körner, unpublished)

inducing changes in community structure in favor of water wasters.

While stomata of tree seedlings have often been found to be similarly responsive to CO_2 as are herbaceous plants, the evidence for adult trees is not unequivocal. To date it seems safest to conclude that stomatal responses in tall trees are much smaller – in a number of cases the response was close to zero. This difference between low stature plants in dense herbaceous canopies as compared with tall trees may be associated with better aerodynamic coupling of the latter (smaller boundary-layer resistance to gas diffusion, causing small changes in stomatal aperture to become more effective).

In summary, water relations will be affected, but possibly less in forests than grasslands, and instantaneous responses to evapotranspiration, if they occur, will be very small ($<10\%$). Whether they will become important, is a question of the duration of rainless periods (cumulative effects). The great unknown is whether atmospheric feedback at larger scales or a changing climate will diminish or enhance these effects. Overall, semi-arid regions are likely to profit (more biomass per unit land area) and very humid regions will be unaffected or may suffer (enhanced runoff and flood risk).

CO_2 AND PLANT TISSUE QUALITY

Irrespective of any growth response, plant exposure to elevated CO_2 alters tissue composition. Leaves have almost always been found to contain less protein and more mobile carbohydrates when exposed to higher CO_2 concentrations. The result is a wider C/N ratio, with a multitude of ecosystem consequences (Cotrufo *et al.*, 1998). The increase of the concentration of total non-structural carbohydrates (TNC) e.g., starch, sugars) is an immediate response (new steady state within a few days), and persists over very long times, as has been documented for plants from natural CO_2 springs. The response appears to be largely independent of sink activity, vigor of growth, nutrient supply, size or age of plant and occurs even in deep shade and in the canopy of tall forests, hence it seems to represent a direct response to ambient CO_2 concentration (references in Körner, 2000). Reduced leaf nitrogen concentration often does not go beyond a dilution effect by enhanced TNC on a dry weight basis, but if it does, it is associated with either partial photosynthetic downward adjustment (less demand) or reduced nitrogen availability in the root environment (less supply). CO_2 enrichment appears to stimulate carbon export by roots, which in turn causes microbial and fungal competition for nitrogen in the soil to increase (e.g., Diaz *et al.*, 1993). Nitrogen concentrations in CO_2-enriched leaves also depend on phosphate availability. Secondary metabolites are affected as well, with phenolics most commonly becoming enhanced (e.g., Poorter *et al.*, 1997).

The most immediate consequence of reduced leaf tissue quality is that on herbivores, which (1) may either consume more (compensatory feeding), (2) consume less and suffer, or (3) switch food plants, unless they are host specific (e.g., Lindroth in Körner and Bazzaz, 1996). Litter quality is commonly not (or less) affected (Norby *et al.*, 1999). A most important but hardly studied question is the effect of elevated CO_2 on wood quality. It seems CO_2 enrichment enhances wood density (cf. Körner, 2000), but the mechanical consequences are still unclear (greater/less risk of wind break?). Seed nitrogen concentration, including that of cereals, is also reduced under elevated CO_2. Among all CO_2 responses, the responses of tissues appear to be the most consistent, and are surprisingly robust for a variety of experimental conditions. The prediction that a CO_2 rich world will be inhabited by plants with tissues richer in carbon seems well founded.

CO_2 AND BIODIVERSITY

For every single type of response to elevated CO_2 discussed above, different plant species were found to differ, which

suggests that CO_2 enrichment will affect species abundance and the composition of plant communities (Körner and Bazzaz, 1996). When all available data are considered, conventional functional types of plants do not appear to exhibit common responsiveness, perhaps with the exception that legumes grown in phosphate-saturated substrates are more responsive and C4 plants in very moist substrates are less responsive than other plants (both very artificial situations). Within herbaceous, non-nutrient limited plants growing in isolation and unlimited moisture, C3 species with a high relative growth rate (RGR), were found to be more responsive to CO_2 enrichment, than low RGR-species, but no systematic difference was found between either monocotyledonous and dicotyledonous species or wild versus crop species (Körner and Bazzaz, 1996). Neither do seedlings or saplings of woody plants respond significantly differently from herbaceous species, nor do evergreen differ from deciduous ones in a systematic way. However, within each of these groups highly responsive and hardly responsive species occur, but whether a species is responsive is often codetermined by the genotype, nutrient regime, light regime or neighboring species. The micro-habitat's light regime is a critical determinant of the ranking of CO_2 responsiveness among tree species (Figure 7).

Mycorrhization is mostly stimulated by elevated CO_2 and may codetermine CO_2 responsiveness of species (references in Staddon and Fitter, 1998). More carbon is commonly allocated to soil fungi than to soil bacteria (e.g., Rillig *et al.*, 1999). There is sporadic evidence that growth of non mycorrhizal species is particularly responsive. For instance, several laboratories independently found that *Carex flacca*, a non-mycorrhizal slow growing sedge, out-ranged the growth responsiveness of any other (mycorrhizal) calcareous grassland species tested (references in Körner, 2000).

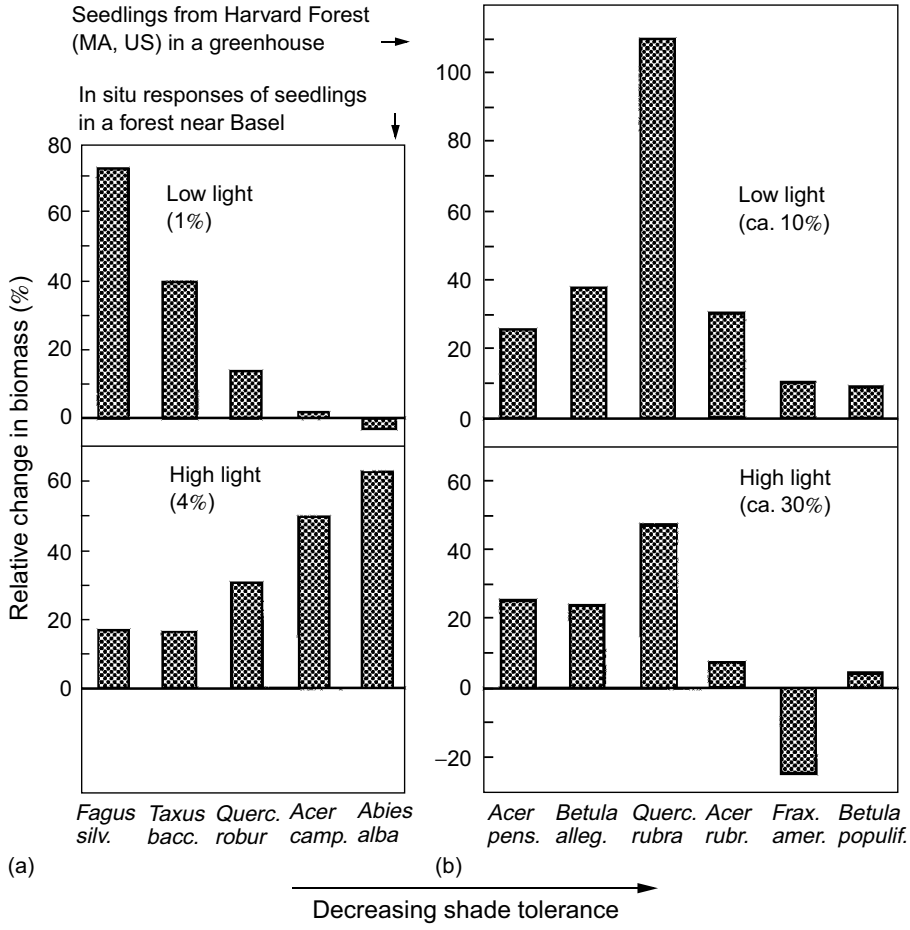

Figure 7 Different plant species respond very differently to atmospheric CO_2 enrichment, but how they respond depends on the concurrent availability of other resources. In the example (a), the availability of either 1 or 4% of full sunlight in the understory of a dense deciduous forest in Switzerland reversed the responsiveness ranking among seedlings of native tree species. Also greenhouse tests (b) document such species and light dependent CO_2 effects. The speci c responses of such species will codetermine future forest species composition (Bazzaz and Miao, 1993; Hättenschwiler and Körner, 2000)

THE FUTURE BIOSPHERE AND THE GLOBAL CARBON BALANCE

Carbon Stocking

As CO_2 rises, the biosphere will be affected in one way or another. However, by far the most significant influence on the globe's biota carbon stock is and will remain human land use. Unless current trends change fundamentally, land use will determine biological carbon pools and biodiversity to such an extent that other influences such as those of elevated CO_2 will remain marginal. The biological impact of elevated CO_2, as presented here, needs to be seen in this larger context, and – apart from controlling emissions – efforts clearly need to be prioritized on achieving sustainable land use and the preservation of a large terrestrial carbon pool. Several authors have recently modified earlier simplistic predictions of a greening earth in view of the past and current trends in atmospheric CO_2 enrichment (Schimel, 1995; Joos *et al.*, 1999). In the face of the magnitude of the land use problem, society should not expect a significant mitigation of atmospheric CO_2 enrichment through CO_2-enhanced biospheric carbon binding. Given that part of the current missing carbon of ca. 1.5 Gt C year^{-1} is explained by recent temperate zone forest re-growth, the pure global carbon fertilization component of this (if there is one) is most likely less than 1 Gt C year^{-1} for the recent dramatic 30% increase of CO_2 concentration above pre-industrial concentrations.

There are only three, quantitatively significant ways for dampening the rate of current atmospheric CO_2 increase through bio-management: (1) a halt to the destruction of carbon-rich pristine forests as well as humus-rich soils, (2) an extension of forests and, within agricultural land, those areas of low energy input agriculture, and (3) the sustainable use of forest- and agro-products in replacement of fossil carbon sources (cf. Marland and Schlamadinger, 1997). Models suggest an upper limit (!) of a CO_2-induced stimulation of carbon binding in biota by the time atmospheric CO_2 concentrations will have doubled (compared with the pre-industrial level) of around 3 Gt year^{-1} or 30 g C m^{-2} a^{-1} on 100 million km^2 of vegetation-covered land, with a mean 15 kg C m^{-2} background value in humus carbon. The total accumulative carbon binding by this time may have reached ca. 200 Gt, not accounting for any effects of land use (ref. in Körner, 2000). By that time humans will have released nearly 1000 Gt of fossil carbon. This upper limit of carbon binding would only be reached if proportional nitrogen and phosphate supplies for the formation of additional biomass and humus became available (this may be so in some polluted, industrialized areas). The narrow C/N ratio of humus will unlikely be converted into a larger biomass carbon pool by way of its wider C/N ratio, as was one of the now revised earlier presumptions (stoichiometric constraints, Nadelhoffer *et al.*, 1999). Hence, the actual CO_2-induced carbon binding will be less than this upper limit (<20% of emissions), and is likely to trap only a small fraction of fossil and land use derived atmospheric carbon. As was explained above, growth stimulation as revealed by experimental CO_2 enrichment, must not be confused with a net landscape carbon stocking effect (IGBP Terrestrial Carbon Working Group, 1998). The biological carbon binding of the ocean, which, in the very long run (many thousands to millions of years), ensures a steady atmospheric oxygen concentration, is estimated to amount to ca. 0.1 Gt C year^{-1} (Reeburgh, 1997), an irrelevant carbon sink with respect to enhanced carbon binding in the light of current global carbon emission rates of ca. 7 Gt C year^{-1} over the periods relevant to society.

CO_2 and the Biodiversity Crisis

Instead of expecting substantial carbon fertilization effects on biospheric carbon stocking, society, scientists and their funding agencies should be concerned about the differential consequences of the rapid dietary change imposed on organisms and their communities via increased CO_2 concentrations. Subtle species-specific responses and effects on organismic interactions represent a substantial biodiversity risk on top of that caused by land use pressure. The rapidity of CO_2 enrichment (Figure 1) leaves little leeway, if any, for evolutionary adjustment, and affects ecosystems at great distance from the prime sources of fossil CO_2. Biodiversity consequences of CO_2 enrichment operate via differential interactions with species' water and nutrient relations, plant–plant, plant–animal, plant–microbe and plant–fungus interactions as was discussed above.

Elevated CO_2 contributes to the biodiversity crises in a slow, invisible manner. It is one of the prime needs of global change science to visualize such possible effects. Many researchers have demonstrated that plants and their microbial symbionts as well as dependent animals respond to CO_2 enrichment in unpredictable ways. Responses depend so much on experimental conditions (Figure 7) and biotic interactions that field-oriented work in non-agro systems should be given a high priority. This sort of ecosystem research is most often more demanding, more expensive and takes much longer to arrive at a conclusive picture, than the study of standardized and simple test systems on disturbed substrates, which have their own place in agro-research (Rosenzweig and Hillel, 1998). This is the price that must be paid to achieve credible answers about the biological consequences of the ever rising CO_2 concentrations. The greatest current limitation of predictions is the unknown response of diverse natural forests, which form the single largest biomass carbon pool and represent a large, if not the largest fraction of global species diversity.

Community Richness

Paul H Harvey

University of Oxford, Oxford, UK

If species are accepted as equivalent and independent entities, then there are two intuitive components of biodiversity at a site: species richness and species evenness. Species richness is a measure of how many species there are, and species evenness measures the relative abundance of different species. If species evenness is low, in the extreme a single species predominates and the site is effectively a monoculture. If species evenness is high, in the extreme all species are equally abundant. There are an infinite number of measures of biodiversity based on species richness and evenness, depending, for example, on the relative weights given to each of the two components.

HOTSPOTS AND COLDSPOTS OF SPECIES RICHNESS

Accepting for the moment that richness is simply a measure of the number of species at a site, a reasonable question to ask is what determines that value? In other words, why are some sites richer in species than others? As scientists, we

should hope to produce generalizations, so that the answer to the question for one taxon would be framed in a way that would apply to other taxa.

A landmark study by Prendergast *et al.* (1993) asked if locations in Britain that are species rich for one taxon are also species rich for other taxa? Butterflies, dragonflies, liverworts, aquatic (angiosperm) plants, and breeding birds were used as representative taxa, and the representative scale was a grid of 10×10 km squares superimposed over the British mainland. Despite the fact that "the fine scale and high intensity of recording in Britain produces distributional data sets that are at least as good as ... those available elsewhere", hotspots (species rich grid squares) and coldspots (grid squares with few species) for different taxa did not coincide. Furthermore, from the perspective of conservation biology, grid squares containing rare species, which might be focussed upon for conservation efforts, did not coincide with hotspots or coldspots.

The failure to generalize species richness from one taxon to those of another was emphasized in a study of endangered animal and plant taxa occurring in the various counties of the United States of America (and therefore including Hawaii). The aim of Dobson's *et al.* (1997) analysis was to determine whether hotspots for endangered species coincide across taxa, and to help identify those areas in need of conservation resources. Using a complementarity algorithm, they first identified the county with most endangered species, then the county with the most endangered species that are not included in the first county, and so on. Most endangered species occur in Hawaii, Southern California, the southeastern coastal states and Southern Appalachia. Their complementarity algorithm also selected counties in those same regions. Overall, between 1 and 5% of total land area delimited those counties, which were required to sample more than 50% of endangered species for particular taxa. However, the counties identified for one taxon were not necessarily those identified for other taxa. For example, they applied the complementarity algorithm to birds to identify the minimum number of counties required to locate all endangered species. That area contained only 30 to 40% of endangered reptiles, amphibians, mammal and plant species, 10% of arthropods and fish, and 2% of molluscs.

Would it, then, be possible to find a taxon that is a much better predictor than birds of the presence of endangered species from other taxa? At first sight the answer appears to be plants. By identifying the minimum area required to conserve all plant species, we would also be conserving 94% of birds, and between 39 and 76% of species in other taxa. The downside to this is that the area containing all the plants is almost 10% of the area of the United States, whereas that for birds is less than 2%.

DETERMINANTS OF SPECIES RICHNESS

The fact that patterns in species richness do not generally coincide across taxa is a disappointment for those seeking general patterns, but this should not detract from an extensive ecological literature, which reveals understanding of the reasons for patterns in species richness for particular taxa or communities. Ultimately, three factors seem to predominate: the number of available niches at a site, the capacity of species to invade those niches, and the time the niches have been available. The time dimension is problematical if species are viewed as independent immutable entities. Of course, when habitats and their component niches first appear, it will take time for species from the local or regional pool to invade. However, occupancy of some niches requires evolutionary adaptation by the new inhabitants, and ultimately speciation may ensue.

The Evolutionary Time Scale

Species richness viewed from an evolutionary rather than a purely ecological perspective provides an historical dimension that is necessary for a comprehensive understanding of the causes of spatial patterns in species richness. What is more, the evolutionary context reveals that all species are not necessarily equivalent. The further back that two species last shared a common ancestor, the more genetically divergent they will have become. If purely confined to phenotypes, the concept of richness does not properly include genetic variation. Closely related species may have diverged phenotypically but be very similar genetically and, alternatively, genetically divergent species may be phenotypically similar.

Vane-Wright *et al.* (1991) pointed out that, when choices have to be made concerning the allocation of limited resources to conservation, the preservation of representatives of two distantly related species would result in the retention of more genetic diversity than the preservation of two genetically similar species. If we assume that genetic divergence increases in a clock-like manner then, using the purely genetic criterion, maximizing the conservation of total branch length on an evolutionary tree will result in the conservation of the maximum amount of genetic diversity, or richness. How important is this message for conservation science? Of course, other things being equal, we should wish to maximize the amount of conserved genetic diversity. Nee and May (1997) tackled this question by simulating evolutionary or phylogenetic trees on a computer and then taking samples of species at random and comparing the amount of genetic diversity in the sample with that in a sample chosen on the criterion of maximizing conserved branch length. Their conclusion was that "80% of the underlying tree of life can survive even when approximately 95% of species are lost, and that algorithms that maximize the amount of evolutionary history preserved are

not much better than choosing the survivors at random". The reason for this is that trees are bushy with a preponderance of recent short branches, and fewer longer branches. It is those longer branches that need to be preserved. So long as one representative taxon from each main phylogenetic group is preserved, the longest branches in the tree of life are all represented and only the short branches have been pruned.

The capacity of species to invade niches depends in large part on the species' phenotypes. On occasion, so-called key innovations evolve which allow species to exploit hitherto unoccupied niches and adaptive radiations may result. Cichlid fishes provide a classic example. Liem (1973, 1980) realized that a small shift in the position of a muscle attachment allowed the pharyngeal bones of cichlids to manipulate their prey items while still holding them. The result was that the mandibular and premaxillary jaws were freed to evolve along new routes, which allowed cichlids to evolve a new diversity of feeding mechanisms. This, Liem argued, led to the adaptive radiations of cichlids in African lakes, despite competition from other fish families. That example is a *post hoc* explanation based on a single innovation. Such explanations are strengthened when the same key innovation is found in independently evolving taxa that have speciated at a higher rate than their close relatives that have not evolved the innovation. Such sister taxon comparisons automatically control for the many differences between sister lineages, because any particular innovation other than the one under test is less likely to be partitioned in the same way among sister taxa.

An example of a repeated key innovation that has resulted in many independent sister taxon comparisons, which reveal high species richness in the taxon with the innovation is provided by phytophagous insects. Half the world's insect species are phytophagous (i.e., they feed on vascular plants), but they are restricted to only nine of the 30 orders of insects. Southwood (1973) imagined that there were considerable barriers to an insect group evolving phytophagy: behavioral and morphological adaptations would be required: (i) to reduce the risk of desiccation; (ii) to remain attached to the host; and (iii) to deal with low nutrient food. Once those problems were overcome, Strong *et al.* (1984) suggested that the diversification of phytophages would be promoted by the great diversity of plants species and diverse plant parts as well as the absence of competitors. As a test of the idea that phytophagy promotes insect diversification, Mitter *et al.* (1988) were able to perform 13 sister taxon comparisons between the diversity of a phytophagous clade and its sister clade. Since sister clades originated at the same time, they have had identical times for diversification. In 11 of the 13 comparisons, there were more species in the phytophagous clade than in the sister group, and in each of those cases the difference was greater than twofold.

A second example of sister group comparisons being used to test ideas for the occurrence of differences in species richness goes back to Darwin. Darwin (1871) suggested that sexual selection by female choice might increase the rate of reproductive divergence between populations and thereby increase the speciation rate. Barraclough *et al.* (1995) tested this idea using passerine birds as a case study. It is generally accepted that mate choice is responsible for the evolution of sexual dichromatism (i.e., where the sexes of a species differ in their plumage coloration) in passerine birds, and so Barraclough *et al.* (1995) used dichromatism as an indirect measure of the importance of mate choice for a species. Passerine species were scored as dichromatic or not. On significantly more than 50% of occasions, the clade with a higher proportion of sexually dichromatic species was more speciose than its sister taxon, thereby supporting the idea that mate choice can increase speciation rate.

The demonstration that, coincident with the occurrence of the same character in different evolutionary lineages, we find increases in speciation rate and thereby high contemporary species richness poses the question: how predictable is evolution? If, by chance, a species invades a new location, to what extent is its evolutionary future predictable, particularly in terms of the number of descendent species it will give rise to? Work by Jonathan Losos on lizards in the Caribbean has tackled that question. There are about 150 species of Anolis lizards in the Caribbean, but only six ecomorphs: phenotypically similar species adapted to particular ecological niches. The ecomorphs are mainly described by the habitats which they exploit: twig, crown-giant, trunk-crown, trunk, trunk-ground, grass-bush. Morphological and ecological comparisons show that the ecomorphs are a valid classificatory tool because they tend to form clusters in multidimensional space when data are summarized by principal component analysis. However, the same ecomorphs have often evolved independently by parallel or convergent evolution, so that different ecomorphs from the same island may be more closely related to each other than the same ecomorph from different islands.

Evolutionary trees for the two independent radiations on Puerto Rico and Jamaica are reasonably well established. When Losos mapped ecomorphs on to phylogenetic tree structure, the two islands revealed very similar pictures (Losos, 1992). The first speciation event resulted in a generalist arboreal lizard and a twig species. The generalist then produced daughter species, a crown-giant and a trunk-ground ecomorph. The trunk-crown ecomorph was the next to evolve (on Puerto Rico this evolved from the trunk-ground species and on Jamaica it evolved from the crown species). The evolution of the trunk-crown species, on both islands, was followed by speciation into a larger and a smaller trunk-crown species. Finally, on Puerto Rico but not on Jamaica, the trunk-ground form spawned a daughter species that lives on grass and bushes independently of

trees. A statistical test demonstrated that the chances of two such similar sequences occurring by chance alone is very small indeed. Instead, the patterns point to a common process at work which Losos interprets as niche partitioning (the tree) with the occasional invasion of new niches (such as the ground, grass and bushes).

The supposed role of niche partitioning in these adaptive radiations implies that interspecific competition may have been an important mechanism forcing species to occupy narrower niches, and the differences between the ecomorphs suggest that particular morphological and behavioral changes should occur over the generations when species invade new habitats.

The Ecological Time Scale

Many species do not need to evolve in order to invade available niches; they simply need to physically migrate. Humans, of course, have frequently changed the scale of such migrations by introducing exotic species to many habitats, sometimes with disastrous consequences including the competitive displacement or predation of the native species. Such extirpations lower global species richness, but generally also have the consequence of lowering species richness locally. Human interference apart, most migrations are local and we have already seen that, at such scales, locations of high diversity for different taxa tend not to coincide. Nevertheless, at a global scale there are very distinct trends in species richness which are repeated, albeit crudely, across taxa, and therefore call for general explanations.

The two most obvious global patterns are marine versus terrestrial differences in species richness, and latitudinal gradients in species richness. Astonishingly for such gross patterns, ecologists are divided over the reasons that the patterns exist. The sea covers much more of the global surface than the land, yet while twice as many phyla are represented in the sea than on land, fewer than 15% of species are found there; this latter result is not simply a result of under-sampling marine environments. May (1994) listed a variety of possible reasons for these differences. If life originated in marine habitats, then, other things being equal, one would expect to find more higher taxa there. May (1994) also suggested the possibility that the evolutionary perspective is likewise responsible for the lower species richness in the sea than on land because marine habitats are less heterogeneous and provide fewer niches for speciation. However, May also pointed to other factors that could be involved, including differences in herbivory and body size distributions between marine and terrestrial ecosystems. In short, we do not yet know the causes of these major differences in both higher taxon and species diversities between the two environments.

The second major and repeated general pattern is that of latitudinal richness gradients. At the extreme, there are many fewer species at the north and south poles than at the equator. This should not surprise us since primary productivity is virtually nil at the poles, and therefore viable plant and animal communities cannot exist there. We might, therefore, conclude that the underlying reason for latitudinal diversity gradients is a consequence of differences in primary productivity: the higher the productivity, the greater the species richness. As we move from polar through temperate to tropical environments, the length of the growing season increases, species richness in plant communities increases, and so therefore does the number of niches available to animal species. However, that level of general explanation is by no means generally accepted. In a review of the literature, Gaston and Williams (1996) quoted reasons for latitudinal gradients as including "the effects of competition, mutualism, patchiness, environmental stability, environmental predictability, productivity, area, number of habitats, ecological time, evolutionary time and solar energy!" Of course, many of those factors are not independent of each other but the depth of the confusion is characterized by quotations from Rohde (1992) that "greater species diversity is due to greater effective evolutionary time (evolutionary speed) in the tropics, probably as a result of shorter generation times, faster mutation rates and faster selection at greater temperatures." Rosenzweig (1992) states that "latitudinal gradients arise because the tropics cover more area than any other zone. Their greater area stimulates speciation and inhibits extinction." Of course, for any patterns there are exceptions, and the field of latitudinal diversity gradients is one where exceptions abound; and have probably been unduly focussed upon, thereby obfuscating the generalities (for example, among insects for mainly unknown reasons, aphids, sawflies and bees are either species poor or not unusually species rich in tropical habitats). There remains a need for good, clear-headed analyses of the massive available databases pertaining to latitudinal diversity gradients, not only to distinguish among alternative explanations, but also to evaluate the relative importance of each.

Given the overriding influence of latitude and its numerous climatic correlates, which frequently co-vary, other gradients have been sought which in various ways control for latitude. The most obvious is longitudinal diversity gradients, though Gaston and Williams (1996) also review altitudinal and depth gradients in species richness. In short, though repeated patterns exist, e.g., mid-altitudinal peaks in species richness among insects, explanations are generally found wanting. There is no doubt that high plant species diversity is generally associated with high animal species diversity, which begs the question of what environmental factors are responsible for high plant species diversity? Until we know the answer to that question, we shall not be

able to predict the ecological time frame changes in species richness that global change has in store for us.

Conservation Biology

Conservation biology is concerned with the preservation of the environment. Earlier, the main objective was to ensure that mankind would be able to enjoy the best possible lifestyle. However, it has become clear that the present enjoyment of the good life is not necessarily consistent with the long-term stability of the environmental circumstances that would foster human comfort. Economics and the desire of humans for an ever-improving lifestyle have severe environmental consequences, which, without intense study in many scientific disciplines, would lead to massive environmental breakdown.

Examples of the need for biological conservation study and action include all aspects of farming, dam construction for water conservation or power generation, the use of fossil fuels, soil conservation (particularly in relation to farming), urban expansion, the mining and lumber industries, transportation (roadways, exhaust wastes). Apart from the more obvious approaches suggested by these areas of concern, the use of indicator plants that are sensitive to or exceptionally tolerant of specific problems shows great promise for detecting and surveying ecosystems for signs of stress. Virtually all human activity impacts ecosystem stability, often negatively. The effective practice of conservation biology will hopefully mitigate some of the problems, both past and future.

Controlled Environment Facilities in Global Change Research

James F Reynolds
Duke University, Durham, NC, USA

Controlled environment facilities (CEFs) are experimental systems in which biotic and/or abiotic variables and factors

are controlled by the investigator. CEFs play a key role in experimental research on global change by providing researchers with tools to aid in disentangling the complexities of natural ecosystems. While direct observation of ecosystem responses in manipulative field experiments is an important approach to the study of global environmental change, the sheer number of environmental variables that simultaneously affect ecosystems poses serious constraints on such studies. To adequately test null hypotheses – and to successfully tease out a signal (effect) against a background of noise (random variation) – it is necessary to have adequate replication and control, something that is often impossible to do in nature. CEFs offer an alternative – but complementary – approach to study nature.

Typical CEFs for the study of terrestrial ecosystems range from the sophisticated complexes that house multiple plant growth chambers, such as the National Phytotron at Duke University, to the construction of model systems of terrestrial ecosystems, such as in the Ecotron (Figure 1). There are many advantages that make CEFs attractive. They can be used to reproduce different types of environments, ranging from the arctic to the desert to the tropics. Researchers are able to maintain precise control over environmental conditions (e.g., soil type, air temperature, light levels, carbon dioxide (CO_2) concentration, relative humidity, nutrients) and the organisms under study (e.g., mixtures of plant and animal species and their spatial arrangement). Hence, experiments can be designed to explore interactions among multiple stressors, e.g., temperature, carbon dioxide and air pollutants. This provides the opportunity to gain increased understanding of the complex interactions between plants and their environment. Such rigor and control are virtually impossible to achieve under natural field conditions. Other advantages of using CEFs include the ability to study without disturbing the organism, the ease of replication and manipulation, and relatively low research costs.

Limitations of CEFs include their small size and their biological and structural simplicity. No controlled environment experiment can, of course, represent the full complexity of nature. For example, the whole community experiments being conducted at the Ecotron cannot replace field observation and experiments. This is true of even the grandest attempt to date to bottle nature: the immense multi-ecosystem network in Biosphere 2 (Table 1), in which synthetic communities of rainforest, desert, savanna, marsh, ocean and agroforestry are encased in a glass and metal shell. Herein lies a paradox: it is the very complexity of the natural world, where experimental conditions are outside the control of the experimenter, which makes simple model systems so attractive. CEFs provide a model or analog of the real world, both biological and abiotic, which fills the gap between complex field ecosystems and the simplicity of laboratory or greenhouse experiments. CEFs

are not intended to mimic the full complexity of nature; rather, they provide models of ecological communities by including many but not all of the biological processes and interactions that occur in the field.

One benchmark of the ability of researchers to understand and predict the behavior of ecological systems is to build their own ecosystems and see if they work as expected. As Lawton (1996) argues, if we cannot understand these simpler communities, how can we expect to understand the full complexity of nature? Because of the diversity of questions and the different levels of biological organization

Table 1 Examples of terrestrial CEFs. Typical abiotic variables controlled include temperature, humidity, irradiance (intensity and quality), day length, gas concentrations (such as carbon dioxide and ozone), water, and nutrients

Facility	Brief description	Web address
Biosphere 2, Tucson, AZ, USA	Covers 1.27 hectares, with synthetic communities of rainforest, desert, savanna, marsh, ocean and agroforestry, all of which are encased in a glass and metal shell. Can be operated in a variety of con gurations including open and closed modes	http://www.bio2.edu/Research/res_entry.htm
Biotron, Swedish University of Agricultural Sciences, Alnarp, Sweden	Thirty- ve chambers, with either natural or arti cial irradiance. Developing a comprehensive experimental database to document performance of different plant species under various controlled conditions; goal is to identify and quantify internal and external factors that limit plant growth	http://www.biotron.slu.se/bio1.htm
Controlled Environment Facility, CSIRO, Brisbane, Australia	Specializes in the growth of tall (up to 8 m) tropical plants, such as sugarcane	http://www.tag.csiro.au/1d_CEF.htm
EcoCELLs, Frits Went Laboratory, Desert Research Institute, Reno, Nevada, USA	EcoCells are sunlit, tempered glass growth chambers (ca. 184 m^3) attached to soil lysimeter; system located inside outer glasshouse; enables studies of material exchange between soil, plants and atmosphere	http://www.maxey.dri.edu/BSC/GBERL/ecocell.html
Ecotron, Imperial College, Silwood Park, UK	Sixteen 5 m^3 replicate terrestrial ecosystems, or microcosms, sustaining up to 40 species of plants and animals (as well as soil microbial organisms) in four trophic (feeding) levels, interacting over several generations	http://forest.bio.ic.ac.uk/cpb/cpb/ecotron.html
Envirotron, University of Georgia, Grif n, Georgia, USA	Nine growth chambers (six 6.7 m^2 and three 3.3 m^2) and eight glasshouses; three movable sunlit chambers (4 m^2) to measure plant CO_2 uptake or loss and water loss	http://www.grif n.peachnet.edu/envirotron.html
National Phytotron at Duke University, Durham, NC, USA	Forty-eight plant growth chambers- over 450 m^2 of growth space (including eight 3.6 m tall chambers, each ca. 15 m^3) - and six CO_2 and temperature-controlled glasshouses (each ca. 200 m^3)	http://www.biology.duke.edu/phytotron/

involved in global change research, a suite of complementary CEFs and methodologies is needed (Table 1). Because of their unique advantages, the use of CEFs in global change research will increase dramatically in the future.

Coral Bleaching (1997-1998)

Barbara E Brown
University of Newcastle, Newcastle-upon-Tyne, UK

During 1997–1998, reports of coral bleaching from all the major tropical oceans suggested that this time period had seen the most geographically widespread bleaching ever recorded, with some areas (e.g., Singapore and the Andaman Islands) witnessing extensive bleaching for the first time in recent history. Coral bleaching has been documented in at least 32 countries and island nations in 1997–1998; with reports from sites in the Pacific, Indian Ocean, Red Sea, Persian Gulf, Mediterranean and Caribbean recording widespread bleaching (Hoegh-Guldberg, 1999). The bleaching response represents a paling of the coral such that it may become entirely white with the white skeleton being reflected through the transparent tissues above. The loss of coloration is due to the release of symbiotic algae and/or their pigments. The symbiotic algae are essential to the health of the coral in that they supply it with carbon (via photosynthesis), sunscreen protection and also accelerated calcification of the skeleton.

Paling of some coral species is an observed seasonal phenomenon in the Pacific, Indian Ocean, and also the Caribbean. Where bleaching is seasonal, or less severe, the likelihood of full recovery of pigmentation is high (Brown *et al.*, 1999). In the 1997–1998 bleaching episode, the response was exceptionally severe with a large number of corals turning completely white and subsequently dying.

Mass bleaching normally occurs when seasonally maximal sea surface temperatures (SST) are exceeded. The likely triggers of bleaching are elevated SST and solar radiation. Research has indicated that these factors act in combination, rather than alone. Additional causes of bleaching, such as extreme low tides and reduced salinities, were also implicated at some sites in 1998. Bleaching was recorded around the world also in 1983, 1987, and 1991 but generally these events were neither as extensive nor as severe as in 1997–1998.

The occurrence of bleaching at specific locations in 1997–1998 was patchy with more severe bleaching recorded in shallow waters than at deeper offshore sites, e.g., bleaching occurred extensively on the inner Great Barrier Reef, Australia but was minimal on the outer reefs (Berkelmans and Oliver, 1999). Not only hard and soft corals, but also sea anemones, zoanthids, giant clams, foraminifera and many other zooxanthellate invertebrates are affected by the loss of their symbiotic algae. Corals can recover from bleaching but death may result if environmental stressors are extreme and/or prolonged. In the Indo-Pacific, fast-growing, branching corals are more susceptible to bleaching than slow-growing boulder corals, leading to a high mortality rate in the former. Recovery of boulder corals was frequently recorded in 1998, often within 1–2 months of initial bleaching. In the Caribbean, however, greater bleaching-related mortality occurred in boulder and plate-like corals than in branching species, which had already suffered extensive mortality from storms, diseases and terrestrial run-off. In the Indo-Pacific, the susceptibility of different corals to bleaching can significantly affect coral community structure and diversity, depress the rate at which the reef builds up, and reduce habitat availability for other reef species. Previous cases of bleaching-induced mortality from 1983 in the Pulau Seribu (Java Sea) and from 1995 in the Similan Islands (eastern Indian Ocean) have provided examples of community change (Brown, 1997). At both sites, shallow parts of the reef were temporarily transformed from being a mixture of branching and boulder corals to areas in which virtually only the boulder corals survived. During the 1998 bleaching, one reef on the Australian Great Barrier Reef was so severely affected that even many of the robust boulder corals (one of them dated as over 700 years of age) were badly damaged or died. Complete

recovery of reefs following severe bleaching is dependent on growth and fragmentation of remaining corals, and on recruitment from stocks in the area. Evidence shows that restoration of the reef to its former state may be slow or, if interrupted by man-made change, may even be halted altogether.

Links have been made between the widespread incidence of coral bleaching in 1997–1998 with one of the strongest El Niños of the 20th century (Stone *et al.*, 1999). While past and present coral bleaching events in many parts of the Pacific appear to be closely matched to El Niño–induced seawater warming, the connections are not clear-cut for all locations in the Pacific. Nor can bleaching in Indian and Atlantic waters be directly linked to only El Niño phenomena. Factors responsible for elevated SSTs in the Indian Ocean, e.g., are likely to be the result of a complex product of El Niño-related, monsoonal and local oceanographic factors which are superimposed on interdecadal patterns in climate variability.

Links between the apparent changing nature and frequency of the El Niño phenomena and global climate change have also been made but are the subject of controversy among climatologists with many suggesting that present patterns reflect the natural variability of the system rather than the effects of greenhouse gas-induced warming. Concerns about the potential effect of global change on future frequencies of severe bleaching events are based on the narrow upper margin of environmental tolerance in corals. While corals display impressive acclimation processes to changes in some environmental parameters, it is not known whether they are able to adapt or acclimatize at rates which match the projected rates of background seawater temperature increase.

The 1997–1998 episode of worldwide bleaching is a major cause for concern. Extensive mortality of corals (80–90%) has been recorded on shallow water reefs throughout the Indian Ocean and although there are signs of recruitment of juvenile corals on some of these reefs, the key question is how frequent and severe will bleaching events be during the next decade? Seawater temperature is rising significantly in parts of the Pacific and Indian Oceans, and also in the Caribbean at a rate of at least 0.13 °C per decade (as measured over the last 50 years). If seawater temperatures were to continue to rise, either as a result of greenhouse gas emissions or natural variability in the ocean/atmosphere system, then we might expect the incidence and severity of coral bleaching to increase yet further with the possibility of substantial changes to the coral reef community structure. It is anticipated that shallow reef flats should be able to keep up with projected sea-level rise over the next few decades but the increased incidence of bleaching may compromise this ability by reducing coral growth rates. The future for corals in a warming world is bleak, with many presently luxuriant coral reefs being transformed into substrates covered by algae (*see* **Coral Reefs: an Ecosystem Subject to Multiple Environmental Threats**, Volume 2).

Coral Reefs: an Ecosystem Subject to Multiple Environmental Threats

Jean-Pierre Gattuso[1] and
Robert W Buddemeier[2]

[1]*Laboratoire d'Océanographie de Villefranche, Villefranche-sur-mer, France*
[2]*Kansas Geological Survey, Lawrence, KS, USA*

Although coral reefs may seem exotic to many residents of inland or temperate regions, the ecosystem plays a major role in the environment and economies of many areas. Where reef communities exist, they often play major roles in both defining the environment and providing resources upon which humans depend, both consciously and implicitly (Wilkinson and Buddemeier, 1994). Many developing country populations inhabit the same tropical and subtropical coastal zones that are home to most of the world's reefs. The demise or deterioration of reef communities would therefore have profound social, political, and economic implications for the world, as demonstrated by acute episodes of reef degradation (Wilkinson et al.*, 1999). Costanza* et al. *(1997) have attempted to estimate the economic value of ecosystems and their services; on a global basis, they developed an average value of US$375 $\times$ 10^9 per year for coral reefs*

(out of a total coastal zone value of US$12 568 $\times 10^9$ per year). Although their approach to valuation is not universally accepted, the magnitude of the estimate places reef values in an economic context.

Large-scale and increasingly well documented degradation and die-off of reef ecosystems or key reef organisms has brought them into focus as a prime example of complex ecosystem responses to various combinations of a wide range of environmental stresses. Local destruction can be easily recognized and understood, and the negative effects of some aspects of global change (such as ocean warming and rising carbon dioxide levels) can be either recognized or confidently predicted. However, there remain important symptoms of ecosystem decline, such as the die-off of Acropora in the Caribbean, and the increased frequency and virulence of disease outbreaks, that cannot be directly attributed to a single factor. The situation thus challenges both scientific understanding of the environmental controls on the ecosystem, and management of those factors that we do understand.

The importance of coral reef ecosystems and their responses to environmental change goes beyond the immediate and obvious issues such as coastal protection, tourism, and fisheries. It is widely recognized that reef and related communities are one of the largest storehouses of marine biodiversity, with untapped resources of genetic and biochemical materials, and of scientific knowledge. Further, the living reef communities are not isolated dots on a map, but part of an interacting mosaic of oceanic and terrestrial habitats and communities, and many reef organisms and processes are important in a much wider sphere of related environments. In many important ways, the condition and responses of coral reef communities can be seen as diagnostic of the condition of the world's low-latitude coastal oceans; a truly global signal.

INTRODUCTION

Coral reef ecosystems occur in shallow waters of the tropics and subtropics. They span approximately 600 000 km^2 of coastline of 115 countries or island states. Coral reefs are characterized by a thin veneer of organisms living on top of massive calcium carbonate structures deposited by their predecessors: scleractinian corals living symbiotically with intracellular microscopic unicellular algae (dinoflagellates), coralline algae, and mollusks, among others. Coral reefs are very diverse ecosystems: 93 000 species have been described, which may represent as little as 10% of the total number of reef species (Reaka-Kudla, 1997).

Approximately 350 million people live in areas with a large component of coral reefs, and 450 million within 60 km of a coral reef (Wilkinson, 1996). Coral reefs play a major role in local communities. Their integrated economic and social value, estimated from recent legal actions, ranges from US$1800–2800 m^{-2} (reviewed by Birkeland, 1997), comparable to the flow value of US$6075 ha^{-1} year^{-1} estimated by Costanza *et al.* (1997). They protect the coastline from wave action, and have traditionally provided building material and food resources. Coral reef fisheries presently account for more than 10% of the world fisheries catch. The aesthetic value of reefs and surrounding areas has led to a recent surge in tourism, of considerable economic significance. The tourism industry of the Great Barrier Reef generates US$505 million per year and the contribution to gross national products is proportionally much greater in developing than in developed countries.

Coral reefs provide a most ingenious paradox: they are geologically robust ecosystems built by organisms that appear biologically fragile (Buddemeier and Smith, 1999). Reef structures dominated by scleractinian corals first occurred 200 million years ago and have continued to reoccur episodically since then despite extreme changes of global environmental conditions. During the last glacial–interglacial cycle, tropical sea surface temperature (SST) exhibited changes of 3–6 °C, and sea level changed by more than 120 m due to melting and accumulation of glaciers and ice sheets. Cycles of such changes over geologic time have induced periods of apparent extinction in the geological record, but coral reefs have remained recurrent features in tropical coastal areas.

In spite of their evolutionary survival, there is accumulating evidence that reef organisms are increasingly subject to stresses at the local, regional and global scales. It has been claimed that up to 70% of the world's reef could be lost in four decades (Wilkinson, 1992). One prominent example of stress is the increased frequency of mass *coral- bleaching* events (loss of endosymbionts and/or photodestruction of algal pigments) since the early 1980s. Bleaching is a stress response that does not necessarily lead to mortality. In less severe events, corals often recover their algal population and normal pigment concentration while several severe bleaching events of the last two decades have resulted in considerable mortality. Another disturbing and poorly understood feature of the recent decline in reefs and corals has been the increased frequency, virulence, and variety of lethal epizootic episodes among reef corals (Harvell *et al.*, 1999). Within the past decade there has been a sharp rise in reports of diseases caused by bacterial, fungal, and/or viral agents, especially in the Caribbean and Florida. The large-scale coral loss and community shifts associated with these diseases seem to be unprecedented in Holocene and Late Pleistocene time (e.g., Aronson *et al.*, 1998). Introduction of new pathogens into the marine environment, alteration of environmental conditions that favors the propagation of existing disease-producing agents, and the general debilitation of coral health that makes coral more vulnerable to infection all appear to play a role in this phenomenon. Although the relative importance of these factors is not yet

known, the extent and novelty of the epizootic phenomenon clearly implicates significant environmental change at the regional or global scale, and offers little basis to expect that conditions will improve.

Coral reefs are sites of very active metabolic processes. The average gross primary production of the shallow water communities inhabiting the reef flats is 247 mol carbon m^{-2} $year^{-1}$ (Gattuso *et al.*, 1998b). This very high rate often gives the false perception that reefs are highly productive ecosystems. However, the average rate of respiration is only a few percent lower, so net community production is only slightly above zero, which is similar to the oligotrophic ocean waters that surround most reefs (Crossland *et al.*, 1991). Reef communities exhibit the largest average rate of net calcification of all marine ecosystems, with areas of moderate to high coral–algal cover depositing 4–10 kg $CaCO_3$ m^{-2} $year^{-1}$. The major feature of whole-reef ecosystems (which include lagoons and surrounding slopes) is high gross and low net organic carbon production, with high gross and net calcification. Such metabolic features make coral reefs small sources of carbon dioxide to the atmosphere (Gattuso *et al.*, 1999b) and place limits on sustainable fisheries harvests.

The structure, function, and geographic distribution of coral reef communities are controlled, to varying degrees, by temperature, carbon dioxide partial pressure, light, salinity and nutrient concentration (Kleypas *et al.*, 1999b), as well as by a range of natural and human disturbances (Table 1). This paper examines the present and future response of coral reefs to changes of global-scale (temperature, pCO_2, sea level and ultraviolet radiation, UVR) as well as to environmental changes of regional or local significance (e.g., nutrients and human use). Further information, as well as references not specifically attributed in this article, can be found in Smith (1992) and Wood (1998) as well as in the following special issues: *Global Change Biology* (Vol. 2(6); 1996) and *American Zoologist* (Vol. 39(1); 1999).

GLOBAL CHANGES

Temperature

At present, reefs are most widespread and abundant in areas subject to weekly minimum and maximum temperatures of, respectively, 18–31.5 °C, but high and low temperature reefs extend to regions with weekly extreme values ranging from 16.0–34.4 °C (Kleypas *et al.*, 1999b). The reefs experiencing the largest range of temperatures are located in the Northern Persian/Arab Gulf. When average annual temperatures are considered, the high and low temperature environments for coral reefs are approximately delineated by the 29 and 18 °C isotherms, respectively (Figure 1).

Sea surface temperature (SST) is expected to rise 1–3 °C over the coming century, with a non-uniform distribution of increases (Pittock, 1999). The rate of increase will probably be somewhat greater than the warming trend of the past several decades, which has culminated in widespread temperature stress that leads to disruption of the coral–algal symbiosis, termed bleaching.

The term *bleaching* is commonly applied to the loss of some or all of a coral colony's algal symbionts or algal pigments (Glynn, 1996). Although it occurs to some degree in healthy corals in natural settings, it is also a general stress response that can result in mortality. Bleaching is a complex phenomenon that depends on the microenvironment and taxonomy of the zooxanthellae as well as on the taxon and the external environment of the host coral. This phenomenon has been suggested as an adaptive and acclimative mechanism in nature (Buddemeier and Fautin, 1993), but there are clearly limits to this potential, and any role in the recent cycle of bleaching events remains undemonstrated (Hoegh-Guldberg, 1999).

The number of reports of extensive and damaging bleaching events has been increasing since the early 1980s, when a shift in the El Niño Southern Oscillation (ENSO) pattern (*see* **El Niño and La Niña: Causes and Global Consequences**, Volume 1) resulted in greatly increased interannual SST variability in many parts of the world. Many of the most widespread and severe episodes of bleaching have been associated with periods of unusually high temperatures associated with clear, calm weather, resulting in combined temperature–irradiation stress. These are often but not always associated with El Niño conditions, and the most widespread and devastating occurrence was in 1998, when areas of the Indo-Pacific that had not previously experienced major bleaching suffered severe damage (Wilkinson *et al.*, 1999) (*see* **Coral Bleaching (1997–1998)**, Volume 2). While the relationship of El Niño conditions to general global warming is still under discussion, the existence of a global warming trend is well demonstrated, and can be expected to result in increased frequencies and magnitudes of high temperature events.

The increase in mean temperature might be considered a net neutral change, disadvantaging reefs on the high side of the temperature optima, but potentially advantageous to those on the low temperature margins. However, the areas subject to amelioration are much smaller and more marginal than those subject to degradation, and the positive effect of average change is overwhelmed by the negative impacts of increasing frequency and magnitude of high temperature events (Figure 1). At global and regional scales, the question is not "Will it be bad?", but "How bad will it be?" The answer depends on the scenario adopted. If the high frequency SST variation of the past 20 years continues and is superimposed on a general warming trend, the acceleration of bleaching occurrence would result in expanding degradation and near complete destruction in

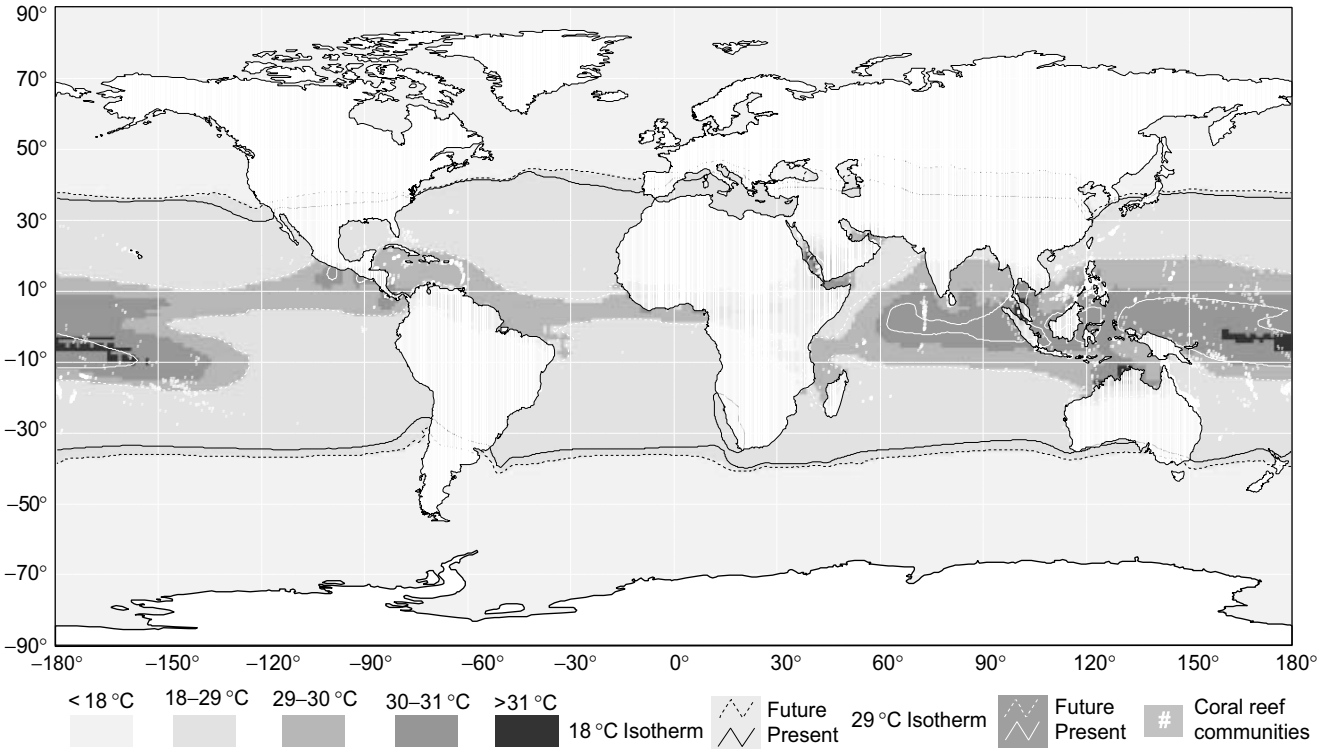

Figure 1 Predicted average annual SST for the years 2040- 2060, with indications of present coral community distribution and of present and future 18 and 29 °C isotherms. Predictions are based on the Canadian Global Coupled Model (CGCM1) with forcing by 1% carbon dioxide increase per year, including the effect of sulfate aerosols (http://www.cccma.bc.ec.gc.ca/data/cgcm1/cgcm1.html). Current SST is from the Reynolds optimal interpolation data set (1982- 1998; http://dss.ucar.edu/datasets/ds277.0/), and reef community locations are from ReefBase (http://www.reefbase.org)

many areas (Hoegh-Guldberg, 1999). Treating the extreme variations as a random phenomenon suggests a possibility of greater intervals between extreme events, but in no case does this translate to a return to previous conditions: the question is whether the next devastating high temperature episode will occur in a few years, or in a few decades.

Frequency and Intensity of Storms and Cyclones

Whether or not global change, and in particular sea surface warming, will result in changes in the locations and intensities of cyclones and tropical storms is an unresolved but significant question. Pittock (1999) reviewed some of the evidence for and potential impacts of such changes. Because coral reef ecosystems are commonly considered disturbance-adapted, changes in storm frequency and intensity would be important, but the detailed effects would be site specific, probabilistic, and difficult to predict. Storm damage is an acute stress that can have critical interactions with long-term chronic stresses such as eutrophication.

Carbon Dioxide Partial Pressure

The marine inorganic carbon system is important to coral reef function because it provides substrates for both photosynthesis and calcification. Total carbon dioxide, or dissolved inorganic carbon (DIC) is the sum of carbon dioxide (aq), HCO_3^-, and CO_3^{2-}. A key factor in the role of coral reefs in the carbon cycle is that photosynthesis is based primarily on the abundant bicarbonate ion, whereas calcification utilizes the relatively scarce carbonate ion.

It is now well established that calcification is controlled by the saturation of seawater with respect to calcium carbonate (Gattuso *et al.*, 1998a; Gattuso *et al.*, 1999a; Langdon *et al.*, 2000; Leclercq *et al.*, 2000):

$$\Omega = \frac{[Ca^{2+}][CO_3^{2-}]}{K'_{sp}} \quad (1)$$

where Ω is the calcium carbonate content and K'_{sp} is the stoichiometric solubility product of the $CaCO_3$ mineral considered (calcite, aragonite or high magnesium calcite). It depends on salinity, pressure and temperature. Since Ca^{2+}

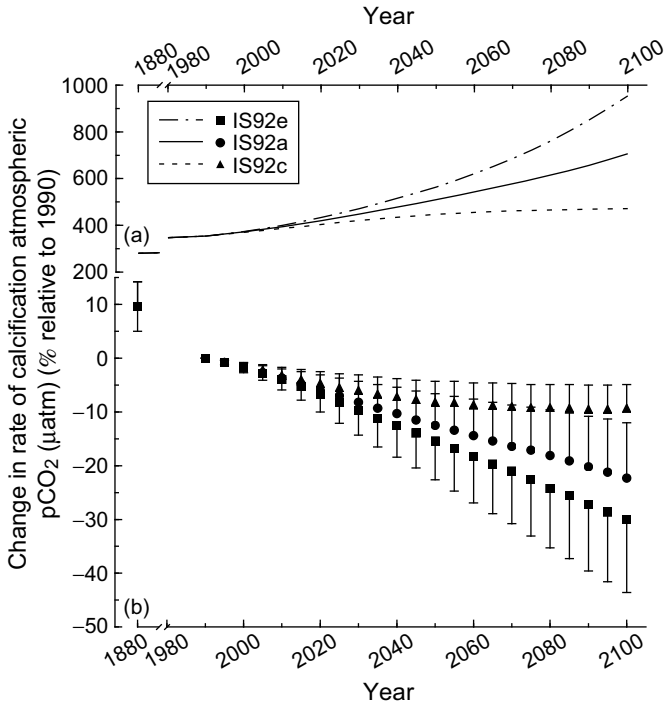

Figure 2 (a) Past and future changes in atmospheric pCO_2. The following scenarios of the Intergovernmental Panel on Climate Change (updated IS92 scenarios; Houghton *et al.*, 1996) are shown: high (IS92e), mid (IS92a) and low (IS92c). (b) Past and future changes in rate of $CaCO_3$ deposition (relative to 1990) of various marine photosynthetic organisms and communities. Mean ± standard error of the mean. (Reproduced by permission of Society for Integrative and Comparative Biology, from Gattuso *et al.*, 1999a)

is about 100 times that of CO_3^{2-} and is a near conservative element of seawater over 10^4 years, Ω is largely determined by CO_3^{2-}. If $\Omega < 1$, undersaturation exists and is favorable to dissolution of $CaCO_3$. A value higher than one indicates supersaturation and is favorable to calcification. Present-day coral reefs occur within an area of the ocean bounded by average $\Omega_{arag} = 3.3–4.1$ (Kleypas *et al.*, 1999b).

Seawater pCO_2 is the most important parameter controlling Ω. The surface ocean tends to equilibrate with the atmosphere; increasing carbon dioxide combines with carbonate ions leading to a decrease in the concentration of CO_3^{2-}, one of the building block of calcium carbonate:

$$CO_2 + CO_3^{2-} + H_2O \longrightarrow 2HCO_3^- \qquad (2)$$

Carbon dioxide partial pressure has increased from 280–368 µatm since the end of the 18th century as a result of human activities (Figure 2). Its present rate of increase is approximately 1.5 µatm $year^{-1}$ (0.4% $year^{-1}$) and, according the average scenario of the Intergovernmental Panel on Climate Change (IPCC; Houghton *et al.*, 1996), pCO_2 could reach 705 µatm in 2100. That would represent a 2.5 fold increase compared to its pre-industrial value. This increase is thought to be beneficial at least in some terrestrial ecosystems that may respond with increased primary production. Very little information is available on the response of reef primary production to increased pCO_2. The first experiments, carried out in a mesocosm, suggest that primary production does not change under elevated pCO_2 (Leclercq *et al.*, 2000). However, the effects on calcification as a result of CO_3^{2-} change are more significant and predictable. The average Ω for the surface ocean between 30 °S–30 °N, was 4.6 in 1880, is currently 4.0, and is projected to drop to 3.1 and 2.8, respectively by the years 2065 and 2100 (Kleypas *et al.*, 1999a). Using data on the effect of Ω on the calcification of temperate and tropical calcifying organisms, Gattuso *et al.* (1999a) predicted the resulting decrease in calcification from mid, low, and high carbon dioxide emission scenarios (Figure 2). It was assumed that the surface seawater and the atmosphere are in equilibrium with respect to carbon dioxide and that the increase in seawater temperature will be identical to the predicted increase in atmospheric temperature. These calculations suggest that $CaCO_3$ deposition by photosynthetic and calcifying marine organisms and communities may have been 10% higher in 1880 than in 1990, and may decrease further by 9–30% (mid estimate: 22%) between 1990 and 2100 (Figure 2).

On the basis of a geographical model, Kleypas *et al.* (1999a) also concluded that the total pre-industrial to 2100 calcification decrease could be as high as 17–35%. They suggested that the reefs likely to experience the largest

absolute decrease in calcification are those presently in high saturation conditions, in the Red Sea, West Central Pacific, and Caribbean. However, the most significant impacts may be due to high relative changes in coral reefs that presently exhibit low rates of calcification and an almost balanced $CaCO_3$ budget (net carbonate loss close to gross calcification). These include high latitude reefs (Bermuda), reefs in upwelling regions (Gálapagos), and reefs subject to intense anthropogenic stresses. Reduced calcification rate is a major impact on the overall fitness of organisms and communities subject to other stresses. Indeed, a decreased rate of calcification may lead to reduced skeletal density and increased vulnerability to physical damage and bioerosion, to reduced skeletal extension that would impair the ability of calcifying organisms to compete for space, or to both.

Sea Level

Because of their dependence on photosynthesis, reef-building corals and coralline algae occur only within a few tens of meters of the ocean surface, yet they are marine organisms tolerating only occasional aerial exposure on low tides. Sea level, and the rate of sea level change, is thus an important control on reef occurrence and growth. However, the protracted stable high-stand of the Late Holocene that humans consider normal is atypical in recent geologic history; the average sea level condition of the Quaternary (the past 1.8 million years) is lower and more rapidly changing than during the past 5000–6000 years.

Eustatic sea level is expected to rise by 10–90 cm during the 21st century, like temperature, a rate similar to but somewhat greater than that observed in the recent past. However, the direct effects, assessed at a global scale, are likely to be somewhat positive for near sea level reefs, many of which have developed large areas that are sea level limited due to the protracted Holocene still-stand. Sea level rise may open up reef flats and other areas for colonization, in locales where there is a ready source of propagules. Increasing sea level will be a disadvantage for extremely marginal deeper reefs; those near the bottom of the depth range of viability, and calcifying or accumulating very slowly.

Locally, sea level rise may have indirect negative effects if increasing coastal erosion mobilizes sediments that are subsequently deposited on nearshore reef areas or coral communities. Issues relating to erosion and sedimentation interact strongly with land use and management practices, and therefore depend on human activities. The increased inundation that may benefit shallow reef communities is likely to be problematic for coastal human communities inshore from reefs, since it will reduce the physical protection afforded by the reefs, resulting in increased coastal erosion and storm damage in addition to the inundation due to sea level rise.

Ultraviolet Radiation (UVR)

More UVR, mostly ultraviolet-B (UVB) in the 300–320 nm waveband, penetrates seawater in the tropics than at higher latitudes because the stratospheric ozone layer is generally thinner (*see* **Ultraviolet Radiation**, Volume 1) and seawater contains less UV-absorbing materials, including phytoplankton. UVR can penetrate to depths of 20 m or more (see Shick *et al.*, 1996). The decrease of stratospheric ozone resulting from anthropogenic inputs of chlorinated fluorocarbons increases the level of UVR reaching the Earth's surface (Madronich *et al.*, 1995). The downward trend of stratospheric ozone observed over the tropics during the period 1979–1994 (2% per decade) is within the background variability. However, the downward trend is significant at slightly higher latitudes (20–30 °N), where subtropical corals exist. The forecast increase in UVR during the next decades, before a projected recovery period during the second half of this century, has led to concerns about the response of coral reef organisms.

Reef organisms have developed a suite of powerful mechanisms and behavior to protect themselves from the deleterious effects of UVR. They produce water soluble compounds, mycosporine-like amino acids (MAAs), that absorb radiation in the UVR waveband, with peak absorption maxima ranging from 309 to 360 nm (Dunlap and Shick, 1998). Corals may contain as many as 10 different MAAs that act as a broadband UVB photoprotective filter. The concentration of MAAs is higher in shallow than in deep specimens and is also higher in exposed versus shaded portions of the same colony. In addition to direct damaging effects, UVR also contributes to the generation of reactive oxygen species that can induce photooxidative stresses (damage of deoxyribonucleic acid (DNA), enzymes, membrane proteins and lipids, and photosystem components). However, algal–invertebrate symbioses possess antioxidant defense mechanisms and the extent of photooxidative stresses in natural conditions is not clearly understood.

Laboratory manipulations and field transplantation experiments demonstrate that although an increase in ambient UVB level stimulates the accumulation of MAAs (e.g., Shick *et al.*, 1999), environmentally relevant increases in UVR have several damaging effects on coral reef organisms (Shick *et al.*, 1996). Exposure to UVR can be fatal both for adult coral colonies and larvae. Natural levels of UVR depress coral skeletal growth as well as photosynthesis of intact corals and isolated zooxanthellae. They are also suspected of interacting with increased temperature and lead to coral bleaching, particularly during doldrum conditions when seawater is especially clear. A recent review concludes that the small increase in UVR will have sublethal effects but that the impact on the distribution of corals and coral reefs will be limited (Shick *et al.*, 1996). The major effect might be a lowering of the minimum depth of occurrence of reef organisms.

REGIONAL AND LOCAL CHANGES

Nutrients

Coral reefs are typically distributed in oligotrophic waters, with undetectable modal values of nitrate and phosphate (Kleypas *et al.*, 1999b), although reefs may tolerate relatively high nutrient conditions (e.g., in the Galápagos Islands). Their net nutrient requirements are low because net ecosystem production is low and similar to that of the nearby oligotrophic ocean (Crossland *et al.*, 1991). Several mechanisms enable coral reef ecosystems to thrive in such conditions (Dubinsky and Stambler, 1996).

1. Many reef invertebrates harbor endosymbiotic microalgae (e.g., corals and mollusks), these mutualistic associations have developed very efficient mechanisms for nutrient conservation and recycling.
2. Elemental C : N : P ratios of reef organisms are generally much higher than in their oceanic counterparts, enabling a higher photosynthetic carbon dioxide fixation per unit of nutrient.
3. Nitrogen limitation is overcome by the capacity of several reef organisms to fix inorganic nitrogen.
4. Very large volumes of oceanic water are advected across many reef flats. Although typically depleted in nitrogen relative to phosphorus, the water is a low concentration, high volume source of phosphorus to the system.
5. Advected planktonic organisms can also represent a significant source of organically fixed nutrients.
6. For some reef locations and processes, sediment-derived nutrient fluxes may be significant. These can include recycling of endogenously fixed nutrients, or geothermal convection of nutrient-rich deep water through the carbonate matrix.

With the probable exception of oceanic atolls, coral reefs are increasingly subject to elevated levels of nutrients due to land management and agricultural practices (use of fertilizers and forest clearing) as well as increased coastal development and general human modification of the global nutrient cycles. The increased nutrient load is delivered through river and groundwater inputs, terrestrial runoff and sewage discharge. Detection of increased nutrient concentration at the regional scale, such as the Great Barrier Reef, has been the source of considerable controversy. The increase at a local scale is nevertheless detectable and significant. High levels of eutrophication can have dramatic direct effects on coral physiology. It decreases skeletal growth and stimulates the growth of symbiotic algae, which retain a larger portion of photosynthates and transfer less to the animal host. More significant in most cases are the indirect consequences of increased nutrient levels, which greatly favor the growth of macroalgae that become more efficient than corals in the competition for space. Eutrophication also increases the phytoplankton standing stock, which increases turbidity and can lead to light limitation of photosynthetic organisms. The decrease in the rate of net carbonate mineral accumulation associated with the stimulation of the activity of bio-eroders also threatens the delicate balance between calcium carbonate precipitation and erosion.

Resource Use

A major factor in the past deterioration and future prospects of reefs is human resource use. This may include various kinds of direct use of the reefs or their products:

1. Overharvesting, whether for food or for sale of organisms in the souvenir or aquarium trades, can easily exceed the limited sustainable harvest capacity of the ecosystem, and more importantly can disrupt ecosystem function by removing key classes of organisms, such as large herbivores (Hughes, 1994).
2. Destructive fishing methods, such as the use of explosives or cyanide on shallow reefs or bottom trawling in areas of deep coral communities, can result in long-term loss of habitat and organisms, far in excess of the actual harvest.
3. Use of the reef materials or area for destructive non-reef development, such as dredging, mining of construction materials, or landfill (e.g., to build airports).
4. Even apparently non-consumptive uses such as tourism can have significant concomitant stresses; high visitor loads can result in damage by boats and divers, incidental contamination, and eutrophication from local tourist development, etc.

Indirect human damage is somewhat more difficult to deal with, since it typically results from activities undertaken for reasons that do not involve consideration of reef effects. Such factors include:

1. Land use and management, even at substantial distances from the coast. Deforestation and agricultural activities in many areas have greatly increased the loads of sediment and nutrients reaching coastal areas. The resultant turbidity, sedimentation, and eutrophication is a major factor in local reef stress.
2. Discharge of waste, including sewage (which contributes to eutrophication) and toxic chemicals.
3. Alteration of the hydrologic cycle (e.g., by urbanization) in ways that increase the likelihood of nearshore salinity stress.

With growing coastal populations and development pressure, these effects are among the most urgently threatening to reefs in spite of the fact that they are the most readily identified and controlled.

CONCLUSION AND PERSPECTIVE

Local direct anthropogenic stresses are presently those that have the greatest short-term damaging impact on coral reefs and must be dealt with urgently. The effects of global change are, by definition, more widespread and longer-term. However, it is clear that both are significant threats to the health and survival of coral reef ecosystems, and will synergistically interact. In general, the reefs at greatest risk are those closest to human populations and major land masses (Smith and Buddemeier, 1992), but the predicted changes in ocean temperature and carbon dioxide levels mean that even the most remote and well situated reefs will experience a significantly deteriorating environment. High levels of concern and research and conservation efforts will be of little value unless the problems of overpopulation and unsustainable development are seriously addressed.

Crop Models

J Goudriaan
Wageningen University, Wageningen, The Netherlands

The total agricultural production in the second half of the 20th century more than doubled. This increase would not have been possible without strong improvement of farming techniques. In particular, increased application of fertilizers has been essential. At the end of the 20th century, the large-scale application of the industrial process of nitrogen fixation (Smil, 1997) has exceeded the total rate of natural nitrogen fixation. There is no reason why the output of the industrial nitrogen fixation process could not go up further, but other constraints to crop production are beginning to be felt. In particular, in South-East Asia the cultivation of rice is already at a level at which further intensification will be difficult. Therefore, it is questionable whether the fast rate of increase of food production can be maintained during the course of the 21st century to the extent that it can keep pace with the growth of the human population. Global climate change could be decisive to the balance between supply and demand, dependent on where the effects will be beneficial and where they will turn out to be negative to agricultural production.

Crop modeling serves as a powerful intellectual tool to study the importance of different constraints to crop growth. Its results enable us to make prognoses and also it helps to tell which changes in farming techniques could be most effective in a warmer climate.

HISTORY OF CROP MODELING

The classic report of De Wit (1965) on photosynthesis of leaf canopies described a numerical model (see Box 1) to calculate daily photosynthesis of a leaf canopy from leaf characteristics and meteorological conditions. In modern leaf-based crop growth simulation models, basically the same approach is still followed (see Table 6.2 in Walker *et al.*, 1999).

Bouman *et al.* (1996) give a historical overview of how a whole suite of models (see Box 2) evolved from this basic concept, most notably the Simple and Universal CROp growth Simulator (SUCROS) group of crop growth simulation models, including ORYZA for rice. Other groups of models such as the CERES models (Ritchie *et al.*, 1991), SOYbean GROwth simulation model (SOYGRO) models (Boote *et al.*, 1996), AFRC–Wheat model (Porter, 1993) were developed independently.

An important simplification to the leaf-based models was the emergence of the whole-canopy light capture models, pioneered by Monteith and his coworkers (Gallagher and

Box 1 What is a computer simulation model?

Nowadays, physical models are rarely used except for demonstration purposes, and by the term *model* we usually mean a computer model. Computer models are extremely exible as they permit us to formulate almost any relationship between input and output. These relationships are quantitative and may consist of numerous smaller submodels. The formulation of the relationships between input and output may be just empirical, but it may also be based on underlying mechanisms, with the objective of making the model more general. The specifying term *simulation* is added when the model is not just a simple input- output mapping, but when underlying processes are crucial for understanding the model behavior.

Box 2 What is a crop model and why do we use it?

Any prediction about the effect of some farming action (for instance of nitrogen fertilization) on crop yield involves the application of a rule, no matter how simple. The rule for such a prediction is based on experience, and this may well be suf cient for normal circumstances. In a crop model, much more experience is included than what would be needed for just the local situation. A model is a generalized but also simpli ed representation of a real world crop and its environment. The information in such a model is normally quantitative and it is processed mechanistically. A model makes it possible to include information from scienti c sources that would otherwise not of been used.

Biscoe, 1978; Monteith *et al.*, 1994). In these models there is no consideration of individual leaves, or of the diurnal fluctuation of radiation, and the daily radiation intercepted by a plant canopy is immediately converted into a net daily growth of dry matter. The success of this bold move has been remarkable, although the value of the radiation conversion factor remains a subject of numerous studies.

Some of the initial simplicity is lost when provisions are made for the effect of temperature, of radiation level, of ageing, of drought, and of many other factors on the value of the radiation conversion factor.

The model SIMRIW (Horie, 1987, 1993) is an example of such a model applied to the growth of rice.

A model makes it possible to include information from scientific sources that would otherwise not have been used.

LIMITATIONS OF CROP GROWTH MODELS

Crop models embody a number of simplifications (see Box 3). Weeds, diseases, and insect pests are often assumed to be controlled; soil conditions are assumed to be optimal; and extreme weather events such as tornadoes are supposed not to occur. However, even in normal situations, crops usually suffer from shortages of water or nutrients (see Box 4; Figure 1). Weeds that capture resources in competition with the crop exacerbate the effect of such shortages. Also, the effects of diseases and pests reduce the crop yields.

Box 3 Simpli cation: a weakness and a strength

A model is a simpli ed representation of reality (De Wit, 1970). A model will therefore fail to capture all the richness of details of the real world. This absence of details is not a weakness, but a strength, as it makes it possible to see a fundamental structure that would otherwise be blurred. There is, however, a subjectivity in the choice of which details are neglected. This subjectivity is characteristic for model building, and it can only be partly overcome by subjecting the model to a range of rigorous tests on model performance.

Box 4 Production situations and limiting factors

Potential yield is the yield of a crop when the crop has been free from pests and diseases and when it has always had an optimal root environment so that there have been no shortages of water or nutrients (Rabbinge, 1993).

Attainable yield is lower than the potential yield, because of limitations due to a shortage of water or nutrients, but not due to pests, diseases or weeds.

Actual yield also includes the effects of weeds, pests and diseases.

For the most important crops of temperate regions, such as wheat and potato, the models have been used and tested extensively, in contrast to tropical crops such as millet and cassava. Estimates of potential yields of such crops, which may respond differently to both climate change and increases in carbon dioxide (CO_2), are needed for better assessment of climate change impacts in tropical and subtropical regions.

There are contrasting reports on the performance of crop growth models in comparison to observed yields. In experimental situations, where many factors are accurately monitored, the models usually do better than for larger scale applications at regional levels. De Koning *et al.* (1993) found that crop growth simulations did not significantly improve the predictions at the regional level in the European Community. The most likely explanation is that too many other factors, unknown to the modelers, masked the observed results. On the other hand, crop growth models do reasonably well on the regional scale (Casanova, 1998), and according to Supit (2000), a major difficulty is to know the actual cropped area for a certain type of crop such as winter wheat.

IN WHAT WAY DO CROPS REACT TO CLIMATE? (SEE BOX 5)

When it is warmer, a plant develops faster; that means that it goes through its normal life cycle faster. The most common expression of this speeding up is an acceleration of flowering, but other reactions such as increased rate of leaf production or stem elongation can also be noticed. In models, this reaction is often represented by the concept of minimal heat sum requirement to reach a certain stage of development. *Heat sum* (*degree days*) is calculated by daily addition of the number of °C by which the average daily temperature exceeds a certain threshold temperature (also called the base temperature).

For instance, to reach flowering in wheat, a heat sum of about 800 degree days, with a base temperature of 0 °C is needed. For other crops, this requirement can be very different. Soybean only begins to develop above a temperature of about 10 °C, and so it is not grown in cool temperate climates such as in northwestern Europe.

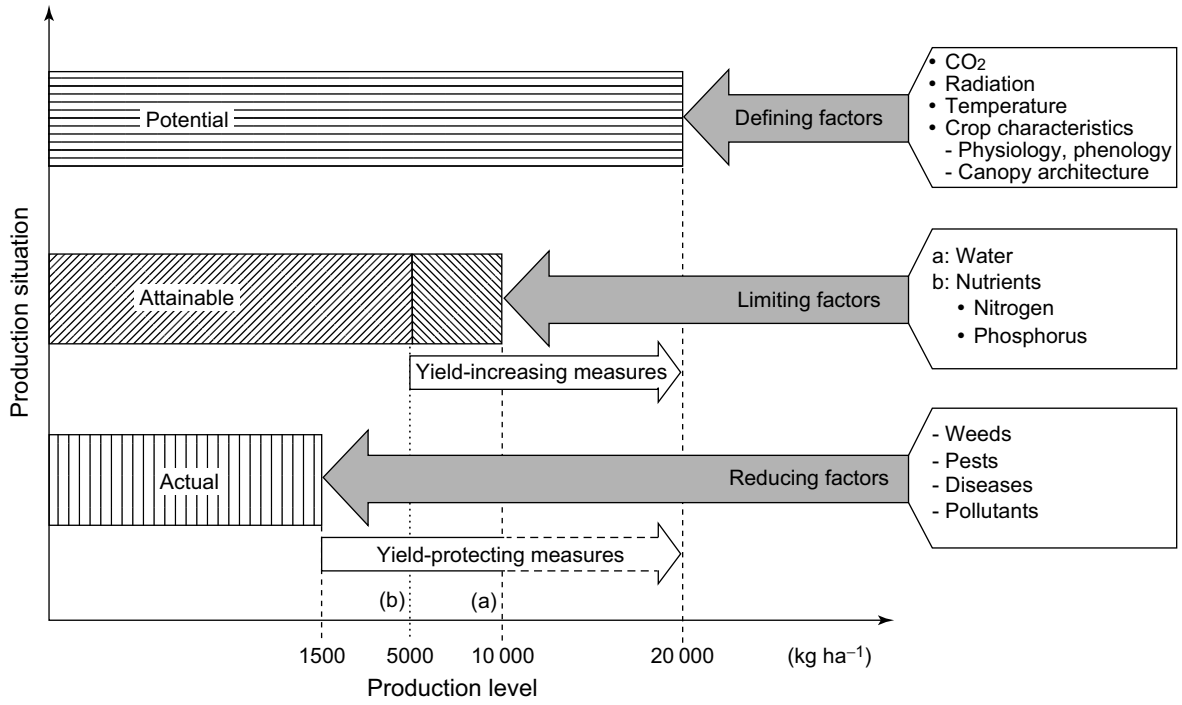

Figure 1 Production situations and their corresponding yield levels. (Reproduced by permission of John Wiley & Sons in Rabbinge, 1993)

Box 5 Crops and their environment

Environmental constraints are comprised of weather, soil, pests and diseases. Soil conditions are important, and encompass soil type and composition. Water and nutrient content may vary strongly during the growing period of the crop. This variation may either be given as input or be calculated within the model itself.

The climatic environment of the crop determines photosynthesis, transpiration and other processes that eventually lead to owering and fruiting. Within any one season, the weather will vary strongly, even from hour to hour. A mechanistic crop growth model allows for these variations in environmental in uences.

How the crop reacts to the environment depends strongly on the type of crop. Therefore, there are different models for different crop types such as wheat, rice, maize, potato, and soybean. A certain crop type is characterized by its genetic coef cients, which tell the model how to calculate the rate of crop development, crop growth, and formation of new organs.

Once the climate of a region is known, its climatic suitability for any given crop type can be calculated, expressed as the potential yield of that crop type. Mapping the boundaries of suitability classes is called agro-ecological zonation.

When transferred to a warmer climate, a crop goes through its lifecycle faster, which means that there will be less time for the formation of harvestable organs. The yield is then smaller. However, crop types are not the same in different agro-ecological zones, as they have been selected for optimal performance in their local climatic conditions.

Development and growth in size are different things. In some conditions, a plant species may be very small and already flower, but in other conditions it may grow in size and remain vegetative. The explanation for such large differences in rate of development is often day length. Day-length sensitivity is a genetic trait that can be changed relatively easily by breeding, and therefore different varieties of one species may have very different day-length sensitivities. This difference in sensitivity explains why the success of a variety is so much linked to a geographical region. Obviously, crop models need to have a correct representation of the day-length sensitivity of the variety for which they are used.

Another important process is leaf area formation. Over the life cycle of a crop, the leaf area grows, reaches a maximum, and then usually declines as the crop senesces. The total amount of radiation intercepted depends on the time integral of incoming radiation multiplied by the fraction of radiation that the leaves can intercept. The fraction of interception is directly linked to the *leaf area index*, the ratio of leaf area and ground area. As a rule of thumb, interception is complete (more than 90%) when the leaf area index exceeds a value of 3.

In simple crop growth models, the daily amount of radiation intercepted is directly converted into a daily growth rate of the crop. The conversion factor is rather stable, of the order of 1 g of dry matter MJ^{-1} of total radiation intercepted, although some variation exists with plant type.

APPLICATIONS TO CLIMATIC CHANGE

Sinclair and Seligman (1996) have given an excellent account of the historical development of crop growth modeling. Since the 1970s, there has been a gradual evolution in studies on the impact of climate change on crop growth from statistical approaches towards crop modeling approaches. The tendency at first was to rely on extrapolations of statistical relationships, with little understanding of the processes that relate the cause to the supposed effects (quote from Parry, 1990). The National Defense University in Washington, DC (1980) conducted such a statistical study in view of disastrous effects of a potential future persistent drought in the major grain-growing regions of the USA and the Union of the Soviet Socialist Republics. There was, however, a growing awareness of the multitude of influencing factors, which makes it difficult to extract significant statistical relationships. The statistical approach was successful in provoking crop growth modelers to come up with explanations as to why some climatic effects predicted by the crop models could not be found in the real world. On the other hand, some strong effects are confirmed, such as the negative effect of higher temperature, which is largely due to accelerated development of the crop, thus shortening the growing period.

The most robust results of crop modeling were not in yield prognoses, but in *agroclimatic zonation* work (see Box 6). The predicted poleward shifts of the limits of crop growing zones are based on rather simple relationships between crop development and heat requirement (Parry, 1990).

MODEL COMPARISON EXERCISES

Each modeling group has worked on the development of its own crop growth model. This is understandable (Sinclair and Seligman, 1996), but it has led to a confusingly large number of crop models, in varying degrees of complexity, robustness, and maturity. This situation called for model comparison exercises that have taken place a few times since the Lunteren meeting in 1993 (Goudriaan, 1996). The Lunteren meeting showed a surprising divergence in the results of wheat models, most likely due to the large environmental range of growing conditions in wheat that presumably had their effects on the implicit model assumptions. In contrast to wheat models, a later comparison of rice models showed that their predictions for potential production were much more convergent, and also quite close to the observed values. This better result is partly because of the more homogeneous conditions for the cultivation of rice than wheat, but the lessons from the preceding wheat workshop may also have played a positive role.

The experience with the wheat and rice comparison exercises has led to an institutionalization of networks, under the auspices of Global Change of Terrestrial Ecosystems/International Geosphere–Biosphere Programme (GCTE/IGBP) (Walker *et al.*, 1999). It has led to quality control of experimental work, of modeling work, of data collection, and of model evaluation. Scientists have learnt to appreciate the usefulness of such networks. At the price of having to sacrifice some independence, the scientist gains access to the work of others, which enables him/her to extend his database. Also, inspection of the data by others has proven to be invaluable to improve the data quality.

Box 6 Major conclusions from the models

Typically models predict an increase of yield and biomass of about 30% as a result of doubling of ambient CO_2 alone. This is well in line with empirical results as far as the mean value is concerned. However, the large variability of the experimental results reported in the literature (ranging from 0 to 100% increase) cannot be explained by models. This means that models are still weak in allowing for interaction with other factors, and also do not suf ciently include other factors such as soil-borne diseases, induction of changes in morphology and other delicate effects in internal balances inside the plant.

The models do predict the general observation of enhanced CO_2 effects under water shortage, and of reduced CO_2 effects under nutrient shortage. Also, the models successfully predict the effect of rising temperature on crop development and its effect on yield.

CROPS AND OTHER PLANTS

In the case of crops and vegetation, it is important to model the physical and biological constraints within the environment, and also those within the plant organisms themselves. Crop models and ecological vegetation models have much in common in terms of physiology. But crops differ, in that they are planted or sown, the soil is managed, weeds, pests and diseases are removed or prevented as much as possible. Finally they are harvested, and the soil is prepared for another crop or season. These human activities remove some of the natural selection pressure and competition effects. Depending on the intensity of management, some pressure of weeds and pests remains.

The major crops of the world are the small grains (mainly rice and wheat), the coarse grains (sorghum and millet), the sugar crops (sugar cane and sugar beet), the tuber crops (potato and cassava), the leguminous crops (soybean, and other beans and peas), and the oil crops (sunflower, oil palm).

Rice and wheat together produce more than half of the total caloric need of the world human population, but apart from these major crops there has been a historic adaptation of the types of crops cultivated, to the large diversity of climates, social cultures and soil types. In spite

of this variation, the unity of physiological mechanisms provides the possibility of a common base for all crop growth models. They all contain the elements of dry matter formation, plant development and uptake of water and nutrients.

In fact, this unity also helps to better understand the ways in which weeds cause lower yields or sometimes even complete loss of a crop. Crop growth modeling offers good possibilities to unravel the interaction of weed damage and climate change, as well as to investigate means to improve weed control.

THE USE OF MODELS FOR ANSWERING ''WHAT-IF'' QUESTIONS

The use of models has become indispensable for future scenario studies (Rabbinge *et al.*, 1994). Scenario studies are not meant to be predictions. Rather, they investigate options for future development, by looking at different possible materializations of scenarios for population, economy, urbanization and climate, in combination with different alternative possibilities for policy measures (see Box 7). In the case of crop models, the scenario studies integrate the best available knowledge in the fields of production ecology, climate, and, for instance, soil science. They use scientific knowledge, both in terms of proven facts and in terms of remaining uncertainty, to find optimal paths for future development. In doing so, scientists do not intend to take over the responsibility of policy makers, but rather to reduce some of the vagueness that often surrounds the promised outcome of policy decisions. Not all uncertainty can be removed, though. Critical consideration of scientific results shows that, often, large error bars have to be attached to observations and predictions. Here it is useful to make the distinction between prediction and exploration. The uncertainty of prediction does not play a role in an explorative study into consequences of different future scenarios. Awareness of a possible disastrous effect may provoke sufficient responses to prevent such an outcome. Yet uncertainties in the model and its parameterizations remain. This is a fact of life and it will require scientific education of the public, including policy makers.

Box 7 Input- output models

Economic input- output models directly specify the empirical relationship between inputs and yield. Such models exist not only for the farm level but also for the level of a region or even for a whole country. Usually these models also allow for technological improvement. Such models are not well suited to predict effects of global change, except for those factors that enter explicitly as input factors.

Daisyworld

Daisyworld is a model constructed by Watson and Lovelock to demonstrate the possibility of self-regulation in a system in which the variation of biological populations and the variation of a selective environment are mutually coupled. In the original model, the populations were daisies of two types (black or white) and the environmental variable was planetary surface temperature, externally driven by a solar radiative output that was postulated to increase with time. The relative proportions of black and white daisies determine planetary albedo, which in turn affects the surface temperature. The authors postulated a world in which the growth of the white daisies would increase as the temperature increased. This created a negative feedback that stabilized the temperature against the increasing radiative input. This stabilization occurred because, when solar output was low, the black daisies were assumed to thrive while, when the solar output increased, they are displaced by the white variety. Planetary albedo was thereby modulated and thermal homeostasis achieved as a system property. The model was important as a demonstration that environmental regulation by the biota, central to Lovelock's concept of Gaia, was conceptually possible without assumptions of purpose or foresight. However, many biologists argued that the model failed to reconcile the Gaia hypothesis with Darwinian theory because the biota of the model (daisies) were endowed by the modeler with response properties (optima for growth versus temperature) which, in real life, would be arrived at by natural selection of genetically determined variants.

Darwin, Charles Robert

(1809–1882)

Charles Robert Darwin was an English naturalist and evolutionist. He was the author of the *Origin of Species* (1859) in which he proposed the controversial idea of evolution by natural selection. He dedicated his life to providing evidence to substantiate it, including important writings on plants and the ancestry of human beings. Before this he traveled around the world on the HMS Beagle collecting natural history specimens, described in *Journal of Researches* (1839). Darwin was plagued by ill health, and consequently welcomed his friends, such as Thomas Henry Huxley, defending evolutionary theory. The *Origin of Species* roused violent public debate that spilled far beyond the domain of science. The concept of evolution by natural selection was only gradually accepted. In retrospect, the proposal can be seen as a major shift in environmental and biological thought that helped create the modern world.

Charles Darwin was born in Shrewsbury, the son of a prosperous medical doctor. After a brief period studying medicine at Edinburgh University, he went to Cambridge with a view to becoming a parson. This never came about. After graduation he joined Captain Robert FitzRoy on the Beagle voyage (1831–1836). The voyage was the key event in Darwin's life, greatly expanding the way he thought about the natural world. The ship visited Tahiti, the Galapagos Islands, New Zealand, and Brazil. He spent several years in South American waters, especially Chile and Tierra del Fuego. Darwin traveled and collected extensively, afterwards writing an account that is today recognized as an important record of natural environments. He learned from Charles Lyell's *Principles of Geology* that the environment is constantly changing. He applied this idea fruitfully to the origin of mountain ranges, coral reefs and other natural

history questions. On his return Darwin became converted to evolution by applying the same idea to biology. The Galapagos finches were very significant but only when properly identified. He took the idea of competitive struggle and survival rates from Malthus's *Principle of Population*. While writing for publication, he received from Alfred Russel Wallace a short essay containing near-identical ideas. A joint publication was arranged at the Linnean Society of London, July 1858, and Darwin published the *Origin of Species* in November 1859. In this he proposed that every animal and plant is variable. Individuals that are best adapted to the surrounding conditions will be the ones that survive and reproduce. Over eons of time, and with gradually changing conditions, organisms evolve. He included many instances of environmental change. Although not the first to propose evolution, Darwin's work aroused intense controversy since Victorians found it hard to accept gradual organic change, and equally hard to remove God from the creative process. The *Origin of Species* was often perceived as a manifesto for social and political reform and as a dangerously atheistic tract. It was vigorously defended by T H Huxley – Darwin's bulldog. In later life, Darwin was revered as a grand old man of science. He was buried in Westminster Abbey.

Data Banks: Archiving Ecological Data and Information

Jonathan M O Scurlock, Richard J Olson, Raymond A McCord[1], and William K Michener[2]
[1]*Oak Ridge National Laboratory, Oak Ridge, TN, USA*
[2]*University of New Mexico, Albuquerque, NM, USA*

Scientific data gathering has a relatively long history, but mechanisms for data distribution and exchange are more recent. Technological developments have made it possible to manipulate environmental data and then to store them. During the 1980s and 1990s, it became routine to transfer environmental data through computer networks; more recently, the Internet has opened up the possibility of browsing multiple large data collections anywhere in the world.

Traditionally, science involves making systematic observations that can be replicated. Over the past 20 years, the environmental sciences have shifted from studies of isolated populations, communities, watersheds and ecosystems towards a broader scale approach including modeling, synthesis, and assessment. In response to recent, dramatic increases in the capacity for access, processing and storage of information, scientists are now collecting data over the Internet in addition to field and laboratory work. As science moves toward regional and global interdisciplinary studies, mechanisms are needed to share data among many disciplines (e.g., ecology, meteorology, hydrology, soil science, agriculture). Consequently, submitting data to banks or archives and acquiring data from archives have become integral to today's scientific process.

Data banks or archives are permanent collections of datasets stored with accompanying metadata (information describing the data) such that users can readily acquire, understand, and use the data. A contemporary bank or archive preserves data and metadata in an electronic form that will continue to be accessible as technology changes. It also provides complete metadata so that secondary users can understand the inherent limitations associated with new applications of the archived data. It should also facilitate data sharing and foster broader scientific discoveries. Throughout this article, we use the terms data bank and data archive more or less interchangeably since both are frequently found, although as a verb archiving is more common than banking. Data center is less prevalent in our experience.

HISTORIC EXAMPLES

Certain well-known archived datasets have contributed greatly to the advancement of scientific knowledge through serendipitous applications not foreseen at the original time of data collection. For example, recent studies of the global carbon cycle have made much use of the measurements of atmospheric carbon dioxide initiated over 40 years ago at Mauna Loa, Hawaii by C D Keeling (Pales and Keeling, 1965; Keeling *et al.*, 1982; Figure 1). The now-famous pulse, representing the interaction between biosphere and atmosphere in response to global climate was later combined with other atmospheric CO_2 data from flask sampling worldwide and air sampling covering the Pacific Ocean from north to south (Keeling, 1998; WMO-WDCGG, 1999). Through the techniques of deconvolution and inversion modeling, global patterns of carbon dioxide sources and sinks were analyzed in the combined dataset, and the notorious terrestrial carbon sink was first identified by Tans and co-workers (Tans *et al.*, 1990).

Another example is provided by records of the net primary productivity (NPP) of vegetation. Data collection began in earnest in the late 19th century as accounts of

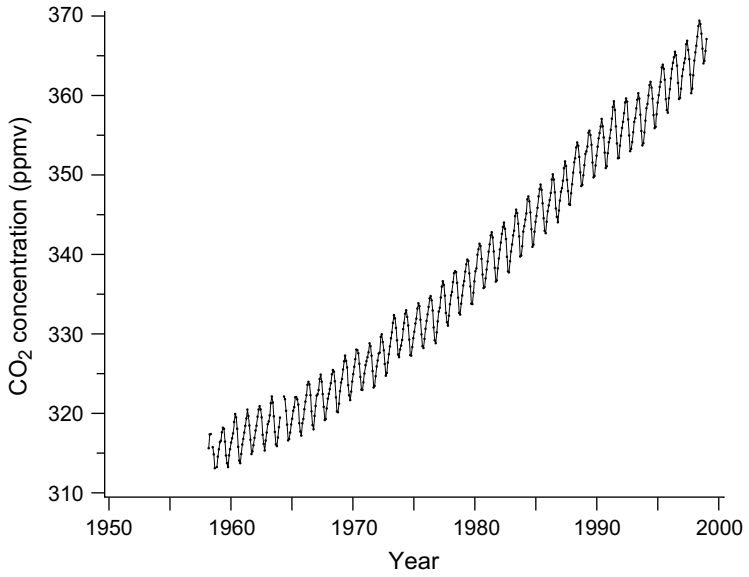

Figure 1 Atmospheric CO_2 record at Mauna Loa, Hawaii, initiated in 1958. (Thoning *et al.*, 1994; reproduced by permission of CDIAC)

the economically valuable production of crops, forage, and forest products. Some of the long-term datasets on NPP originated from such commercial agricultural interests (e.g., the Park Grass experiment at Rothamstead, UK; Silvertown *et al.*, 1994; rangeland forage production at the Central Plains Experimental Range, Colorado, USA, Lauenroth and Sala, 1992). However, long-term studies where the productivity of natural vegetation was explicitly monitored did not begin until the 1950s; coordinated efforts since that time have included such well-known scientific projects as the International Biological Program (IBP) and the US Long-term Ecological Research (LTER) program (Golley, 1993; Franklin *et al.*, 1990). Today, NPP data from many study sites worldwide are scattered throughout the peer-reviewed literature as well as in government reports and other printed matter of limited circulation, but comprehensive summaries of NPP data are rare (e.g., DeAngelis *et al.*, 1981; Cannell, 1982). More recently, the need for data to validate ecosystem models of NPP in response to increasing CO_2 and climate change, coupled with the recent growth of access to high-speed personal computers and data networks, has stimulated the formation of a world NPP data archive (Scurlock *et al.*, 1999; Scurlock and Olson, 2000).

DATA BANKS TODAY

What is a Data Bank?

Data banks comprise more than just data and metadata. Other key components are the data storage system (the media on which the data are stored, including security and back-up), the information system (which describes the data), the network connections, promotional and advertising material, optional data analysis tools, staff to maintain the archive, and, most importantly, staff to provide user services. Typically, these staff are a mixture of systems specialists, database administrators, user interface specialists, information specialists, and scientists.

The goal of a data bank is to support data use in the future, not merely to stockpile data (Kanciruk, 1997). To meet this principal objective, a data bank must be able to incorporate new data, provide user support, and maintain the integrity and accessibility of stored data (for computer systems this includes future upgrades of software, hardware, storage media, and network connectivity). See also Figure 2.

Examples of Data Banks

Most well-developed environmental data banks have limited themes and contain large amounts of data collected over long time spans at many places. For example, the network of World Data Centers (WDCs) include several data banks that have an environmental focus. The WDC system was first established through data management plans to serve various scientific disciplines in the International Geophysical Year of 1957–1958 (which itself was modeled on the International Polar Years of 1882–1883, the first large-scale international scientific enterprises). WDCs in the United States include the US National Climatic Data Center (NCDC), the Carbon Dioxide Information Analysis Center (CDIAC; for atmospheric trace gases) and the EROS Data Center (remotely sensed land data). The NCDC, for instance, which is operated by the US National

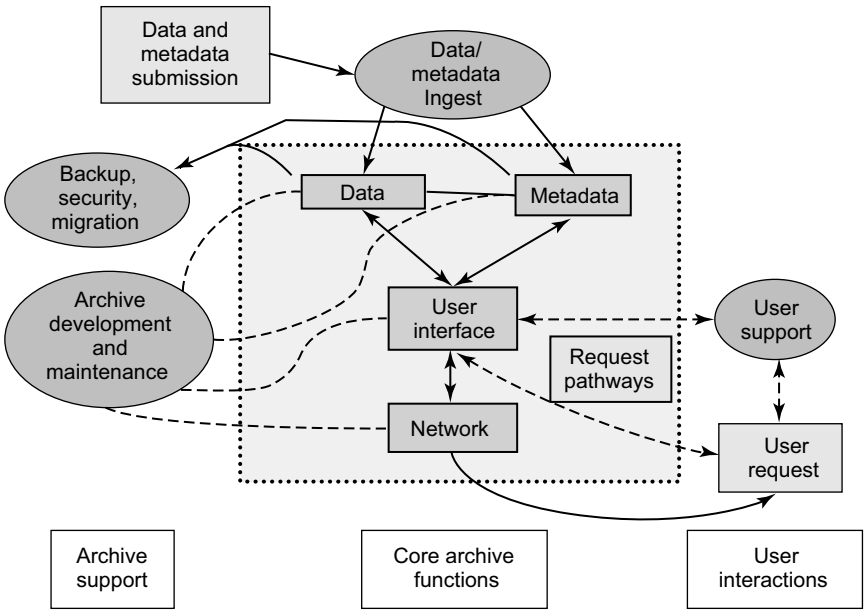

Figure 2 The ow of data and metadata from data submission to users' requests showing the internal archive and system functions. Solid lines indicate the primary ow while dashed lines indicate actions that periodically occur as needed or requested (Olson and McCord, 2000, reproduced by permission of Blackwell Science Publishers, Oxford)

Oceanographic and Atmospheric Administration (NOAA), was established in 1951, contains data collected since the 1800s), and is among the largest in terms of data volume (55 gigabytes added each day) and numbers of requests (over 170 000 data requests per year). Another relevant WDC is the International Soil Reference and Information Center (ISRIC) in the Netherlands, which stores broad-scale soils information in its Soil Information System.

Oak Ridge National Laboratory (ORNL) in Tennessee maintains two comprehensive environmental data banks: CDIAC, funded by the US Department of Energy (DOE), and the ORNL Distributed Active Archive Center (DAAC) for Biogeochemical Dynamics, funded by the US National Aeronautics and Space Administration (NASA) (Table 1). CDIAC already has a long-standing reputation for distributing data that are of high quality with known accuracy and reliability (NRC, 1995). It has produced data packages since 1982 that include extensive data description, detailed format information, extensive quality-assurance (QA) checks, examples of data applications, and copies of key associated literature. More recently, it has moved from producing annual reports and publications to providing data online. CDIAC produces value-added products for the global change research community and uses a process by which they are certified as valid by those that collected the data and carried out the quality-control checks (NRC, 1997).

The Earth Observing System (EOS) is the centerpiece of NASA's Earth Science Enterprise (ESE) (see http://eospso.gsfc.nasa.gov/), consisting of a science component and a data system supporting a coordinated series of satellites for long-term global observations – a major contribution to the US Global Change Research Program. The EOS Data and Information System component (EOSDIS) is a distributed system to support archiving and distribution of data at multiple data centers or DAACs. These centers are connected by an Information Management System (IMS) which provides an interface for one-stop shopping for earth science data allowing users to search for and order data from multiple data centers. While most of the DAACs primarily archive imagery data from the EOS satellites, the ORNL DAAC maintains data related to biogeochemical dynamics to support the validation and interpretation of satellite products. The ORNL DAAC originally grew out of the need to provide a data bank for large-scale NASA field experiments such as FIFE (First ISLSCP Field Experiment) ISLSCP (International Satellite Land-Surface Climatology Project) and BOREAS (Boreal Ecosystem-Atmosphere Study). These involved pulling together and synthesizing data from multiple sources (ground level, carbon dioxide flux towers, aircraft, satellites, etc., Sellers *et al.*, 1988; Sellers *et al.*, 1997).

Many other data facilities and research networks store and distribute environmental data, although they may represent different stages of development toward a comprehensive data bank (Table 1). Many of these systems are evolving rapidly because of significant changes in technology such as internet access and reduced costs for storage devices. Typically, their datasets contain a relatively small number (tens) of measurement types generated by a few types of instruments, methods, and sensors.

datasets relevant to global change research, including those covering climate change, the biosphere, hydrosphere and oceans, geology, geography, and human dimensions of global change (Figure 3). The European Environmental Agency maintains a Catalogue of Data Sources (CDS), a locator system on environmental information. CDS supplies information on who has what information in Europe, in which form and where the data exist, as well as how to gain access. (See Table 3 for a selected list of other sources of environmental data on global environmental change.)

DATA ARCHIVE FUNCTIONS

Preparing Data For Archive

Olson and McCord (2000) describe the process of preparing data for submission to a data bank. Projects that synthesize and model ecological processes at multiple spatial and temporal scales often involve bringing together and sharing data from numerous sources. The resulting collections of data from such projects are ideally suited for storage and distribution through an archive. An information system model is described by Olson *et al.* (1999) that facilitates assembling, managing, and sharing diverse data from multiple disciplines, scales, and sites to support integrated ecological studies. In this model, working groups from particular scientific domains coordinate the development of data associated with their domain, including decisions about data requirements, data to be compiled, data formats, derived data products, and schedules across multiple study sites. The data and information system is Web-based, comprising nodes for each working group plus a central node that provides data access, project information, data query, and other functionalities. This approach incorporates scientists and computer experts in the working groups and provides incentives for individuals to submit documented data for archiving.

Experience with managing environmental datasets over the past 30 years suggests that, at minimum, basic guidelines must be observed to avoid future problems with data and metadata (Slagel, 1994; Olson and McCord, 2000). For example:

1. each measurement event should be represented by only one value in the dataset i.e., there are no duplicates (such as may occur when the same values are entered with different punctuation, case, string length, etc.);
2. each value is associated with a unique place name or location (e.g., latitude/longitude);
3. data transported between organizations are accompanied by summary statistics to confirm a correct transfer, including number of records, mean, minimum, maximum, number of missing values.

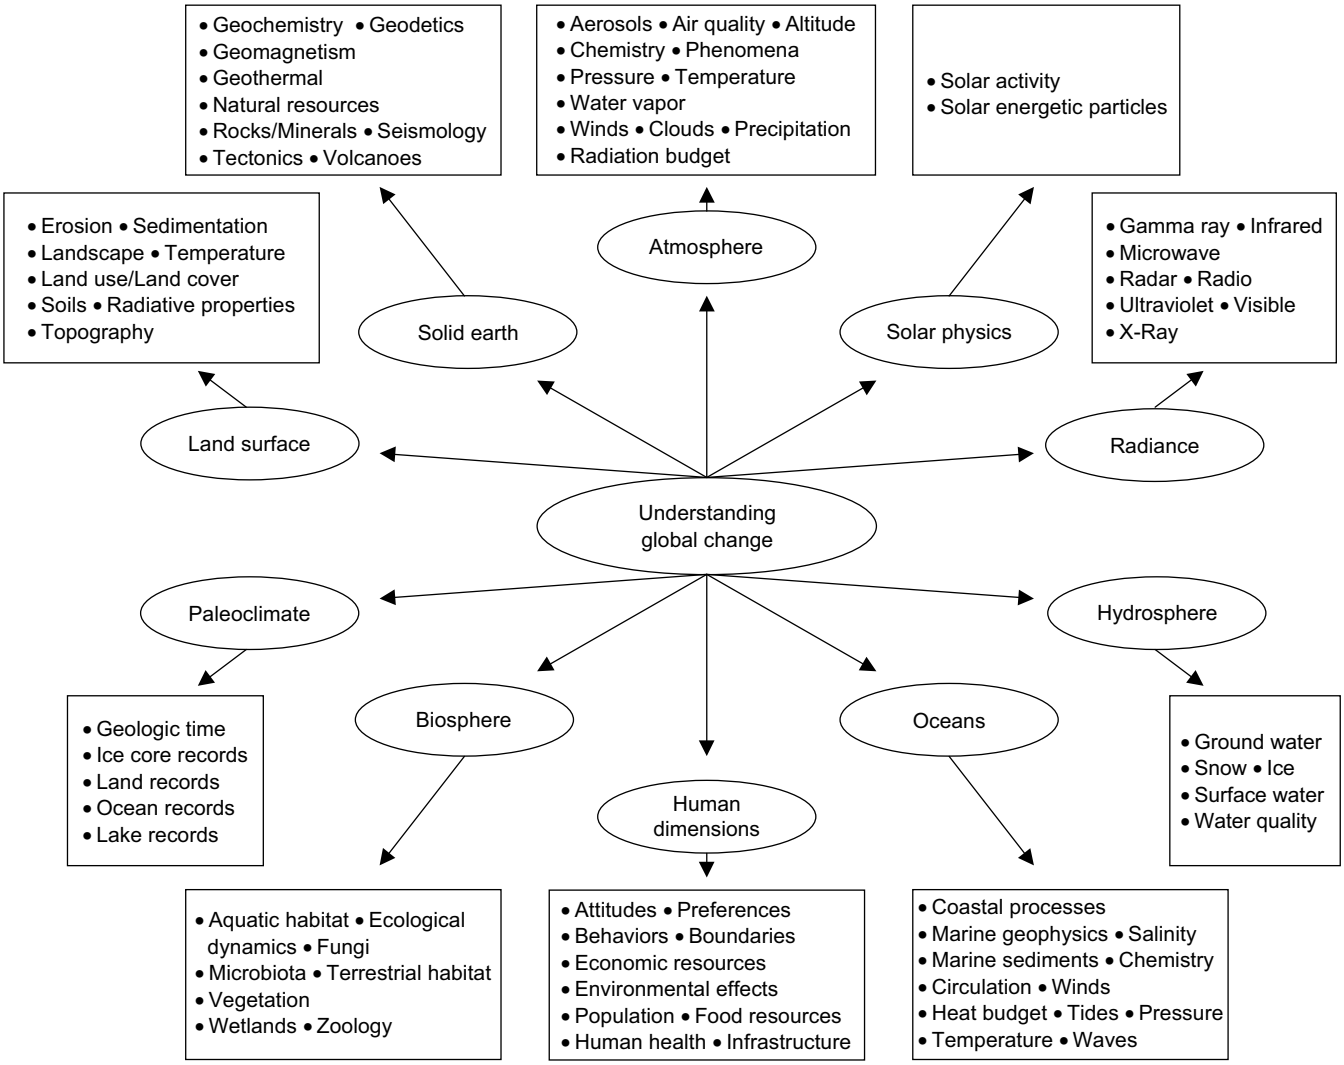

Figure 3 NASA's Global Change Master Directory (GCMD) covers a wide range of datasets including climate change, the biosphere, hydrosphere and oceans, geology, geography, and human dimensions of global change

Adding Data

Although there may be many variations on the overall process, an initial step for archiving is to connect a contributor with the appropriate data archive to add new data. Most archives continually work to identify user needs, availability of new data, and establish priorities to acquire new data. Often a data archive is associated with a specific program or has a thematic orientation and will actively seek selected datasets. The data archive provides guidelines to the contributor for formatting and submitting data and metadata. The contributor prepares data and metadata as completely as possible and submits them to the data bank, following established guidelines.

Archive staff review data and metadata and may reformat them to achieve consistency and completeness, making sure that the metadata include citation information so that the original data contributors can be correctly acknowledged. Staff also review the quality assurance that was performed on the data as documented in the metadata. They may also select keywords based on the metadata to be used in search and order functions. Archive staff and contributors work together to resolve questions and review changes. After consensus is reached, metadata and data are entered into the archive for public access and long-term storage.

Data Preservation

One of the prime responsibilities for a data archive is to ensure that the data will be accessible beyond the life of projects and programs. There are many examples of lost data, such as the ecological data from the IBP that were stored on early forms of electronic media in the early 1970s with the promise of long-term availability but are no longer

accessible (Gross *et al.*, 1995). Storing data on electronic media is no guarantee that the data archive problem is solved! Obsolescence of older computer technology seems to be the price paid for continual improvements. The lessons are twofold – maintaining paper copies of valuable datasets is a worthwhile practice for key datasets; and planning and resources are required in order to continually upgrade electronic storage, such as transferring from floppy diskettes to CD-ROMs, to DVDs (Digital Versatile Disks), and future media.

Rothenberg (1995) reviews hardware and software considerations to ensure that future generations can successfully read present-day digital files, such as avoiding data compression, avoiding proprietary storage formats and devising bootstrap standards as an input to future programs. Libraries have not had to address this problem with paper archives such as books, but periodic upgrading of storage media requires both long-term planning and funding. Life cycles seem to be about 3–5 years for current technology and around 10 years for available technology. The reliability of extending the functional life of archives beyond these limits should be carefully considered. The *20 year rule* is a practical guideline for archiving data and metadata. The aim is for the data to be fully comprehensible and employable to a user unfamiliar with the data or how they were obtained, 20 years after the data were archived, based solely on the documentation provided (NRC, 1991).

Back-up and security are important for insuring the longevity of the archive. Even the most carefully managed information systems risk information loss from mistakes, accidents, and malicious actions. Back-up copies should be stored on media that are independent of the primary storage system; ideally these should be physically located in another building as a guard against catastrophic loss. The procedure for retrieving the data from back-up should be tested routinely, and updated whenever the archive itself is updated. Limited access to the back-up copy contributes to the security of the information (security procedures should limit and record any transactions that can change the data or metadata, covering all networking and database software).

Digital Formats

There is no universal way to preserve data and metadata in a digital format. With evolving computer technology, both media and formats have changed and will continue to change. Currently ASCII flat files appear to be the most stable, neutral format for both data and metadata. Avoidance of proprietary software packages is recommended, since these may become obsolete or lack forwards- or backwards-compatibility. Most commercial packages have built-in functions to output ASCII files, such as comma-separated variables (CSV) from spreadsheets.

A drawback of ASCII formats is that a tedious, error-prone process is required to read a ASCII file into a software package (e.g., a spreadsheet or relational database management system) to use the data. It may also be difficult to detect format errors and there is no way to confirm the completeness of ASCII documentation. Several self-documenting, semi-neutral formats are emerging, including network common data form (NetCDF) and hierarchical data format (HDF). *Self-documenting* means that the files includes information about the data they contain.

NetCDF is an interface for scientific data access that implements a machine-independent, self-describing, extendible file format. It was developed for atmospheric and other data types by UCAR (University Corporation for Atmospheric Research, Boulder, Colorado, USA). It is a widely used, robust binary format with a variety of database functions and subroutines. The UCAR website at http://www.unidata.ucar.edu/packages/netcdf/ has more information.

HDF was developed by NCSA (US National Center for Supercomputing Applications, Champaign, Illinois) to assist users in the transfer and manipulation of scientific data across diverse operating systems and machines. HDF is a self-defining file format that supports a variety of data types: scientific data arrays, tables, and text annotations, as well as several types of raster images and their associated color palettes (*raster images* are patterns of closely spaced rows of dots).

Further information can be found at http://hdf.ncsa.uiuc.edu/.

A User's Guide (v.4.1r2) is available from the NCSA FTP (File Transfer Protocol) server (ftp.ncsa.uiuc.edu) in the directory: /HDF/Documentation/HDF4.1r2/Users_Guide/.

Locating Data

Representing the contents of the archive to the potential user community is a significant objective. It is essential that scientists be involved in the archive operations, where they may play a critical role in the organization and presentation of data, quality-assurance and quality-checking (QA/QC) review of data and metadata, and development of value-added products. Success of the communications between the archive and scientists depends on the proper selection of a documentation structure (how are datasets categorized) and language (what keywords are used). Input from scientists about the suitability of documentation is very important. In addition, a scientific advisory group can be a valuable link between users and sponsors.

Index System

The computing technology associated with the index or catalog is typically a database. This database contains key

fields and words that allow for tabulation of data attributes (e.g., How many datasets or records of what type? From what place? From what time?) and querying of dataset records that match user-specific criteria. The database technology required for this function of the archive includes relational databases and report generation utilities or more integrated data analysis software (e.g., Statistical Analysis Software (SAS), Statistical Package for Social Sciences (SPSS)). The database software may include functions that respond to users' queries with either the display of selected data records or summary reports. The database may also be required to record user attributes (name, e-mail address, phone number, etc.) and file access processing (FTP logs, mass storage staging status). Secondary analysis tools should also be included in the database functionality. Statistical and graphical summaries of data stored or data accessed are helpful for describing the contents of the archive, identifying data of interest, and justifying its continued operations.

User Interface

The user interface may be the most visible component of the computer technology associated with an archive. The interface provides descriptions of the archive contents to potential data users. These descriptions can be organized in hierarchical lists (e.g., sample locations within field sites within eco-regions, measurement types within environmental discipline within temporal or spatial scales). In some cases, the structural relationship of the datasets is too complex or numerous to be represented as a hierarchy and the descriptions are presented after a data base search on keywords, time intervals, or geographic regions. The user interface must be able to process the following major functions:

- The implementation of links between different levels of a hierarchy. (HTML protocols support this processing in web technology.)
- Entry and display of database parameters. The entry function provides a mechanism for the interface to record user preferences for query criteria. The display function processes the output of query results. This output includes simple statistics (number of matching records), record display (titles of descriptions), and bulk text (sections of documentation may originate from the database).
- Display of multimedia information that includes maps, graphs, text, sound, animation, and video. The documentation of environmental data frequently includes these non-text information types.
- Transmission of information by way of the Internet. This information includes the text and graphics associated with data documentation (i.e., by way of web technology). The information exchange also includes the transfer of data files by way of FTP.

The user interface is typically implemented with locally developed software that incorporates logic provided by applications software such as database servers, forms generation utilities, and image display tools. The web protocols are a common mechanism for implementing the functions of the user interface.

Subsetting

Archives that store information in databases may include logical functions that allow users to fully specify a desired data subset (e.g., by spatial, temporal, or thematic criteria), although archives that comprise collections of files or datasets (groups of loosely related files) are unlikely to generate subsets with consistent and complete structures. The end product of subsetting is customized extraction of information for the user (i.e., only those data records that match the time period, locations, parameters measured, and measurement range). The subsetting function is an important feature for archives that contain very large data objects (e.g., satellite images) or very long sequences of similar information (e.g., weather or stream flow records). The US NCDC and NWIS are examples of archives that provide subsetting from large data collections (Table 1).

Data Delivery

After the user has identified data of interest, the archive is responsible for delivering the data. Options for delivery include network, tape, and diskette. Network delivery is possible by Web transfer or FTP, but if the network connection and reliability are insufficient for the quantity of data, then tape or diskette options should considered. Data delivery on tape may be appropriate when quantities of data are large and immediate data access is not essential. However, it is important to confirm compatibility of tape hardware and formats between the archive and the user, since several tape media types are currently available, each of which has performance options that may be proprietary for the tape drive hardware or computer operating system. When networking is not available, small quantities of data may be provided on diskette, including floppy disks, disk cartridges, and CD-ROM, each of which have a limited number of format options.

Supporting Users

Other functions of the archive that may enhance these basic functions include conducting QA on the data and metadata beyond what the original data compiler performed, and combining archive data with other data. Often synthesis and modeling projects may contribute to an archive an integrated collection of data (a value-added data product) that is of particular interest to other users. Therefore, processing performed by the archive to promote the consistency and completeness of data (e.g., converting to SI metric units)

enhances the value of the data. An archive may also be able to generate summary statistics on data users (e.g., by country or Internet domain), and may be able to contact users when updates and additions to data are available.

In addition to maintaining a long-term, secure data archive, the archive staff also provide post-project support, such as answering user questions, identifying sources of reference information, informing users of updates and additions, and maintaining user statistics. Archives can perpetuate their growth and value of their data holdings by including a strategy for incorporating data updates, value-added products (especially from synthesis and modeling applications), and user feedback. Staff can collaborate with scientists to determine useful enhancements to datasets (e.g., add common variables, aggregate to common units, or calculate uncertainty) based on user needs. It is also crucial for the staff to promote the availability of the data by interacting with the user community, attending professional meetings (and staffing exhibition booths), and utilizing other marketing techniques.

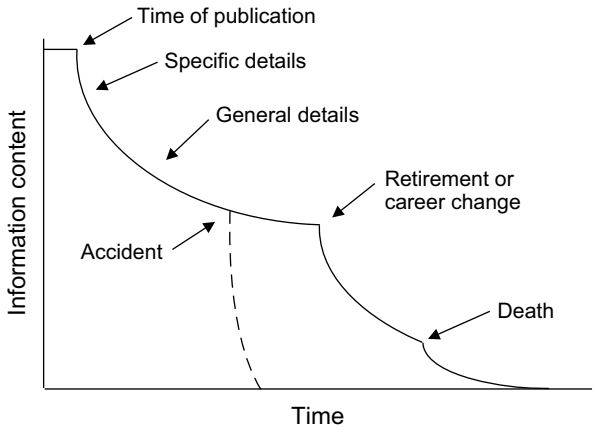

Figure 4 Example of the normal degradation of information content associated with data and metadata over time (''information entropy''). Accidents or changes in storage technology (dashed line) may eliminate access to remaining raw data and metadata at any time. (After Michener *et al.*, 1997, by permission of the Ecological Society of America)

DATA SHARING, INCENTIVES FOR ARCHIVING, AND DATA RESCUE

Data Sharing

Data may be collected as part of a project with integral data planning and funding resources for an archive, or they may follow a more haphazard path before finally arriving at an archive or data bank. In general, data flow from a principal investigator (PI) or group of PIs (those who collect, process, analyze, and publish data) towards the sharing, integrating, further analyzing and re-publishing of data. The maturing of data associated with large field projects is described by Strebel *et al.* (1994) as moving from initial infancy through adolescence to maturity. In the infant stage, data are collected and processed, while in the adolescent stage colleagues may peer review the data, which may be revised before moving to the adult stage as a free-standing, independent, published dataset. An alternative perspective is provided by Michener *et al.* (1997), who describe information entropy as the long-term degradation of information content associated with data as an investigator's personal knowledge of the data is forgotten or data or metadata are accidentally lost (Figure 4). Data archiving is one way to promote the sharing of data, to minimize the entropy of data, and to accumulate equity from research investments.

Typically, the PI has the greatest and most immediate interest in analyzing and publishing the data that he or she just collected. Only limited data sharing may occur before these initial interests have been fulfilled, such as a graduate student completing a dissertation. Although the data may thus be processed before any metadata are forgotten, data archiving may fail when PIs fear that providing immediate access to their data could result in others scooping the analysis or applications. Some funding agencies have attempted to circumvent this by specifying a specific exclusive time period for PIs.

In large collaborative multi-investigator research programs, project priorities such as research synthesis or model development may override those of individual PIs. Newly collected data may be unique, providing a fresh perspective on a science problem. Sometimes PIs may share specific information or less-sensitive data summaries while continuing to analyze their more detailed data. Prior to publication, project co-investigators and colleagues may form a wider user group around the PI. Typically the members of this group know the PI, have equivalent technical expertise and can recognize data limitations. They may be collaborators on a large project, requesting the data directly from the investigator and not requiring an independent source of extensive documentation in order to use the data.

Once data are described in a publication, an additional set of users may become interested. The next generation of data users may be from disciplines that are very different from that of the original investigator, and will require more documentation to understand the limitations associated with using the data for a particular application (Strebel *et al.*, 1994). By this time, the original scientist may have moved on to another project and may not have the resources or interest to provide additional technical support to these secondary users.

Several factors may promote a high level of interest in and demand for a particular dataset. As more publications cite a particular study and its data, there may be positive feedback in user demand for the data. However, if it requires months or years to get data into an archive for

access by others, then the archiving process may become a constraint to conducting science involving synthesis and modeling. Secondary users such as modelers will use whatever is available, or may generate their own estimates.

Incentives for Data Archiving

Project leaders, sponsors, and science managers can provide the following incentives for investigators to archive data, complementary to those incentives associated with conventional publications:

- establish a citation policy which gives credit to those who contribute data (in some cases there may be multiple contributors) as well as those who process and integrate datasets;
- provide adequate resources, guidance, and planning for data management to investigators;
- involve data personnel in the initial project planning;
- provide guidelines and training for metadata preparation;
- produce high visibility data products (e.g., CD-ROMs or hardcopy data products);
- give credit (i.e., include in promotion and salary review) to those that produce well-documented datasets.

In order to facilitate free and open exchange of data among ecologists and to create the reward structure necessary to encourage ecologists to share and exchange data, the Ecological Society of America has launched a new electronic publication (Ecological Archives) that enables the publication of peer-reviewed data papers as well as data-rich Appendices and supplements to print journals: http://esa.sdsc.edu/esapubs/Archive_main.htm.

Similarly, the British Ecological Society (BES) provides a venue for publishing ecological data as part of the *Journal of Ecology* data archives: http://www.demon.co.uk/bes/jearcmen.htm.

The BES archive contains material in HTML files, such as data, complex methods, etc., referred to in papers printed in the *Journal of Ecology*. In this case, authors are solely responsible for the accuracy of their archive material and no peer review is conducted.

Data Rescue

Sometimes datasets may enter an extended period (possibly several decades long) of low interest to be followed by renewed interest when they become part of a larger collection over time or space. Long-term data are especially valuable to detect rare events, subtle processes, and complex phenomena (Gross *et al.*, 1995). Often these datasets are orphaned because the investigator and documentation may not be readily available or because the data were recorded in an electronic format (or on punched cards) with no currently available technology to read the old files. The challenge is to be able to identify potential orphan data with legacy value that may become a key to understanding environmental trends and patterns.

An example of a data compilation and rescue effort is the hosting by the British Museum of Natural History of the Web-based Caterpillar Hostplants Database: http://www.nhm.ac.uk/entomology/hostplants/index.html.

This project offers a central facility to pool and permanently record rearing data of all Lepidoptera groups from anywhere in the world. Records of caterpillar host plants are scattered through published and manuscript sources and are difficult to retrieve. Many rearing records are never published and so are not accessible to other entomologists. Collected host plant records in this database form a valuable scientific resource that can be used to answer broader biological questions about how Lepidoptera and plants interact.

Other examples of data rescue are known from datasets contained in the NPP database at the ORNL DAAC data center: http://daac.ornl.gov/NPP/npp_home.html.

One collection of over 700 estimates of global terrestrial NPP was compiled in the early 1980s but was never made available to the scientific community. These data (the Osnabrück NPP dataset) were reviewed, documented, reorganized, and published in a citeable form (Esser *et al.*, 1997). Less auspicious is the case of the IBP Woodlands Dataset (DeAngelis *et al.*, 1981) and other datasets from the IBP, which were originally stored on magnetic media in the 1970s, but became unusable and had to be re-entered laboriously from faded computer printouts and/or printed summaries (see also “Data Preservation” above).

FUTURE DIRECTIONS

Research related to global environmental change is likely to be driven by sustainable production, protection of biodiversity, land use change, and other interdisciplinary issues. It has been suggested that this requires the establishment of not only traditional data archives, but information analysis centers that can integrate data across disciplines and disparate spatial and temporal scales (Kanciruk and Farrell, 1990). Attempts to scale research across regions, continents and the globe require an unprecedented level of collaboration among scientists, sharing of data across national and disciplinary borders, and ready access to high-quality, well-documented data from archives. Widespread use of the Internet and a gradual change in scientific philosophy to a less hierarchical and more cooperative paradigm is helping to bring this about.

However, data pertaining to different environmental resources may be incompatible, uncoordinated or stored in obscure locations. To alleviate this problem, a US government advisory committee known as PCAST (the President’s

Council of Advisors on Science and Technology) proposed the development of a federated information infrastructure (FII) whereby very large volumes (terabytes) of data from satellite, field and laboratory sources could be searched efficiently and compiled for re-analysis and re-synthesis in issue-driven research (PCAST, 1998). The FII would operate seamlessly, so that data layers such as soils, land-use and satellite imagery could be accessed from multiple databases, regardless of where these are physically located. Functions such as subsetting, merging or *concatenating* (linking) datasets would be one-click operations. The current challenges and barriers to achieving this utopian level of functionality are technical (although computer networking, communications, processing and storage are advancing rapidly), semantic (in terms of different standards and formats between multiple data sources) and social (in terms of modifying the current scientific reward structures to encourage data sharing and documenting).

Recommendations

Sharing and archiving of data can be more efficient if the following general principles are considered in the overall project planning and operations:

1. establish the flow of data from investigator to a long-term data archive as part of the work plan;
2. process data to achieve consistency and completeness of data and metadata;
3. institute policies to give the data producers adequate credit for their data archival efforts.

To more fully share data, we suggest that the environmental research community take the following actions:

- provide incentives for sharing and archiving data;
- recognize datasets with metadata as valuable research products;
- establish a universal citation policy for data;
- establish guidelines or expectations for metadata;
- develop data distribution and archive centers (including information analysis centers);
- ensure long-term financial and institutional support.

As the marginal cost of data distribution approaches zero for most types of data, and since most publicly-funded research data have already been paid for (by the public, who make up many of the users), a strong case may be made that data banks should distribute data for free (Kanciruk, 1997).

The use of environmental data will continue to expand during 21st-century synthesis and assessment studies that address long-term global and regional issues (Olson and McCord, 2000). Many future discoveries will depend on the intensive analysis of very large aggregations of data. Further reductions in cost per unit of electronic storage will continue to enable opportunities for expanded archives (storage capacity per unit hardware cost has decreased one thousand-fold over the past 10 years, and this trend is expected to continue). Exponential increases in the size of data holdings – in conjunction with increased demand for the information and knowledge necessary for informed decision-making – will require additional advances in data mining and knowledge discovery tools, as well as new technologies that can facilitate data processing (Michener, 2000). However, a minimal level of consistent information will probably still be required in order to reduce uncertainties and make data mining an effective technique. Likewise, more value-added products – such as integrated datasets for modeling – will also become available, and tools for documenting data will be used routinely.

ACKNOWLEDGMENTS

This research was sponsored by the Terrestrial Ecology Program, Office of Earth Science, US NASA, under Interagency Agreement No. 2013-I096-A1 with the US Department of Energy, and under University of Tennessee-Battelle LLC contract DE-AC05-00OR22725 with the US Department of Energy. W K Michener was supported by the US National Science Foundation. The authors also wish to thank Paul Kanciruk of Oak Ridge National Laboratory for critical comments on the manuscript.

De Wit, C T

(1924–1993)

Kees (Cornelis) De Wit grew up in a rural village in the eastern part of the Netherlands. As a consequence of enrollment at the Landbouwhoogeschool (Agricultural College, the predecessor of Wageningen Agricultural University), he spent most of World War II as a farm laborer. This greatly increased his interest in the complexities of farming and in farmers and was to guide his professional career. He completed his studies after the war with a PhD thesis (*A Physical Theory on Placement of Fertilizers*, 1953).

Subsequently, as a Dutch development worker, he joined the Ministry of National Planning of the Union of Burma and established the Agricultural Research Station in Gyogon. That period widened his interest in agriculture to developing countries.

After his return in 1956, De Wit remained in Wageningen. He was employed at the Institute for Biological and Chemical Research on Field Crops and Herbage (IBS) and its successor, Centre for Agrobiological Research (CABO), and produced some of his most influential papers:

- *Transpiration and Crop Yields* (1958); a major reinterpretation of crop water use data, based on a physical analysis of canopy processes aiming at understanding and generalizing.
- *On Competition* (1960) describing in physical and mathematical terms the interaction between plants of different species.
- *Ionic Balance and Growth of Plants* (1963, with Dr Wim Dijkshoorn), elaborating on the chemical composition of plants and the crucial role of anion/cation balance.
- *Photosynthesis of Leaf Canopies* (1965) introducing computer modeling in crop physiology.
- *A Dynamic Model of the Vegetative Growth of Crops* (1968, with Dr Rienk Brouwer), the first publication on crop growth simulation.

These publications are still widely quoted and constitute significant steps in the progress in agricultural science.

De Wit was appointed professor at Wageningen Agricultural University in 1968 to create the Department of Theoretical Production Ecology. Through its research and teaching (De Wit (co-)supervised 32 PhD theses), under his strong leadership, systems analysis and modeling gained a firm footing in the agricultural research community. "No simulation without experimentation," and later also the reverse, were among his most vivid expressions, always presented with characteristic conviction. He was the initiator of the series *Simulation Monographs* (Publisher PUDOC, Wageningen), that in the 1970s and 1980s formed the major outlet for publication of models of agricultural production systems.

In the 1980s, De Wit was member of the Dutch Scientific Council for Government Policy (WRR) and of the Technical Advisory Committee (TAC) of the Consultative Group on International Agricultural Research (CGIAR), and either initiated or took a very active part in discussions on environment, sustainability and development. For him, these appointments were challenges to combine biophysical and socio-economic sciences at a scientific and an operational level. His innovative efforts yielded a new approach to multi-stakeholder planning of land use and agricultural development (1988), an unconventional view of *Resource Use Efficiency in Agriculture* (1990) and transparant priority setting for international research (1992).

De Wit traveled extensively, had excellent professional and personal contacts around the world, and held several honorary appointments. Numerous illustrious visiting scientists profited from his insight and inspiration. His scientific qualities, his keen interest in human beings, deep feelings of justice and equality, his informality and his very sharp and systematic mind made him welcome, unavoidable and outstanding in any meeting. He received the Wolf prize of the State of Israel, the Nobel Prize for Agriculture, in 1975.

His approach to science has been adopted by many in the international science community, both within and outside agriculture. In Wageningen, The C T De Wit Graduate School for Production Ecology bears his name as a lasting testimony to his achievements.

Deposition, Dry

Dry deposition is the term used to describe, collectively, the processes by which atmosphere gases and particles are removed from the atmosphere and deposited at the surface of the earth, which do not involve precipitation. The term is also used to describe the flux (i.e., mass per unit time per unit area) of such material to the surface. Individual processes which contribute to dry deposition include gravitational sedimentation (primarily of larger particles), the turbulent transfer of small particles and gases to the near surface region, uptake of small particles at the surface by impaction and retention, adsorption, dissolution, chemical reaction, and biological uptake (e.g., through stomata). The effectiveness of dry deposition depends on a number of atmospheric and surface conditions: the atmospheric

concentration of constituents, their physical characteristics and chemical properties; the intensity of vertical exchange processes in the atmosphere which bring material to the near surface region; and the characteristics of the surface itself i.e., wetness, roughness, reactivity, and chemical, physical and biological properties.

Dry deposition is important because it is an effective mechanism for removing gases and particles (e.g., pollutants) from the atmosphere, and of transferring these same constituents to surface ecosystems where they may be beneficial (e.g., as nutrients; nitrates, iron) or harmful (e.g., as contaminants; sulfate in acid rain, organic chemicals). Dry deposition and wet deposition are important pathways in the biogeochemical cycles of some chemicals, transferring material from the atmosphere to the marine and terrestrial reservoirs. Dry deposition has played an important role in a number of environmental issues: lead deposition in urban areas, the transfer of semi-volatile organic species from tropical source regions to the Arctic, and the deposition of toxic metals and organic chemicals.

The relative importance of wet and dry deposition is species and location dependent. Close to sources dry deposition tends to exceed wet deposition, whereas far from source regions, wet deposition becomes dominant. For soluble and insoluble species, wet and dry deposition dominate, respectively. In the case of sulfur, for example, wet and dry deposition are of comparable magnitude on a global basis.

The quantity of dry deposition is very difficult to measure directly in most cases, and is currently done more often in a research mode than systematically in networks. Instruments to measure dry deposition are not standardized, are often very sophisticated, and tend to be species specific.

DOUGLAS WHELPDALE *Canada*

Deposition, Wet

Wet deposition is the term used to describe, collectively, the processes by which atmospheric gases and particles are removed from the atmosphere and deposited at the surface of the earth by rain, snow or other forms of precipitation. The term is also used to describe the flux (i.e., the mass per unit area per unit time) of such material to the surface. Individual processes which contribute to wet deposition include nucleation of cloud droplets, scavenging within and below clouds, and subsequent transport to the surface in precipitation. The effectiveness of wet deposition depends on the type and intensity of precipitation, and on the physical (e.g., size, shape) and chemical properties (e.g., solubility, reactivity) of the atmospheric constituents.

Wet deposition is important because it is an effective mechanism for removing gases and particles (e.g., pollutants) from the atmosphere, and of transferring these same constituents to surface ecosystems where they may be beneficial (e.g., as nutrients; nitrates, iron) or harmful (e.g., as contaminants; sulfate in acid rain, organic chemicals). Wet deposition and dry deposition are important pathways in the biogeochemical cycles of some chemicals, transferring material from the atmosphere to the marine and terrestrial reservoirs. Wet deposition has been a key element of several environmental issues: removal of radionuclides from nuclear testing, acid rain, excess nitrate fertilization, deposition of toxic metals and organic chemicals.

The relative importance of wet and dry deposition is species and location dependent. Close to sources where atmospheric concentrations are relatively high, dry deposition tends to exceed wet deposition; whereas far from source regions, wet deposition becomes dominant. For soluble and insoluble species, wet and dry deposition dominate, respectively. In the case of sulfur, for example, wet and dry deposition, are of comparable magnitude on a global basis.

The quantity of wet deposition can be reliably measured. This is done using standardized instruments, methods and quality control procedures. Several national and international networks (such as the Global Atmosphere Watch) operate around the world to measure wet deposition systematically and the resulting data are stored in accessible data systems.

Disturbance

Virginia Dale
Oak Ridge National Laboratory, Oak Ridge, TN, USA

A disturbance can be defined as any relatively discrete event in time that disrupts ecosystem, community, or population

structure and changes resources, substrate availability, or the physical environment (White and Pickett, 1985). Disturbances are an integral part of most ecological systems. Rather than being catastrophic agents of destruction, many disturbances are normal, perhaps even integral, parts of long-term system dynamics. The composition, structure, organization, and developmental and trophic dynamics of these systems are, partially, the products of disturbances. In fact, some ecological systems contain species (e.g., lodgepole pine (Pinus contorta)) that have evolved in response to disturbances. Disturbances shape landscapes, and the disturbance-generated mosaic has important influences on biotic structure and ecosystem processes. Understanding the nature of landscape patterns and the factors controlling them is essential for understanding and predicting ecosystem dynamics and vegetation development.

Disturbances are typically characterized by their size, spatial distribution, frequency or return interval, predictability, and magnitude, including both severity and intensity. Severity describes the effects of disturbance on the biota, and intensity refers to the energy released or the force exerted by the disturbance. Severity and intensity are related. Disturbance severity is important in its own right, e.g., hurricanes of the same spatial extent may have highly variable severities, which strongly influence ecological responses to these different large-scale events. The relationship between severity and disturbance size (i.e., area impacted) is complex. The heterogeneity created by disturbances refers to the spatial distribution of disturbance severities across the system.

Disturbances span a broad range of sizes and frequencies. Small, more frequent disturbances include individual tree falls; small fires and ice storms; annual floods; and small, patchy insect outbreaks. Large, infrequent disturbances include volcanic eruptions, crown fires, and extreme floods or storms. The latter are ecologically important because the imprint they leave on the ecosystem is large in area and may persist for a very long time (Turner and Dale, 1998). Indeed, a large disturbance may even become the dominant force structuring the system, creating the template upon which subsequent ecological processes and interactions among species occur. Large crown fires in boreal forests, for example, create a mosaic of stands of varying ages that may persist for several centuries. Volcanic eruptions create a spatial structure of vegetation patterns that may endure for millennia. Large, intense disturbances can set an ecological system back to an early stage in its developmental sequence or initiate a different successional pathway. Typically, large disturbances do not result in extensive areas of uniform impact. Rather, large disturbances create complex patterns across the landscape in which the disturbance may affect some locations more intensely than others. For example, even very large fires leave some stands unscathed because of wind shifts or natural fire breaks.

In assessing the ecological effects of disturbances, residuals that remain after the disturbance are critical. Ecological residuals of disturbance have both biological and physical components. Biotic residuals, or legacies, refer to the types, quantities, and patterns of organisms and biotic structures that persist from the pre-disturbance ecosystem. Residuals may include surviving individuals, standing dead trees, vegetative tissue that can regenerate, seeds, litter, carcasses, and components of the microbial and fungal soil community. Abiotic legacies are physical modifications of the environment that may result from the disturbance, e.g., mass movements like mudslides or slope failures, lava flows, boulder movements during floods in high-gradient streams, channel and bank movement, and silt deposition. Abiotic legacies may restructure the system. The spatial distribution of both biotic and abiotic legacies is important to the recovery of affected ecosystems.

Some species and even ecosystems are adapted to either frequent or large disturbances. For example, lodgepole pines (Pinus contorta) have cones that only open subsequent to exposure to intense heat such as occurs in a forest fire. The evolution of attributes that enable a species to respond to a disturbance relates to the frequency of the disturbance events, relative to the life span of the organism of concern.

Disturbances may serve as catalysts for sudden and unexpected changes in ecological systems – there may be surprises or threshold effects that are only manifested following extreme events (Paine et al.*, 1998). For example, disturbances may lead to the unanticipated recruitment of species or may increase the likelihood of alternative successional pathways developing at a site. Ecologists need to understand the forces that may lead to such unanticipated changes across a landscape. Global environmental changes will likely both include alterations in disturbance regimes and be affected by disturbances.*

NATURAL AND ANTHROPOGENIC CAUSES OF DISTURBANCE

The origin of disturbances can be considered as a continuum from entirely natural to entirely anthropogenic (Dale *et al.*, 1998). Some disturbances are caused solely by natural processes. El Niños, hurricanes, and volcanic eruptions are examples of such disturbances. An important feature of naturally induced disturbances is that they may have complex origins.

Several different disturbances, each with its own characteristics, can interact synergistically to produce different post-disturbance conditions. For example, the 1980 eruption of Mt St Helens in Washington State, USA produced a complex array of disturbance agents (e.g., pyroclastic flow, debris avalanche, mudflows, ash deposits, and blowdown). At specific sites, several agents interacted to affect the degree of damage and the course of recovery (e.g.,

snow cover protected under-story vegetation and small trees; some sites were protected by topography from the northward directed blast). Additionally, combinations of post-disturbance site characteristics can influence the biota. For example, the 1985 tornado blowdown in Northwest Pennsylvania, USA created a variety of physical habitat types, each of which affected survival, recruitment, and interaction of organisms that could contribute to the forest recovery.

Disturbances that are totally anthropogenic constitute the other extreme. These disturbances can be accidental or purposeful. Oil spills are examples of accidental, anthropogenic events that have no analog in nature. Some anthropogenic events, however, are similar to natural disturbances. The 1996 floods created in the Grand Canyon, USA, are an example of an intentional human-caused disturbance that was meant to approximate natural floods. In some cases, unintentional human-caused disturbances mimic nature, such as fires that are set by humans but have gotten out of control.

Land use can be considered a long-term, broad-scale, chronic disturbance by humans. The diversity of land uses ranges from actions that wholly transform the system into a unique ecological situation (e.g., farming creates agriculture systems) to actions that mimic natural disturbances (e.g., the practice of silviculture is meant to simulate how natural disturbances affect trees). Land use can also unintentionally replicate the effects of natural disturbances, as is the case with military training at Fort McCoy in Northern Wisconsin, USA. The training activities produce effects similar to fires that historically burned these areas; both create oak savannahs which are requisite for the obligate host plant of the endangered Karner blue butterfly (*Lycaeides melissa samuelis*), which thrives on the military reservation.

Many disturbances are cascading (Dale *et al.*, 2001). For example, drought often weakens tree vigor, leading to insect infestations, disease, or fire. Insect infestations and disease promote future fires by increasing fuel loads, and fires promote future infestations by compromising tree defenses. Increased fire intensity or extent enhances the potential for landslides. Also, changes in land use, forest management, and atmospheric chemistry can interact with natural disturbances. For example, an increase in landslide frequency may result from harvest and road establishment in landslide-prone areas coupled with increased precipitation (that might occur with global climate change). Establishment of ski slopes in the Alps has increased the frequency of mudslides. In the southern Appalachians of the USA ozone exposure coupled with infestations of exotic insects (*Adelges piceae*) and climate change appears to be increasing Fraser fir (*Abies fraseri*) mortality and red spruce (*Picea rubens*) stress. In some cases, however, a combination of disturbances may ameliorate impacts. Under droughty conditions, stomata tend to close, reducing the effects of high ozone exposure.

Nevertheless, when ecosystems experience more than one disturbance, the multiple effects can lead to new domains. A new domain is entered when the system has not recovered from the first disturbance before a second perturbation occurs, leading the system to a new long-term condition. For instance, the combination of overgrazing with severe drought can lead to rapid desertification. Furthermore, the combination of climatically driven wildfires, fragmentation caused by agriculture, and logging in the boreal forest has resulted in significant and unprecedented changes in forest composition with a decline in the species that take a long time to reach maturity, have serotinuous cones, or the potential to reproduce vegetatively (Paine *et al.*, 1998, Cushman and Wallin, 2000). Under climate change these multiple interactions may be unprecedented and unpredictable. They are likely to appear slowly and be difficult to detect.

Such perturbations can sometimes yield ecological surprises. For example, in the winter of 1982–1983, kelp forests off the coast of Alta and Baja California, Mexico were devastated by the combination of 4–5 °C warm-water anomalies (instigated by El Niño-Southern Oscillation) coupled with storms (common winter events to which they are well-adapted) (Paine *et al.*, 1998). Similarly, the combination of the introduction of an exotic mollusc (*Potamorcubula amurensis*) and drought followed by extreme floods has initiated sweeping changes in ecosystem structure in the San Francisco Bay, USA. Thus, understanding synergistic effects of disturbances is critical.

Sometimes the factors instigating a disturbance can be detected, but often the prime causal force cannot be identified. In these cases the historical influences may be subtle, and their effects may be indirect. For example, insect disturbances to forests appear to be more frequent now either because many pest insects have been introduced by human activity or because humans have altered the state of some ecological systems (e.g., via air pollution) and, thereby, increased their vulnerability to attack. Climate change can affect forests indirectly by altering the frequency, intensity, duration, and timing of fire, drought, impacts by non-native species, insect and pathogen outbreaks, hurricanes, windstorms, ice storms, or landslides (Dale *et al.*, 2001).

The constraints and context of a disturbance may be influenced by human manipulation of disturbance events. For example, flood control has created systems that are now susceptible to large-scale, infrequent flooding rather than smaller scale, more frequent natural flooding regime. Similarly, the buildup of fuel on the forest floor as a result of fire suppression means that a subsequent fire might be particularly large and devastating. As another example, the historical patterns of farming in an east Tennessee, USA,

watershed have influenced subsequent patterns of insect outbreaks. Clearly, humans can both instigate disturbances and influence their impact.

Because humans can alter the susceptibility of systems to disturbances, they can also alter disturbance regimes. The frequency, intensity, rate of spread, and size of a disturbance are subject to human modification for some types of disturbances. Fire may be the best example of this phenomenon. In Southern Ethiopia, fire suppression leads to expansion of bush cover and a decline in range conditions (Oba *et al.*, 2000). At Eglin Air Force Base in Northern Florida, USA, decades of fire control led to the establishment of fire-prone forests dominated by sand pines (*Pinus clausa*). As biologists set controlled fires to gradually return the system to chronically burned forests, the sand pines are now being replaced by the naturally occurring longleaf pine (*Pinus palustris*) forests. One of the implications of recent changes in climate may be alterations in the frequency and intensity of natural disturbances.

Changes in disturbance regimes can alter the landscape. For example, human-managed systems tend to have more linear features (e.g., roads and straight lot lines) than systems dominated by natural patterns of disturbances. Disturbance regimes can affect plant distribution, and the size, shape, and distribution of patches are influenced by disturbance frequency and size. For instance, the substitution of a widespread, relatively uniform anthropogenic disturbance regime (e.g., clear cutting) for the patchy disturbances of the pre-settlement forests of Wisconsin, USA, has resulted in a more homogeneous forest (White and Mladenoff, 1994).

DISTURBANCES AND GLOBAL CHANGE

The impacts of global change are moderated by interactions between climate and disturbances. Therefore, it is important to understand how particular disturbances influence ecological systems and are affected by climate change. Furthermore, the frequency, size, intensity, seasonality, duration and type of the disturbances often depend on weather and climate in addition to site characteristics. As a long-term phenomenon, climate change is likely to interact with other types of disturbances.

A challenge to understanding effects of climate change on ecological systems is not only obtaining information on the impacts of temperature and precipitation but also acquiring knowledge about how climate change affects disturbance and how disturbances affect the ecological system. The impacts of disturbances on ecosystems are often not easy to predict (e.g., there are at least 12 possible outcomes of hurricanes in tropical forests (Lugo, 2000)). Furthermore, new disturbances, such as the spread of introduced species, can cause unforeseen effects (Simberloff, 2000).

The link between climate change and disturbances needs to be formally integrated into our understanding of climate change. There are relatively few field studies on how climate change interacts with disturbances. Fires and droughts are the cases where such interactions have been explored with field experiments (Flannigan *et al.*, 2000; Hanson and Weltzin, 2000).

Such interactions between climate, disturbances, and ecological systems may be critical in determining how global change expresses its effects. For example, changes in species diversity are most quickly apparent after a disturbance has cleared the landscape and species adapted to the new climate become established. Because forests are so long-lived, it may be that many climate change effects on forests are most easily observed in places where the successional pathway has been disrupted by a disturbance.

MANAGEMENT IMPLICATIONS

The realization that disturbances play an integral role in ecological processes influences management of disturbance-prone systems. Some disturbances are readily incorporated into planning and management. For example, forest thinning is designed to replicate small disturbances in forests.

Large, infrequent disturbances are difficult to plan for. When such disturbances do occur, they may trigger departures from average conditions. Even so, the costs and benefits of management actions are assessed at relatively small temporal and spatial scales. For example, even in hurricane-prone coastal areas, flood insurance is generally available to homeowners except in the days immediately preceding an impending hurricane. Furthermore, planning for response to large disturbances does not typically consider the length of time required for repair to occur naturally. In the same sense planners do not always recognize that human developments in the vicinity of the disturbance may have broad-scale implications. For example, although it may be cost-effective for an individual locality to build a levee to protect it against floods, the levee can increase the chance of downstream floods. Failure to anticipate decadal increases in the costs of flood damages in the US is partially caused by this short-term perspective. Traditional economic analyses do not anticipate such broad-scale costs that result from suppressing disturbances on a local scale.

Infrequent disturbances may not be included in planning because people's perceptions are most influenced by what has occurred during their life times. The temporal and spatial scale of large, infrequent disturbances is so immense that our impressions are dominated by the lack of such disturbances. Even actuaries struggle with how to include catastrophes. Institutional memories are often no better than individual memories in dealing with disturbances. Thus, management goals typically do not consider what aims are appropriate in the face of disturbance.

A key challenge of dealing with disturbances is developing and employing management strategies to cope with the changes. For management purposes the conditions that lead to or result from disturbances need to be understood so that manipulations can be developed, when possible. Management plans may focus on the potential for managing (a) the system prior to the disturbance, (b) the disturbance itself, (c) the system immediately after the disturbance, (d) the recovery process, or (e) a combination thereof (Dale *et al.*, 1998).

MANAGING THE SYSTEM PRIOR TO THE DISTURBANCE

Preparatory actions in anticipation of a disturbance are designed to manipulate the system and be consistent with management goals. The system can be manipulated to alter its vulnerability, its resistance or its response to a disturbance. An example of changing a system's vulnerability is altering fuel loads in a forest so that fire is more or less intense when it occurs. Resistance can be increased at some location in the system so that the extent of the disturbance is limited (e.g., through fire breaks, spraying for insects or planting windbreaks). Then the disturbing force can still occur with its full intensity, but the system will not be altered to the extent it would have been without the management intervention. For example, restoration of the Kissimmee River in FL, USA, involves reconnecting the river and the floodplain through channel restructuring so that flood events improve dissolved oxygen conditions in the stream and enhance wetland communities. Greater attention is needed on the potential for managing ecosystems so that they can better withstand a disturbance. Tools for accomplishing this goal include intercropping, silvicultural techniques, species selection, genetic engineering and experimenting with new species combinations. For example, novel combinations of native species, naturalized species and non-invasive, non-native species can create a system that is more resistant to disturbances. An example of a system made more resistant is the historical development of vegetation in New England, USA: as the effects of disturbances such as hurricanes, winter storms, and massive deforestation, agriculture, and land abandonment have taken their toll, the types and spatial patterns of forest communities that prevail in the New England landscape have changed dramatically, as has the area's susceptibility to disturbances. In some cases the landscape impacts of changing the resistance of systems may be severe. For example, in the aftermath of the massive 1988 fires at Yellowstone National Park, USA, it was recognized that the large scale of those fires was, in part, the result of previous fire-control actions that connected patches of fire-prone forests.

MANAGING A DISTURBANCE

The disturbance itself can be managed in one of three ways: no action, prevention of the disturbance or manipulation of its effects. Note that "no action" is not a default but a conscious management decision based on knowledge about the potential disturbance, the system and the management goals. "No action" is taken when nothing can be done about the disturbance (as in the case of most tornados, volcanoes or hurricanes) or when one can accept the consequences of the event. For instance, the 1988 fires in Yellowstone National Park were initially not fought because it was felt that the effects would be acceptable. As another example, with today's technology it is prohibitively expensive to prevent the wide-scale destruction that could result from meteors crashing into the Earth, i.e., by launching nuclear bombs on rockets to intercept the meteors, explode, and thus, change the meteors' courses.

Prevention is usually motivated by the desire to satisfy a human concern. Managers attempt to prevent disturbance when the costs of such efforts are perceived to be balanced or exceeded by the anticipated benefits. Thus, dams, levees, reservoirs and coastal barriers are built to prevent disturbances caused by water action.

Disturbance manipulation requires human intervention with the causal forces which, when possible, is always costly and difficult. Disturbances can be manipulated to either reduce their effects or to increase their impacts in an attempt to recreate more natural conditions. The disturbances most amenable to manipulation may be the ones that result from anthropogenic activities, such as some fires. However, other attempts have been made to create disturbances that mimic natural events. For example, in March 1996, the water flow of the Colorado River was increased by releasing flood-level volumes from Glen Canyon Dam. The goal of this anthropogenic flood was to instigate geomorphic and biotic conditions similar to those of the natural flooding regime of the Colorado River that had been kept in check by dams for many years. The result of the flood was an increase in suitable habitat for a variety of native fish species and a reduction in the density of non-native riparian species (such as the naturalized and highly invasive plant, tamarisk).

MANAGING THE SYSTEM AFTER THE DISTURBANCE

An inability to anticipate disturbances is often paired with a lack of recognition of the potential for recovery. Recovery typically is a slow, step-by-step process by which individual organisms become established and, eventually, trophic interactions and other ecosystem processes become re-established. Because the potential for recovery is seldom recognized by either the public or the political system

and because public attention is heightened after a large disturbance, managers are often pressured to do something. In more than one instance, such actions have not only been very costly but also detrimental to the natural recovery process. For example, leaving the system alone made more sense than some of the intensive recovery actions taken after Hurricane Hugo, the eruption of Mount St. Helens and the Exxon Valdez oil spill.

After Hurricane Hugo passed over Puerto Rico in 1989, stream channels in the Luquillo Experimental Forest were packed with logs from trees knocked down by the high winds. Some of the logjams near bridges or recreation areas were safety hazards and were removed. However, in other locations, logjams were allowed to remain in the streams because such structures provide cover and food for stream organisms and retain valuable nutrients, sediments, and organic matter in place (Covich and Crowl, 1990). As a result, the recovery of the stream community following a flood is faster with the logjams than without them. This realization allowed forest managers to focus their limited resources on safety hazards and other priorities rather than clearing all log jams, actions that would have been counterproductive or neutral in terms of sustaining natural-system functions.

In contrast, the use of non-native seeds in an attempt to reduce erosion in the aftermath of the 1980 eruption of Mount St. Helens is an example of money poorly spent in recovery actions (Dale, 1991). Petitions from scientists and a resolution from the International Congress of Systematic and Evolutionary Biology curtailed the wide-scale distribution of non-native seeds; nevertheless $50 000 was spent distributing seeds by helicopter onto 32 000 ha of the new volcanic material. Subsequent studies showed that the non-native seeds had no effect on the erosion problem. In fact, areas containing the non-native species had a higher mortality of native conifer seedlings and a lower diversity of native species. A similar experience occurred in landslide areas in the Luquillo Experimental Forest after Hurricane Hugo. Non-native species planted on the landslides failed to grow and were rapidly overwhelmed by native vegetation.

Steam cleaning birds after the 1989 Exxon Valdez oil spill may also have been unnecessary (Wiens, 1996). Although more than 30 000 oiled bird carcasses were retrieved following the spill, little evidence remained of the event four years later, even in oiled environments. The demonstrated resilience of these communities raises the possibility that the effectiveness of expensive cleaning activities immediately after the spill requires more analysis and study.

MANAGING THE RECOVERY PROCESS

Because managing recovery can be thought of as managing succession, knowledge of natural succession processes increases the likelihood that the management plan will be achievable. The first step in managing recovery is to evaluate the site potential. This activity includes the evaluation of the spatial pattern of the effects, the biological and physical residuals of the disturbance, site environmental conditions, the potential for naturally dispersed seeds to aid in the recovery, and the influence of structural heterogeneity on the re-establishment of plants and animals.

Following a disturbance, the site may be changed in many ways, but one important set of characteristics of the disturbance is what remains, i.e., the residuals. Residuals include organisms, their seeds and other reproductive parts, abiotic site characteristics and organic matter. These are soon joined by migrants whose rate of arrival can be characterized by their distance from the site and their ability to spread. These organisms may interact in myriad ways by providing shade, moisture, nutrients or future propagules.

A common goal of recovery management is to shorten the process of succession or to halt the process of succession when a state has been reached considered particularly desirable for human purposes. Thus, following some disturbances, the recovery plans for the area may include altering the patterns of landscape connectivity or suppressing or removing undesirable residuals, under the assumption that such action is cost-effective. In some cases after a significant disturbance, non-native plant species may occupy the recently open site to the detriment of the native species that one is attempting to re-establish. The negative influences of the non-native cheat grass (*Bromus tectorum*) on sagebrush community recovery following wildfire are well documented (Mack, 1981). A classic tropical example of this phenomenon is the invasion of grasses (e.g., *Imperata cylindrica*) after a disturbance which subsequently inhibits forest recovery – a situation that can be avoided by site preparation or planting of native trees (Otsamo *et al.*, 1995). Thus, humans can act as agents of migration for a variety of desirable species, thereby shortening the process of succession and establishing species that prevent invasion of undesirable forms. The establishment process can be hastened in a variety of ways: by fertilizing, providing shade, providing mulch, adding mycorrhizae or undertaking other activities that allow desirable species to rapidly establish and reproduce. Managing the interactions of species and of landscape attributes is a bit more difficult and costly. Often so little is known about these interactions that the only alternative is to establish a management situation in which natural processes are likely to occur and then let the community develop on its own.

Sometimes, the effects of a disturbance or the combined effects of a disturbance and human modifications of sites (e.g., past land uses) alter the direction of succession. This situation may occur when sites are highly degraded after the disturbance. For example, forest recovery in abandoned pastures in Puerto Rico with non-native species (10 of 112

species listed) experienced a different rate of succession than sites recovering only from hurricanes (Aide *et al.*, 1996). Under the former conditions, species that are usually considered undesirable because they are invasive or non-native become desirable because they enhance repair of site conditions and the eventual restoration of native species. Similar trends appear in temperate successions and should be assessed in management scenarios.

A disturbance may be so large that the only practical approach to manage the system immediately after the disturbance is simply to allow the area to regenerate naturally with some limited surgical management to ensure that undesirable, outside forces do not influence the trajectory of recovery. For example, species may be planted to create shade under which many weedy plants cannot flourish. In other cases extensive management activities may be necessary to attain the desired goal. The balance between cost and desirability of a return to a given endpoint must be weighed in making these decisions.

In developing recovery plans, managers should focus on critical stages of the process: migration, establishment, biotic interactions (such as competition, predation, or mutualism) and the reaction of the systems to the changes that occur over successional time. For each successional stage a management prescription can be developed that offers three alterative interventions: add something to the system, kill or remove a biological component, or alter the structure of the system. For example, during the migration process a manager could add seeds, eggs or attractants for seed dispersers (e.g., posts that birds might rest upon). Alternatively, one could physically remove existing propagules from the system by events, such as an intentional flooding that removes zebra mussels from rivers. On the other hand, a manager could frighten away or exclude animals that might eat the propagules or could remove the dispersal agent of undesirable seeds. Structural additions to the system might include bird perches and alterations in landscape structure so that seed input is enhanced.

Successional trajectories after a disturbance event can follow a variety of directions, but in many cases they culminate in functional communities similar in structure and composition to the original ones. Alternatively, the successional trajectory can involve novel or unfamiliar successional communities if the magnitude and low-frequency of the disturbance sets succession back to early or uncommon stages. For example, after Hurricane Hugo, stands in the Luquillo Experimental Forest in Puerto Rico were invaded by vines and herbaceous species not observed at that site in more than 50 years (Scatena *et al.*, 1996). Yet, this early stage in the recovery of the rain forest quickly gave way to more familiar successional trees such as *Cecropia peltata.* Within seven years after the hurricane, vines and herbaceous vegetation had assumed their previous low abundance in specialized locations, such as in the canopy gaps of tall forests. However, their dominance after the hurricane was critical to immobilizing nutrients released by the disturbance and in re-establishing forest conditions. In this case non-arboreal vegetation did not inhibit forest regeneration. The traditional management practice of eliminating vines and weeds when they occur in tree plantations would have been counterproductive in the context of managing a hurricane disturbance. Anyone who witnessed a damaged stand covered by vines (e.g., Kudzu (*Pueraria thunbergiana*)) might not have imagined that the trees covered by native members of this life form would eventually grow and replace them. This lack of foresight underscores the need to base disturbance management on ecological principles and not on headlines, personal memory, or ideas about what is attractive.

As the Earth's environment continues to change, it is necessary to understand how disturbances are affected by these changes. It is also necessary to improve the scientific underpinnings of management actions that can be implemented in the face of these changes.

DIVERSITAS

Ghillean T Prance
University of Reading, Reading, UK

A description is given of the programs, administration and structure of DIVERSITAS an international program to promote biodiversity science. It is sponsored by six international scientific organizations and functions through five Core Programmes (CPEs) and five special target areas of research (STARs). CPEs: (1); the effect of biodiversity on ecosystem function; (2) origins, maintenance and change of biodiversity; (3) systematics, inventory and classification of biodiversity; (4) monitoring of biodiversity; (5) conservation, restoration and sustainable use of biodiversity. STAR: (1); soil and sediment biodiversity; (2) marine biodiversity; (3) microbial biodiversity; (4) freshwater biodiversity; (5) human dimension of biodiversity. During 2001–2002 DIVERSITAS is also organizing the International Biodiversity Observation Year (IBOY).

DIVERSITAS is an international program of biodiversity science. It was created in 1991 to bring together under one umbrella, scientists of the many disciplines that study biodiversity. DIVERSITAS was the name selected by the original founders of the organization and is not an acronym. It is co-sponsored by six international scientific organizations: the International Union of Biological Sciences, the Scientific Committee on Problems of the Environment, the United Nations Educational, Scientific and Cultural Organisation, the International Union of Microbiological Societies (IUMS), the International Council for Science (ICSU), and the International Geosphere–Biosphere Programme. In 1966, DIVERSITAS was re-organized and a new Scientific Steering Committee of experts from many areas of research was set up to coordinate the work and set its operational plan. This work is divided into ten program elements, each focused on a fundamental scientific question about the diversity of life on Earth. Five of these elements are considered the CPEs and five are STARs. The CPEs are:

1. *The effect of biodiversity on ecosystem functioning*: which addresses the issues of how biodiversity influences ecosystem stability and resilience and how global climate change affects these relationships. It also studies the role that biodiversity plays in ecosystem processes (e.g., productivity, decomposition and nutrient cycling). This includes programs on soil and sediment biodiversity, the impact of global change on the biology of soils, the study of global change and ecological complexity.
2. *Origins, maintenance and change of biodiversity*: this element supports research at the intraspecific genetic, population and community levels, and research on the processes and mechanisms of species extinction and community organization. It seeks to understand the population and genetic processes leading to biotic diversification as well as loss, and will use this knowledge to develop effective strategies for maintaining biodiversity. The focus is on the integrating population genetics and ecological studies and integrating levels or organization from an individual to the community. Central to this element is the study of interactions among species and of habitat fragmentation as well as the ecology and genetics of rare species.

3. *Systematics: inventory and classification of biodiversity*: which has held a series of international meetings to develop consensus on the methods and priorities for a systematic inventory of the world's species, and analyze and synthesize the information obtained into predictive classifications that reflect the evolutionary history of life. A 1998 workshop discussed the conceptual and methodological framework and tools for establishing and evaluating systematic inventories. Workshops held in Crete in 1997 and in Darwin, Australia in 1998 have drawn attention to the pivotal role of systematics to all biodiversity science. Affiliated to this is the Species 2000 programme, which is gradually forming a link between taxonomic databases around the world. The ultimate goal of Species 2000 is to provide a worldwide service of an index to all known animals, plants, fungi and microorganisms. This index will form a baseline reference system for communications about biodiversity.
4. *Monitoring of biodiversity*: this element seeks to develop efficient and standardized methodologies and priorities for monitoring changes in the current and future state of biodiversity. This is essential in order to obtain more reliable and predictive comparisons between sites around the world. It is obviously closely linked and dependent upon Programme Element 3 on Systematics. The monitoring of species of all organisms and their interactions with other species and with the abiotic environment is essential to the understanding and management of biodiversity. Decisions for investigating and maintaining global biodiversity, considering its change, including the actual manipulation of this change, must be based on scientifically informed data and analyses.
5. *Conservation, restoration and sustainable use of biodiversity*: the conservation and the sustainable use of biodiversity are both crucial to the maintenance of global stability. This element focuses on the conservation of genetic diversity in wild species, especially the wild relatives of cultivated plants and domesticated animals, also on strategies for restoring degraded ecosystems and landscapes, and how to determine how different land use and land management practices could sustainably maximize production for human consumption, while simultaneously conserving ecosystem services and biodiversity. This element is also closely involved with conservation policy legislation and the Convention on Biological Diversity (CBD) and is working on how the dynamics of biodiversity affects conservation policy development.

The STARs are themes which cut across the boundaries of the Core Programme Element themes and focus on problems of special concern within biodiversity science that are often neglected or receive only limited attention elsewhere.

1. *Soil and sediment biodiversity*: are poorly known yet play a central role in ecosystem processes, including the control of the transformation of nutrients and the generation of greenhouse gases. The oxygenation of soil and sediments and formation of organic matter are other dynamic processes performed by soil biota that contribute to the sustainability of the planet. DIVERSITAS seeks to facilitate and coordinate information on how soil and sediment species composition and community structure influence ecosystem function, and to determine how human intervention and global change impact this relationship and influence feedback to global processes. The understanding of what differences exist in soils and marine and freshwater sediments and how they control particular ecosystem processes, the vulnerability of their species to disturbance, their distribution, abundance and interactions are questions that cut across many international scientific programs.
2. *Marine biodiversity*: the conservation of marine ecosystems, which are often considered as a global commons, requires expanded and improved understanding of the patterns and processes that control the diversity of life in the sea. The effects of biodiversity loss at sea are poorly understood. This STAR seeks to investigate how marine biodiversity is affected by fisheries operations, eutrophication, alteration of the physical habitat, exotic species invasion, and other human impacts on this vital ecosystem. This element of DIVERSITAS concentrates on the building of networks among interested institutions as well as addressing aspects of marine biodiversity origin, maintenance and ecosystem function.
3. *Microbial biodiversity*: plays a critical role as the basic component of many food chains and biogeochemical cycles. Despite their importance, less than 5% of the world's microorganisms have been described. New molecular techniques allow the much more rapid investigation of this area. This element of DIVERSITAS seeks to stimulate the development of innovative methods and techniques to accelerate the discovery and functional characterization of microbial biodiversity, and develop a database mechanism to collect and exchange information on the biological characteristics of microorganisms. The microbial diversity STAR is integrated throughout the other elements of DIVERSITAS and is fundamental to its mission since microbial diversity is important in soil fertility, nitrogen fixation, agricultural production, water safety and public health. In the field of microbial conservation, DIVERSITAS seeks to stimulate the

better integration of extant culture collections in many countries around the world. This STAR interacts closely with the IUMS one of the co-sponsors of DIVERSITAS.

4. *Freshwater biodiversity*: the investigation of freshwater biodiversity poses special scientific and conservation challenges because of the variety of habitats, their isolated bodies of water and their extremely rich flora and fauna. Research in this area also involves studies of water supply for various human uses, physical alteration of habitats, chemical pollution and eutrophication, over-exploitation of fish and other fishery organisms, invasion of exotic species, global change, including the effects of acid rain, potentially rising temperatures and desertification and also changes to lake circulation and nutrient supply.
5. *The human dimensions of biodiversity*: this STAR studies the relationship between biodiversity and human well-being and is acting as a catalyst in generating and synthesizing scientific information for understanding linkups between the cultural attributes of societies and their relevance for building a scientific understanding of biodiversity, evaluating the effects on human well-being of the relationships between population pressure and biodiversity dynamics; analyzing the highly complex ways in which traditional and modern human societies have managed and are managing biodiversity; and evaluating strategies for ensuring people's participation in conserving biodiversity and sustainable managing of biotic resources. The major objectives of this STAR are to acquire a better understanding of the complex relationships among the ecological, social, economic, cultural and behavioral dimensions involving humans, and also to utilize this information for managing biodiversity in a sustainable way to fulfill human needs. This STAR is involved in capacity building, and the education of a new breed of scientists who will be able to co-ordinate their research efforts with local communities and policy planners at all levels.

THE ADMINISTRATION OF DIVERSITAS

A Scientific Steering Committee manages DIVERSITAS, and is composed of experts in particular research areas of biodiversity, in consideration of the program's overall scientific balance and goals. An independent DIVERSITAS Secretariat has been established to provide overall coordination for, and access to, the program and its expertise in biodiversity science, as well as to assure relationships among current and emerging policy issues. The DIVERSITAS Homepage on the Web contains up-to-date information of its activities, at www.lemp.jussieu.fr/icsu/DIVERSITAS/.

Linkages with the Convention on Biological Diversity (CBD)

DIVERSITAS, through its access to ongoing integrated research activities, has signed a Memorandum of Cooperation with the CBD Secretariat. DIVERSITAS has been officially cited by the Conference of Parties (Bratislava, 1998) to be used as a mechanism to provide advice to the Subsidiary Body on Scientific, Technical and Technological Advice.

The Formation of DIVERSITAS National Committees

National Committees are indispensable to the DIVERSITAS program, in order to adapt to national concerns and priorities: biodiversity implies a diversity of organisms and ecological systems, a diversity of human-related impacts, as well as a diversity of approaches.

National Committees

- Can create targeted national programs to feed into DIVERSITAS program Elements. This will also help in the consolidation of different scientific disciplines within the country and coordinate with other national initiatives (systematics, genetic resources, conservation and restoration);
- involve the scientific community in the international scientific area. Science is thought to transcend all boundaries but this is not always the case. Very often, nations operate on a bilateral system, but rarely on a multi-national system;
- stimulation of international initiatives such as workshops both within and outside the country;
- facilitate the obtaining of funds. There are many national ministries or donor organizations that receive requests for funds for various projects within the country. Forming National Committees can organize and consolidate the activities, creating a unified front with the best possible science guaranteed;
- aid in the CBD process. Ensure that the information channel is open from the bottom up as well as top down;
- at present the following countries have established national committees: Brazil, France, Norway, Germany, Indonesia, Malaysia, Peru and Russia.

DIVERSITAS WESTERN PACIFIC AND ASIA (DIWPA)

One of the most active programs of DIVERSITAS is DIWPA, which has formed an international network among the countries of the Western Pacific and Asia to promote cooperative studies and information exchange on

biodiversity. The main activities are: (1) the promotion of inter-regional research projects; (2) the facilitation of an international citizens' program; and (3) the promotion of governmental and non-governmental activities for the conservation and sustainable utilization of biodiversity. DIWPA has held several international meetings and issues a regular newsletter. The office is at DIWPA, Center for Ecological Research, Kyoto University, Shimosakamoto 4, Otsu 520, Japan.

INTERNATIONAL BIODIVERSITY OBSERVATION YEAR

As part of its program, DIVERSITAS coordinated an initiative for 2001/2002 entitled the IBOY (IBOY now extends into 2002). This is an important step in the effort to know and better understand the biological diversity of our planet, and to bring biodiversity science to the forefront of the scientific agendas of nations and international organizations interested in this subject. One of the most important objectives will be to educate the general public.

There is an urgent need to fill in the gaps of information about biodiversity, at every level from the genetic variability of individual species to the workings of ecosystems – and to add that to data about how human societies interact with, and depend on, natural systems. IBOY will cover the levels of biological diversity (genetic, species and ecosystems), surveying the field for the most obvious lacks in our knowledge of global patterns of biodiversity, focusing on those areas most amenable to a short term, intensive year of international cooperation in data collection. It is hoped that the results of the integrated products of this program will be of value towards managing the Earth System and providing tools for stemming the tide of diversity losses.

IBOY is inspired by the 1957 International Geophysical Year (IGY), when scientists worked together across national and academic boundaries to advance knowledge about the earth, oceans and atmosphere. It brought unprecedented cooperation among disciplines as well as added momentum to these disciplines. Similarly, it is hoped that IBOY will generate unprecedented long-term interest and momentum for research on, and conservation of, biodiversity. Like the IGY, DIVERSITAS/IBOY will focus on projects amenable to international cooperation in data collection, with room for scientists from developing nations to participate, however modestly. It is expected to integrate what is already known and to add new data to advance the state of knowledge about biodiversity and earth's living systems.

Ecosystem Services and Costing

Steven Cork
CSIRO Sustainable Ecosystems, Canberra, Australia

Ecosystem services are the processes and conditions by which natural ecosystems, and the species that make them up, sustain and fulfil human life. Ecosystems are suites of living organisms interacting with one another and with their non-living environment. Ecosystem services emerge from these interactions and we expect the delivery of the services to decline when components of ecosystems are removed or degraded.

Just as we know we have received a professional service when we feel fulfilled personally (e.g., after attending a performance by an accomplished musician) or have received a product that we value (e.g., a piece of clothing). We can tell we have received an ecosystem service when natural ecosystems have fulfilled or sustained our lives or have provided us with goods that benefit us. Examples of ecosystem services include: maintenance of a breathable atmosphere, livable climates, and drinkable water; protection from pests and diseases; mitigation of damage from floods and other severe weather; maintenance of genetic resources from which we obtain foods and useful medicinal products; and provision of opportunities for recreation, and spiritual and cultural fulfillment. The maintenance of other species by ecosystem processes is also an ecosystem service, because it is fulfilling to humans to know that other species are surviving even if we don't use or benefit from them directly.

The concept of ecosystem services is important for assessing the effects of global change because it focuses on a limited set of outputs from the environment that encompass what is important to, and can be recognized by, most people. To put the concept into practice, we need more information on what services come from which ecosystems, how human activities are affecting these services, what the impacts of declining services will be for human welfare, and how we get the balance right between ecosystem services and technological alternatives or supplements.

Much of the literature on ecosystem services has focused on economic valuation. A major reason for a decline in many ecosystem services is that they do not pass directly through conventional markets and hence do not acquire economic value like other goods and services. Various methods have been developed to assess what people are willing to pay for ecosystem services or what it will cost to replace them, but these measures depend on how well people are informed and what technological alternatives to ecosystem services are available. This means that the economic value of ecosystem services can change through time for reasons other than global environmental change.

This suggests that economic valuation of ecosystem services is not a reliable way to assess the effects of global change. However, as economic valuation improves and moves closer to its ultimate objective of measuring overall human welfare, a measure of how well life-fulfilling and life-sustaining services are being delivered by ecosystems and technology in combination could be a powerful way to assess the impacts of global change on humans.

ECOSYSTEM SERVICES: THE CONCEPT

The terms *nature's benefits*, *nature's services*, and *ecosystem services* have been coined to describe "the conditions and processes through which natural ecosystems, and the species that make them up, sustain and fulfil human life" (Daily, 1997). This definition is not meant to imply that the needs of humans are more important than those of other species. Rather it seeks to characterize the outputs from natural ecosystems in terms of a limited set of services that all humans are capable of recognizing as important, rather than focussing on complex concepts and processes that only specialist ecologists or economists

can fully appreciate. In this way the approach potentially makes the concept of sustainable management tangible to a wide range of people. It is important to note that fulfillment of human life includes altruism towards other humans and other species just as much as it includes individual self-interest.

Table 1 lists a typical set of ecosystem services. Figure 1 presents a slightly different way of categorizing ecosystem services. It depicts three broad types of service:

1. services that transform natural assets into goods or other products of value to humans (including everything from food to life-fulfilling feelings);
2. services that assimilate the residues and by-products from production back into natural assets;
3. services that maintain natural assets via processes within ecosystems.

In our everyday lives we know we have received a professional service when one of two types of transformations takes place. Firstly, we recognize services when we are transformed (or fulfilled) personally, such as when a hairdresser styles our hair, making us feel better, when a singer or an actor's performance gives us enjoyment, or when the hands of a masseuse relieve pain from sore muscles. Secondly, we recognize services when we receive goods

Table 1 A classi cation and examples of ecosystem services (adapted from Daily, 1999)

Broad category	Sub-category	Examples
Production of goods	Food	Terrestrial animal and plant products, forage, seafood, spice
	Pharmaceuticals	Medicines, precursors to synthetic drugs
	Durable materials	Natural bre, timber
	Energy	Biomass fuels, low-sediment water for hydropower
	Industrial products	Waxes, oils, fragrances, dyes, latex, rubber, precursors to many synthetic products
	Genetic resources	The basis for the production of other goods
Regeneration processes	Cycling and ltration	Detoxi cation and decomposition of wastes, renewal of soil fertility, puri cation of air and water
	Translocation	Dispersal of seeds necessary for revegetation, pollination of crops and native vegetation
Stabilizing processes		Coastal and river channel stability, compensation and substitution of one species for another when environments vary, control of the majority of potential pest species, moderation of weather extremes (such as temperature and wind), partial stabilization of climate, regulation of the hydrological cycle (mitigation of oods, droughts)
Life-ful lling functions		Aesthetic beauty, cultural, intellectual, and spiritual inspiration, existence value, scienti c discovery, serenity
Preservation of options		Maintenance of ecological components and systems needed for the future, supply of goods and services awaiting discovery

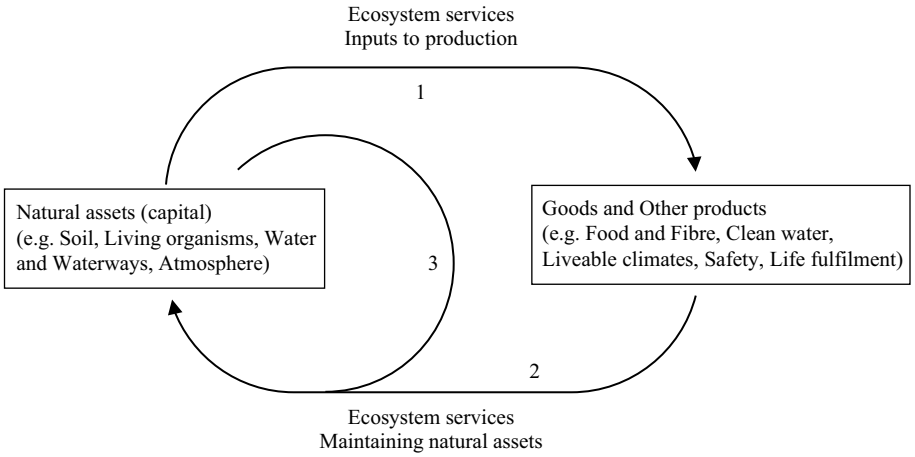

Figure 1 Schematic classi cation of ecosystem services into three broad categories: (1) services that transform natural assets into goods or products of value to humans; (2) services that assimilate the residues from production of products back into natural assets; (3) services that maintain natural assets via processes within ecosystems

of value to us that have been produced by someone else transforming materials of lesser value; for example, the production of a table from timber, bread from wheat, or a floral arrangement from a collection of individual flowers.

Similarly, ecosystem services can be recognized when people are transformed (fulfilled) by their use, or knowledge of, natural assets, or when the natural assets themselves are transformed by ecosystem processes to provide products that are either valuable to humans or help to maintain the natural assets upon which humans depend. Natural assets include the various non-living components of the atmosphere, water and soil, as well as the living organisms (plants, animals, fungi, bacteria and others) that live in, use, and help to maintain the non-living components (Figure 1).

A major strength of the concept of ecosystem services is its ability to bridge gaps in understanding and language between scientists and economists and between these disciplines and other members of the community. The concept provides a framework and a language within which the complexities of ecological and social sciences (including economics) can be simplified into ideas and language that allow debate about the key issues across disciplines and among people not formally trained in these disciplines. Lack of clarity and simplicity in defining the terms ecosystem, natural, and services can hinder this objective, not only because some people are unclear about what the terms mean but also because others have strongly-held but diverse views on what the terms mean.

Ecosystems are suites of living organisms interacting with one another and with their non-living environment. Ecosystem services are those services that emerge from these interactions. They are thus properties of ecosystems that amount to more than the sum of the properties of individual species. We can debate what degree of human influence distinguishes between a natural and an unnatural ecosystem. This begs the question of how much we should consider humans and their activities a part of nature. This debate can be very unproductive. What is important is that organisms and interactions among organisms have evolved with varying influence from natural selection; and benefits have come to humans from that evolution. Many of the benefits continue to be delivered from city parks, agricultural fields, and urban gardens, even though these have been changed greatly under the influence of humans.

There is a degree of inconsistency in the literature about the distinction between ecosystem services and ecosystem processes. Again this is an area where semantic arguments can be unproductive. Processes that transform natural assets occur at all levels of organization within ecosystems. Species, genes and chemical reactions provide products used by one another. In practice, it is useful to acknowledge a hierarchy of processes as illustrated in Table 2. As we move down the hierarchy, it becomes more difficult for most people to recognize and appreciate the significance of the services or processes. For example, while most people are aware that fruits and vegetables come from nature, they are surprised to learn that the services of pollination, natural pest control and maintenance of soil structure and fertility support the production of food.

Table 2 A hierarchical classi cation of ecosystem services

High-level services	Lower-level ''supporting'' services
Production or maintenance of: food, fuel, bre, medicines, building materials, liveable climates and atmosphere, human safety from natural disaster, ltered and puri ed water, biodiversity, aesthetic, cultural, intellectual value, raw material for scienti c discovery options, for the future	Detoxi cation of human wastes Dispersal of seeds, spores, and other propagules Maintenance of ecosystem resilience Maintenance of soil fertility and structure Pollination of crops and native vegetation Regulation of the hydrological cycle Control of pests and diseases Stabilization of waterways

HOW CAN THE CONCEPT OF ECOSYSTEM SERVICES BE USED TO ASSESS THE EFFECTS OF GLOBAL CHANGE?

The services that people need from nature are not just ecological but also economic and social (Table 1). The concept of ecosystem services integrates these diverse needs into a small number of major services, the importance of which we could estimate with the right additional information. Because the concept focuses on a level of complexity that most people can understand, it offers a way to communicate the significance of global change to a wide range of people and to engage those people in debate about solutions.

Investigating the impacts of global change on ecosystem function and the interactions with social and economic processes is difficult or impossible to do experimentally, so researchers rely heavily on models (see the next section).

UNDERSTANDING AND ASSESSING ECOSYSTEM SERVICES

In a recent report to the president of the US (PCAST, 1998; Daily, 1999), a group of eminent scientists, industry representatives and bankers identified a set of questions that need to be addressed to allow an efficient, effective and equitable balance between economic development and

ongoing delivery of ecosystem services. These questions are summarized in the following list:

1. What ecosystems provide which life support services?
2. Who benefits and over what scales of time and space?
3. What are the impacts of humans upon the supply of services?
4. How is the supply of services related to the condition of ecosystems?
5. How much damage has been done already? What is needed to repair damaged ecosystems?
6. Where are the problems geographically?
7. How interdependent are ecosystem services?
8. How reliant are ecosystem services on biological diversity?
9. How much can technology substitute for ecosystem services?
10. Given likely future technology, what area of natural ecosystems will be needed to support human life into the future?

Subsets of these questions have formed the basis for various attempts in the last decade to assess the nature of services coming from natural ecosystems around the world and to estimate their importance to humans. This work builds on research over a similar time frame that seeks to understand how biodiversity affects the way ecosystems function.

Assessments of the contributions of ecosystem services to human welfare have been done with varying degrees of rigor and with varying numbers of assumptions and expert judgements included to fill the usually considerable gaps in data. Most assessments to date have focussed on the magnitude and value of services delivered under current or past land management regimes. This is important as it informs people of what benefits they are getting now.

For example, a lower-bound estimate of the contribution of natural nitrogen fertilization to global crop production can be obtained using average estimates of net primary production and the nitrogen concentration in the crops produced (Daily *et al.*, 1997). The economic value of this contribution can be estimated as the cost of fertilizer to replace the naturally fixed nitrogen (US$45 billion per year), taking into account that fertilizer nitrogen is used much less efficiently than naturally fixed nitrogen. A value for the contribution to production of all land plants can be estimated similarly (US$320 billion).

Most major decisions relating to sustainable land management, however, require information on how the delivery of ecosystem services might change under various scenarios. This demands a more complex modeling approach linking ecology and economics dynamically, which pushes current knowledge and modeling approaches to their limits (Bockstael *et al.*, 1995).

If we want to estimate changes in delivery of fertilization services, we must take account of the effects of changed management on many influencing variables, including hydrological processes (surface and subsurface water flows), erosion, tillage and harvesting regimes, fire, climate and the many variables that in turn affect them. A typical result from simulation modeling suggests that reductions in ecosystem services by clearing vegetation in the US and Europe is leading to losses of soil, water-holding capacity, soil organisms, and nutrients that are causing a 1–8% decrease in crop productivity per year (Pimentel *et al.*, 1995). Declines in other parts of the world are higher. Such predictions can be converted readily into estimates of economic, social and broader ecological impacts.

One of the best examples of a scenario-based approach is the work of Higgins *et al.* (1997), who developed a dynamic ecological–economic model of ecosystem services provided by the mountain Fynbos Ecosystems of South Africa. The model investigated the cost-effectiveness of a set of alternative scenarios that differed with respect to management of fire, alien plants, wildflower harvesting, and controlling hikers and ecotourists to control invasion by alien plants. The model comprised five interactive submodels of hydrology, fire behavior, plant ecology, management regimes and economic valuation. For each scenario, two levels of economic benefit were considered for wildflower harvesting, hiking and ecotourist visitation, water production and future use of genetic resources stored in endemic plants. This was done to encompass uncertainty associated with estimating values. It was concluded that water production and genetic storage were the most valuable ecosystem services and that the costs of clearing alien plants would be a tiny proportion of the overall value of the ecosystem services protected.

In Australia, an attempt is being made to assess what services come from a range of ecosystems around the country and the condition of the natural assets that deliver the services. This is being accompanied by development of models that allow decision makers to ask "what if ... agriculture were practiced differently, cities were managed in other ways, or innovative new market structures, economic incentives, social policies or institutional structures were put in place?" (Cork and Shelton, 2000).

Ecological processes associated with water are frequently the focus for integrating ecosystem services and hence the scale of study is frequently the watershed or catchment. A study by a Swedish group (Rockström *et al.*, 1999) pointed out that most analyses of water use and movements in catchments fail to consider the requirements of natural ecosystems for water and that diverting water from these ecosystems for human consumption or use in irrigation potentially means declines in the services coming from the ecosystems.

The concept of ecosystem services relates strongly to the concept of the *ecological footprint*, which considers the relationship between humans and the natural environment in terms of both the impacts and needs of towns and cities (*see* **Ecological Footprint**, Volume 3). A major study linking these concepts (Folke *et al.*, 1997) estimated that on average around 1000 km^2 of forests, arable land, wetlands, and inland and marine waters are required to provide natural resources and assimilate carbon, nitrogen and phosphorus wastes per km^2 of city around the Baltic Sea. Generalizing the analyses to the 744 largest cities in the world, it was estimated that the world's needs for waste assimilation already outstrip capacity substantially (Folke *et al.*, 1997).

All models such as these represent trade-offs among realism, generality and precision. The balance between these will be determined by the objectives of the modeling. In the case of modeling ecosystem services, a prime objective will be to reduce the complexity of multiple interactions among ecosystem processes sufficiently for decision makers and stakeholders to understand what has been done, while making the uncertainty associated with predictions both clear and within acceptable limits.

Another emerging approach to investigating the complex and changing interactions between ecological and social systems is the use of complex adaptive systems models (*see* **Integrated Assessment Models of Global Change**, Volume 4; **Modeling Human Dimensions of Global Environmental Change**, Volume 5). This approach provides a framework for simplifying the multiple interactions and understanding the organization of social–ecological systems. It recognizes the grouping of processes at a limited number of scales, the partial autonomy of the groupings, and the key interactions among them. Unlike mainstream ecology and economics, it addresses non-linear change (Abel *et al.*, 2000). It acknowledges that when people are doing research and making decisions about how to manage ecosystems, these decisions will affect the way that ecosystems adapt. In turn, the response of the ecosystems will affect the thinking and actions of the decision-makers in ways that can be complex and difficult to predict (Carpenter *et al.*, 1999).

KEY ECOLOGICAL ISSUES STILL TO BE ADDRESSED

When considering ecological measurements, we need to know not only how much service is being delivered but also how that level meets people's needs and expectations. The key to understanding what will happen to the services in the future is to understand how the components of ecosystems interact and what the effects of changing the balance between components might be. We need also to know when to start worrying about change; that means thinking about what the critical levels of service are, how to tell when we are getting near these levels, and how long it might take to get there or to come back.

In ecological terms we need to look for points where the relationship between ecosystem change and delivery of a service is approaching a threshold or a situation where a small change in the ecosystem could bring about a large change in the level of services (Figures 2 and 3). The more rapidly that change is likely to occur, the more fragile the ecosystem or landscape (Figure 2). If we want to repair an ecosystem, we need to know whether the rate of recovery of ecosystem services will be the same as the rate of decline. Another key question is how the delivery of ecosystem services, is influenced by the numbers and functional types of species and genes in an ecosystem, and how this functional diversity affects the resilience of ecosystems (their ability to maintain function in the face of disturbance). For example, if a system has may species

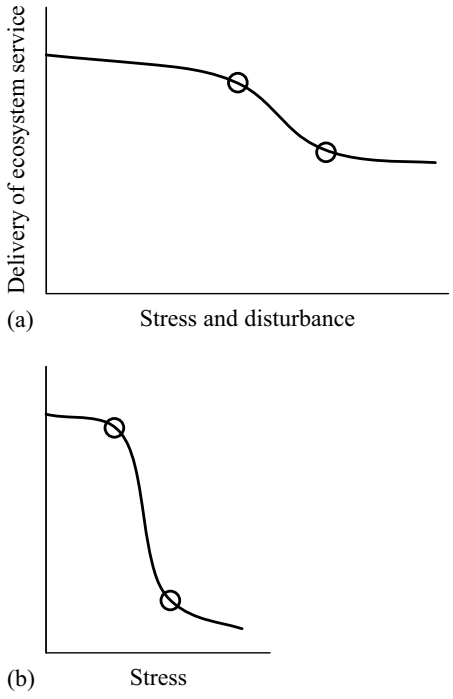

Figure 2 Hypothetical examples of how the delivery of ecosystem services might change with stress or disturbances to ecosystems within a landscape (adapted from Tongway and Hindley, 2000). (a) Represents a robust landscape which is relatively insensitive to stress and disturbance, whereas (b) represents a fragile landscape, which deteriorates rapidly with only small changes in stress and disturbance. The left-hand (upper) circle in each case indicates the point where an increasing rate of deterioration begins. We need to know how close we are to this point, and standards and management should be set to keep landscapes comfortably to the left. The right-hand (lower) circle is suggested to be the point beyond which landscapes will not return to their original state in an appropriate time frame once stress and disturbance are reduced

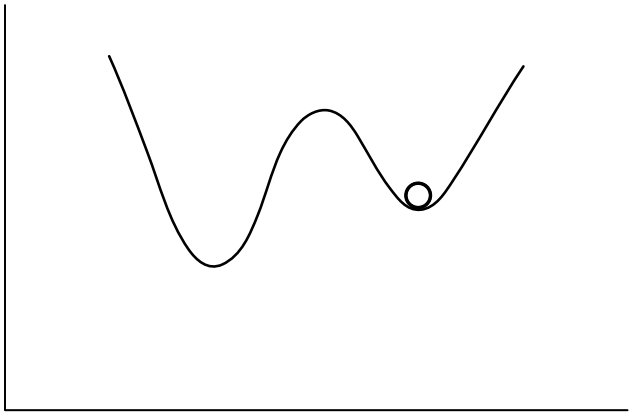

Figure 3 A ball-and-topography analogy for multiple stable states in ecosystems (Krebs, 1972). The two valleys represent alternative stable states. The different states could deliver a different set of ecosystem services. Once an ecosystem is in one of these states, external forces (e.g. ecological disturbance) is required to move it to the alternative, just as force is needed to move a ball against gravity. If the ball (or ecosystem) is only half way up the valley wall, then a small amount of extra impact might not change its state greatly and removing any external forces will allow it to return rapidly to its original state. However, if the ball (or ecosystem) is near a peak, then a small amount of additional force could cause a rapid change in state, and hence a major change in delivery of ecosystem services

performing similar functions, is it more likely to continue to deliver ecosystem services when climate or management change than a system with fewer replicates of functional types? (Walker *et al.*, 1999).

There are few data to use to construct these kinds of relationships for ecosystem services. Such information tends to emerge only once the services start to decline. For example, around the world the understanding of water chemistry and hydrology has increased greatly in recent years due primarily to the establishment of water quality regulations by governments in response to declines in natural water purification services as well as increased input of contaminants into waterways. Similarly, increasing attention is being paid to how we measure the ecosystem service of carbon sequestration since it has been recognized that concentrations of carbon in the atmosphere are reaching alarming levels and governments are discussing regulations to control emissions. We might expect to see similar attention given to the role of forests in stabilizing soil and protecting against extreme weather in the near future given the increases in damage and loss of life from floods, avalanches and mud slides in the last decade. In some places concern is rising about the decline in native pollinators for crops and other vegetation, and researchers are looking for ways to assess trends in the effectiveness of pollinators and pollination processes. For examples of these and other ecosystem services see Daily (1997).

KEY SOCIAL ISSUES TO BE ADDRESSED

The social dimensions of the ecosystem services concept have only recently been addressed in their own right. There are many questions about how people perceive their relationship with ecosystems and how that determines the importance they attach to environmental issues. When considering what our critical requirements are for ecosystem services, there is as much a social as an ecological element. Taking an ecological approach, we might consider the views of scientific experts on where ecological thresholds might exist. A social and economic approach might consider the relationships between delivery of ecosystem services and the costs of healthcare or legal liabilities. For example, standards for water quality around the world are based at least partly on considerations of human health, what levels of regulation will be tolerated by industry, and what risks of disease will be tolerated by society. When physical scientists can provide the understanding and methods to measure delivery of a service, even without identifying the critical levels, it allows regulations and standards to be developed and enforced. This is a critical interaction between the physical and social sciences (Salzman, 1997).

Another critical issue for social scientists is how we design better formal and informal institutions and organizations to identify and deal with changes in ecosystem services. These institutions need to be flexible, adaptable and able to deal with uncertainty. Some researchers have suggested that one service that ecosystems could provide to humans is a model for how to design these institutions (Berkes and Folke, 1997).

ECONOMIC VALUATION OF ECOSYSTEM SERVICES AS A MEANS OF ASSESSING THE EFFECTS OF GLOBAL CHANGE

The literature on ecosystem services has focussed strongly on methods for economic valuation (e.g., see Bingham *et al.*, 1995; Heal, 2000). The rationale for this focus is that many ecosystem services are undervalued in decision-making, leading to inequitable, inefficient and ineffective use of natural resources worldwide. Texts have been written on the concept of *value*, and expert panels have been convened to seek a unifying definition. The consensus seems to be that it is not possible to develop a single unifying definition of *value* and that it is more constructive to recognize and understand the different perceptions within society and how they relate to one another. Economic value is seen by some as just one of many values that nature can have, while others argue that properly carried out economic valuations encapsulate all societal values under the banner of social welfare. Some commentators suggest that applying economic valuations to nature enhances rather than slows its degradation, while others argue that both the causes

and solutions to environmental degradation lie in economic assessments. With respect to ecosystem services, the choice of which services to value is in itself a value judgement usually made on the basis of economic and social values. A pragmatic approach is to focus on the full range of welfare-enhancing benefits of ecosystem services, accepting that economic value is often considered in decision-making but is rarely the sole or primary determinant.

Three broad reasons are proposed for the failure of economic structures to capture the full value of ecosystem services. Firstly, people are ignorant of the benefits they obtain from ecosystem services, a problem that can be addressed by obtaining and communicating better information. Secondly, many of the benefits from ecosystems are not privately owned and consequently cannot be sold or bought directly in markets. Thirdly the costs incurred by degradation of ecosystem services are often incurred outside the market and so do not affect the price of traded goods and services.

Approaches to Valuation

Markets are a mechanism to reveal how much people will pay for tradable goods and services. Some ecosystem services contribute directly to the productions of goods that have an established market value (e.g., food, fiber, fuel, pharmaceuticals). The goods themselves can be valued by conventional techniques, but valuing the ecological processes that contributed to the goods requires detailed information on the role of each process. Often, information is not available in sufficient detail.

Indirect valuation approaches are applied to ecosystem services that do not pass through markets. These approaches include assessing the extra amounts people pay for real estate in a natural setting (*hedonic pricing method*) or for travel to natural places (*travel cost method*). The choices people make about tradeoffs between non-market and market goods and services can be analyzed (*choice modeling*) to reveal the value they place on the environmental components of the choice. Alternatively, people can be asked directly what they will give up to keep the service or would accept as compensation to lose it. This contingent valuation has been used most commonly to estimate the value of intangible services like the value of knowing that natural systems and the species within them exist.

In recent years there has been considerable attention paid to the cost of replacing ecosystem services, or the cost avoided by conserving the services, as a measure of their value. This approach requires us to consider, on the one hand, the capital costs and ongoing maintenance costs of possible technological alternatives, appropriately discounted to give net present value (*see* **Discounting**, Volume 5), and on the other hand, our ability to repair and protect ecosystem processes and to predict the long-term flows of those services. This can be difficult to assess (Salzman, 1997), but the exercise leads to many possibilities for different approaches to managing natural resources.

For example, the estimates of the contribution of natural soil fertilization services given in a previous section ('How can the concept of ecosystem services be used to assess the effects of global change?') were costs of replacement. In a similar way, the cost of replacing the role of soil in supporting plants physically and the nutrient translocating services provided by the living and non-living components of soil have been estimated at over US$900 000 ha^{-1}. The services of water filtration and purification provided by ecosystems in the catchment for New York City were recently estimated to be worth at least US$8 billion, which was the difference between the cost of repairing the ecosystems and building artificial filtration facilities to replace the degraded capacity of the ecosystem services (Chichilnisky and Heal, 1998). A study of the water catchment for the city of Melbourne in Australia suggested that the catchment was worth more if managed on long rather than short rotations of timber harvesting because of the increased amount and quality of water produced when the catchment contained mostly mature forests.

Costs avoided by conserving ecosystem services are not necessarily the same as costs of replacement, since the degradation of ecosystem services can have far reaching social and economic implications that should be taken into account when considering the effects of global change. Considering these social costs is called *shadow pricing* (Starrett, 2000).

Pollination services provide an extreme example of how very large numbers can be obtained if considering the value of ecosystem services as replacement costs. About 92% of plants worldwide are pollinated by animals, and in about half of these reproduction is determined more by the numbers of pollinators visiting them than by weather, soil fertility, diseases, parasites or animals that eat their flowers (Nabhan and Buchmann, 1997). There are more than 1200 vertebrate species and between 100 000 and 200 000 invertebrates involved in pollination of flowering plants, yet the main pollinating species of crops around the world is the European honey bee (Nabhan and Buchmann, 1997). Pollination by honey bees is estimated to be responsible for agricultural production worth US$2–8 billion annually in the US alone (Nabhan and Buchmann, 1997).

Concern has been raised about this heavy reliance on one pollinator species. A pollination crisis has been predicted in the US due to a major decline in honey bees caused by a range of diseases and mite infestations and the low numbers and capacity of native pollinators remaining after land conversion for agriculture. For some small enterprises, replacing bee pollination by manual pollen transfer by people or machines is conceivable, but the technology and expense of replacing insect pollination over large geographic scales is inconceivable at present. Some economists

have argued that the true value of many ecosystem services, measured in terms of what it would cost to replace them or what people would be prepared to accept as compensation to lose them, is infinite.

While estimates of total replacement costs get the attention of decision-makers due to the large numbers, the more relevant question for day-to-day decision-making (and for estimating the effects of global change at local scales) is whether a small, or marginal, change in ecosystems would affect the delivery of ecosystem services and their economic consequences. The ability of ecologists to make these sorts of predictions about marginal changes in ecosystem services is limited. For example, although we are now confident that concentrations of atmospheric carbon dioxide need to be reduced, we cannot predict confidently what changes to climate will occur in response to the sorts of changes we can bring about within a few years or decades.

The results of research in progress in Australia suggest that improved management of soil structure and biodiversity can be achieved over time frames of 5–10 years that could halve the amount of water, pesticides and fertilizers necessary in orchards (Matt Colloff, personal communication).

Two of the most often discussed issues relating to valuing ecosystem services are the public versus private value dichotomy and the issue of discounting.

Private Versus Public Ownership of Ecosystem Goods and Services

Privately owned ecosystem goods and services (e.g., food produced on a farm or the soil used to grow crops there) should in theory be protected by the owner in his/her own interest. On the other hand, it is often unclear who should take responsibility for ecosystem goods and services that are not owned privately or by a specific group. Examples include wildlife, water filtration services, pollination services from native insects and birds, and flood mitigation services. When impacts of declining services are external to the decision making of the people causing the impact (e.g., the impacts of removing trees on water tables, salinity and carbon sequestration), there are no traditional economic forces to encourage better practices (*see* **Commons, Tragedy of the**, Volume 5).

Discounting

In both economic and non-economic decisions, humans tend to put more value on having goods and services now than later. The primary economic rationale is that a future benefit, had it been received today, could have been invested and earned interest. Economists conventionally discount the future value of the benefit at the annual rate at which it could have earned interest. Future costs are likewise discounted because it is assumed that whoever will pay the cost is meanwhile earning interest on it. Any positive discount rate works against sustainable management of ecosystem services (*see* **Discounting**, Volume 5). Many economists argue that applying discounting is ethically indefensible because future generations will pay the full cost, and receive the full benefit. The discounted values are only from the perspective of current generations making an investment now. Discounting is valid and rational only from that perspective. A practical solution to the dilemma is to estimate benefits and costs with and without discounting, then make the investment decision based on both ethical and economic considerations. Arbitrary reductions of discount rates are not helpful because they mask the actual benefits and costs from the perspectives of both current and future generations.

Consumer or Ecosystem Sovereignty?

Some economists recently argued that while applying the criterion of economic efficiency based on the preferences of individuals is relevant when considering many day-to-day, short-term decisions, achieving longer-term sustainability requires integrated assessment of ecological, social and economic systems and consensus-building among stakeholders, to reflect societal rather than individual preferences and a wider range of objectives than economic efficiency. Whereas democratic principles and traditional economic analyses give equal weight to the preferences of all individuals, it is argued that achieving sustainable delivery of ecosystem services requires weighting for certain key life support services. In the language of economics, this means a change in focus from consumer sovereignty to ecosystem sovereignty (Costanza and Folke, 1997). Such a change almost certainly requires changes in our institutions, which in general are not sufficiently flexible and adaptive and do not work at the scales of time and space needed to fit well with ecosystem processes (Berkes and Folke, 1997).

Is Economic Valuation Useful for Assessing the Effects of Global Change?

The issues discussed in the previous sections suggest that economic valuation should be interpreted cautiously when assessing the effects of global change. On the other hand, it could be argued that a practical and realistic assessment of the impacts of global change should include an economic assessment integrated with social and ecological assessments. The challenge is to make this assessment in ways that avoid distortions that are not necessarily related to human welfare.

Such distortions can emerge in several ways. The relationship between rarity and economic value means that increasing economic value of ecosystem services is undesirable. Clean water, which is vital to human existence, has

long been worth very little economically because it has been so abundant relative to human needs but is now taking on increasing importance and value due to increasing human demand and decreasing supply. Similarly, the prices paid for properties with views of water or other natural settings are huge in most countries because of the relative rarity of such properties and the importance that humans place on natural scenery.

Mainstream economists argue that these are examples of markets working as they should and that increases in price will encourage us to move our attention away from over-exploited natural assets towards finding alternative ways to obtain the necessary services. *Ecological economics* (a new branch of economics) questions this confidence in markets, suggesting that the fundamental requirement for efficient markets (that people are fully aware of the costs and benefits of the services) is unlikely to be satisfied, and that those markets that do develop will do so too slowly to regulate ecosystem services within acceptable limits (*see* **Ecological Economics**, Volume 5).

Economic value also is affected strongly by government regulations and policies. Imposing standards for water quality or atmospheric carbon dioxide emissions, for example, imposes a regulated scarcity because the ecosystem assets and processes often have to be enhanced to meet the standards.

As pointed out earlier, economic value can be affected by how well people are informed about the benefits that they are likely to receive. Similarly, a change in the cost and feasibility of technological alternatives to ecosystem services can change the economic value of the services without any change in the state of the ecosystem. For example, the high value of New York's water comes largely from the high cost of the technological alternative. A decrease in the cost of that alternative, due for example to improved technology, would devalue the water filtration services even if the ecosystem did not change at all.

Most of these problems would be solved if individual countries and the world had an accounting system that could track changes in the biological status of ecosystems, and the services they provide, and measure the importance of changes in terms that could be considered along with changes in other economically and socially important assets and flows. There has been major discussion nationally and internationally about including natural capital in national accounts, but there remain large problems to overcome. Many economists suggest that there is a need for better ways to assess welfare at community and societal scales, and there is spirited debate about how this could be achieved. If approaches can be developed that allow changes in delivery of ecosystem services to be assessed in terms of overall human welfare, including both market and non-market values and societal as well as individual needs and preferences, then this might ultimately be a powerful way to assess the impacts of global change.

Ecosystem Stability

Ecosystem stability is the ability of the ecosystem to resist change or to recover from change. Stable ecosystems are presumed to have mechanisms that facilitate adaptation and internal structures (i.e., interconnections and relationships among species and among other components of diversity) which tend to dampen perturbations.

The notion of stability pertains to at least three different facets of ecosystems: their component parts, their structure, and their dynamic processes. Different measures of stability correspond to each facet. For instance, measures of the viability of populations of individual species in the ecosystem correspond to component stability; measures of the persistence of species composition or food web organization reflect on the ecosystem's structural stability; measures of the sustainability of net ecosystem productivity gauge process stability. The stability of each facet is generally linked to that of the others, and for each, substantial fluctuations may occur at scales ranging from those of local ecosystems to landscapes (e.g., as a result of cycles of succession following periodic disturbance) without destabilizing the ecosystem.

There are two different but interrelated aspects to ecosystem stability and this has resulted in much confusion in terminology. *Resistance* (or local stability or *engineering resilience*) is the capacity of an ecosystem to remain constant and predictable in the face of minor disturbance (*see* **Resilience**, Volume 2). Resistance mechanisms are those characteristics of an ecosystem's current steady state that allow it to absorb a small perturbation with little discernable impact so that the perturbation does not grow into a large one and throw the ecosystem into the domain of an entirely different steady state. Resistance is often measured by the rate of return to the original steady state following perturbation. When resistance is overcome, an ecosystem must rely on its resilience to remain stable.

Ecosystem resilience (or ecological resilience) is the ability of an ecosystem to return to its original steady state after a large perturbation has thrown it into an entirely different one (*see* **Resilience**, Volume 2). Resilience is measured by the magnitude of disturbance that can be absorbed before the ecosystem loses its capacity to return to its original steady state. The process of succession after an intense periodic disturbance (e.g., severe wildfire in mature boreal forest) exemplifies resilience. Species composition may change substantially (putting the ecosystem into an early successional state) but ensuing succession eventually returns the ecosystem to mature forest, its original steady state (with the same productivity, nutrient cycling, and species composition it had before disturbance). Thus resilience confers persistence in the face of severe disturbance.

Evolutionary theory suggests that species evolve mechanisms to deal with the disturbances they historically experience in an ecosystem, and that these adapted mechanisms confer both resistance and resilience on the ecosystem as a whole. Instability occurs if the ecosystem is thrown over a threshold from which recovery to a former state is either impossible (e.g., extinction) or, if possible, occurs only over very long time periods, or only with outside subsidies of energy and matter (e.g., fertilizer to replace lost topsoil). Destabilizing perturbations tend to differ from those experienced historically (e.g., industrial pollution, climate change, alien species, fire in tropical, but not in boreal, forests).

Ecosystem Structure and Function

For purposes of focused study and practice, conventional sciences of all kinds have long classified particular perceptions of phenomena as relating to either form or function. Different terms may be used in different sciences for this distinction, e.g., statics and dynamics, fixed and variable, goods and services, and constraints and freedoms. In the literature on ecosystems, the contrast is frequently stated in terms of *structure* and *function*.

Some versions of a systems approach focus mostly on either one or the other of these complementary kinds of perceptions. Frequently both perceptions are interlinked, especially within system dynamics approaches, say. Modernist reductionists may use the differential and integral calculus to inter-link perceptions of structure and function while post-modern synthesists may use relational algorithms, as Berlinski (2000) has pointed out.

Within an evolutionary systems mindscape – as in contemporary cosmology, geology, biology, ecology and sociology – nothing may be perceived to be permanent for all time and space. Anything that we perceive from this evolutionary perspective has some rate of change appropriate to it. Change may occur continuously and smoothly or episodically and discontinuously, or both together. A statistical concept like *half-life* may be invoked in this respect; it is the length of time required for half the items within a homogeneous set of phenomena to change into other kinds of phenomena. The longer the half-life, the more permanent a structure is perceived to be and the slower the relevant rate of change or frequency of transformation. With humans, a related concept is called the average lifespan or span of a generation.

Implicitly or explicitly, evolutionary scientists do have in mind some time-related concept when using the first of any of the pairs of terms mentioned above, e.g., structure, fixed, etc. In turn, the second term of each pair (e.g., process, variable, etc.) relates directly to a perception of change and also has some rate of change appropriate to it. Here too a change may occur gradually or in a step-wise manner. The rate of change with a function or process is comparatively rapid, and the manifestation of any temporary structure-like phenomenon within a process has a short half-life or short average life, and may therefore be ignored for purposes of approximation.

Consider an example. Some ecologists study the wave spectrum of heat radiated from the earth's surface to outer space, say while the sky is cloudless. They note that forested patches are, on balance, comparatively cool while urban areas with roofs, pavement and bare ground are hot. A simplistic analytical schema may be used for this complex phenomenon. The structure part of such a schema may consist of the type of surface. The function part may include the intensities and spectral compositions of the in-coming and out-going radiation as well as what happens to light and heat during the transformation at the surface, i.e., within the biospheric shell at that site.

As another example, a park warden with a particular interest in trees may perceive them to be crucial long-lived habitat structures for many animals and other kinds of organisms with shorter lives. Small, short-lived creatures may be lumped together and taken to be part of the decomposition and nutrient-recharging process for the benefit of the trees, say. In turn, a commercial forester may perceive the trees as contributing to a dynamic pool of renewable resources of a flow type, to be accumulated naturally and harvested at sustainable levels at optimum time intervals. Such a commercial forester may perceive tree growth to be a process and the whole forest as a semi-permanent structure, the goal being to achieve sustainability of both structure and process to be sustained in a productive state.

The time rates of change of different features of living things differ in part because of relevant gene-based information that operates through enzyme and hormone complexes, stated simplistically. A particular enzyme, say, generally manifests a set of rate parameters that are sensitive to temperature, e.g., a minimum temperature at which the enzyme begins to act, a rate that rises with temperature to an optimum temperature, then rises somewhat further to a temperature at which the rate is maximal, and then falls rapidly to a maximum temperature at which the enzyme may be denatured or destroyed, perhaps together with the living thing. For natural rates, whether slow as with phenomena that we may call structures or fast as with processes, the rate constant for the intermediate, rising range of the function described above generally has an exponential form first inferred by Svante Arrhenius a century ago (Lin and Regier, 1995).

This Arrhenius empirical relationship has been invoked in studies of the effects of climate warming on both structures and processes in natural and cultural features of large ecosystems. What may be perceived to be structures have Arrhenius coefficients with comparatively small absolute values; in turn, processes have coefficients with larger absolute values. The values of such coefficients are positive where growth occurs and negative where decomposition or erosion occurs. In effect, climate-warming scales up the

effects modeled by these coefficients and thus acts to shift all these phenomena towards a more dynamic state, in terms of conventional time.

Within living things, matter-based structures may be perceived to have slower rates of change than energy-based flows. (Of course, Albert Einstein showed that matter and energy are ultimately inter-convertible, but we are dealing here with matter and energy as distinct, as at the usual temperatures in ecosystems.) But at the level of enzymes operating under direction by the gene complex, these matter-related and energy-related rates must meld. At this level, the information content of individual genes, operating under poorly understood guidance by the whole genetic complex or genome, may have long permanence. Some of the genes in humans, say, appear to be the linear descendants of genes of primitive organisms that first emerged a billion years ago. So the information of genes, that guides the flows of matter and energy through the structures of a living system, may be the most permanent or structural part of that living system. We use the term *heritage* for such structures, as in our efforts to preserve biodiversity.

An ecosystem, whether in a natural, a cultural or a mixed state (*see* **Phase Shifts or Flip-flops in Complex Systems**, Volume 5), may be perceived to consist of semi-autonomous smaller systems nested within semi-autonomous larger systems. Each of these constrained self-organizing systems is called a *holon*. The whole nested structural complex of holons, with the many functional interactions among holons of all levels, is called a *holonarchy*. The latter connotes a kind of hierarchy in which each element or holon acts to maintain structural and functional integrity consistent with its information canon. That canon in turn contains nearly permanent gene-based structural information complemented by other kinds of information including temporary experience-based process learning at the level of an organism. With such a complex, use of the terms *structure* and *function* depends strongly on the reasons that motivate a researcher's study and where that study's primary focus falls within some larger systemic complex.

All the above is cast within an evolutionary perspective. Nowadays, science contains no alternative perspective to rival it. Structure and function are complementary conveniences for perceiving something in a system, and together the concepts help to clarify evolving systems. It should be apparent why science does not nourish a hope that it, i.e., science, will eventually provide a full understanding of such phenomena.

Ecotones

Paul G Risser
Oregon State University, Corvallis, OR, USA

Ecotones are transitional areas between adjacent habitats or types of vegetation. For example, the fringe area between a forest and an adjacent field is called an ecotone. At a larger spatial scale, the timberline area between a conifer forest and the open alpine tundra on a mountaintop is an example of an ecotone. At the continental scale, the savanna zone between the eastern deciduous forest and the central plains grasslands in North America can be called an ecotone. Thus, ecotones are defined at various spatial scales.

Ecotones have always been of interest to scientists who study the relationships between climate and the distribution of plants and animals. At a mountain timberline, the climate and soil conditions are marginal for trees to survive. By studying the environmental conditions in this ecotone, it is frequently possible to understand the most significant factors controlling plant distribution. At the continental scale, scientists can study the ecotone between forests and grasslands, observing the behavior of various species in these regions during periods of drought and increased precipitation. These observations about ecotones and changing climate conditions have become particularly important recently as we learn about global climate change, and attempt to predict the biological consequences of changes in climate.

Within the last 20 years, scientists have learned that ecotones sometimes influence the movement of water, nutrients and soil particles across the landscape. For example, strips

of forest along streams are a type of ecotone called gallery forests or riparian forests. These ecotonal forests play several roles. For example, they may capture nutrients and sediments that would otherwise flow from adjacent fields into the stream or river. In other situations, these riparian forests produce large trees that eventually die, and during storms, fall into streams thus contributing crucial habitat for some fish species.

In summary, ecotones are transitional areas between different types of habitat or vegetation. Ecotones are scale-independent and can be defined at small spatial scales, such as local habitats, or at broad spatial scales across the continent. Ecotones may provide important habitats, serve as indicators of climate change, and influence the movement of plants, animals, water and materials across the landscape.

DEVELOPMENT OF THE CONCEPT OF ECOTONES

The concept of an ecotone as a transitional area between habitat types or vegetation types began in the first half of this century from three different perspectives over a range of spatial scales (Risser, 1995a). In the 1930s, ecotones were described locally and used in a very practical way, mostly by wildlife managers. Habitat descriptions of both mammals and birds frequently noted that certain species preferred areas that contained edges of some vegetation types or mixtures of habitats (Leopold, 1933). For example, habitat descriptions of white-tailed deer (*Odocoileus virginianus*) in North America or the fieldfare (*Turdus pilaris*) in Europe frequently mention a preference for the ecotones between forests and open fields. In most of these instances, animals select ecotones as preferred habitat because of the combination of food, cover and breeding conditions available within these transitional areas.

During the same time period, scientists began to examine the transition between the high-altitude forested areas and the adjacent alpine tundras of mountains (Griggs, 1938). This interest arose because it appeared obvious that trees were at their limit of physiological existence, and conditions of weather, soils, and topography restrained their growth farther up the mountain. Thus, the ecotone between forests and tundra offered an opportunity to study the environmental factors controlling plant distribution.

In studying these montane ecotones, several instances were noted where dead trees were found above the current tree line. This indicated that in previous times, trees had survived in habitats now occupied by tundra, that is, in areas where trees were not growing today. Among the possible explanations were that disturbances such as fire had influenced the distribution of vegetation, and/or that the climate had changed so trees were no longer able to grow at the higher elevations. A more detailed description of tree-line responses to climate change is presented later in this discussion.

At the continental spatial scale, scientists were interested in the transitions between vegetation types, such as between the eastern deciduous forest and the more western grassland biomes in central North America (Weaver and Albertson, 1956). This interest increased during and after the droughts of the 1930s and 1950s. Under drought conditions trees at the edge of the grassland died, and in effect, the grasslands moved farther eastward. The more drought-tolerant grasses of the central Great Plains became more conspicuous in the normally more humid grasslands of the eastern Great Plains. In other words, the ecotones between the forest and grasslands, and between different kinds of grasslands in the Great Plains, were not stable but rather moved depending upon the climatic conditions. Similar considerations of continental-scale ecotones have been considered elsewhere, for example, the productive zone at the edge of the receding ice edge of the Antarctic continent (Smith and Nelson, 1985).

Ecotones frequently support relatively high levels of biodiversity because they contain habitat characteristics of both adjacent ecological units and have unique characteristics of the ecotone itself. Within ecotones at all spatial scales, the ranges of plants and animals frequently overlap and thus species from two or more biomes may occur together. This combination of species distributions and the unique habitat characteristics found in ecotones frequently support a distinctive flora and fauna leading to higher biological diversity. Despite this intuitively logical explanation, evidence of high biodiversity in ecotones, while available is not plentiful (Delcourt and Delcourt, 1992). Moreover, because habitats are usually fragmented within broad ecotones, within-population genetic variation may be constrained because of isolation or small local habitat size (Holsinger, 1993).

At local and landscape spatial scales, ecotones frequently control or modulate the movement and migration of plants and animals. An example is found along the Garonne River in southwestern France (Decamps, 1993). Harvey's groundsel (*Senecio harveyanus*), introduced from South Africa, was found along the Garonne River in 1936. During the next 50 years, the species migrated along the ecotonal forests of the Garonne and Adour rivers, both upstream and downstream (Figure 1). The groundsel is a weedy species and the periodic flooding of the rivers provided a sequence of disturbed habitats along the ecotone for colonizing and migration.

Ecotones can also influence the movement of water, nutrients and other materials. These controls occur at the local or landscape levels, frequently in the ecotonal forests along streams and rivers. Peterjohn and Correll (1984) studied a landscape in the eastern United States that consisted of agricultural fields with ecotonal riparian forests along

the streams. The flow of nitrogen and phosphorous from the fields into the streams was significantly modified by these riparian ecotones. Much of the phosphorous that was attached to soil particles in erosional surface flow from the fields was trapped in the riparian forests. Similarly, a significant amount of the nitrogen washed from the fields was captured by the ecotones. Nitrogen was taken up by the trees from the soil water or lost from the forest floor by denitrification. There are numerous examples of riparian forests capturing soil particles from erosion and thus reducing the sedimentation in streams.

The concept of the ecotone has developed over the past 50 years or so from a relatively static, habitat descriptor to one of an active participant in the ecological processes occurring at several spatial scales. With the observations that ecotones apparently moved under different climate conditions, it became obvious that ecotones are dynamic and responsive to environmental conditions. Studies demonstrated that ecotones can influence the movement of plants, animals, water and various materials. Ecotones were also found to support relatively high levels of biodiversity at the community and species levels, although diversity at the genetic level has not been conclusively characterized. As described below, our understanding of ecotones continues to unfold and to become more complex. The relationships between climate change and ecotones are complicated but promise to be instructive for anticipating possible changes in ecological systems in the forthcoming decades.

Based on these studies conducted earlier this century, it is now possible to define ecotones more clearly. First, ecotones are not static, but are responsive to climate change. Second, ecotones are spatially scale-independent, that is, they are defined at many spatial scales ranging from local habitats to biomes. Third, ecotones serve as specific habitats for some organisms, and they mediate the flow of organisms and materials across the landscape.

Gosz (1993) has provided a useful framework for a hierarchical organization of ecotones based on their spatial scale (Table 1). This framework also postulates the possible major controls over the structure and function of ecotones. Global climate change would be expected to influence ecotones directly at the larger spatial scales, i.e., at the scales of biomes or landscape. Controls or constraints on ecotones at smaller spatial scales would be caused by the effect of macroclimate on the microclimate of smaller patches of vegetation or of individual plants. Gosz suggests that there are more recognizable controls at the smaller spatial scales.

RESPONSES OF ECOTONES TO CLIMATE CHANGE

Early studies of ecotones and their response to climate change were relatively simple, such as the observations made by Weaver and Albertson (1956) who noted that the boundary between the North American eastern deciduous forest and the adjacent Great Plains grassland shifted

Table 1 Ecotone hierarchy for a biome transition area. Each level in the ecotone hierarchy has a range of constraints and interactions between the constraints: × symbolizes interactions between constraints. (Reprinted from Gosz, 1993)

Ecotone hierarchy	Probable constraints
Biome ecotone	Climate (weather) × topography
Landscape ecotone	Weather × topography × soil characteristics
Patch ecotone	Soil characteristics × biological vectors × species interactions × microclimatology
Population ecotone (plant pattern)	Interspecies interactions × intraspecies interactions × physiological controls × population genetics × microtopography × microclimatology

during the droughts of the first half of the 20th century. More recent studies have begun to demonstrate additional complexity in the relationships between ecotones and climate change.

At the biome level, water balance and cold winter temperatures usually control the ecotone position (Neilson, 1993), and both of these processes are affected by global climate change. Delcourt and Delcourt (1992) propose that the following are most likely to influence the response of ecotones to climate change: rate and magnitude of environmental change; the physiological tolerance of the dominant species; the proximity, competitive abilities and dispersal capabilities of the invading species or pathogens; differences in soil characteristics; and the ability of organisms to withstand a different suite of environmental conditions. These processes are similar to those suggested by Gosz (1993) at the finer biome scales.

In the Chihuahuan desert in southwestern United States, there is a broad ecotone between desert grassland and shrubland (Grover and Musick, 1990). In general, the shrubland invades the more semiarid grassland under drier climatic conditions. This invasion was examined using photographic records taken over a 50 year period. The shrubland vegetation invaded the grassland and within the ecotone itself, the patches of shrubs expanded in size. The shrubland near the ecotone became more like the interior of the shrubland, thus not only was there a movement of the major vegetation type, but the size of the patches of vegetation changed during the response of the ecotone (Gosz, 1993). As more studies are conducted, it has become more obvious that the response of ecotones to climate change does not simply result in the movement of a coherent zone across the landscape (Hobbs, 1994).

Various authors have attempted to construct models to predict the response of ecotones to climate change. These predictions have involved both the behavior of individual species (e.g., Peters and Darling, 1985; Payette and Filion, 1985) and entire vegetation types (e.g., Emanuel *et al.*, 1985; Davis and Zabinski, 1992). On mountain tops at the tree line, it would be expected that increased concentrations of carbon dioxide and higher ambient temperatures would allow lower altitude plants to move into the colder regions at higher elevations. However, at the montane tree line wind stress is greater so lower-elevation species may not be able to expand their range (Woodward, 1993). Using a different model for mountain ecotones at lower altitudes, Noble (1993) has postulated that fires in the higher elevation grasslands would reduce the likelihood of trees moving upward with global warming.

In a particularly useful study, Lloyd and Graumlich (1997) reconstructed the tree line in the southern Sierra Nevada mountains in California, USA. During the 3500 year period of study, the tree line was higher than now, but there were two notable declines. The first decline in the elevation of the tree line occurred during a relatively warm period. However, these warmer temperatures were accompanied by drought conditions which caused mortality of adult trees. The second decline occurred during a 400-year period of colder temperatures which reduced reproduction and also caused adult mortality.

Throughout the 3500-year period under study, the abundance of the trees changed continuously, both increasing and decreasing. The tree line, however, remained static for long periods of time, and then moved only in brief periods. Thus, the high-elevation tree line itself may not be as responsive to climate change as the absolute and relative abundance of individual species. In fact, the changes in tree abundance preceded the changes in tree line by about 400 years (Lloyd and Graumlich, 1997). These results are consistent with those of Payette and Filion (1985) who found that climate warming led to changes in forest density rather than changes in position of the ecotone.

Iverson and Prasad (1998) took a different approach to the question of how vegetation pattern would be expected to respond to climate change. They combined the habitat conditions of 80 tree species with the predicted conditions with a doubling of ambient CO_2 in the atmosphere. Depending upon the actual climate change scenario, 30 tree species would expand their range or become more important in a community by at least 10%. Nearly half of the tree species (36/80) would have their range shifted by at least 100 km, and the range of seven species would move more than 250 km (*see* **Plant Dispersal and Migration**, Volume 2).

In reconstructing species changes in the Holocene (*see* **Holocene**, Volume 1), most species changed their range,

but the rates and directions were largely individualistic. Species assemblages changed and at these large spatial scales it was difficult to discover whether competitive and dispersal mechanisms played an important role. However, these changes occurred over thousands of years and through landscapes largely devoid of human-constructed barriers. Responses to global change will occur with faster climate changes and over fragmented landscapes (Iverson and Prasad, 1998).

Neilson (1993) has offered a generalized model to predict the ways in which biodiversity and habitat structure of ecotones might respond to climate change. If global warming is accompanied by water stress, the entire landscape should become fragmented because every variation in topography and soil becomes important to water balance and survival. Under these conditions, many different survival strategies operate and diversity remains high in the ecotone with an eventual equilibrium occurring at a new ecotone. If global warming is not accompanied by water stress, then fragmentation should not occur and organisms will simply move in a more or less homogeneous pattern in response to changing temperature. Thus, in Neilson's model, the degree to which an ecotone is an effective indicator of climate change will depend upon interactions among climatic and habitat factors. With more habitat heterogeneity, it is less likely that the ecotone will respond in a uniform manner.

Ecotones may have characteristics that are closely tied to changes in the global climate. Decamps (1993) examined the behavior of ecotonal riparian and floodplain forests along four rivers (Figure 2). Denitrification occurred in the saturated soils of the riparian forests and the floodplain forests, just as in the previously cited study in North America (Peterjohn and Correll, 1984). If climate change affects the flows of rainfall and river flows, there would be direct connections with the amount of denitrification and loss of nitrogen to the atmosphere. Thus, the relationship between ecotones and climate change is not limited to the distribution of organisms, it also includes the ecological roles of ecotones on the landscape (Pinay and Decamps, 1988).

Because organisms are at the edge of their ranges at ecotones, it would be expected that ecotones would represent ideal locations to monitor the effects of global climate change. However, as noted in the above empirical and modeling studies, the relationship may not be a simple one. First, there may be countervailing forces (such as drought, wind, fire or pathogens) that reduce the ability of organisms to respond directly to climate change. Second, ecotones are frequently fragmented and their spatial pattern is altered in response to climate change. As a result, measurement of ecotonal responses may require careful analysis of spatial patterns (Hansen and diCastri, 1992). Third, during glacial periods individual species have responded as individuals (Davis, 1989; Davis and Zabinski, 1992) so there is little reason to expect that intact ecotones would move in response to climate change even if the rate of climate change is significantly faster than during glacial times. Fourth, the abundance of species may be more responsive than the position of the ecotone to climate changes. Thus, it is likely that individual species may be a more effective target for measuring responses to climate change rather than the ecotone itself. However, ecotones probably represent ideal locations for identification of organisms for these studies (Risser, 1995b).

Ecotones that might be suitable for monitoring global climate change are probably those that occupy steep environmental gradients and those that recover rapidly from disturbances. Because these steep environmental gradients result in minimal fragmentation, they would be expected to differentiate species and ecological processes in finer spatial scales. The rapid recovery of organisms and processes from disturbance suggests that responses to climate change are less likely to be obscured by the impacts of disturbance.

In summary, the definition and understanding of ecotones has progressed significantly from the early attention to wildlife habitat and descriptions of boundaries among vegetation types. Ecotones represent an information-rich ecological system in which to understand responses to climate

change. These responses are complex, but there is sufficient research information on which to base observational and experimental studies and to draw initial conclusions.

Ehrlich, Paul

(1932–)

Paul Ralph Ehrlich, American ecologist, evolutionist, and environmental scientist is internationally renowned for the breadth, originality, and importance of his scientific insights. His far reaching contributions shaped profoundly the way people approach problems in fields ranging from biological and cultural evolution to conservation biology, global change and ecological economics. Ehrlich is also distinguished for his social leadership on issues of environment and society. His tireless efforts greatly elevated public awareness worldwide of the importance of: population

growth and over-consumption as factors in environmental impacts; the meaning of biodiversity loss to humanity; the value of ecosystems as capital assets, delivering services to society; the relationship between socioeconomic equity and environmental sustainability; and numerous issues in evolution, such as resistance to antibiotics and genetic determinism.

He received his BA from the University of Pennsylvania (1953) and his doctorate from the University of Kansas (1957). His early work on the higher classification of butterflies remains the standard to this day, but after taking part in the numerical taxonomy revolution of the 1950s, he joined the faculty of Stanford University in 1959 and turned his major attention to studies of the biology of butterfly populations. His continuing work on checkerspot butterflies, integrating studies of ecology, evolution, and behavior, is considered a model of long-term research on natural populations. In the 1960s he (along with P H Raven) founded the field of *coevolution*, and he was a pioneer in establishing *conservation biology*. Ehrlich his best known to the public for his work in *human ecology*. In the 1960s and 1970s, with his wife Anne and colleague John P Holdren, he mapped out the framework for modern environmental science. More recently he has focused his efforts on developing the interface between the natural and social sciences, especially economics, to help the transition of society to an environmentally sustainable course.

Ehrlich has done fieldwork on every continent, and from alpine zones to the sea floor, carrying out research on plants, invertebrates, reef fishes, reptiles, birds, and mammals. He is the author of several dozen books and some 800 scientific papers and articles. In recognition of his scientific distinction and long crusade for environmental sanity and social justice, he has received virtually every prize and honor the scientific and environmental communities can bestow, including the Craford Prize of the Swedish Academy of Sciences, an explicit substitute for the Nobel Prize in fields where the Nobel is not offered.

Elton, C S

(1900–1991)

Charles Sutherland Elton is one of the founders of Animal Ecology. His major contributions stemmed from several books, all of which he wrote quickly and with crystal clarity. The first of these was *Animal Ecology* (1927). This set out the key features of animal communities in terms of their species composition, species richness and zonation. He defined the concept of a species' niche as the animal's role in the community, analogous to a person's occupation in human society and discussed the segregation of species by their niches described in terms of time, weather and their size. He recognized that the relative numbers at each level of a food chain constitute a "pyramid of numbers". He also explored the main concepts in population ecology; here, stimulated largely by his own experience in the arctic, he pointed to the cycling of natural populations. He highlighted the role of natural enemies in the regulation of many populations, but suggested that for those at the top of a food chain, territory should be the limiting factor. There is almost no area of modern ecology that is not introduced in this work; he records that he wrote it in 85 days. Between 1930 and 1933 he published three small books that expanded on or summarized topics in Animal Ecology. His concerns about nature conservation led to another book that was truly seminal: *The Ecology of Invasions by Animals and Plants* (1958). It was derived from a series of three broadcasts he had given the previous year. In this work he contrasted the likely outcome of an invasion of a continent by an introduced species with the impact on an island and analyzes the reasons why invasions fail or succeed. The book ends with two chapters devoted to the ideas of conservation. He also published two large and more detailed books that stemmed from his own research: *Voles, Mice and Lemmings* (1942) and *The Pattern of Animal Communities* (1966); both are mines of information but have not had the lasting impact of his other works.

He published relatively few substantial research papers. As was appropriate for someone who considered ecology to be "scientific natural history", he authored many short notes on natural history observations. He founded and for many years edited the *Journal of Animal Ecology*.

Elton was born in Manchester, UK, but for most of his childhood his father was Professor of English Literature at Liverpool University. A large part of his vacations was spent in the country and, a naturalist from an early age, these allowed him to develop his interests. By the time he entered Oxford in October 1919 he was a very knowledgeable natural historian. The course in comparative anatomy failed to arouse his enthusiasm and he was only saved from relative failure through the influence of his tutor, Julian Huxley. In the summer of 1921 he accompanied Huxley and others on an expedition to Spitzbergen; he wrote a brilliant report on his observations there and on the strength of this continued at Oxford, eventually (1936) being appointed Reader in Animal Ecology. He founded the Bureau of Animal Population there and was its Director until his retirement in 1967. He was elected a Fellow of the Royal Society in 1953 and received the Tyler Award in 1976. Very quietly spoken, he had an unpretentious and gentle manner, but these qualities belied the strength with which he held his views.

ENRICH (European Network for Research in Global Change)

see European Network for Research in Global Change (ENRICH) (Volume 2)

Environment

The term *environment* refers to the physical, chemical, and biotic factors that affect an organism or an ecosystem and ultimately determine its form or structure and survival. All organisms living in a particular area, including humans and anything that influences or is influenced by those organisms are part of the environment.

Constituents of the environment can be classified as either *abiotic* (including climate, minerals, soil, sunlight, water, and all other nonliving elements) or *biotic* (i.e., living organisms).

The flow of energy and the cycling of nutrients link these constituents together. The major components of the Earth's physical environment include the atmosphere, climate, weather, continental landforms, hydrosphere, cryosphere and oceans. The relationship between the principal physical components of the environment, and the major ecosystems of the Earth is mediated through the biosphere.

Human interference in the global environment is widespread and accelerating. Most of this interference derives from three basic contributing factors: human population growth, pollution, and misuse of resources and natural ecosystems. Because these three factors are interrelated, environmental problems are extremely complicated. Another factor in global environmental change is that the world is changing at an increasing rate, with internationally coordinated environmental stewardship seeming to fall ever further behind social and economic development. Environmental gains from better policies and improved technology are being outstripped by the pace and scale of human population growth and economic development. Major environmental issues include climatic change, biodiversity loss, stratospheric ozone depletion, nitrogen overloading, air and water pollution, and deforestation.

European Network for Research in Global Change (ENRICH)

Pierre Mathy
European Commission, Brussels, Belgium

ENRICH is an initiative developed by the European Commission, within the European Framework Programme for Research, Technological Development and Demonstration (RTD) activities.

The mission of ENRICH can be characterized by three broad aims:

- *to improve and facilitate research networking and capacity building between European researchers and the wider international research community in the area of global change;*
- *to improve the flow and exchange of information on global change research with a particular emphasis on the relevance and value of research investment to European policy, society and economic activity; and*
- *to provide a focal point for European collaboration with complementary international initiatives such as the Inter-American Institute and the Asia Pacific Network.*

DEFINITION OF GLOBAL CHANGE

Global change research seeks to understand the integrated Earth system in order to: (i) identify, explain and predict natural and anthropogenic changes in the global environment; (ii) assess the potential regional and local impacts of those changes on natural and human systems; and (iii) provide a scientific basis for the development of appropriate technical, economic and societal mitigation/adaptation strategies. In this context, global change encompasses climate change; changes in atmospheric physics and chemistry (e.g., ozone depletion, tropospheric pollution); changes in land use and cover; variability in marine environments and ice cover; changes in biogeochemical cycles; impacts of these changes on natural balances (ecosystems), on natural resources (freshwater, forest products, crops, marine resources), and on socio-economic balances (sustainable development, industrial development, human health, quality of life); biodiversity related issues.

IMPLEMENTATION: PROJECTS SELECTION

ENRICH was initially conceived as a joint initiative primarily based on three specific programs of RTD: Environment and Climate; Marine Science and Technologies; and Cooperation with Third World Countries and International Organizations, part of the 4th Framework Programme (FP4) for RTD activities. ENRICH was implemented through two calls for proposals followed by evaluation and selection procedures applied within FP4.

Those calls sought proposals for additional catalytic activities, accompanying measures and supporting initiatives falling in the remits of the RTD programs indicated above. Proposals were sought to fill gaps that cannot be supported by individual research projects alone and that:

- add value to ongoing research activities carried out in the area of global change through the promotion of voluntary scientific coordination including data compatibility schemes and the corresponding information systems and information sharing/dissemination arrangements; or
- prepare the ground for more coherent and integrated research undertakings based on sound and functional research partnerships that might be considered for implementation at a later stage.

ACTION TYPES

The proposals falling within the remit of ENRICH had to include in a scientifically coherent and operationally feasible way, one or more of the following types of action:

- Development of cooperative links and networking actions, in particular with a view both to strengthening integrative and interdisciplinary approaches in the European Union (EU) and associated states and also promoting partnerships between their researchers and those in other countries.
- Improving visibility and exchange of data and scientific information; collation of disparate datasets; strengthening harmonized data collection, distribution and modeling strategies; integration and consolidation of research results; development of information systems and information sharing arrangements.
- Improving research capacity to address the issues of regional implications of global change (impacts on natural resources, implications for natural resources management, etc.) and for policy analysis relating to the global implications of regional changes in natural and socio-economic resources.
- Identification of regional gaps such as the need for data, experimental settings, methodological improvements and regional research priorities to improve the integrated knowledge of global change processes and impacts and their policy implications.
- Contributions to the development of science agendas or science plans for interdisciplinary research on global change of mutual interest to the EU and its partners, with particular attention to Eastern and Central European regions; Mediterranean Regions; Arctic and Boreal Regions.
- Promoting and improving the packaging and diffusion of research results on global change in a manner responsive to the specific needs of users, such as policy makers; natural resources managers; industrial, economic and societal actors.
- Projects selected continued until 2000. A new call for proposals was launched in November 1999.

Eutrophication

Eutrophication is the enrichment of streams, lakes, ponds, bays and estuaries with nitrogen and/or phosphorus, the two macronutrients that normally limit the photosynthesis of phytoplankton. The nutrients come from leaching of inorganic fertilizers, from manures, human wastes, industrial processes and from atmospheric deposition. Water transparency and color are the most obvious indicators of eutrophication: transparent oligotrophic (nutrient poor) waters support low plant productivity and appear either blue or brown (when stained in peaty regions). Eutrophic waters have high primary productivity as large amounts of phytoplankton make them turbid and limit their transparency to less than 50 cm.

Advanced eutrophication is marked by blooms of cyanobacteria and siliceous, scum forming, and also potentially toxic, algae. Eventual decomposition of this phytomass creates hypoxic or anoxic conditions near the bottom. The most worrisome consequences range from offensive taste and odor of drinking water and formation of trihalomethanes during water chlorination to serious health hazards to livestock and people ingesting soluble neurotoxins and hepatotoxins released by decomposing algal blooms. Reduced fish yields, extensive summer fish kills and changed composition of fish species in affected water bodies are common. Another particularly offensive consequence of eutrophication includes the growth of thick coats of algae on any submerged substrates, be they aquatic plants, stones, docks or boats.

Coastal eutrophication now threatens the Great Barrier Reef, the world's largest coral formation, by smothering them with algae as well as by promoting the survival and growth of the larvae of *Acanthaster planci*, the crown-of-thorns starfish, that has recently destroyed large areas of the reef. And as the Baltic unfortunately demonstrates, even a whole sea can become eutrophic: a third of the sea bottom of the Baltic proper (the southern part of the sea) is now intermittently deprived of oxygen. The worst affected offshore zone in North America is a large region of the Gulf of Mexico where the nitrogen load brought by the Mississippi and Atchafalya rivers creates every spring a large hypoxic zone that kills many bottom dwelling species and drives away fish.

VACLAV SMIL *Canada*

Evolutionary Processes in Ecosystems

Michel Loreau
Ecole Normale Supérieure, Paris, France

Environmental changes are major drivers of evolutionary changes. Although evolution is typically a slow process, there is increasing evidence that the time-scale of evolution can be shorter than previously believed under strong selective pressures.

The prediction and understanding of these evolutionary changes and their implications, however, require identification of the proper context of constraints within which natural selection operates. The ecosystem provides such a context, because an organism's environment is made up of interacting biotic and abiotic components which constitute a local ecosystem. Ecosystem processes can channel selection in different directions from those expected in the absence of these constraints. In particular, nutrient cycling is a key process which transmits predictable indirect effects in ecosystems. These indirect effects can be so strong that they prevail over direct effects and exert effective selective pressures on the species involved, provided that there is sufficient spatial heterogeneity in the system or trade-offs between traits associated with the direct and indirect effects.

Thus, the merging of evolutionary and ecosystem perspectives, which have been increasingly separated in modern ecology, is fundamental to predict the responses of ecological systems to environmental changes.

ENVIRONMENTAL CHANGES AND EVOLUTIONARY PROCESSES

All organisms experience environmental changes continuously. Many of these changes, however, are regular or frequent enough so that organisms can adapt to them. Diurnal or seasonal cycles, for instance, are so regular and predictable for most organisms that they are perceived as an integral part of a constant environment. Other changes are catastrophic or directional, and impose new environmental conditions on organisms, either suddenly or gradually. Most environmental changes generated by human activities – habitat destruction, biological invasions, changing atmospheric composition, global warming, and pollution – are of that kind. What distinguishes them from similar changes in the past is their rhythm and scale, which are, in many respects, unprecedented.

Faced with such changes, organisms have three basic alternatives: to migrate, adapt, or die. Catastrophic changes, such as habitat destruction, often result in

massive mortality, population extinctions, and eventually, species extinctions. This is the unfortunate fate of an increasing number of species today. More gradual changes, such as climatic changes, often result in progressive migrations and shifts in species distributions, as testified by palaeoecological records. A less obvious but widespread outcome is the adaptation to changed conditions through the evolution of species traits.

Evolution is ultimately the result of three basic processes: mutation, which generates genetic variability within populations; genetic drift, which increases genetic variability among populations; and selection, which reduces genetic variability selectively within populations. There is increasing evidence that environmental stress can directly affect mutation frequencies or the expression of accumulated *silent* mutations in organisms as different as bacteria or fruit flies (Pennisi, 1998; Rutherford and Lindquist, 1998), thereby increasing the genetic variability allowing rapid evolution. It is also known that habitat fragmentation and population subdivision favor genetic drift, and ultimately, speciation; this is the basis of the widely accepted model of allopatric speciation, in which new species are formed in geographically distinct areas. Finally, environmental changes modify the adaptive landscape of species and the selective pressures that are exerted on them; they determine the direction in which natural selection drives evolution. Thus, environmental changes are major drivers of evolutionary changes, and ultimately, of the generation of species diversity. This shows that they are not intrinsically detrimental to biodiversity. The current (and unfortunately, mostly future) biodiversity crisis is fundamentally a problem of the rhythm and scale of environmental changes. Massive numbers of species are currently driven to extinction without being replaced by new species because evolution simply cannot keep pace with the current environmental changes for most organisms.

Evolution is typically a slow process because it is based on changes in gene frequencies between generations. However, there is increasing evidence that the time-scale of evolution can be shorter than previously believed under strong selective pressures i.e., in the order of a few generations (Thompson, 1998). This is still long in *human* time-scales for long-living organisms such as trees, but it may be very fast for short-lived organisms such as bacteria. Even in vertebrates, significant evolutionary changes have been documented in the field over a period of a few years, using long-term experiments or observations of populations under changing conditions (Grant and Grant, 1995; Reznick *et al.*, 1997; Losos *et al.*, 1997). Small organisms with short generation times and high population abundances can even adapt to genuine environmental catastrophes. The most dramatic examples of such rapid evolutions include the resistance of bacteria to antibiotics and the resistance of pests to insecticides. These examples point to the limits of our ability to control nature, even when we orchestrate large-scale chemical or biochemical catastrophes to destroy the organisms in question. Thus, the potential for, and implications of, evolutionary changes resulting from environmental changes cannot be ignored.

THE ECOSYSTEM AS THE PROPER CONTEXT OF NATURAL SELECTION

Predicting and understanding these evolutionary changes and their implications, however, requires identification of the proper context of the constraints within which natural selection operates. Traditionally, evolutionists have considered constraints to be internal to the organisms, such as from allocations among competing needs. In the classical view, the environment is regarded as external to the organism and constant (Figure 1A). Although most evolutionary biologists today would probably agree that this view is an oversimplification of reality, it has been, and still is, widely used in theoretical evolutionary biology as an implicit conceptual framework because of its simplicity. The modern view of natural selection recognizes that organisms modify and interact with their environment, which generates an organism–environment feedback in the operation of natural selection (Figure 1B; Lewontin, 1983). However, in order to understand the full implications of this feedback, it is further necessary to resolve an organism's environment into its real physical, chemical and biological constituents and their interactions. This is what I call the ecosystem

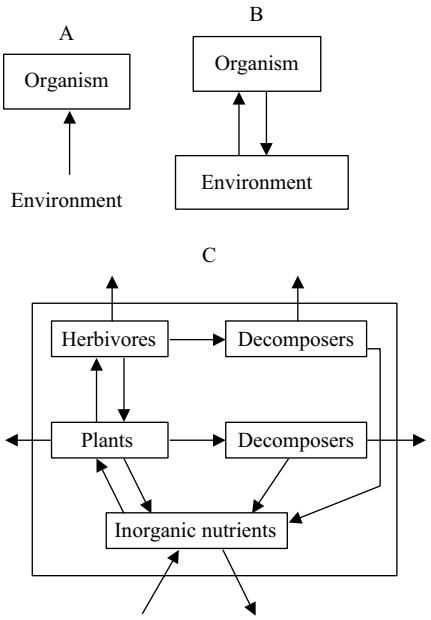

Figure 1 Three views on how natural selection operates: (A), the 'classical' view; (B), the 'modern' view; and (C), the 'ecosystem' view

view of natural selection, for an ecosystem is precisely a local system of interacting biotic and abiotic components (Figure 1C). Since each organism's environment is constituted by other organisms or components, the ecosystem concept contains both the organisms and their environments, and thus, transcends the duality between organism and environment. Recognizing the ecosystem as the proper context within which natural selection, and hence evolution, operates is a major challenge for ecology today, with important implications in both basic science and applied areas, such as conservation biology and ecosystem management. This challenge emphasizes the need to overcome the barrier that has increasingly separated population and evolutionary ecology on one hand, and ecosystem ecology on the other hand.

Feedbacks via ecosystem processes can channel selection in different directions to those expected in the absence of these constraints. As an example of a simple organism–environment feedback that has this property, consider the effect of changing soil nutrient supply on the evolution of plant antiherbivore defense. The classical resource availability hypothesis (Coley *et al.*, 1985) predicts that low resource availability favors plants with inherently slow growth rates, which in turn favors large investments in antiherbivore defense. This hypothesis has been influential and attractive because it seemed to explain the patterns of plant defense and herbivory in a wide range of ecosystems. It hinges, however, on a simple theoretical argument with a number of simplifying assumptions, in particular, the assumption that the amount of available resources is unaffected by plants. This implicit assumption of a constant environment led Coley *et al.* (1985) and subsequent authors to measure plant fitness by what they called the plant *realized growth rate*, which, in effect, is a potential growth rate which ignores the feedback generated by plant resource consumption. This fitness measure may make sense for pioneer species colonizing temporary environments, but is inappropriate for species competing for limited resources in more stable environments. Whenever plants have accumulated enough biomass to affect the amount of resources in their environment, they compete for these resources, and their growth hinges on their ability to tolerate low concentrations of the resource that is limiting. If the environment is homogeneous, fitness is determined by the ability to deplete the limiting resource (Tilman, 1982). If the environment is spatially structured, fitness is determined by the basic reproductive rate (Loreau, 1998).

Taking into account this plant–resource feedback explicitly changes the theoretical predictions altogether (Loreau and de Mazancourt, 1999). If the environment is homogeneous, with all plants having equal access to the limiting nutrient, and the plant–nutrient system is allowed to reach an ecological equilibrium, the evolutionary optimal defense investment is determined by features of the plant–herbivore interaction, but is independent of both plant maximum growth rate and nutrient availability. If the environment is spatially structured and competition obeys a competitive lottery for vacant sites, the outcome is strongly dependent on the factor that determines a plant's ability to produce successful propagule establishment in vacant sites, which, in itself, determines fitness. The optimal defense investment may then either increase, stay constant or decrease with nutrient supply (Figure 2). Thus, the classical view that lower resource availability favors evolution towards larger investment in antiherbivore defense has little theoretical support once the interaction between plants and their limiting resources is taken into account.

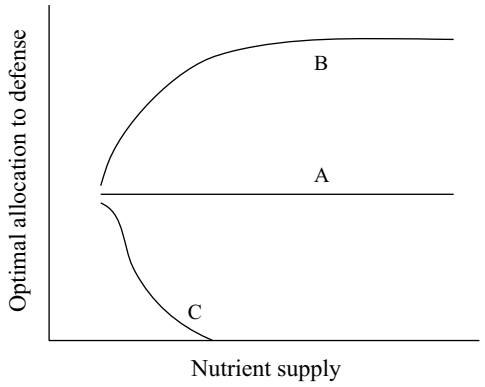

Figure 2 Evolutionary optimal plant allocation to defense as a function of nutrient supply. Optimal defense investment is: (A) independent of nutrient supply in most cases i.e., when either the environment is homogeneous, or the environment is spatially structured and plant tness is proportional to the part of biomass that is mobilized for growth or to total productivity; (B), increases with nutrient supply when plant tness is proportional to total biomass; and (C), decreases with increasing nutrient supply when plant tness is proportional to the part of productivity that is allocated to growth. (Loreau and de Mazancourt, 1999)

EVOLUTION OF INDIRECT INTERACTIONS IN ECOSYSTEMS

Many indirect interactions, and hence, of indirect organism–environment feedbacks, are likely to occur among organisms because of the complexity of ecosystems (Puccia and Levins, 1985; Wootton, 1994). These indirect effects can be weak or unpredictable (Yodzis, 1988), but some can be strong and predictable. In particular, material cycling is a key ecosystem process that drives a circular causal chain in ecosystems, thus transmitting predictable indirect ecological effects and evolutionary constraints to their component species. Thus, plants (*autotrophs*) and decomposers (*heterotrophs*) are involved in an indirect mutualistic interaction through the cycling of limiting nutrients, such as nitrogen or phosphorus. The ecological and evolutionary

dynamics of this indirect interaction can explain broad-scale successional and evolutionary trends in the functional properties of ecosystems, in particular those towards increased productivity and biomass, a decreased productivity/biomass ratio, and tighter nutrient cycles (Loreau, 1998).

A more controversial, but illuminating case of the mutual dependency between autotrophs and heterotrophs generated by material cycling is provided by plant–herbivore interactions. These interactions have been traditionally regarded as antagonistic because herbivores have a negative direct effect on plants through biomass consumption. This view, however, has been challenged by the *grazing optimization hypothesis*, which states that primary productivity, or even plant fitness, is maximized at an intermediate rate of herbivory (Owen and Wiegert, 1976; McNaughton, 1979; Hilbert *et al.*, 1981). One mechanism capable of producing grazing optimization is nutrient cycling, which mediates a positive indirect effect of herbivores on plants. Although this hypothesis has been hotly debated (e.g., Silvertown, 1982; Belsky, 1986; Paige and Whitham, 1987; Bergelson and Crawley, 1992; Belsky *et al.*, 1993; Lennartsson *et al.*, 1997), recent theoretical work has been able to identify general rules that govern grazing optimization in the form of increased primary production through cycling of a limiting nutrient (Loreau, 1995; de Mazancourt *et al.*, 1998). Qualitatively, this requires that: (1), the proportion of nutrient lost while flowing along the herbivore recycling pathway is sufficiently smaller than the proportion of nutrient lost while flowing in the rest of the ecosystem; and (2), nutrient inputs into the system exceed a threshold value, which depends on the sensitivity of the plant uptake rate to soil mineral nutrient. These results are very general; they do not depend on the structure of the ecosystem or on the functional form of herbivore consumption. They are also potentially relevant to natural ecosystems (de Mazancourt *et al.*, 1999).

Does this imply that ecosystem-level constraints make the plant–herbivore interaction actually mutualistic, not antagonistic? The evolutionary consequences of grazing optimization, and of ecological indirect interactions in general, are complex, for two main reasons. First, increased plant productivity does not necessarily translate into increased plant fitness. Second, when it does, it is not absolute, but relative fitness that counts. If two plant types (species or genotypes) are mixed, one of them being tolerant (*mutualistic*) and the other resistant (*antagonistic*) to herbivory, the resistant type is expected to outcompete the tolerant type because it benefits from the positive indirect effect of increased nutrient cycling, but does not suffer the negative direct effect of herbivore consumption. As a result, tolerance should not evolve, even though it is indirectly beneficial.

Two factors, however, counteract this advantage of antiherbivore defense. First, the spatial structure of the plant–herbivore system can generate spatially heterogeneous nutrient cycling (de Mazancourt and Loreau, 2000). If herbivores recycle nutrients in the vicinity of the grazed plants, or plants from the same type are aggregated, herbivores tend to recycle proportionally more nutrient on the plants that are more heavily grazed, thus augmenting the indirect benefit of grazing for the grazed plants. Evolution is then governed by the balance between two conflicting levels of selection (Wilson, 1980): (1), individual selection within patches, which favors the resistant type over the tolerant one because it has a higher relative fitness; and (2), group selection between patches, which favors patches with a higher proportion of the tolerant type because they have a higher average absolute fitness. The outcome of evolution depends on the strength of spatial aggregation and patch size; tolerance to grazing will evolve provided that the spatial aggregation is strong enough or the patch size is small enough (de Mazancourt and Loreau, 2000).

The second factor that counteracts the advantage of antiherbivore defense is its cost in terms of nutrient investment, which generates a trade-off between defense and nutrient uptake in plants. A theoretical study of plant adaptive dynamics (Dieckmann, 1997) in a spatially structured model ecosystem shows that, for most ecologically plausible trade-offs, plant evolution then leads to a single *continuously stable strategy* i.e., a strategy to which evolution converges and which cannot be invaded by any other close strategy (de Mazancourt *et al.*, in preparation). This evolutionary strategy has complex relationships with the strategies that maximize plant production or plant biomass, depending on ecosystem parameters. Due to this complexity, different ecological and evolutionary scenarios of herbivore addition or removal are possible, which highlight the ambiguity of the notion of 'mutualism'. It is useful to distinguish two types of mutualism: an ecological mutualism, in which each species gains a benefit from the presence of its partner in the absence of any evolutionary change, as revealed e.g., by an ecological press perturbation; and an evolutionary mutualism, in which the mutual benefit persists even after evolution has occurred (de Mazancourt *et al.*, in preparation). The conditions for an evolutionary mutualism are more stringent than those for an ecological mutualism because interacting species may have evolved a mutual dependence, so that the removal of one species may have a negative impact on the other in the short term, but this negative impact may disappear after each species has had the opportunity to evolve and adapt to the new conditions created by the absence of its partner (Douglas and Smith, 1989; Law and Dieckmann, 1998).

When a plant's reproductive ability is determined by its productivity, herbivory is indeed capable of improving plant performance on both an ecological and an

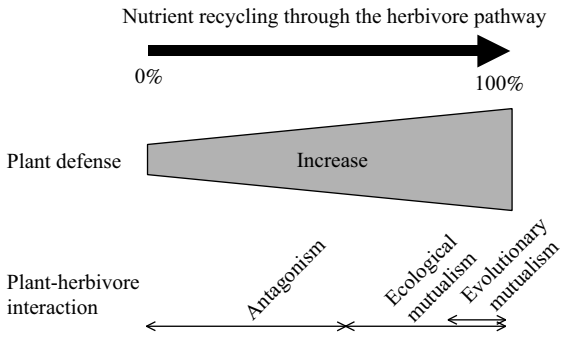

Figure 3 Changes in the plant-herbivore interaction along a gradient of increasing herbivore nutrient recycling efficiency, under the assumption that plant reproductive ability is proportional to plant productivity. Plant defense increases as herbivores are more efficient at recycling the nutrient, but at the same time, the interaction becomes increasingly mutualistic. (de Mazancourt *et al.*, in preparation)

evolutionary time-scale, provided that the herbivore recycling efficiency is sufficiently greater than plant recycling efficiency, thus generating a plant–herbivore mutualistic interaction. As expected, the requirements on herbivore recycling efficiency are more stringent for an evolutionary mutualism than for an ecological mutualism. Surprisingly, however, as herbivore recycling efficiency is increased, the plant–herbivore interaction becomes increasingly mutualistic (first ecologically, then evolutionarily), but at the same time, plants evolve to increase their level of antiherbivore defense because they gain a higher benefit from not being consumed relative to less defended plants (Figure 3). Thus, mutualism can go hand in hand with increased conflict between partners. Although paradoxical at first sight, such evolutionary conflicts are also known in other mutualistic interactions (Anstett *et al.*, 1997; Law and Dieckmann, 1998).

CONCLUSION

Evolutionary processes are capable of leading to a significant transformation in species ecological properties over relatively short time-scales. However, the evolutionary dynamics of species are embedded in the dynamics of ecosystems as complex systems of interactions among species. Species traits and the evolution of species traits are ultimately constrained by ecosystem processes, just as ecosystem properties are constrained by the ecological and evolutionary history of interacting species. Indirect effects mediated by ecosystem processes can be so strong as to prevail over direct effects and exert effective selective pressures on the species involved, provided that there is sufficient spatial heterogeneity in the system or trade-offs between traits associated with the direct and indirect effects. They are even able to change the nature of species interactions, both in an ecological and an evolutionary sense. Thus, merging the evolutionary and ecosystem perspectives, which have been increasingly separated in modern ecology, is fundamental to predict the responses of ecological systems to environmental changes.

Extinctions and Biodiversity in the Fossil Record

Ricard V Solé and Mark Newman
Santa Fe Institute, Santa Fe, NM, USA

Life has existed on Earth for more than three billion years. Until the Cambrian explosion about 540 million years ago, however, life was restricted mostly to single-celled microorganisms that were, for the most part, poorly preserved in the fossil record. From the Cambrian explosion onwards, by contrast, we have a substantial fossil record of life's development, which shows a number of clear patterns, including a steady increase in biodiversity towards the present, punctuated by a number of large extinction events that wiped out a significant fraction of the species on the planet, and in some cases, caused major reorganizations amongst the dominant groups of organisms in the ecosphere.

The history of life on the Earth begins in the oceans during the *Achaean eon*, somewhere around 3.8 billion years ago, probably with the appearance first of self-reproducing RNA molecules and subsequently of prokaryotic single-celled organisms. At the start of the *Proterozoic eon*, around 2.5 billion years ago, the atmosphere changed from reducing to oxidizing, as a result of the depletion of stocks of elemental iron in the Earth's crust, and oxygen-breathing life became possible. Eukaryotes, multicellular life, and sexual reproduction all appeared for the first time during the Proterozoic, although the exact order and dates are still in dispute, since the fossil record of this period is poor. The earliest firm evidence of multicellularity dates from about 575 million years ago.

About 540 million years ago, for unknown reasons, an enormous increase in the diversity of multicellular animals took place. This event, known as the *Cambrian explosion*, produced all the major body plans of animals seen today, as well as a number of others that have since become extinct. The first land-dwelling plants appeared during the *Silurian period*, about 430 million years ago, followed shortly afterwards by the first land-dwelling animals, which were insects, and then the first land-dwelling vertebrates during the *Devonian*. About 250 million years ago, at the end of the *Permian* period, the largest mass extinction of all time took place, killing at least 90% of all species on the Earth, and ending the eon named the *Paleozoic*.

The *Mesozoic*, colloquially known as *the age of the dinosaurs*, followed the Paleozoic. In addition to dinosaurs, the Mesozoic also saw the first appearance of mammals and of flowering plants. It ended about 65 million years ago with the *Cretaceous–Tertiary (KT) extinction event*, which wiped out the dinosaurs along with about 70% of all other species then alive. The interval from the KT event until the present, known as the *Cenozoic eon*, saw the radiation of the mammals to fill many of the dominant land-dwelling niches and, eventually, the evolution of mankind.

This information comes from geological studies and from the substantial fossil record of extinct lifeforms. The currently known fossil record includes about one-quarter of a million species, mostly dating from the time interval between the Cambrian explosion and the present. There are numerous biases in the fossil record, which make accurate quantitative investigations difficult, including the following.

1. Older fossils are harder to find because they are typically buried in deeper rocks than more recent ones.
2. Accurate dating of fossils is difficult. Radiocarbon dating, for example, is not useful for rocks that are hundreds of millions of years old. Radioactive isotopes other than carbon with longer half-lives are used for most of the geologic time-scale, but resolution of dates using these isotopes can be poor.
3. Particularly rich fossil beds, or particularly zealous investigators, may produce very complete records for some time periods or groups of organisms, while other periods or groups may be comparatively poorly researched.
4. Prehistoric environmental disturbances can upset the deposition processes by which fossils are formed and give rise to time periods in which the fossil record is poor.
5. Marine organisms tend to be much better preserved than land-dwelling ones, because deposition is much more uniform and reliable in the oceans than it is on land.

Despite these biases, a number of trends are clear from the fossil record.

Figure 1 shows a plot of the best estimate of the number of living families of marine organisms, as a function of time since the start of the Cambrian. As the plot shows, diversity appears to increase substantially over time, and this is believed to be a real trend. On average, there have been more families, and indeed more species, alive in recent times than earlier. Over the course of the plot, diversity appears to increase by a factor of about five, although some of this increase is an artifact of the greater availability of fossils of recent species in more easily accessible rocks.

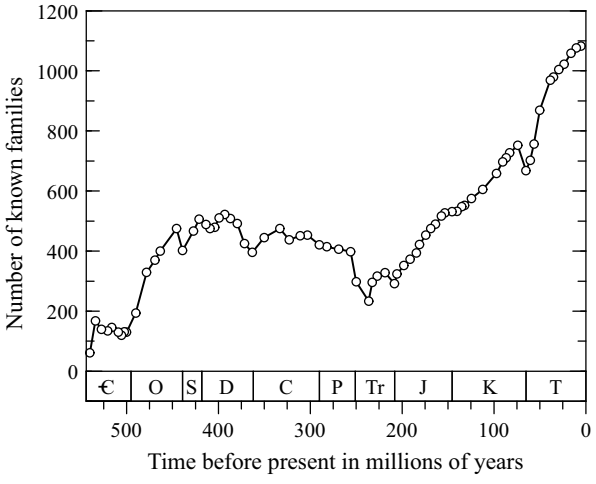

Figure 1 Number of known marine families alive over the time interval from the Cambrian to the present. (The data are taken from Sepkoski, 1992)

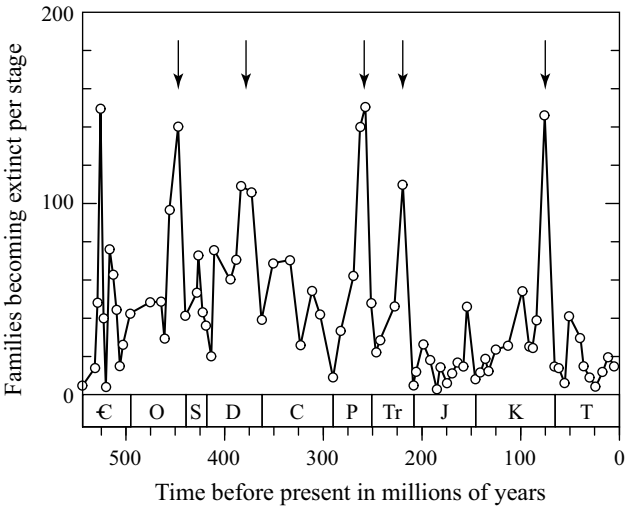

Figure 2 Estimated extinction of marine animals in families per stratigraphic stage since the Cambrian. The arrows indicate the positions of the big five mass extinction events discussed in the text

Figure 2 shows the extinctions, again of marine organisms, as a function of time over the same interval. The graph gives the number of families becoming extinct per stratigraphic stage. Stages are uneven intervals of time based on recognizable geological and paleobiological markers, with typical length about 7 million years. As the figure shows, there has been considerable variation in the intensity of extinction over prehistoric time. Of particular note are the five large peaks in extinction marked with arrows. These are the big five mass extinction events that marked the ends of the Ordovician, Devonian, Permian, Triassic, and Cretaceous periods. A sixth peak in the Cambrian is also visible, but this is thought probably to be an artifact of poor fossil preservation during that period rather than a real extinction event. The basic features of the big five extinctions are as follows (see also Table 1).

The end-Ordovician event about 440 million years ago appears to have occurred in two bursts, separated by about

Table 1 Extinction intensities at the genus and species level for the big five mass extinctions of the Phanerozoic. Estimates of genus extinction are obtained from directed analysis of the fossil record while species loss is inferred using a statistical technique called reverse rarefaction. (Figures are taken from Jabionski, 1991)

Extinction	Genus loss (%) (observed)	Species loss (%) (estimated)
End Ordovician	60	85
Late Devonian	57	83
Late Permian	82	95
End Triassic	53	80
End Cretaceous	47	76

1 million years, which between them wiped out about 85% of then-living species. The event was confined to marine species, since multicellular life had not yet colonized the land. Particularly affected were brachiopods, bivalves, echinoderms, bryozoans, and corals. The immediate cause of extinction appears to have been the continental drift of a significant landmass into the south polar region, causing a global temperature drop, glaciation, and consequent lowering of the sea level, which destroyed species habitats around the continental shelves. The sea level rose again with the end of the glacial interval about a million years later and caused a second burst of extinction.

The late-Devonian extinction around 360 million years ago is complex and rather poorly understood. It is probably, in fact, composed of a number of separate events – as many as seven – spread over about 25 million years, including particularly notable extinctions at the ends of the Givetian, Frasnian, and Famennian stages. Overall, about 80% of living species died out in the late Devonian. Particularly hard hit were corals, brachiopods, bryozoans, ammonoids, and fish. The causes of these extinctions are unclear. The leading theories suggest that changes in sea level and ocean anoxia, possibly triggered by global cooling or oceanic volcanism, were most likely responsible, although the impact of an extraterrestrial body such as a comet has also been considered.

The late-Permian extinction around 250 million years ago was the largest extinction event of all time, killing some 95% of marine species and about 70% of land-dwelling species. Like the end-Ordovician event, it seems to have been composed of two bursts, separated by an interval of about 10 million years, the second being the larger of the two. Notable extinction happened again amongst brachiopods, ammonoids, and corals, as well as gastropods and, unusually, insects. Despite an enormous amount of research on the subject, the causes of the late-Permian event are still a subject of debate. It is clear, however, that the sea level rose during this period, levels of oxygen in the oceans were low, and carbon dioxide (CO_2) levels were high. There is some suggestion that a cometary impact may have been involved, or a shift in ocean circulation driven by climate change, or CO_2 and sulfur release following large-scale volcanic activity. The late-Permian event had a profound effect on the terrestrial ecosystem, which is still being felt today, a quarter of a billion years later. A particularly notable example amongst marine faunas is that of the bivalves, a relatively minor group during the Paleozoic that took advantage of the ecological vacuum left by the extinction to establish a solid grip on shallow-water environments, leading to their dominance over the previously very successful brachiopods and gastropods.

The end-Triassic extinction around 210 million years ago is probably the most poorly understood of the big five extinction events. It appears to have killed about 80% of species then living, either in one burst or possibly in two, separated by about 20 million years. Major extinction is observed particularly amongst ammonoids, bivalves, gastropods, and brachiopods. Leading theories of the causes of the end-Triassic event are ocean anoxia, massive volcanism, or possibly an asteroid impact.

The end-Cretaceous event, usually called the *KT event*, has attracted the most popular interest of any extinction because it saw the death of those perennial movie stars, the dinosaurs, but it was in fact the smallest by quite a wide margin of all the big five. The KT event appears to have been a single pulse of extinction around 65 million years ago, which wiped out about 70% of all species then living. As well as the dinosaurs, it extinguished many other land-dwelling vertebrates, especially large-bodied ones, along with large numbers of (marine) bivalves, gastropods, and foraminifera. The proximal cause of the KT event was, almost certainly, the impact of a large comet or meteor near the present site of the town of Puerto Chicxulub on the Yucatán peninsula in eastern Mexico, with an associated drop in sea level and possibly short-term cooling or heating, or acid rain.

The fossil record can give us valuable insight into the nature of extinction and the effects of large-scale environmental change. It also indicates that recovery from extinction is a slow process by human standards, typically taking on the order of 5 or 10 million years. Thus, it is important to fend off such extinctions before they happen, rather than hoping that the ecosystem will prove robust enough to take care of itself.

Comparison between fossil and present-day extinction is not straightforward since, as mentioned above, the fossil record consists largely of marine organisms, whereas interest in contemporary extinction focuses mostly on land-dwelling organisms. Also recently extinct or currently endangered species tend to be rare, whereas the fossil record primarily reflects the most abundant and numerous biotas. Still, there are a number of general patterns in the fossil extinction record that may help us in the conservation of modern-day biodiversity.

First, we note that habitat loss, such as the destruction of shallow-water environments on the continental shelf as a result of changes in sea level, appears to have been an important cause of extinction again and again. A rise in sea level as a result of global warming over the next century, for example, could be devastating for reef communities. In this context, human-driven habitat loss is leading to extensive habitat fragmentation, i.e., to the generation of spatially isolated subareas. In many cases the subdivision of a large population into many weakly connected subpopulations substantially increases extinction risk. Again, the fossil record is very useful in providing a source of comparison. Habitat fragmentation enhanced the extinction of large

mammals during the Pleistocene (75% of them are extinct). The area reduction during glacial cycles led to widespread habitat fragmentation and eventually to the extinction of many species. A considerable number of current endemisms in plant species are due to the confinement to small areas during the Ice Age.

Second, most past extinction events appear to have been selective to some extent. The end-Ordovician event, which was associated with a period of global cooling and glaciation, particularly favored species that were well adapted to cold-water conditions, and was particularly harsh on those who were not, for obvious reasons. The KT boundary event, as mentioned previously, appears to have come down especially hard on large-bodied animals. A number of explanations for this latter effect have been put forward. Large-bodied animals have smaller populations and greater area requirements, and are thus more sensitive to habitat loss or fragmentation. Moreover, their trophic requirements and low rates of population growth make them slow to recover from environmental change. It has been suggested that the loss of large herbivorous faunas could trigger major changes in biogeographic vegetation patterns that could in turn trigger further extinctions.

This last observation leads us to an additional question: to what extent do interactions between species affect the response of an ecosystem to environmental stress? Ecological interdependence between species may have heightened the impact of some of the mass extinctions; some studies, for example, have suggested that the collapse of marine food chains at the end-Cretaceous contributed to the KT extinction event. The KT event had a rapid effect on most biotas and a subsequent long-term effect perhaps related to a decrease in primary productivity. This seems particular likely in the case of marine biotas, which show a marked dip in the rate of accumulation of carbonates, especially calcium carbonate, following the KT boundary, indicating a decrease in productivity. The resulting decrease in food supply would then produce extinctions at higher trophic levels. Similar mechanisms may also have been at work during the human-driven end-Pleistocene extinctions of mastodons and mammoths in North America, which were associated with widespread changes in vegetation patterns and the disappearance of many other species. One may well ask whether the current extinction of large herbivorous species in African ecosystems will result in similar concurrent extinctions. It is also believed that symbiotic and parasitic species are particularly vulnerable to extinction, as a result of their dependence upon a partner or host. Many living species may, in fact, already be doomed to extinction, because of the loss of a partner in an essential symbiotic relationship (Figure 3). The situation with parasites may be even worse, since most parasites are specific to a single species of host, and extinction amongst

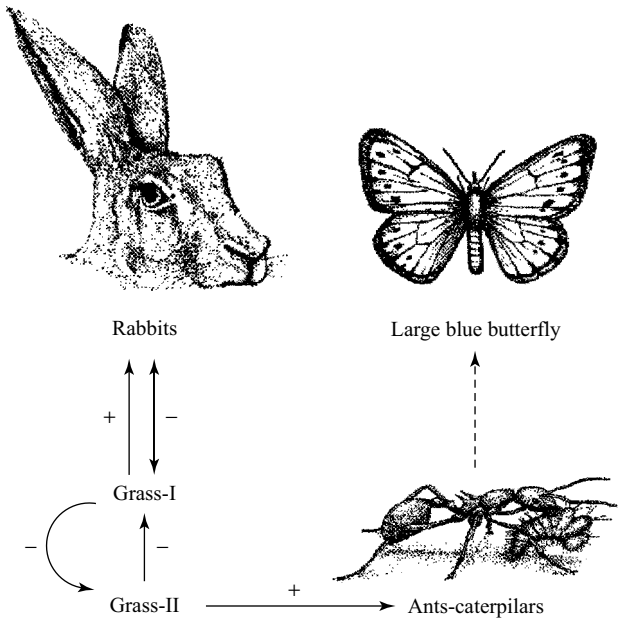

Figure 3 An example of coextinction: the introduction of the myxoma virus to rabbit warrens in England triggered the extinction of the Large Blue butter y (*Maculina arion*), an already endangered, endemic species. Myxomatosis caused a dramatic decline in rabbit populations and a consequent surge in the abundance of a species of grass on which the rabbits previously grazed (Grass-I). Another previously dominant species of grass (Grass-II) was unable to compete and declined substantially in its abundance, giving rise to a shortage of nesting material for certain variety of ant (*Mynnica*). As a result of a symbiotic dependence between the butter y *Maculina* and this species of ant, the butter y then became extinct

parasites often goes unnoticed, even though their importance in maintaining diversity has been stressed by many studies. Since all known animals and plants have some parasitic load, extinctions of parasites must be widespread in evolutionary history. The eggs of what are believed to be ectoparasitic mites have been discovered on fossilized dinosaur remains, indicating that coevolutionary parasitism, and hence coextinction (the coupled extinction of ecological partners) is an ancient phenomenon. Estimating extinction rates for parasites is unfortunately difficult, since they are poorly represented or difficult to identify in the fossil record, and internal parasites are basically not preserved at all.

Overall, recent extinction rates in most plant and animal taxa are relatively low, but for some groups they do approach the levels associated with prehistoric mass extinction events (Table 2). These observations have led some researchers to suggest that the biosphere may be on the verge of another such event. Some claim that the world has already entered a sixth period of mass extinction, driven primarily by the human population explosion. Theoretical studies of long-term ecological responses to habitat

Table 2 Comparison between different features of past mass extinction events (as reported from the fossil record) and present-day, human-driven mass extinction. Here the effects of habitat loss are widespread but different mechanisms were at work: changes in sea levels and continental breakup (fossil record) and human-driven habitat destruction/fragmentation (present day) respectively. (Estimations of species loss are from Wilson, 1992)

	Fossil record	Present day
Time resolution	$\sim 10^5$ - 10^6 years	1 year
Most affected biotas	Tropical biotas	Coral reefs, rainforests
Selectivity on size	Large-sized species	Large-sized species
Loss of endemics	Not well known	Widespread
Effects of habitat loss	Widespread	Widespread
Time scale of recovery	~5- 10 Myr	Not known
Direct effects on food webs	Very important	Very important
Indirect effects on food webs	Not known	Very important
Extinction rates	75- 80%	$\sim 10^4$ species year^{-1}

destruction suggest that steady increases in extinction rates are to be expected in the near future. Paleontological studies indicate that rare, localized, or specialized species that have evolved to survive in particular niches are the mostly likely to become extinct, while widespread or adaptable species, or opportunistic colonizers are likely to prevail. The fossil record is thus more than a cautionary tale.

As paleontologist David Jablonski has put it:

> The lessons from the past are inevitably blurry at a coarse scale. At the present stage of knowledge, the fossil record is more revealing for potential long-term consequences than for immediate solutions. However, the history of life of Earth provides an array of worst-case scenarios ... that are sufficiently spectacular to militate against inaction.

Extinctions (Contemporary and Future)

Thomas M Brooks

Center for Applied Biodiversity Science, Conservation International, Washington, DC, USA

The current documented rate of species extinctions is known to be maybe a hundred times higher than natural. Estimates of the overall rate converge at thousands of times higher. It is clear, then, that the planet faces a loss of species comparable to the five great extinction events of the geological past (Raup, 1986). In this essay, I begin by examining the causes of this loss of species. I then review the evidence that documents the size of the current extinction crisis, and assess how we can estimate the overall extinction rate. I conclude by highlighting the key geographical priorities for action to avert this crisis.

*I must give four points of reference as to what this essay is and what it is not. First, as the title suggests, I discuss contemporary (since approximately 1500) and future extinctions, not prehistoric nor even historic extinctions, which are amply treated elsewhere (*see ***Extinctions and Biodiversity in the Fossil Record****, Volume 2). Second, I discuss global species extinctions, not extirpations (the local extinctions of populations), although such extirpations are extremely important and, taken together, eventually lead to global extinction (Hughes* et al.*, 1997) nor the selective loss of deeper evolutionary units (McKinney, 1997). Third, I discuss only the mechanics, magnitude and geography of extinction, not what we should do to prevent it nor indeed why we should care. Fourth, I discuss, primarily, bird*

extinctions, not just because I am an ornithologist, but also because birds are one of the few groups well enough studied for us to understand species extinctions in reasonable detail.

What predisposes a species towards extinction? Three factors stand out: species that have low abundances, small range sizes (often making them endemic to specific areas) and specialized ecological niches tend to have a high probability of extinction. In combination, these factors comprise the seven forms of rarity (Rabinowitz *et al.*, 1986). Beyond these, a wide variety of biological correlates of extinction proneness have been identified including, for example, large body size, slow reproductive rate (K-selection) and high population variability in space or time (Gaston, 1994). However, these factors do not cause extinction *per se*, only increase its probability if threats are operating. What are these threats?

Diamond (1984) identified four factors (*ultimate causes*) by which people cause species to decline towards extinction:

(1) direct overkill, which primarily affects large, tasty species, and those that people catch because of their attractive colors or songs;
(2) the introduction of species into environments where they were not previously found (often oceanic islands), allowing them to run rampant and drive native species to extinction through predation or competition;
(3) habitat destruction, whether through deforestation, wetland drainage, conversion of grassland to agriculture, or damage to aquatic environments;
(4) indirect knock-on effects within the ecological community, whereby impacts on one species are transmitted through the food web to drive the extinction of another.

While these factors cause species to decline towards extinction, another set of factors (*proximate causes*) is likely to deliver the *coup de grace* to the last individuals: (Simberloff, 1986).

(1) Demographic stochasticity leads to extinction when no individuals of a species can reproduce, maybe because they are all of the same sex, or because they cannot find any mates.
(2) Genetic deterioration of a species occurs when a population becomes so small that inbreeding and subsequent loss of individual fitness occurs, or when a population is swamped by hybridization with a closely related species.
(3) Social dysfunction, prevalent when species with evolutionary adaptations to abundance (such as colonial breeding or group foraging) decline to scarcity in short periods of time.
(4) A wide range of extrinsic forces – unfortunate natural disasters like fires, storms and drought, and human disasters like war – can kill off the last individuals of a species.

The ultimate and proximate causes of extinction are usually hard to disentangle. Pimm (1996) illustrates with the case of Hawaii how few extinctions can be pinned onto any particular cause. This is partly because the ultimate and proximate mechanisms driving extinction appear to be inherently synergistic, and partly because species that become extinct tend to be rare and so, almost by definition, we know very little about them.

This paucity of knowledge has led to great problems in the documentation of contemporary extinctions. Only maybe a million and a half species have been formally described, while the actual number of species on the planet may well be ten or even a hundred times that number (May, 1988). As a result, we must be causing the extinctions of huge numbers of species for which we do not even have names. The most notorious example of this is the case of the Centinelan extinctions (Dodson and Gentry, 1991). In 1975, the flora of Centinela forest in western Ecuador was surveyed for the first time and found to hold about 100 plant species not known anywhere else in the world; by 1988, the forest had been completely cleared. Were it not for that single 1975 survey, those 100 species would have disappeared unnamed and unmourned.

There are clearly enormous gaps in what we know of those species that have names, too. I illustrate this problem in Figure 1 by plotting the numbers of known contemporary extinctions listed on the International Union for the Conservation of Nature and Natural Resources (IUCN) Red Lists (Baillie and Groombridge, 1996; *see also* **World Conservation Union (IUCN) Red List of Threatened Species**, Volume 4) and approximate numbers of described species (Smith *et al.*, 1993) for seven major taxa. The numbers of species are plotted on a logarithmic scale to allow comparison between the two sets of values. The proportion of extinctions among birds and mammals is an order of magnitude higher than it is among less well-known vertebrates and plants, and two orders of magnitude higher than among those invertebrates for which we have names.

Even for vertebrates, our knowledge of the loss of individual species is astonishingly poor. MacPhee and Flemming (1999) recently compiled rigorous documentation for contemporary mammal extinctions and found only 49% compatibility between their list and that given by Baillie and Groombridge (1996). The situation for birds appears likely to be only a little better. Most dramatically of all, a similar survey by Harrison and Stiassny (1999) could identify only three freshwater fish species for which there is conclusive evidence of extinction. This compares with no less than 93

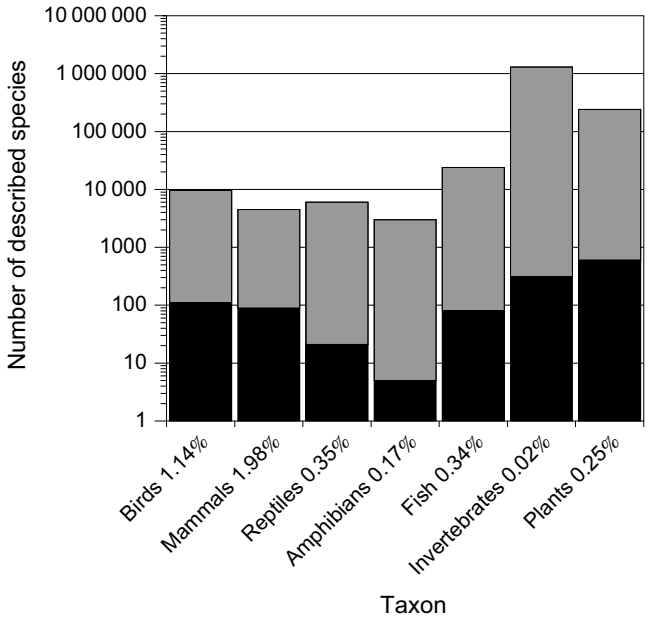

Figure 1 Numbers of known contemporary extinctions listed on the IUCN Red Lists (Baillie and Groombridge, 1996) and approximate numbers of described species (Smith *et al.*, 1993) for seven major taxa

species listed as extinct by Baillie and Groombridge (1996), of which more than half are cichlids from Lake Victoria, recently demonstrated to be of uncertain conservation status (Seehausen *et al.*, 1997).

What could explain these discrepancies? Partly, they are due to Baillie and Groombridge's (1996) use of a more precautionary principle in listing species as extinct unless proven extant (Diamond, 1987). Probably, however, they are due to the fact that the Red Lists are (extremely powerful) conservation tools aimed at documenting threats to species that can still be saved, and so little concerted effort has been invested in documenting species that have already crossed the threshold into extinction. In an attempt to rectify this, an independent committee on recently extinct organisms (http://creo.amnh.org) has recently been formed; their work is currently in progress.

Since extinctions are a natural part of the history of life, absolute numbers of species lost would be rather meaningless for comparative purposes, even if we had such numbers. The contrast between the current crisis and the natural background is one of extinction rate, that is, number of extinctions per unit time. Further, since, as I have shown, we have no idea how many species exist in total, it is sensible to compare extinction rates per unit species – extinction rates per, say, every million species. We term this measure *extinctions per million species years* E/MSY (Pimm *et al.*, 1995). The background extinction rate across diverse fossil taxa is 0.1–1 E/MSY (May *et al.*, 1995). Figure 1 plots extinctions documented over the last 500 years, and so if we trust the numbers of extinctions for birds, at least, we can see that the contemporary extinction rate is $100/(9500 \times 500) = \approx 20$ E/MSY. Most of these extinctions have, in fact, been in the last century, and so the contemporary documented bird extinction rate is a bit higher than this, maybe two orders of magnitude greater than the background rate.

How can we look forward to assess likely extinction rates in the near future? A number of techniques have been used to do this (Table 1). Maybe the simplest of these is to return to the Red Lists (Baillie and Groombridge, 1996) and assume that, for well-known taxa, trends over the last 500 years of human activity will continue. Thus for the 1215 threatened and extinct species of birds, this gives a very conservative extinction rate of ≈250 E/MSY. Using the new IUCN criteria for threatened status on the Red Lists, it is also possible to sum extinction probabilities across species, giving a higher estimated extinction rate of

Table 1 Estimates of global extinction rates, measured as number of extinctions per million species-years

Source	Method	Extinction rate
May *et al.* (1995)	Background rate (13 studies)	0.1- 1
Baillie and Groombridge (1996)	Bird species extinct since 1500	20
Baillie and Groombridge (1996)	Assuming extinction of all Red List bird species	300
Ehrlich (1994)	Increasing human energy consumption	10 000
Mace (1994)	Extinction probabilities from vertebrate Red List categories	1100- 2200
Myers (1979)	Extrapolation of exponentially increasing numbers of extinctions	4000
Pimm and Brooks (1999)	Half-life of 50 years for threatened birds	1000
Reid (1992)	Species-area relationship from deforestation rates (nine studies)	1000- 11 000
Smith *et al.* (1993)	Movement of birds and mammals through Red List categories	1400- 2000

1100–2200 E/MSY for various vertebrates (Mace, 1994). A twist to this technique is to apply calculated "times to extinction" for birds in recently fragmented forest to the threatened species on the Red List, which yields a rate of 1000 E/MSY (Pimm and Brooks, 1999).

An alternative method is to extrapolate the exponentially increasing number of extinctions of the last few centuries forward in time. Assuming that there are 10 million species worldwide, this gives an estimated contemporary extinction rate of 4000 E/MSY (Myers, 1979). A more detailed extrapolation technique uses the rates at which bird and mammal species listed as threatened in the Red Lists are upgraded to higher categories of threat, to produce an extinction rate of 2000 E/MSY (Smith *et al.*, 1993). This method is flawed by the fact that changes in the Red List categories are more a product of changing knowledge than of changing conservation status (Cuarón, 1993), but that it falls within the same order of magnitude as the estimate from simple extrapolation is striking.

These methods are limited, of course, by our lack of knowledge of the conservation status of nearly all species. One way to avoid this problem is to use the species-area relationship, $S = cA^z$, well-known for predicting species numbers in areas of different sizes over space, and instead adapt it to predict surviving species numbers in shrinking habitat areas over time (Reid, 1992). Basing calculations on the assumption that most species – approximately two-thirds of the world's total (Raven, 1988) – are found in the tropical forests, on a conservative estimate of the total number of species – approximately 10 million worldwide (May, 1988), and on known rates of tropical deforestation – approximately 1% $year^{-1}$ (Whitmore, 1997) – this technique estimates global extinction rates to lie between 1000 and 11 000 E/MSY (Reid, 1992). The species-area approach to estimating extinction rates has been criticized, largely because it is so difficult to prove (Budiansky, 1994). However, it has been successfully applied to predict the number of extinctions following historical habitat destruction in North America for both mammals (Dial, 1994) and birds (Pimm and Askins, 1995).

The broadest but most mechanistic technique used to estimate extinction rates is that of Ehrlich (1994), who shows how increases in extinction rates are tightly correlated with increases in human energy appropriation. Since global human energy use has increased approximately 10 000-fold since the beginnings of agriculture 10 000 years ago, it seems reasonable to assume that extinction rates will have been elevated by a similar factor, to maybe 10 000 E/MSY. While this calculation is likely to be an upper estimate, it falls into the same range as rates calculated by other methods.

Estimates of overall extinction rates in the immediate future are, therefore, hundreds of times higher than the contemporary extinction rates documented to date. Why this difference? For one thing, tropical deforestation continues apace, and so near-future extinction rates must be increasing (Whitmore, 1997). Over and above this acceleration of habitat loss, though, there is a time lag between habitat loss and extinction. Areas where human impacts have been severe for several centuries have typically lost as many species as would be predicted from the loss of their habitat, as in eastern North America (Pimm and Askins, 1996); or more, as in Hawaii (Pimm, 1996). In contrast, there have been far fewer extinctions in the recently-deforested continental tropics than we would predict, based on the extent of habitat loss. However, if we include currently threatened as well as extinct species, we find that both in Indonesia and the Philippines (Brooks *et al.*, 1997) and in South America's Atlantic forests (Brooks *et al.*, 1999), as many species are on the verge of extinction as we would predict given habitat destruction.

This test can be more generally applied by examining those concentrations of rarity and threat, where species extinctions are happening most rapidly. A number of recent efforts have mapped these concentrations, of which three stand out. Mittermeier *et al.* (1999) of Conservation International delimited 25 hotspots to each of which 0.5% of the global flora are endemic and within each of which <30% of the original habitat remains. Olson and Dinerstein (1998) of the World Wildlife Fund mapped the global 200 most biological valuable ecoregions, the most outstanding examples of each of the world's habitat types. Stattersfield *et al.* (1998) of Bird Life International identified 218 endemic bird areas that hold two or more bird species with ranges restricted to <50 000 km^2. The convergence between these prioritization systems is high (Figure 2).

Looking within each of these areas of convergence, we can use data on their proportion of habitat lost and number of avian endemics (Mittermeier *et al.*, 1999) to make predictions of bird extinctions based on habitat loss (Pimm *et al.*, 1995). We can then compare these to the numbers of endemic birds within each hotspot that are actually threatened (Collar *et al.*, 1994) or extinct (Baillie and Groombridge, 1996) by simply plotting the two

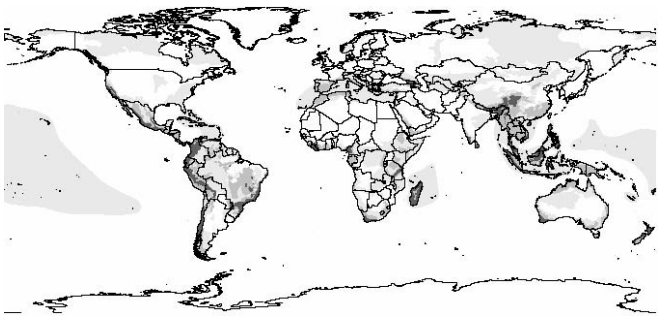

Figure 2 Hotspots (Mittermeier *et al.*, 1999), Global 200 ecoregions (Olson and Dinerstein, 1998) and Endemic Bird Areas (Statters eld *et al.*, 1998)

Table 2 Hotspots (Mittermeier *et al.*, 1999) and their habitat loss, avian endemism, predicted extinctions (Pimm *et al.*, 1995), and threat (Collar *et al.*, 1994) plus extinction (WCMC, 1992)[a]

Hotspot	Habitat remaining %	Avian endemics	Predicted extinction	IUCN Red List of threatened + extinctions
Tropical Andes	25.0	677	198	105
Mesoamerica	20.0	251	83	20
Caribbean	11.3	148	62	34
Chocó-Darién-Western Ecuador	24.2	85	25	10

Southwest Australia	10.8	19	8	4

[a] The number of avian endemics (including non-forest species) in the Atlantic Forest Region is an update (Brooks *et al.*, 1999).

sets of numbers against each other (Table 2, Figure 3). We accurately predict bird extinction and threat in areas that have already been highly degraded, such as the Atlantic forests (Brooks *et al.*, 1999) and Philippines (Brooks *et al.*, 1997). Habitat loss overestimates threat and extinction in the tropical mountains of South and Central America, maybe because montane endemic species tend to be abundant within their (albeit tiny) ranges (Manne *et al.*, 1999). Conversely, the extent of habitat loss underestimates threat and extinction on islands, notably in the Pacific, where the effects of species introduced into these naïve ecosystems have been so severe (Pimm, 1996). Overall, though, we can see that the extent of habitat loss within these hotspots tends to predict rather well the number of bird species endemic to that hotspot that are either threatened or already extinct. Conservation must now focus within these areas to prevent species extinctions while still possible.

To conclude, I will summarize the key messages of this essay:

1. A number of factors increase the probability of a species' extinction, and these interact with a range of threats to actually cause extinctions. However, these interactions are complex, and only rarely do we have the information to identify a single cause of extinction.
2. This lack of information is reflected in how little we know about biodiversity overall, and translates into almost insurmountable difficulty in documenting extinctions for most groups of species. For the few vertebrate groups for which we have any confidence that data on extinctions are comprehensive, contemporary documented extinction rates appear to be about two orders of magnitude higher than natural rates.
3. A variety of techniques can be used to predict near-future extinction rates, some based on extrapolation of contemporary extinction and threat, others on the relationships between human impacts and species loss. These techniques produce estimates of near-future extinction rates converging at about four orders of magnitude higher than natural rates.
4. This difference between documented and overall extinction rates is largely due to the time-lag between

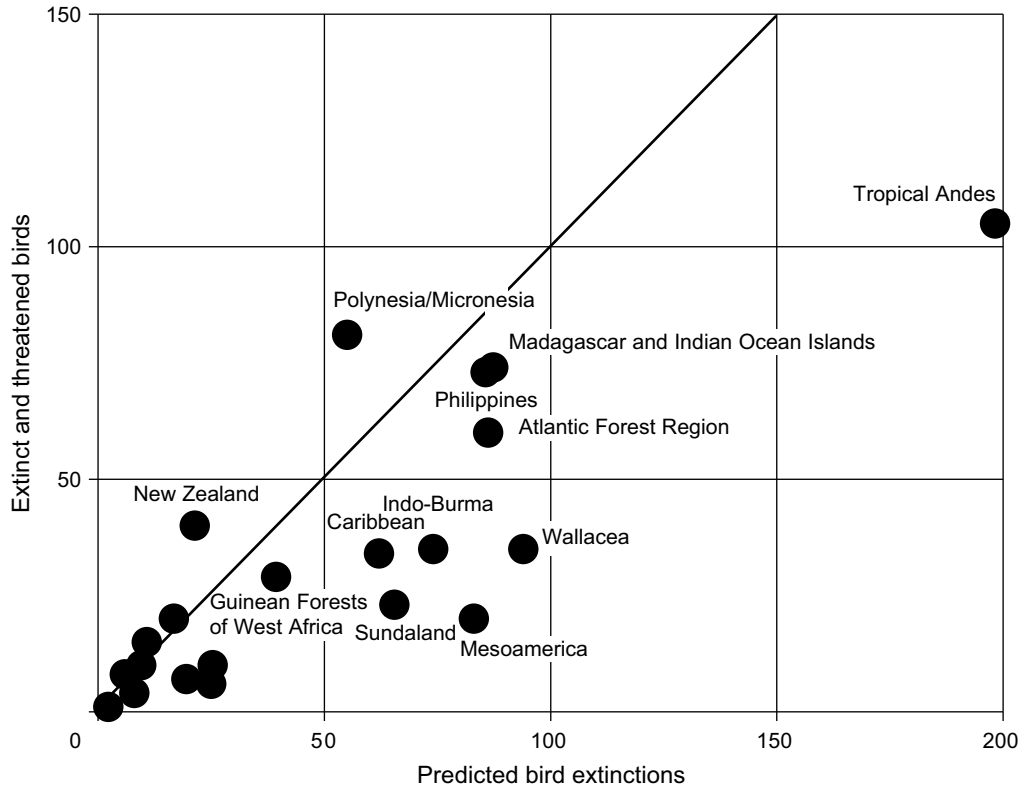

Figure 3 Comparing numbers of predicted bird extinctions in the hotspots, calculated using data on habitat loss and bird endemism (Mittermeier *et al.*, 1999) and the species-area relationship (Pimm *et al.*, 1995) with numbers of threatened (Collar *et al.*, 1994) and extinct (Baillie and Groombridge, 1996) species

habitat loss and extinction. This can be demonstrated by using habitat loss to predict the number of birds likely to become extinct in the world's hotspots of threat: these predictions match actual threat rather closely. Conservation must now target these areas to prevent further species extinctions.

see Fisheries: Effects of Climate Change on the Life Cycles of Salmon (**Volume 3**)

Fixed Nitrogen

Molecular nitrogen may be assimilated by various microorganisms and reduced to ammonium. The process is known as *nitrogen fixation*, and the product is *fixed nitrogen*. This process is of greatest significance to the growth of plants because nitrogen is their most important nutrient and because they are unable to utilize molecular nitrogen themselves. Therefore unless they are agriculturally fertilized, they must rely on decaying organic matter (*see* **Nitrogen Mineralization**, Volume 2) or nitrogen fixation. Nitrogen is lost from soils by mineralization and leaching (*see* **Nitrate Leaching**, Volume 3); therefore nitrogen fixation is essential for the continued fertility of natural ecosystems.

Nitrogen fixation is accomplished mainly by free living bacteria such as *Azotobacter* (aerobic) or *Clostridium* (anaerobic) and by several species of blue-green algae, both free living and in associations with such plants as ferns and cycads. But by far the most important nitrogen fixing system is the symbiotic association of *Rhizobium* bacteria with legumes. The bacteria infect the roots and induce the formation of nodules in which they live and fix nitrogen using energy derived from metabolites from the host plants. Considerable energy is required: to reduce one mole of molecular nitrogen requires over 80 kcal, which is derived ultimately from host photosynthesis.

The enzyme of nitrogen fixation, nitrogenase, involves both iron and molybdenum cofactors, and these elements must be available in the soil (or the oceans). In addition, oxygen required for bacterial metabolism is transported into the nodules by leghemoglobin, which is similar to animal hemoglobin. Leghemoglobin is a truly symbiotic product: the two parts of the molecule are synthesized independently in the bacterial and host cells and assembled in the bacterial environment within the host tissue.

Much effort has been spent in attempts to develop or create symbiotic associations between nitrogen fixing microorganisms and major crop plants such as maize. While it is true that photosynthetic production (i.e., crop yield) would be decreased because of the energy drain for fixing nitrogen, the overall economic balance would be strongly positive because of the high cost of nitrogen fertilizer. The ecological benefits would be much greater. Even with careful management a substantial portion of nitrogen fertilizer is leached out of fields. Not only is it wasted, it contributes to eutrophication and environment degradation. While efforts to apply these ideas have been unsuccessful, the agricultural application of *Rhizobium* to legume plantations (to the seed or in the field) has been very successful in increasing production while reducing fertilizer requirement.

Food Webs

Gary A Polis[1] and Gary R Huxel
University of California, Davis, CA, USA

Food webs occupy a central position in community ecology. Charles Darwin (Darwin, 1859) introduced the concept of

[1] Deceased March 27, 2000.

an entangled bank in which he envisioned many kinds of species interdependent upon each other in a complex manner governed by laws acting around us. In the simplest context, food webs incorporate the two factors that, a priori, one would consider most fundamental to the success or failure of a species: resources and enemies. All species must acquire resources (food or nutrients) and suffer energy losses or mortality from enemies (predators, parasites, pathogens). The abundance and success of any species is thus a product of these feeding interactions. This inclusion of such bottom-up (productivity and resources) with top-down (consumption) factors largely determines the distribution and abundance of almost every species on the planet.

Knowledge of food web structure and dynamics is central to our understanding of almost all aspects of population and community ecology. By their very nature of representing feeding relationships between species, food webs have the capacity to embody the rich complexity of natural systems. In fact, most important interactions (e.g., competition, predation, mutualism) cannot be isolated from a food web context. Many important advances have arisen from those analyses that concurrently incorporate more than one interaction in a food web: keystone predation and herbivory, the intermediate predation and disturbance hypotheses, the size efficiency hypothesis, trophic cascades, intraguild predation, apparent competition, and recognition of the importance of indirect effects. The outcome of virtually all interactions within a community can be modified, directly and indirectly, by other members of the food web. This insight penetrates all areas of community ecology. For example, the results of experiments must be interpreted carefully for at least two reasons. First, indirect effects, moderated by other species in the web, may exert large and sometimes contradictory effects to the direct effects of the manipulation. Thus, under some food web configurations, removal of a predator may directly increase the level of its prey or may actually cause the prey to decrease because of indirect interactions. Second, changes in species dynamics claimed to be caused by one factor may actually be a product of a second process.

TYPES OF FOOD WEBS

Food web research has grown at a tremendous rate and taken a diversity of forms. Not surprisingly, ecologists have diverged in their methods, emphasis and approaches. Nevertheless, trophic relationships in communities can be delineated in three basic ways. Paine (1980) and Polis (1991) distinguished three types of food webs that evolved from ecological studies (Figure 1). The first is the classic food

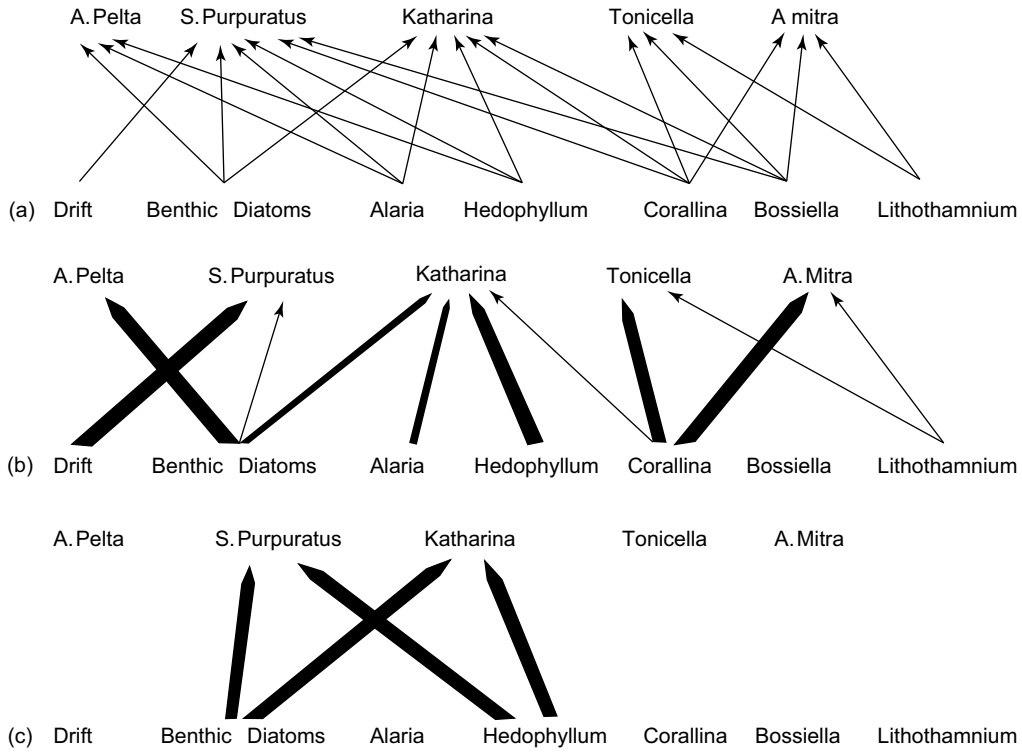

Figure 1 Three conceptually and historically different approaches to depicting trophic relationships, illustrated for the same set of species. The connectedness web (a) is based on observation, the energy ow one (b) on some measurement and literature values, and the functional web (c) on controlled manipulation. (Reproduced by permission of Blackwell Science Ltd., from Paine, 1980)

web, a schematic description of connectivity specifying feeding links. Such connectivity food webs simply demonstrate feeding relationships. Examples of these are the early food webs of Forbes (1887) and Summerhayes and Elton (1924) (Figure 1). The second web type is also descriptive, quantifying the flow of energy and matter through the community. These energetic food webs quantify the flow of energy (and/or materials) between trophically connected species. The third type use experiments to dissect communities to identify strong links and dynamically important species. Such interactive or functional food webs demonstrate the most important connections in an ecosystem (Figure 1). These food webs depict the importance of species in maintaining the integrity and stability of a community as reflected in its influence on the growth rates of other species. They require experimental manipulations of the community (by either removal or addition of particular species). In the next section, we discuss the strengths and weaknesses of each approach. Of the three, only the last two have contributed substantially to our understanding of natural systems.

Connectivity Food Webs

Connectivity food webs are representations of who eats whom without inference about the strength or type of interaction and energy flow (Figure 1). Early food webs were constructed for essentially two reasons: first, to depict the interconnectivity of natural systems, second, to examine issues of the balance of nature, i.e., to analyze how harmony is maintained through complex predatory and competitive interactions within communities (Forbes, 1887). Such an approach was applied to agricultural systems to examine pests and possible food web manipulations to control pests. As early as the 1880s, beetles were introduced into the US to control agricultural pests (following the success of *Vedalia*, a coccinellid ladybird beetle, in controlling Cottony-cushion scale in California in 1888, about 50 more coccinellids were introduced in the 1890s).

The knowledge required to construct connectivity food webs is straightforward: a rough, qualitative knowledge of who eats whom is all that is necessary to produce a simple food web whereas experimental manipulations or quantitative measurements are necessary to construct webs of interaction or energy flow. Consequently, connectivity webs most frequently represent trophic interactions in communities and have received the most attention. Hundreds of such webs slowly accumulated over a century. They were useful to illustrate, in a totally non-quantitative manner, the feeding interactions within a specific community. Different scientists constructed webs of different diversity, complexity and resolution, depending on their knowledge of the system and bias or understanding of particular groups. For example, some may emphasize birds, and represent all insects as one group. Others will divide the insects into scores of groups and represent one to two bird species (see Figure 2).

There are many problems with descriptive webs, of which only a few are mentioned here:

1. Most vastly under-represent the species diversity in natural communities. Most communities have $100\,s - 1000\,s$ of species, yet these webs represent $<10-30$ species on the average. As a consequence, most connectivity webs have severe problems with lumping species and taxonomic biases. Some trophic levels are distinguished by species (e.g., birds or fish) while other groups suffer a high degree of aggregation, e.g., all species of insect or annual plants are represented as one super-species, insects or plants.
2. Most vastly under-represent the true number of feeding connections within a community. Species eat and are eaten by $10\,s - 100\,s$ of species, yet these depictions show averages of two to four links with resources and enemies. It is an arduous task to represent the actual diet of even one to two species. Doing this for a complete community is truly a Herculean task that likely will never be accomplished without some technical breakthrough that analyzes a consumer's body tissue to determine the diversity of its foods.
3. Most species are highly omnivorous, feeding on many resources and prey. Each species has a distinct trophic history, and is often at a different trophic level than other species. Because diet is so difficult to delineate, most connectivity webs greatly under-represent the true nature of omnivory. This poses several fundamental problems (see the section on omnivory and the structure of food webs).
4. Connectivity webs only offer a static view of the world. Food webs are usually idealized representations that show all linkages that occur over large spatial and temporal scales. Therefore much of the important variability and changes due to local environmental conditions and great natural heterogeneity are lost.

The consensus today is that the connectivity webs are highly over-simplified and probably speak more about the pattern of the human mind and constraints on edited publications than of real biological communities. They provide quick glimpses of a community but there is little value in their analysis. The hope is that someday, the actual food web of a few communities can be delineated completely. Analyses of a few such communities could offer great insight into the structure of complex natural communities.

Energetic Food Webs

Starting with the classic studies of Summerhayes and Elton and Lindemann (1942), food web studies turned towards

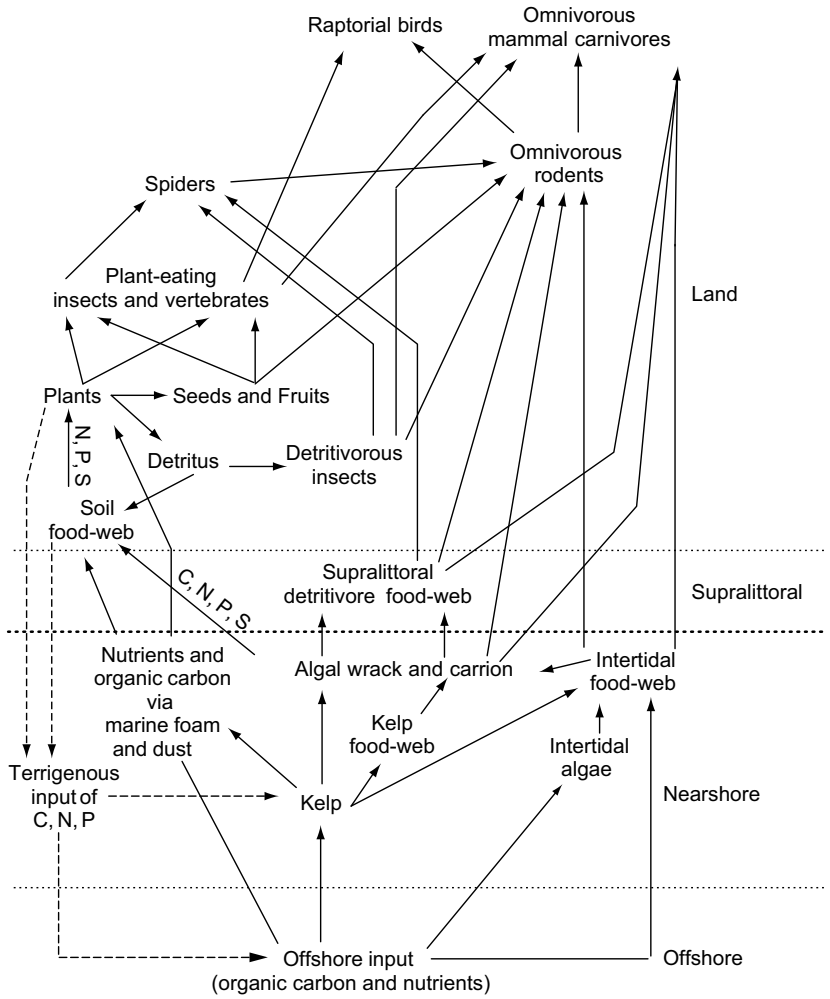

Figure 2 Food web

quantifying flows of energy and nutrients in ecosystems and the biological processes that regulate these flows (e.g., Figure 2). This approach is an alternative to connectivity food webs to describe trophic connectedness within communities. This process-functional approach explicitly incorporates producers, consumers, detritus, abiotic factors, flow out of a system and the biogeochemical recycling of nutrients. It views food webs as dynamic systems in time and space. Such an approach necessitates analyzing energy and material fluxes in order to understand the behavior of ecosystems. Thus, a typical analysis would quantify the amount of energy or matter as it travels along different pathways (e.g., plants → consumers → detritus → decomposers → soil). For example, the tracking of energy and dichloro-diphenyl-trichloromethane (DDT) through a food web in a Long Island estuary enabled researchers to study bioaccumulation effects on top predators.

This approach has provided a rich understanding of the natural world and allowed us to understand a great deal about ecosystems. Several important processes are included in energetic webs. First, they quantify energy and material pathways and key species or processes that facilitate or impede such flows. Second, they include an explicit recognition of the great importance of detritus, a subject virtually ignored in connectivity webs. (10–99% of all primary productivity from different habitats immediately becomes dead organic detritus rather than being eaten by herbivores; see the section on detritus). Third, this approach recognizes that a great amount of energy, nutrients and prey originates outside the focal habitat, a key insight to understanding natural communities. These resources are also known as spatial-subsidies. In general, nutrient inputs (nitrogen (N), phosphorus (P), trace elements) increase primary productivity; detrital and prey inputs produce population increases in their consumers. Thus, energetic webs show how ecosystems function and which species dominate biomass and energy.

The analysis of energy and matter flow is also necessary and central to understanding the dynamics of populations and communities. The success of a population is always

strongly related to the energy and biomass available to it. Consequently, it is difficult or impossible to understand the dynamics and structure of food webs and interacting populations without incorporating energy flow from below. However, this energetic approach *per se*, although necessary, is not sufficient by itself to understand the dynamics of communities because energy flow and biomass production are themselves functions of interactions among populations within the food web. The transfer of energy and matter becomes complicated as these resources pass through the many consumers that populate community food webs. For example, increasing the amount of nutrients to plants may increase the biomass of each consumer in the web or may just increase the biomass of a subset of consumers (e.g., only the plants; plants, herbivores, and predators; only the herbivores; only the plants and predators), depending on the relationship between consumers and their resources.

In order to understand the dynamics of energy and material transfer, pathways must be placed in the context of functional food webs to determine how organisms modify and regulate such transfers.

Functional or Interactive Food Webs

These webs use experiments to determine the dynamics within a community. They are also called interaction or dynamical webs. Starting with Connell (1961) and Paine (1966), empiricists began to examine the species to species interactions within communities and food webs to discover which species or interaction most influenced population and community dynamics. They did so with experiments, whereby they manipulated species that natural history or energetic analyses suggested were important. They used either press (continual) or pulse (singular) experiments to manipulate populations of single species and follow the response of other species within the food web and community. The philosophy of these studies was to simplify the complexity of natural systems with the recognition (belief) that many species and links between species were unimportant dynamically. Paine (1980) tested this belief and found that indeed many links between species were weak (essentially zero), but a few very strong species often characterized a community.

Experimental analyses of food webs are designed to identify species and feeding links that most influence population and community dynamics. These alone are placed into an interaction web that, in theory, encompasses all the elements that most influence the distribution and abundance of member species. However, unlike connectivity webs, key species are identified through experiments rather than diet frequency or energy transfer. The initial process of choosing certain species and interactions for experiments and excluding others is subjective, optimally based on strong intuition and a rich understanding of the natural history. As the researcher learns more, some elements are discarded and others are subject to further experimentation. Eventually, the community is distilled into an interaction web, a subset including only species that dominate biomass and/or regulate the flow of energy and matter.

This approach has been used by experimental and theoretical ecologists to produce a rich understanding of the processes that most influence their communities. They have been remarkably fruitful and have introduced many food web paradigms right to the center of ecology: e.g., keystones species, the intermediate disturbance or predation hypothesis, the size-efficiency hypothesis, top down and bottom up control, trophic cascades, apparent competition.

However, this approach is not without limitations. Three major problems stand out. First, many statistical shortcomings can beset experimental manipulation of food webs. For example, replications are commonly difficult (time consuming, expensive) and so experiments often lack the degree of replication and the statistical power necessary to avoid Type 2 statistical errors (significant biological differences exist among treatments but low sample size precludes their detection statistically). Second, the number of possible experiments is almost infinite. Which ones should be conducted, which species should be manipulated?

The third and perhaps most troublesome problem is that experiments isolate a subset of species and links from the community food web, largely ignoring how manipulations interact with the remainder of the community. Thus, unobserved indirect or higher order interactions may exert important effects on the dynamics of experimental species and, in theory, make the outcome of experiments indeterminate. For example, predators are thought typically to suppress their prey. However, if a predator is omnivorous, eating not only the prey but also consuming a more efficient predator of the same prey (i.e., it is an intraguild predator), it may actually relax the predation load on their shared prey, thus increasing the shared prey's abundance. To illustrate: guilds of biological control agents must be carefully structured because some species eat not only the host but also other predators/parasitoids and thus their presence decreases the number of control agents and increases target pest populations. Many other cases exist where consumers, via such intraguild predation, may indirectly facilitate its prey while concurrently exploiting it via direct consumption. Another example of indirect effects mediated by species other than the studied focal species is shown by the interaction between Australian bell miners and their homopteran (an order of plant feeding insects) food. After these birds were removed experimentally, the insects first increased greatly in number and then vanished when other bird species invaded the now

undefended miner bird territories. Thus, the apparent effect of leaf miners on lerp insects (here, suppression or facilitation) depends on when the insects were surveyed. Such complications have undoubtedly interfered with seemingly clear interpretation of many experiments. The caveat is seemingly clear: experiments can be indeterminate, producing contradictory, counterintuitive or no results, depending on the relative strengths of the direct and indirect effects.

These problems can be anticipated and partially negated with the application of good intuition of the natural history of the system and important mechanisms. Such intuition is a product of intimate empirical knowledge gained through observation and guided by a conceptual awareness of which of the interactions are potentially important. Initially, this process is essential to design the appropriate experiments and identify which species and trophic links may be dynamically important. At the end, experiments must be interpreted in a food web context to assess possible indirect and higher order effects. Experimental results must be complemented with good descriptive, mechanistic and comparative data to produce a deep understanding of the system. This is one role for energetic and dietary data. Experiments in the absence of natural history often do not succeed and may mislead.

In summary, this section conveys many important messages. The complex food webs of natural communities can be simplified and understood by isolating key species and links into interaction webs. Experiments are absolutely necessary for this process. Experiments must be designed and interpreted with sound intuition based on natural history, the community's food web and theory.

CURRENT TOPICS/TRENDS IN FOOD WEB STUDIES

Here relatively under-studied aspects of food webs perceived to be central to understanding populations, communities, and ecosystems are identified. Some of the topics are now major focal points for food web research, both empirical and theoretical.

Omnivory and the Structure of Food Webs

Consumers are classified in terms of resource specialization (i.e., number of species eaten within one group, e.g., plants) or trophic specialization (i.e., number of different types eaten, e.g., plants, detritus, arthropods). Species vary from resource specialists that eat a few species of the same resource type to trophic generalists (omnivores) that feed on several food types. Empirical research and logic have shown that the vast majority of consumers on this planet are quite omnivorous, feeding on many types of food throughout the entire food web. This is not to say that all species are so catholic in their diets. Specialists abound, e.g., many herbivores or parasites consume only specific plants or hosts. However, these form a minority of consumers. The ubiquity of omnivory carries many implications for our efforts to produce theory and models to understand how food webs function in nature.

Omnivory occurs ubiquitously when consumers eat prey from general classes of prey (e.g., plankton, arthropods). The existence of multiple trophic types within these classes causes consumers to feed on species from many trophic levels. To illustrate: arthropodivores such as many birds or lizards eat whatever properly sized arthropods are available (e.g., predaceous spiders and insects; insect parasitoids, herbivores and detritivores) without pausing to discriminate amongst their prey according to trophic status. For example, in the Coachella Valley desert delineated by Polis (1991) over 10 years of study, predaceous and parasitoid arthropods formed 41% of the diet of vertebrate and 51.5% of invertebrate arthropodivores, the remainder of the diet being herbivorous and detritivorous prey. Similarly, inspection of diet data of planktivores, piscivores, insectivores, carnivores, or benthic feeders reveals that such omnivory is almost universal with the exception of those few taxa that specialize on one or a few species of prey.

Another important type of omnivory occurs when consumers eat whatever resources are available or abundant at a particular time or place, regardless of their trophic history. The diet of a single species usually shows great differences through time (e.g., seasonally) and space (patches or habitats). For example, many, or perhaps most, vertebrates opportunistically switch from plant to animal foods with season. For example, granivorous birds, rodents and ants primarily eat seeds but normally feed on arthropods (i.e., insects from all trophic levels and spiders) when they are abundant in spring. Alternately, many omnivorous, arthropodivorous and carnivorous species consume significant quantities of seed or fruit. In the Coachella Valley, 79% of 24 primary carnivores eat arthropods and/or plants. For example, coyotes eat mammals (rabbits, rodents, gophers, antelope, ground squirrels, kit foxes, other coyotes), birds (including eggs and nestlings of roadrunners, doves, quails), snakes, lizards, young tortoises as well as scorpions, insects and fruit. Overall, it appears that most consumers eat whatever is available that they can catch.

Life history omnivory describes the great range of foods eaten during growth and development by most species. Such omnivory includes abrupt diet changes in species undergoing metamorphosis (e.g., many marine invertebrates, amphibians, and insects that undergo complete metamorphosis – also called holometabolous insects) and gradually changing diets in slowly growing species (e.g., reptiles, fish, arachnids, and insects that do not undergo complete metamorphosis – also called hemimetabolous insects). Changes at metamorphosis can be great; e.g., 22% of the insect families in the Coachella

Valley desert community undergo radical change in diet: larvae are predators or parasitoids and adults are herbivores. Although not as dramatic, significant changes characterize slowly growing species so that differences in body size and resource use among age classes are often equivalent to or greater than differences among most biological species.

Incidental omnivory occurs when consumers eat foods in which other consumers live. Thus, scavengers and detritivores not only eat carrion or organic matter but the trophically complex array of microbes and macroorganisms that live within these foods. Frugivores and granivores commonly eat insects associated with fruits and seeds. Predators eat not only their prey but the array of parasites living within the prey. In each case, consumers automatically feed on at least two trophic levels.

These types of omnivory are widespread and common. Their ubiquity poses many questions. First, how does omnivory affect food web structure? Most obviously, it increases complexity and connectivity. Second, can we ignore omnivory in the analyses of food webs? By its very nature, omnivory causes consumers to have a great number of links, each of which may be numerically rather unimportant in the diet. For many reasons delineated below, we cannot arbitrarily ignore apparently minor diet links if we hope to understand dynamics (see next section).

Food Webs as Open Systems

Virtually all natural systems are open and can exhibit tremendous spatial heterogeneity. Nutrients and organisms ubiquitously move among habitats exerting substantial effects on the food webs (e.g., increased productivity and a subsequent increase in consumers) in which they are deposited. Trophic linkage between habitats depends upon the degree of differentiation in the structure and species composition. Systems that have moderate differences tend to have broader transition zones and greatly overlap in species composition and include grassland–forest, littoral–sublittoral, and benthic–pelagic zonations. Habitats that have significant and abrupt changes in structural and species composition include aquatic–terrestrial and photic–aphotic zones. Photic zones are those in which phytosynthesis by phytoplankton is the primary source of productivity; whereas aphotic zones are those areas where photosynthesis does not occur and the energy sources are dead organisms sinking from the photic zones.

Moving resources (energetic or nutrients) can be utilized by different trophic levels and the organisms that move across boundaries also may be of different trophic levels (e.g., predators and prey). Studies of communities on island systems by Gary Polis and his research group have shown that most of the allochthonous resources (i.e., inputs from another habitat) from the ocean are available to detritivores and predator/scavengers. Other systems whose consumers are heavily dependent on such inputs include: caves; mountaintops; snowfields; recent volcanic areas; deserts; soil communities; marine filter feeding communities in unidirectional currents or advective areas; and shaded headwater streams that receive most energy from leaf litter inputs. The movement of herbivores such as hippopotamuses and geese across habitat boundaries to feed can also result in large energetic and nutrient flows across habitats.

Allochthonous inputs into the top level include carrion or carcasses, the movement of prey species into the habitat and movement of predators across habitats. For example, the *Allen paradox* describes cases where secondary production within streams is insufficient to support levels of fish production found in them. Similarly, studies of coyote populations along the coast in Baja California demonstrate that they are highly subsidized by inputs from the ocean (47.8% of their diet) and are able to maintain a three to ten times higher density than in adjacent inland areas. Predators moving along the interface between ecosystems (i.e., shorelines, river banks, benthic and pelagic systems) can utilize resources across habitat. In addition, allochthonous inputs may enter at multiple trophic levels. The river continuum concept argues that allochthonous resources entering into small headwater streams provide much of the productivity for organisms downstream in larger order streams. These allochthonous resources include prey, dissolved and particulate organic matter, and litter fall. This type of pattern is also seen in estuarine systems in which rivers carry allochthonous inputs into estuaries. Similarly, run-off from terrestrial systems into aquatic systems (and *vice-versa* in the case of marine to terrestrial) provides litter, dissolved and particulate organic matter, and prey.

Spatial coupling can be key to dynamics (Polis and Strong, 1996). Abundant detrital kelp from the sublittoral zone promotes dense intertidal limpet and urchin populations, that then graze on non-coralline algae. Allochthonous subsidies commonly influence stream systems: leaf fall subsidizes herbivores, who in turn, depress algae. Many species that live along the coasts of streams, rivers, lakes or the ocean are often very dense because they feed on aquatic insects. Subsidies allow consumers to be more abundant than if supported solely by *in situ* resources with consequent suppression of *in situ* resources decoupled from *in situ* productivity.

Detritus

Little of the energy fixed by plants passes directly into the grazing food chain – herbivores eat plants and are eaten by carnivores. Most primary productivity is uneaten by herbivores (median $>80\%$ on land, $\sim 50\%$ in water). Uneaten plants (and animals) enter the detrital web where

they are processed by microbes and some Metazoa. Most ecosystems are not net accumulators of undigested biomass, and most plant biomass is thus soon digested by detritivores, with nutrients and energy passing through functional compartments comprised of diverse microbes and animals where several factors regulate the flow and control the availability of detritus and detritivores to consumers. What happens to this dominant chunk of the world's productivity? Is the detrital web a self-contained sink internally recycling energy and nutrients, or a link that affects the population dynamics of the larger species?

Detrital energy and nutrients reenter grazing chains when detritivores are eaten by predators that also eat herbivores. Such detrital shunts are common, interweaving energetics and dynamics of *biophages* (i.e., consumers of living organisms) and *saprophages* (i.e., consumers of dead organic matter). Bypassing herbivores, this linkage can affect herbivore regulation in a manner analogous to the spatial subsidies to consumers discussed above. Predator populations, subsidized by detritivorous prey, can increase and suppress other predators or herbivores.

The exact effect of detrital shunts depends on the relative benefits for each species and where detritus reenters (to producers, herbivores, intermediate or higher consumers). For example, nutrients from detritus greatly influence plant productivity; models show that a 10% reduction in detritus can cause a 50% reduction of plant biomass. The dynamics of consumer control within the detrital web and those produced by infusion of detritivores into the grazing web are crucial to community structure and dynamics.

Age Structure Effects in Food Webs

Almost all species display complex life cycles, marked by moderate to radical changes in diet and habitat; such life histories fundamentally must affect every species with which they interact. Yet, our understanding of how age and stage-structured processes affect food webs and communities is embryonic.

Life history omnivory describes shifts in diet during development. Such shifts are often accompanied by ontogenetic changes in habitat. Diet can change substantially either discontinuously (e.g., at metamorphosis) or slowly with growth. Such life histories are widespread; an estimated 80% of all animal species undergo metamorphosis. Changes in resource use can be dramatic (e.g., predaceous juveniles – plant-feeding adults in parasitoids and many other insects; herbivorous tadpoles and predaceous frogs and toads) with prey size variation as great as three to four orders of magnitude. Even among non-metamorphic species, diets change greatly with age, with diet differences among age classes often more distinct than those among most species.

Life history omnivory can either impede consumer control or amplify resource suppression via dynamics similar to those of spatial subsidy or detrital shunts. Overall, complex life histories and age structure omnivory can exert diverse effects on food chains, from thwarting or amplifying top-down control of resources by consumers.

The Roles of Nutrients and Stoichiometry

Animals require both energy and a variety of nutritional requisites to grow, complete their life cycle, and reproduce. Important nutrients include nitrogen, phosphorus, some trace elements, fatty acids, and vitamins. Nitrogen is an integral component of many essential compounds – it is a major part of amino acids, the building blocks of protein, including the enzymes that control virtually all cellular processes. Other nitrogen compounds include nucleic acids and chlorophyll. Phosphorus is used for adenosine triphosphate (ATP – the energy currency of all cells), nucleic acids (deoxyribonnucleic acid (DNA), ribonucleic acid (RNA)), and phospholipids, particularly in cell membranes.

The availability of nutritional requisites constrains growth and reproduction in virtually every species. Nitrogen and phosphorus are particularly important. The ratio of carbon (C) to nitrogen (C–N) in plants ranges from 10/1–30/1 in legumes and young green leaves to as high as 600/1 in some wood. The C–N ratios in animals and microbes are much lower, ordinarily falling between 5/1 and 10/1. Such differences in C–N ratios between plants and their consumers lower the rate of decomposition by microbes. There is ample evidence that heterotrophs chronically lack adequate nitrogen to grow or reproduce optimally. The importance of nutritional restriction is reinforced by the foraging literature that clearly shows that herbivores choose their foods based on nutrient as well as energy content.

In many cases, phosphorus availability constrains herbivore success. The Redfield ratio describes the approximate stoichiometric mix (110 C–250 H–75 O–16 N–1 P) of elements essential to organisms (*see* **Redfield Ratio**, Volume 2). In particular, the N–P ratio crucially determines productivity and species composition. Thus, energy (C–C bonds) and nitrogen could be abundant, but neither individuals nor populations grow maximally because phosphorus is insufficient. As phosphorus is essential to cell division (and thus reproduction), a high N–P ratio especially limits the growth of organisms that have high potential r-max (high reproductive ability), such as most herbivores and detritivores. These organisms are key to the potential regulation of plant biomass (and detritus). Evidence now suggests that high N–P ratios can impede trophic cascades. For example, *Daphnia*, a key to many lake cascades, respond sufficiently rapidly to phytoplankton productivity to depress plant biomass. In lakes with inadequate phosphorus, slower

growing copepods replace *Daphnia*; these copepods do not have the reproductive capacity to depress phytoplankton biomass.

Ecologists are beginning to understand how stoichiometry and nutritional balance affect population and food web dynamics. Nevertheless it is extremely likely that herbivore growth is often less than maximal solely because its environment does not provide sufficient quantities of all key nutritional requisites. In fact, the greatest disparity in biochemical, elemental, and stoichiometric composition in the entire food web occurs at the link where herbivores convert plant material into animal tissue. The implication is clear: even in a world full of green energy, many or most herbivores cannot obtain enough requisite resources to grow, survive, or reproduce at high rates. Nutritional shortages regulate herbivore numbers and often limit their effects on plant biomass.

RECOGNITION

Professor Gary Allen Polis died in a boating accident on March 27th, 2000. The loss of Dr Polis is a great tragedy to those of us who knew Gary professionally and personally – we will miss him greatly.

Forest Gap Models

Herman H Shugart
University of Virginia, Charlottesville, VA, USA

Computer models designed to simulate the dynamics of a forest by following the fates of each individual tree in a forest stand were created initially in the mid-1960s. The earliest such model was built by Newnham (1964), followed by similar developments in several Schools of Forestry in the US. These early models involved using a digital computer to dynamically change a map of the sizes and positions of each tree in a simulated forest. Importantly, these initial models were as complex and as detailed as their present day descendants. With increased computing power becoming cheap and available, applications using these models have become increasingly frequent (Shugart and West, 1980).

Gap models simulate the changes in a small patch of forest on the order of 0.1 ha in size. The models project the annual growth of each individual tree on the patch as well as the death of each tree and the regeneration of new individual trees. Gap models are important because of their widespread applications in assessing the effects of environmental change on forests. The models have been applied to develop theories about the overall functioning of forested landscape and have also been used to reconstruct the composition of forests of the past and under future conditions.

Gap models are a special case of the more general individual-based models. They have been used particularly for forest ecosystems. Because gap models have been applied in a very wide range of ecosystems, often the term, gap model, is used interchangeably with other individual-based models when applied to mixed age and multi-species ecosystems. The models simulate landscapes as dynamically changing mosaics with each element of the mosaic having an interactive population of trees of different species and sizes. Output from the models resembles field data as sampled from a standard forest survey unit: a list of the diameters of each tree (and its species) alive on the patch for each year. These model data can be transformed to estimates of biomass (and hence, net production), leaf area profiles through the canopy, and tree ring histories for each tree.

INDIVIDUAL BASED MODELS IN FOREST ECOLOGY

Since gap models are a relatively widely used subset of individual-based models, it is appropriate to initially describe this class of ecological model and the associated modeling philosophy. Since the mid-1960s, a broad range of ecologists (including animal behaviorists, population

biologists, and ecosystem ecologists) have independently created a diverse array of such models (Huston *et al.*, 1988). The catalyst for this development was undoubtedly the increased availability and power of digital computers, the necessary tools needed in order to use most of these models. The earliest such models were developed by population ecologists (Holling, 1964; Rohlf and Davenport, 1969) interested in incorporating animal behavior into population models and foresters who were interested in relating tree growth to forest yield.

Most ecologists are interested in variations in individuals (a basis for the theory of evolution and a frequently measured aspect of plants and animals) and appreciate spatial variation as being quite important. Increasingly, models that simulate the dynamics of ecological systems by accounting for changes in each of a large number of individuals in the system have been developed and applied in population and ecosystems ecology (Huston *et al.*, 1988; DeAngelis and Gross, 1992). One advantage of such models is that the following two implicit assumptions associated with the more traditional approaches used in ecological population modeling are not necessary:

1. The unique features of individuals are sufficiently unimportant to the degree that individuals are assumed to be identical.
2. The population is perfectly mixed so that there are no local spatial interactions of any important magnitude.

Individual-based models spring from a rejection of these assumptions. Indeed, these assumptions seem particularly inappropriate for trees which are sessile and which vary greatly in size over their life span. This may be one of the reasons that tree-based forest models are among the earliest and most widely elaborated of this genre of models.

A HISTORY OF THE DEVELOPMENT OF THE GAP MODELING CONCEPT

Among the earliest individual-based models in ecology were models of forests based on the growth of the individual trees that comprise the forest stand. These models were developed by quantitatively oriented foresters and were focused from their inception toward practical issues in production forestry. That trees were an initial focus for individual-based models springs naturally from the ecology and biology of trees. An emphasis on sizes of individual trees in the understanding of forest change has been traditional in forestry and forest ecology for over 200 years. This, associated with an interest in the changes in sizes of trees with changes in numbers (from birth and death processes), lead naturally to an interest in simulating the changes in individual trees as a basis for understanding forest dynamics. Some of the first individual-based models used in ecology were for trees.

Individual-based models in forestry were focused on solving several general problems involving *stand yield tables*. Modern forestry uses stand yield tables as a scientific basis for making decisions about the expected productivity of forest stands under different conditions to plan harvest and thinning schedules. Yield tables use the site index (the expected height growth of trees at a given age) to calibrate the expected changes in tree sizes and densities based on study plots remeasured over decades or centuries. Stand yield tables are calibrated by using data on the performance (height and diameter growth) of individual trees from study plots, with different densities of trees per unit area and grown under different conditions. Some of the European yield tables are based on continuous studies of such plots for as long as 200 years. However, the large detailed data sets required to develop a yield table represent a weakness in the approach. If one is interested in the growth and yield of plantations of an exotic, such as Radiata Pine (*Pinus radiata*), a species that is being planted in dozens of tropical and sub-tropical countries as a source of softwood, then how does one develop a yield table in the absence of a long data calibration set? Similar predicaments arise in evaluating altered forestry practices such as forest fertilization; in projecting response of forests affected by air pollution; in predicting yield in forests with genetically improved species. Indeed, any condition that alters the performance of individual trees from the conditions for which a yield table is calibrated is a potential source of difficulty. This very early interest in projecting forest performance under altered conditions presaged the use of this class of models in problems involving the prediction of climate change effects on forests.

GAP MODELS

An important sub-category of individual organism based tree models that have been widely used in ecological (as opposed to traditional forestry applications) are the so-called gap models. Shugart and West (1980) coined the term, *gap model*, to emphasize the similarity of the simulation unit in the models (a ca. 1/10 ha plot) and the venerable concept of mosaic dynamics as a basic feature of the dynamic change in forests (Watt, 1947). The first such model was the JABOWA model (Botkin *et al.*, 1972) developed for a forest in New England. Several gap models were subsequently developed (see Shugart, 1998 for a more detailed review) for a wide range of forests; and eventually, for grasslands and savannas (Coffin and Lauenroth, 1989; Menaut *et al.*, 1990). The earlier versions were used for inter-ecosystem comparison (Shugart, 1984) and adhered relatively closely to the original JABOWA formulation. More recent models have diverged, particularly in the addition of spatial competition among trees, in a range of modifications to allow simulation of a wider range

of environmental conditions, and in additional biological and/or physiological mechanisms. These latter models are essentially at the same level of detail and spatial resolution as the first individual based forest models developed in the 1960s.

STRUCTURE OF GAP MODELS

In a gap model, as with other individual-based models, each tree is simulated as an independent entity. The model structure emphasizes two features important to a dynamic description of a vegetation pattern:

1. The response of the individual tree to the prevailing environmental conditions.
2. How the individual tree modifies those environmental conditions.

The models are hierarchical in that the higher level patterns observed (population, community, and ecosystem) are the integration of plant responses to the environmental constraints defined at the level of the individual.

The models include random processes with the birth and death of trees. To implement the models, one typically averages the responses of 100 or so independent simulated plots. The models can assemble forests by producing ecological succession from bare ground. The models can also be initiated from forest survey plots to simulate a parcel of land from the time it was sampled. The richness of the output data allows a number of direct comparisons with forest survey data and for this reason the models have been tested extensively in a number of contexts, including the reconstruction of past forests and associated climates.

The parameters in the models are essentially of two sorts: First, the individual tree parameters are used in species-specific equations for the growth, relation between diameter and height, and other biological and ecological descriptors. Second, parameters for equations in the model that characterize the interactions among trees (for example, shading of light through different levels of the canopy, water availability) or that simulate the overall condition on the plot (depth of leaf litter, soil temperature, etc.).

Growth

The growth of an individual is calculated using a species-specific equation to predict the expected diameter increase for each tree under optimal conditions (Figure 1). This increase in diameter is functionally related to the tree's current diameter. This optimum increment is then modified by the environmental response functions and the realized increment is added to the tree. There are several different

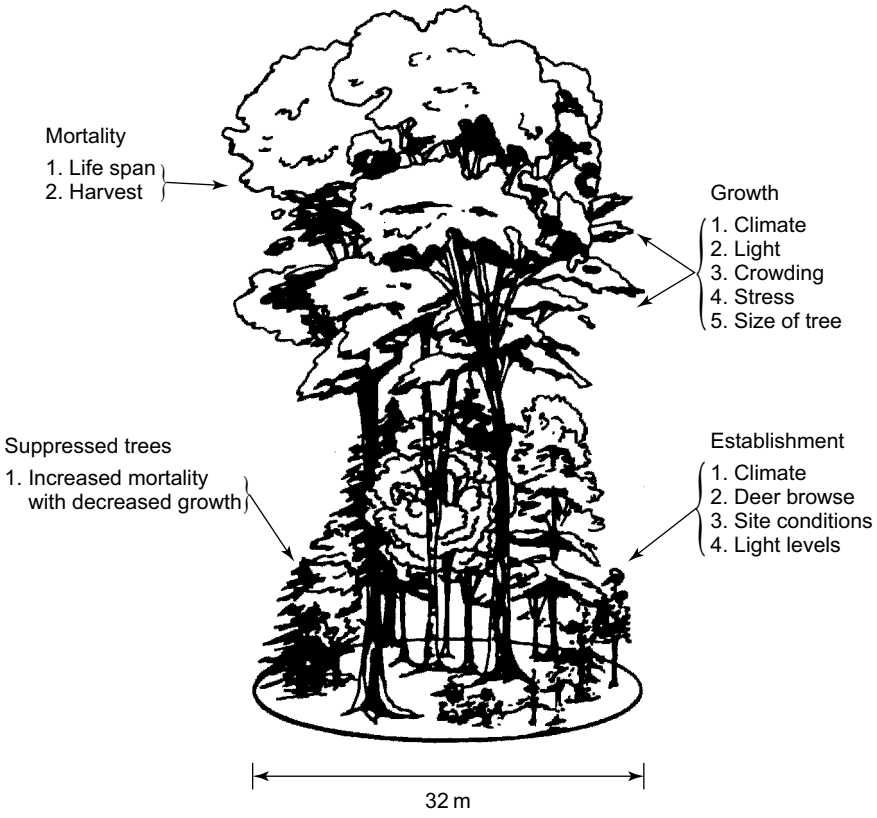

Figure 1 Schematic diagram of the function of a typical gap model

growth equations used in the set of gap models developed over the past three decades. Usually they are developed with an assumption that growth in trees is the consequence of two opposite processes:

1. A positive process based on the argument that as trees get larger, the leaf area of the tree increases, which increases potential growth. The magnitude of this positive growth rate depends on the net photosynthetic rate of the tree per unit of leaves.
2. Opposing this positive rate is a negative rate that is associated with the energetic cost of maintaining a given volume of living tissue. Presumably, as a tree increases in size, these negative costs increase.

The difference in these two rates is the actual growth, which becomes smaller as trees become larger. Botkin *et al.* (1972) included these effects in the initial JABOWA model using a simple derivation based on arguments on the relations among diameters, leaf areas, growth, height and longevity of trees. A principal advantage of this initial formulation was that the parameters for the models could be obtained from available ecological descriptions of tree species silvics.

Moore (1989) developed what is probably a better tree growth equation, if such an equation is based on the assumptions stated in the initial formulation. Moore noted that the initial formulation used in the JABOWA model implied that the losses associated with large size in trees increased at a rate greater than the increase in the tree's volume. He developed an alternate formulation based on a simplification of a carbon metabolism-based representation of the constructive versus destructive metabolism of the individual tree. This formulation currently is used in the FORCLIM model (Bugman and Solomon, 1995). Leemans and Prentice (1987) derived an equation for tree volume increment that included the effects of vertical canopy geometry. Pacala *et al.* (1993) argued that gap models should have the parameters in the models tied to direct empirical observations. Their model developed toward this goal uses several regression relations to improve the response of an individual-based model intended as an extension of the existing gap models. Growth is driven by an index of local light availability that integrates annual light condition (a complex function of changing sun angles, ratios of diffuse and direct radiation, and the canopy pattern).

Environmental Constraints and Resource Competition among Trees

Gap models simulate each individual tree's response to light availability at height intervals on the plot. Even in the early gap models, the vertical structure of the canopy is modeled explicitly. The sizes of individuals (height and leaf area predicted by regressions on each tree's diameter) are used to construct a vertical leaf area profile. An equation for the extinction of light through the canopy is computed to capture the effect of trees shading one another.

Other resources are incorporated to varying degrees in different gap models. These include soil moisture, fertility (often available nitrogen, specifically), temperature, as well as disturbances such as fires, hurricanes, floods, and wind throw. In most of the models, the environmental responses are modeled via a constrained potential paradigm; a tree has a maximum potential behavior under optimal conditions (i.e., maximum diameter increment, survivorship, or establishment rate). This optimum is then reduced according to the environmental context of the plot (e.g., shading, drought), to yield the realized behavior under ambient conditions. The curves describing species response to environmental resources tend to be generic curves that scale between 0.0–1.0, and species are often categorized into a small number of functional types.

The limitation effects of resource shortages in the models were initially computed in a multiplicative fashion (Botkin *et al.*, 1972; Shugart, 1984). This would mean that if, due to shading, the lack of light reduced the optimal growth of a tree to 90% of the optimal and water availability was 80% of optimal, then the growth would be 72% of the optimal ($0.90 \times 0.80 = 0.72$). Some later models use other approaches, notably assigning the growth reduction to that of the most limiting factor (Pastor and Post, 1986).

Competition in the model depends on the relative performance of different trees under the environmental conditions on the model plot. These environmental conditions may be influenced by the trees themselves (e.g., a tree's leaf area influences light available beneath it), or may be modeled as extrinsic and not influenced by the trees (e.g., temperature).

The tree that has the best performance, relative only to other trees on the plot, is the most successful. Competitive success depends on the environmental conditions on the plot, which species are present, and the relative sizes of the trees. Each of these varies through time in each simulation from a gap model. Competition for light is asymmetric and exploitative: a tree at a given height absorbs light and reduces the resource available to trees at lower positions in the canopy. In most gap models, competition for belowground resources (water and nutrients) is symmetric. Each tree experiences a resource level common to the plot. This approach to modeling the competition process has the result that competitive ability depends strictly on the context of the modeled gap.

Mortality

The death of individuals is modeled as a stochastic process. Most gap models have two components of mortality: age related and stress-induced (Figure 1). The age-related component applies equally to all individuals of a species

and depends on the maximum expected longevity for the species; this age is typically on the order of 300 years, yielding an annual survivorship rate of around 1–2%. The probability of mortality of each individual tree is determined as a stochastic function. Each tree is assumed to have an intrinsic mortality rate such that, under normal conditions, 1% of the individuals in a cohort could be expected to live long enough to attain their maximum height and diameter.

The mortality of plants, in general, and certainly of trees is a relatively poorly known aspect in plant ecology and the formulations in many of the gap models reflect the state of knowledge. The tendency in most of the existing gap models has been to use relatively straightforward descriptions of mortality in the anticipation of additional information. Trees that are growing slowly have an increased probability of death. In the earlier gap models, trees with a minimum diameter increment of only 1 mm per year are subjected to additional mortality that has the effect of allowing only a 1% chance that they will survive 10 years. In more recent gap models, stress is defined with respect to a minimal diameter increment (typically 10% of optimum growth for a given size of tree) and individuals failing to meet this minimal condition are subjected to an elevated mortality rate.

Establishment

The complexity of the regeneration process in trees and its stochastic nature makes it nearly impossible to predict the success of an individual tree seedling. This problem is compounded when spatial effects are also considered. Most gap models are designed to treat regeneration in trees from a pragmatic view that the factors influencing the establishment of seedlings can be usefully grouped in broad classes (Figure 1). Tree establishment and regeneration are largely stochastic, with maximum potential establishment rates constrained by the same environmental factors that modify tree growth. Each simulation year, a pool of potential recruits is filtered through the environmental context of the plot, and a few new individuals are established.

Malanson (1996) has applied a spatially explicit gap model to investigate the effects of dispersal probability on forest dynamics. He found that relatively rare instances of a given species of tree entering the patch and establishing itself could have profound influences on the forest dynamics and diversity. Unfortunately, such events are also very difficult to observe, much less quantify, under field conditions.

TESTS AND APPLICATIONS OF GAP MODELS

Gap models are well suited for examining vegetation response to changing environmental conditions because the response to the environment is not limited to reproducing present day vegetation patterns. The individual-based approach also provides a useful link between more detailed physiological models and larger-scale responses. The models have also been tested in terms of their ability to reproduce important features of a wide variety of forests and other ecosystems (Table 1). Simulation models, in general, and individual-based gap models, in particular, have several features that incline scientists to expect a high standard of model testing. The models seem to lack the parsimony that is expected in models; mathematically, the models are not open to formal analysis as are many simpler population models; the high level of detail in model output implies a concomitant degree of detail in testing of models. Since the models are often used in application domains outside the range of conditions used in model development, good scientific practice requires continual model testing and assessment.

Simulations involving forest response to complex gradients and the applications of the models to simulate prehistoric forests (Table 1) are germane to the use of the models in assessment of global environmental change. While gap models have been tested to a relatively great degree compared to most ecological models, the models are under a continual revision as new phenomena are incorporated and should be continually tested. Further, any model is an abstraction and as such may not incorporate all the relevant phenomena for a given assessment. Any model extrapolations of future vegetation should be regarded with caution and compared with other equivalent evaluations from other bases.

Gap models have been applied to examine the response of forested systems to climate changes in both predictive and reconstructive modes. The models have been used in the reconstruction of prehistoric Quaternary forests (for example, Solomon and Webb, 1985). These reconstructions serve to test whether or not the species-level information in the models appears to be consistent with paleoecological data given a climate condition thought to have been the norm in the past. These reconstructive applications have inspired model projections of possible consequences of future climate changes. These model-based predictions are for changes in species composition, vegetation structure, productivity and standing biomass.

As an example of the application of a gap model to assess the effects of a regional climate change, the effects of several different climate change cases was inspected for forests growing on sites in the North American boreal forest at a site near Fairbanks, Alaska (US). The model was developed and tested on its ability to simulate the stand composition, recovery after fire and response to slope and aspect of the site. Fairbanks is in the zone of discontinuous permafrost. North facing slopes and poorly drained sites have permafrost, a persistent presence of an ice layer in the soil, and are dominated by Black Spruce (*Picea marina*), one of the few tree species than can grow under such

Table 1 Examples of the types of model tests used on various gap models; details can be found in Chapter 8 of Shugart (1998)

Type of model test	Example cases
With a priori parameter estimation for species, predict forest level features (total biomass, leaf area, stem density, average tree diameter, etc.)	Prediction of biomass for oodplain forests of the Mississippi River Predict effects of timber harvest on nutrient regimes in northern (US) hardwood forests Similar predictions for a diverse array of systems: Estonian conifer forest, New Zealand southern beech forests, Paci c Coast Douglas- r forests, West African Savanna: etc.
Run model for a long period of time, test results against mature forests preserved in a region	Predict structure and composition of relic mature forests in Sweden Predict old growth forest in montane spruce re zone in Southern Appalachians, in Mississippi River oodplain, upland forests in Arkansas and in Chinese mixed forests
Calibrate model on stands of a given age; predict stand structure on stands of a different age	Using a model that predicts the structure and composition of old growth forests in the Great Smoky Mountains National Park (US), test by independently predicting composition and structure of forest clear cut 40 and 70 years before Predictions of the composition and structure of Canadian forests, diameter structure of Puerto Rican rain forests stands of different ages, Australian rain forest at different ages after harvest
Use introduction of disease or change in conditions (e.g., re frequency, etc.) as a natural experiment	Predict the composition of mature forests in East Tennessee (US) before the introduced chestnut blight eliminated one of the major tree species Predict composition or structure of forest at different re frequencies in mixed conifer forests, for Puerto Rican montane rain forests under different hurricane conditions
Predict independent tree diameter increment data	Predict the growth and diameter increment by species and diameters for subtropical rain forest Predict diameter frequency distributions for Puerto Rican montane rain plots of different ages
Predict forestry yield tables	Test model on its ability to reproduce Swedish yield tables Predict Eucalyptus yield tables for montane Australian forests, for Loblolly Pine, for Swiss forests and for Chinese mixed forest
Predict forest composition change to single environmental gradients	Predict change from deciduous to coniferous forest in the mountains of New England Predict changes in forest composition as a function of ood frequency, at a range of locations in the boreal zone, along latitudinal gradients in China
Predict forest composition response to multiple environmental gradients	Predict composition and structure of boreal forests on north and south facing slopes and for different ages since wild re in Fairbanks, Alaska region Tests against re and altitude variables in mountains of California and Australia. Tests in complex terrain (slopes, altitudes, soils) in Switzerland
Reconstruct composition of vegetation under past climates (Paleo-reconstruction)	Reproduce 16 000 year record of forest change based on fossil pollen chronology from East Tennessee Reproduce forest composition under full glacial and other conditions

conditions. South facing slopes have no permafrost and the recovery of the system after a wildfire features a succession from birch and aspen (*Betula* and *Populus*) to a forest dominated by White Spruce (*Picea glauca*).

Using the boreal forest gap model to assess climate change effects, Bonan *et al.* (1990) and Smith *et al.* (1995) investigated the responses of the forest by taking several different examples of climate change predictions from general circulation models of the atmosphere (an example of two such cases are shown in Figure 2). The climate change was administered by running the models for several hundred years on 100 simulated plots for conditions associated with north facing and south facing slopes. The climate conditions used in the models were then transitioned to those associated with a greenhouse warming over a 50 year period (see monthly temperature and precipitation information on Figure 2). The results of this model experiment were to produce conditions in which the cold forests of Black Spruce growing on north facing slopes was largely unaffected by the climatic warming, but the warmer, White Spruce forests of the south facing slopes were strongly impacted by the change. Conditions on the south facing slopes were outside the ecological conditions under which the common tree species near Fairbanks are known to survive. For White Spruce the limiting condition appeared to be moisture stress brought on by the temperature change. Significantly, tree ring studies a decade later, which investigated the effects of the current run of warmer-than-usual

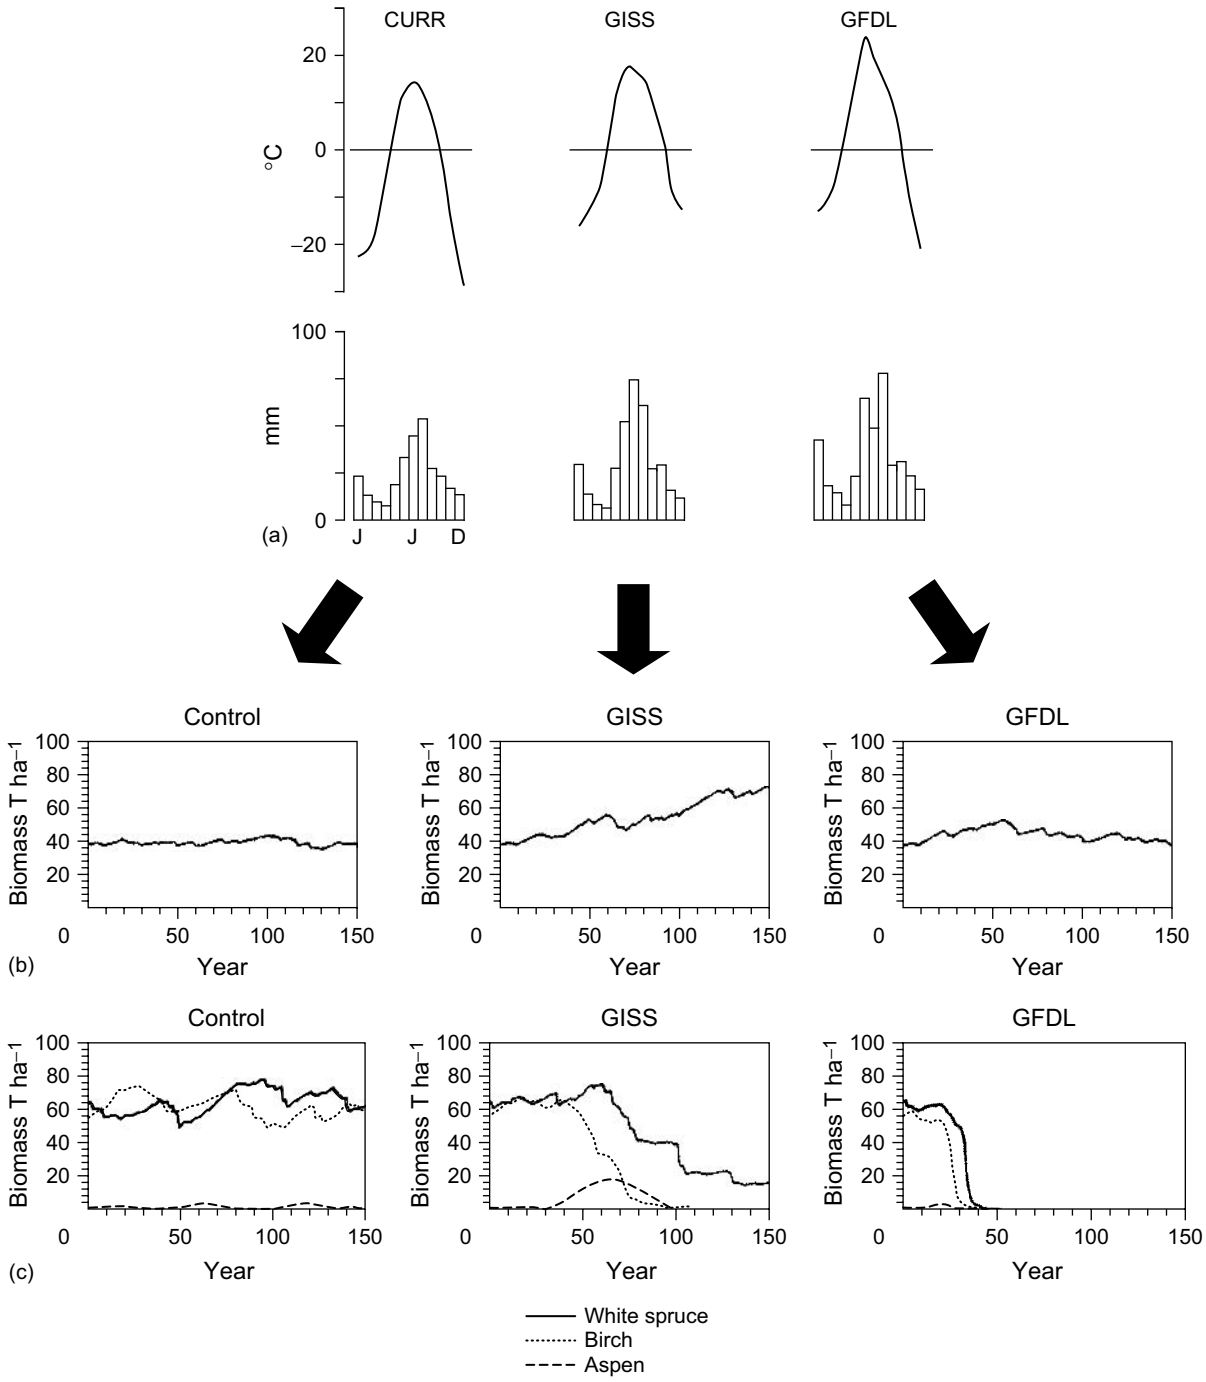

Figure 2 Application of a gap model to predict the dynamic response of forests associated with the current climate and two different climate change scenarios for forests growing in the vicinity of Fairbanks, Alaska. (a) The monthly temperature and precipitation for Fairbanks and equivalent information from the GISS Hansen *et al.* (1988) and UKMO Mitchell (1983) climate simulation models. Note the elevated winter temperatures in both models. (b) Average of 100 gap models simulating forest change over 150 years on north facing slopes. The transition from the current climate to the new climate occurred incrementally over the first 50 years. The only tree species that occurs in these conditions is Black Spruce (*Picea marina*). (c) Average of 100 gap models simulating forest change over 150 years on south facing slopes. The three species that normally occur in these settings are eliminated from these sites

decades on White Spruce near Fairbanks, have found evidence for the same moisture stress-mediated effect predicted by the gap model a decade before (Barber *et al.*, 2000).

The field validation of *a priori* predictions from a gap model is reassuring for those who would apply the models to assessing climate change. However, this example also points to a valuable attribute of gap models; the potential ability to predict change across landscapes including the heterogeneous nature of these changes. The prediction of the models for a warmer Fairbanks, Alaska are for a landscape featuring Black Spruce forests in north-facing slopes and other colder sites. A novel vegetation type, without trees, is expected over the rest of the landscape. The condition might be something like the boreal forest transition into grassland (the Taiga-Steppe) found south of Krasnoyarsk, Siberia, Russia. Other climate evaluations using gap models have also indicated a complex landscape-level response to climate change. An example (predicted as a response of a warming for forests in Minnesota, US by Pastor and Post (1988)) would be the occurrence of a landscape mosaic of both deciduous and boreal forests; each of these forest types would be stable and would have very different nitrogen cycles.

Forest Stand

The term *forest stand* is used in many contexts, from industrial forestry to the conservation of biological diversity. A forest stand is a group of contiguous trees, which are similar enough in condition, arrangement of age classes, and species composition to be considered a homogeneous unit. The smallest spatial unit for which forest management can feasibly plan cuts is typically a group of stands, which are administered as an integrated whole. Ideally, management uses ecological and silvicultural principles in planning the sequence and the methods by which individual stands are harvested to reach the target wood volume.

Problems can arise during planning, however, if large groups of dissimilar stands are managed as though they each matched the overall average conditions of the management unit. Nonetheless, somewhat arbitrary decisions are always needed about how small a stand can be considered as a separate entity during planning. The number and size of stands distinguished depends on the variation in site conditions, the degree of management intervention, and stand value. Stands as small as one hectare may be distinguished in areas where intensive forestry is conducted; a similar forest might be separated into management units of at least several hundred hectares where crude, extensive forestry is practiced.

Stand structure refers to the distributions of tree sizes and species. It results from the species' inherent growth characteristics as modified by management interventions and environmental conditions during stand development. Two structures are commonly distinguished: *even aged* and *uneven aged*. Trees in even-aged stands are relatively consistent in height and belong to a single age class (which typically extends over 10–20 years). Thus a natural stand which seeds over several years may still be considered even aged. Even-aged stands develop when environmental conditions or disturbances allow trees to become established over a single, brief, reproductive period. In uneven-aged stands, the trees originate almost continuously and therefore vary in size and age class from germinating seedlings to the over-mature.

Forest: The FAO De nition

The FAO has an agreed definition of a forest: land of more than 0.5 hectares, with a tree canopy cover of more than 10%, which is not primarily under agricultural or urban land use.

The motivation for an internationally accepted definition is the need for consistency across national borders in forest cover inventories.

Forests are defined both by the presence of trees and the absence of other predominant land uses. The trees should be able to reach a maximum height of 5 m *in situ*. Areas under reforestation which have yet to reach a crown density of 10% or tree height of 5 m are included, as are temporarily unstocked areas, resulting from human intervention or natural causes, that are expected to regenerate (see Figure 1).

The FAO recognizes that this definition is understandably a subject of debate, for at least a couple of reasons:

1. some feel that a threshold of 10% canopy cover is too generous, although the definition does exclude areas where other land uses dominate;

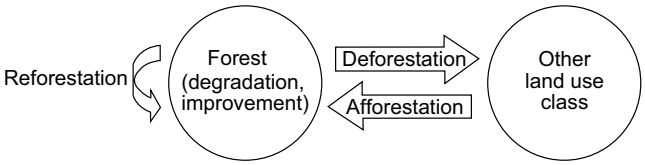

Figure 1 Relationships between forest change terms. Forest degradation and forest improvement occur within forests that continuously stay above the 10% canopy threshold. Reforestation occurs when forests regrow after temporarily having had below 10% canopy cover, but were considered as forests throughout the time. Deforestation and afforestation represent the transfers between forest and other land use classes

2. the classification of particular vegetation types is sometimes difficult. Trees in dry tropical areas may present a particular problem as no distinct boundaries may exist between areas of varying canopy cover.

Further information on the FAO definition may be obtained from robert.davis@ fao.org or peter.holmgren@fao.org.

Other definitions relating to forests include:

Reforestation, deforestation, afforestation: see Figure 1 (FAO, 2000);
Closed forests: forests where 40% or more of tree crowns are interlocked (Singh *et al.*, 2001);
Old growth forest: any forest that has evolved its own complexity under benign conditions over extensive periods of time; *see* **Phase Shifts or Flip-flops in Complex Systems**, Volume 5.

Fragmentation and Corridors

Richard J Hobbs
Murdoch University, Murdoch, Australia

Land transformation constitutes one of the major global changes, affecting over half the Earth's land surface.

Fragmentation is one component of land transformation, and refers to the process whereby existing land cover types are removed or altered by agriculture, forestry, urbanization or other human land uses. The process of removal leaves patches of the pre-existing cover types, which are of a variety of sizes and are isolated to a greater or lesser extent by a modified matrix. Remaining patches are subject to the impacts of local and landscape-scale changes in environmental characteristics, including altered microclimate and hydrology and invasion by non-native organisms.

Biota within remaining habitat patches are affected not only by these influences but also by the overall reduction in habitat area, isolation of individual patches and reduced ability to move around the landscape. The extent to which the connectivity of the landscape is affected by fragmentation depends on the mobility of the organisms involved, the extent to which the intervening matrix acts as a barrier to movement, and the extent of connection between patches by either corridors or other connecting habitat. Management of fragmented habitats requires consideration of the habitat and movement requirements of species of conservation concern, and current and potential habitat configurations in relation to the likely viability of populations. Management of not only habitat patches but of the overall matrix is required, leading to notions of reserve networks and integrated management of conservation and production lands.

Fragmentation of natural ecosystems has been called one of the most pervasive changes in terrestrial ecosystems across the Earth. It occurs wherever land transformation results in the removal of the pre-existing land cover and its replacement with other cover types, be it urban, agriculture, production forestry or other human-dominated land uses. Such activities may remove most of the pre-existing cover types, transforming landscapes and regions in relatively short periods. Examples include deforestation in tropical areas such as Amazonia, and clearance for agriculture in the mid-west of the United States and in Australia (Hobbs and Saunders, 1993; Laurance and Bierregaard, 1997; Schwartz, 1997). In these and many other cases, the result of such activities is that the pre-existing cover types are left as patches in a modified matrix of production land. These patches may be of varying sizes and may be isolated from other such patches to varying degrees.

IMPACT OF FRAGMENTATION ON BIOTA

Considerations of fragmented landscapes have focussed on factors which influence the likelihood of persistence of the biota retained in the remaining fragments of habitat. Obviously, the major impact of transforming one ecosystem type to another is the dramatic reduction in the amount of habitat left for those species dependent on the pre-existing ecosystem type. The actual area of many ecosystem types is reduced to a few percent of their original extents, and this not only affects their representation in the landscape and in any reserve system that is developed, but also affects the ability of individual species to survive. Species vary greatly in their habitat requirements, and it is likely that in fragmented systems, populations of some species are limited simply by the amount of habitat available.

In addition to the simple amount of habitat remaining, the spatial arrangement of that habitat may also be important. Considerable debate centered for many years on whether fragmented systems would perform better in terms of retaining species if they consisted of a few large fragments versus lots of small patches. The so-called single large or several small (SLOSS) debate stemmed from ideas generated from the theory of island biogeography, which related species numbers on islands to the island size and isolation. There is no real resolution to this debate, since different types of organism will probably require different amounts and distributions of habitat. For instance, large mammalian predators probably require large uninterrupted tracts of habitat, whereas insects and plants can probably survive well in much smaller areas.

Other factors may also limit populations, however. For instance, some species may be limited, not by the areal extent of habitat, but by the availability of a particular resource on which they depend. An example may be nectivorous birds, which depend on a continuous supply of nectar throughout the year. If the fragmentation process removes a particular plant community or species, which provided nectar resources at a critical time of year, nectivorous birds could no longer survive in the area.

CONNECTIVITY AND CORRIDORS

A further factor influencing population viability may be the ability of species to move around the landscape. Species need to move for numerous reasons, such as to fulfil resource requirements, to disperse to new territories, or to migrate. Some species may move only short distances and hence be able to exist entirely within an individual habitat patch, but others may need to move either between different habitat types or across the landscape between different fragments. Others may need to move across entire continents as they follow migration routes.

Population survival in fragmented landscapes has often been discussed in terms of metapopulation dynamics (McCulloch, 1996; Hanski and Gilpin, 1997). The idea of metapopulations proposes that species populations can exist as a series of interlinked sub-populations or metapopulations, which persist in separate habitat patches but may be linked by inter-patch movement. Populations are hence spatially structured into assemblages of breeding populations and movement among the local populations

may have some effect on local dynamics, including the possibility of population re-establishment following local extinction. Hence occupancy of a particular patch by a species may be intermittent and dependent on movement of that species from one patch to another.

In an unfragmented landscape, the ability of species to move depends entirely on the permeability of the different ecosystem types present, i.e., the extent to which different patch types either aided or hindered movement. The permeability of different landscape elements is likely also to vary from species to species. Some species will only move in thickly vegetated cover types, whereas other species favor more open country.

In a fragmented landscape, dense wooded cover is often replaced with low, open crop or pasture. In this situation we might expect that the permeability of the landscape would decrease for species which require wooded cover. The exact impact of the fragmentation depends both on its extent and pattern and also on how particular species view the landscape. Using simple geometric models, it can be shown that the extent to which the various habitat patches in the landscape remain connected declines as the extent of habitat removal increases. However, there is also evidence that the relationship is not linear, and that there is a threshold in connectivity at about 60% habitat removal, at which the level of connectivity declines sharply.

The question of landscape connectivity is a complex one and a frequent component of discussions on the topic revolves around the question of corridors. Using the standard dichotomy of habitat/non-habitat or patch/matrix, it has frequently been espoused that a major way to retain or improve landscape connectivity in fragmented landscapes is by the provision of connections between habitat patches. These connections can be thought of as linear strips of habitat which either act fully as habitat, allowing fauna to live in them, or provide enough habitat characteristics to allow species to move along them and hence move between habitat patches. Many fragmented landscapes do, in fact, retain extensive networks of linear strips, for instance along road verges or hedgerows, and there is evidence that these strips play an important role as habitat for some species and a conduit for movement of others (Hobbs, 1992; Bennett, 1999). Nevertheless, the importance of corridors in conservation networks remains controversial, and it is difficult to obtain conclusive evidence for their role in aiding species movement. Despite this, corridors are a central component of plans for conservation networks, and linear habitat elements often make up a significant proportion of the remaining habitat in highly fragmented landscapes.

So far we have considered fragmented landscapes using a simple dichotomy between habitat and non-habitat, but this model ignores the possibility that the matrix retains some habitat characteristics or is at least still semi-permeable and allows species to move within it. An example might be where scattered trees are retained in an otherwise deforested landscape or where the pre-existing ecosystem type is utilized for grazing rather than actually being cleared. Such landscapes have been termed variegated, and they may function quite differently from what have been classically described as fragmented landscapes (McIntyre and Hobbs, 1999). This emphasizes the conclusion that the degree of fragmentation and the type of management practiced in the matrix may both influence the impacts on the biota. Also of importance will be the pattern of fragmentation, and factors which may be important here will include the number and size of remaining patches, and their spatial distribution (whether they are clumped together or dispersed). Also of importance is the condition of the patches, as discussed next.

EDGE EFFECTS AND LANDSCAPE PROCESSES

In addition to the actual removal of the pre-existing ecosystem type and the creation of the patch/matrix type landscape discussed above, ecosystem modification can also occur, whereby the pre-existing ecosystem type is not removed entirely, but is altered by human use, such as by grazing, timber harvesting and so on. The two processes of fragmentation and modification can occur simultaneously, and often fragments remaining in a modified matrix are also severely impacted by modifying influences (McIntyre and Hobbs, 1999; Hobbs, 1993). Thus, often it is important to consider not only the amount of a particular ecosystem which is left, but also the condition of the remaining patches.

Factors which can influence the condition of patches include both factors operating within individual patches and factors arising from the surrounding landscape. An important feature of fragmented ecosystems is that the pre-existing disturbance regime can no longer operate (Hobbs, 1987). For instance, fire frequency and intensity may increase or decrease in isolated fragments, and this in turn affects the survival and regeneration of the plant communities in the fragments. Also, if movement of faunal species around the landscape becomes restricted, seed dispersal, and hence gene flow, of plant species may be reduced or cease. As species are lost from fragmented systems, so too are any functions that these species performed. For instance, if burrowing mammals disappear from fragmented systems, soil disturbance and turnover are reduced, and hence nutrient cycling and water infiltration to the soil may be affected.

The isolation of fragments in a modified matrix opens the fragments up to a range of microclimatic, hydrological and biotic changes (Saunders *et al.*, 1991). A primary result of this isolation is the creation of an edge between the pre-existing ecosystem and the modified matrix. At this edge, the conditions prevalent in the matrix impinge into the fragment, and a series of edge effects can occur (Murcia, 1995). These effects can include dramatic differences in

radiation input, temperature, frost frequencies, moisture relations, and impact of wind. Such changes can result in considerable mortality of the species up to 100 m from the fragment edge (Laurance *et al.*, 1997), and this impact can be particularly severe in small fragments where virtually the entire fragment becomes edge rather than interior habitat.

Other edge effects can include the input of nutrients or pesticides, either in spray drift from adjacent agricultural operations or in soil blown from adjacent fields. An array of biotic edge effects can also occur; in particular, weed invasion and nest predation may increase greatly at fragment edges.

In addition to the localized edge effects, the surrounding landscape can influence fragments more generally. For instance, significant changes in hydrology can result from the process of replacing one cover type with another. These large-scale changes influence not only the production matrix but also the ecosystems remaining in fragments (George *et al.*, 1995). Also, animals and plants prevalent in the management matrix may exert profound influences on the biota in fragments. In particular, domestic stock can dramatically alter the structure and composition of fragmented systems by grazing and trampling. Similarly, feral predators can be responsible for the decline of faunal species, which would otherwise survive in the fragmented system. Finally, invasive plant species may disperse into fragmented systems from the surrounding matrix, and again these have the potential to significantly alter the structure and dynamics of the fragmented system. Hence fragmentation results not only in the formation of small, isolated fragments, but also in landscape-scale system changes.

Freshwater Fisheries

Robin L Welcomme[1] and Henry A Regier[2]

[1]*Imperial College, London, UK*

[2]*University of Toronto, Toronto, Canada*

Water is essential to living organisms. Its various chemical properties have come to be exploited by organisms in the course of evolutionary time, sometimes as opportunities and sometimes as constraints. But water's desirable features can also create difficulties for the organism. Water as atmospheric precipitation carries many substances downward from the atmosphere which are then harmful to organisms immersed in the receiving surface water. Also, the water dissolves, corrodes and erodes many substances in cities and on land and transports these to the streams and lakes either as surface runoff or ground water discharge. Humans drain or spill many kinds of polluted wastes directly into surface waters; currents in these waters then help to disperse the wastes downstream. All freshwater fish in the world are now subject to some adverse effects of the discharge of human-made wastes into the atmosphere, the soil and the water anywhere in the Biosphere. Some waters are so fouled that no fish at all can survive in them.

A FISH IN ITS HABITAT

Molecular water, often complexed with many other compounds, contributes most of the body mass of organisms. In the cells of these organisms the water contains dissolved substances of many kinds which create osmotic pressure within the cells that leads purer water from outside a cell to pass through a cell's membrane into a cell. Generally fresh water, but not sea water, has less dissolved matter in it than does water in a fish's cells, hence fresh water tends to migrate from the outside into a fish. To prevent physiological flooding, a fish in fresh water must try to keep such unwanted water out of its cells and to pump out excess water from them. Such pumping is difficult to do biochemically and requires that the cell and organism do work to accomplish it.

Oxygen is used in the body of creatures to combine with organic substances, that contain stored chemical energy, in order to liberate some of that energy in another form in which it can be used for the work of the cell and of the creature's body. Oxygen is only slightly soluble in water, whether in the cell or in the habitat. Hence organisms generally have evolved some special oxygen carrying devices such as blood corpuscles and complex organs such as gills to arrange for exchange and transport of oxygen from the habitat to the cells where it is needed. Again the process is biochemically difficult and requires work by the fish.

The organism's biochemical processes involved in managing water and oxygen within itself, and many other more complex processes, such as growth and reproduction, are all strongly affected by temperature. For any particular process there is a window of vitality for the various environmental factors. With respect to temperature, this window consists of an interval of temperature below which or above which a particular physiological process does not work at all, or works only in a pathological way. Generally the more complicated a physiological or behavioral process, the narrower is the relevant window with respect to the range in temperature included within it.

Within the window of vitality, most biochemical and physiological rates are strongly dependent on temperature, with an optimum rate often a few degrees below the upper limit of the window. Fish have some behavioral capabilities to select habitat at a temperature near their optimum if such appropriate habitat at that temperature is available, but have practically no physiological capability to control their bodies' temperature. To do so would be very costly of energy in any case, because the water in which fish are immersed has a high heat capacity and would thus rapidly cool any fish that is warmer than its habitat. (Fish have never evolved the capability to create their own insulation from the environment such as sub-cutaneous blubber or external feathers and fur.)

Since the temperature of fish varies with its habitat, which in turn varies daily and seasonally, fish must cope with different muscular, neural and endocrine rates and capabilities at different times of the day and year. Fish have some genetic capability to adapt physiologically and behaviorally to an annual cycle of habitat temperature. Thus both limits of the window of vitality may shift gradually toward a higher temperature during spring and summer, and to a lower temperature in fall and winter. Tasks such as actively rearing young and predatory feeding, for example, may require vigorous and complex activity. Fish tend to schedule such complex and vigorous activities in seasons or daily periods when the habitat temperature is near optimal for the species. A particular family of species tends to have its own general adaptation pattern to these fundamental parameters of fish life, with a finer scale of differences between species.

The concept of a window of vitality can also be used for other environmental factors, such as chemical substances dissolved in water or complexed with food substances. Thus there are lower and upper limits for the concentration in the body of fish for many substances that have been in the fishes' habitat throughout evolutionary time. Such substances include the hydrogen, copper, sodium, chloride and nitrate ions, for example. But some recent man-made chemicals, such as some of the organohalides and polycyclic aromatic hydrocarbons, are new to fish and some are harmful as genetic toxins and disruptive of endocrine functions. For such substances, the concept of a window of vitality appears to have little meaning, since any amount at all may be disabling and lethal to at least some individual embryos and older individuals of a population.

Because of the properties of water chemically and hydrologically, and the fact that fish have no choice but to relate intimately with that water, fish must cope with consequences of many effects of human activity in the upstream watershed and in the atmosphere upwind of the watershed. In effect, such fish are integrative indicators of cultural stress effects, interacting with the natural stress regime in the watershed. Fish have long been used as such indicators in human attempts to control and correct abuses upstream and upwind of their habitats.

DIFFERENT KINDS OF HABITAT - FISH COMPLEXES

All surface waters have flows and currents, both in horizontal and vertical dimensions. The velocities of liquid water are somewhere between those of gaseous water as part of the atmosphere, and those of the solid water of slowly flowing glaciers covering an even more slowly flowing lithosphere at high latitudes and altitudes.

Any currents in open environments have self-organizing capabilities and dynamics that are unpredictable in part.

Some features emerge unpredictably for fish and also for the most expert humans. Fish find opportunities and challenges in liquid habitats to which they must adapt continuously. For a particular species, and more generally for genera or sub-families of species, windows of vitality can be inferred with respect to salient features of water currents. Some fish taxa have evolved to thrive in torrential habitats while others need placid, slowly flowing waters. If humans alter water bodies with respect to such habitat features, then the fish species association changes adaptively in those locales.

Researchers use abstractions with respect to flow regimes, e.g., continuous flow and pulse flow. As an ideal notion, continuous flow relates to currents in rivers and along lake shores that do not fluctuate markedly in volume and velocity over time, as between seasons in a year or within a period of years. With pulse flow, much of the flow occurs over a short period of time, during which the volume and velocity is much higher than at other times. The current regimes of most freshwater surface waters of the biosphere fall somewhere between these two extremes.

Consider that a watershed includes the groundwater-fed headwater lakes and streams as tributaries, the main stem of the river to transport much water, and the branching distributaries that self-organize to spread the river flow into the receiving coastal sea or ocean. The association of fish species within such a watershed includes some that have become adapted through evolution to a continuous current regime, some to a pulse regime, and some to a combination of the two. Further, a particular species may have evolved to exploit pulse features for part of a life cycle and continuous features for another part. Such a complex life history may involve migration of a population from one part of the watershed to another part, to find the appropriate current regime seasonally (*see* **Fisheries: Pollution and Habitat Degradation in Tropical Asian Rivers**, Volume 3).

Currents in lakes are complex and are caused by the action and interaction of many forces. These include the inertial force of inflowing river water, surface forcing by winds, Coriolis forces due to the Earth's rotation, gravity forces acting vertically on waters of different densities, etc.

The shores and bottom of a lake and river act to constrain the direction of a current in a lake, so currents are often strong near shore and in a long-shore direction. The currents of rivers and lakes carve channels and shorelines to create patterns for which empirical generalizations have been inferred. Generally the currents tend to bend in a counter clockwise direction north of the Equator and clockwise south of it. Because of the current regime, lakes are sometimes referred to as one-sided rivers. Near shore in a lake, where currents are strongest, the association of fish and other biota resembles that in the mainstem of the inflowing rivers, in part because of the similarity of current regimes.

Pulses occur with seasonal or occasional flooding due to rapid spring snow melt, to intense rainy seasons such as monsoons, or to massive precipitation events such as those accompanying hurricanes. These pulses tend to have their largest ecological effects on floodplains and coastal zones of downstream rivers, lakes and estuaries with their distributaries. Permanent wetlands in flood plains and coastal zones usually owe their existence to such pulses: the bigger the pulses, the larger the areas of wetlands generally. After a pulse event, waters of wetlands or slowly moving mainstem reaches may become relatively quiescent, with an increase in temperature in summer and a reduction of oxygen concentration due to decomposition of organic materials carried into these waters by the pulse currents.

From the perspective of a watershed's current regime, as some seasonally varying mix of continuous and pulse features, the species of fish in a watershed can be classified, very approximately, into three types: white, gray and black. Again, the colors used to code these types are abstractions. Here white fish tend to be light colored or silvery, partly translucent and reflective of light due to soft and transparent scales. Gray fish often have mottling or colored patches with thicker scales and spines and a relatively opaque appearance. Black fish may have dark leathery skin. There are many anatomical, physiological and behavioral features associated with these color differences.

White fish, as defined here, prefer clear and clean currents of waters with much oxygen and often of cool to cold temperatures. If the current regime in a locale of a watershed fluctuates between continuous and pulse phases, then the whitefish may move longitudinally from locale to locale, including the distributor waters in a downstream sea or ocean.

Gray fish prefer near shore waters where their habitats include large aquatic plants, rocky coasts and reefs, woody debris, etc. Where and when large current pulses occur, gray fish species may move into the flood plain and flooded coastal zone, but then retreat back to the river proper when these flood waters recede.

Black fish prefer shallow waters with low currents, including the relatively stagnant waters of wetlands after flood waters have receded. Because these waters may become anoxic, some black fish species have adapted anatomically by creating primitive lung-like structures, which are filled with air periodically by gulping at the surface. In addition, a species may have adapted physiologically so that it can obtain energy from its food through anaerobic metabolism. In extreme pulse situations, where the water in a wetland dries completely on an annual basis, some fish species adapt by creating moisture-holding cocoons of mud in the bottom, which then dries out.

With each of these three functional classes of fish, there are some species in which individuals become large and

old and may therefore be considered to be K-selected in that they thrive in closely organized natural settings. Individuals of other species remain small, reproduce at a young age and all die within a few years of birth. These are r-selected and thrive where an aquatic ecosystem is markedly unstable either for natural reasons or because of destabilizing activities by humans. At early stages of a pulse event, for example, the r-selected species of all three types may erupt which are then preyed upon by K-selected species of the three types during the less turbulent, waning stages of the pulse event (*see* **r–K Strategies**, Volume 2).

Generalizations like those above should be interpreted heuristically and not as deterministic inferences to apply to individual fish or populations; ecosystem life is much too complex to be described fully in such terms.

DIRECT USE AND INDIRECT ABUSE OF FISH

Many fish species of all three types (white, gray and black) are preferred foods for humans; some larger, older K-selected species are generally, but not always, valued more highly than are younger, smaller r-selected species. Recreational fishers value K-selected white and gray species in particular. The ornamental pet fish trade prefers colorful, r-selected gray fish. Bait fisheries in North America prefer r-selected white fish.

Direct harvesting by commercial and recreational fishers generally selects and thus suppresses K-selected species of all three types, to the advantage of r-selected species. Ornamental and bait fishers complement this effect by harvesting r-selected species where they are abundant because predation by K-selected species has been relaxed. The overall effect on the fish species association is a shift toward small, young fish in which r-selected species can reproduce and thrive but not so with K-selected species.

Humans alter the watery parts of a basin with respect to its current regime, shores, flood plains, toxic burden, oxygen concentration, temperature, etc., all in ways to make the habitat more turbulent, less predictable and more stressful for fish. Overall there is usually a shift in current regime toward the pulse type, combined with a more erratic timing and magnitude of the pulses. If allowed to progress toward extreme modification due to careless human activities, the aquatic environment becomes a disorderly mess. Only the most tolerant of opportunistic r-selected species may be found in such locales, and then perhaps only during seasons when the complex of stresses is least intense.

DIFFERENT KINDS OF FISHERIES AND GOVERNANCE CONVENTIONS

Organized fisheries have existed for millennia, all over the world. Until about five centuries ago fisheries were generally small and local. With the technical innovations that are associated historically with modernization, some individual fishery enterprises have extended their operations from the local to the regional and eventually to the global. But local versions, often using less advanced technology, have persisted with difficulty in many places.

The generalization above relates to each of what are usually termed commercial food fisheries, recreational fisheries as a service industry, the ornamental pet fish trade, and aquaculture enterprises.

Small-scale local fisheries initiatives occur all over the world. Sometimes these provide opportunities as an occupation of last resort, for the poorest of the poor people of a region. The available fish resources are not of sufficient quality or quantity to make it worth an entrepreneur's effort to pre-empt them coercively for external markets.

Water and aquatic habitats are usually treated as property held in common by the people of a locale. Complex governance regimes, with controls on access and harvest for example, are usually in place to share these resources among fishers and the community served by the fishers. A widespread myth, sometimes attributed to Garret Hardin, that common property resources under local governance are inevitably over-harvested is simplistic if not wrong, effective governance has occurred in many places for centuries (*see* **Commons, Tragedy of the**, Volume 5).

Modernized fisheries, serving markets distant from a locale in which the fishing occurs, usually operate under a quite different governance regime than do local artisanal fisheries. Modern fishers often shared implicitly a cornucopeian view that the fish were abundant and resilient to harvesting activities and that the fisher's capabilities to capture preferred fish were generally severely limited. When difficulties arose with respect to collapses of the most preferred species and competitive animosities between individual fishers or fishing fleets, only the least constraining kinds of regulations were imposed. Thus the amount of *fishing effort* permitted by a group of fishermen was set legally. But the effort concept could not be defined rigorously in practice, and fishers generally adapted by making their allocated effort more effective in capturing fish. To make a long story short, the end result of modern fishing practices and modern fishery regulation, is an over-fished fish association, an uneconomic fishery, and a politically unstable fishing community. (Note that this too is a simplistic version, and is a wrong analysis for what happened in some fisheries.)

Late in the 20th century a growing interest emerged in the earlier governance regimes, some of which still persist with respect to artisanal and small-scale local fisheries. Perhaps effective regimes will self-organize to transcend both historical approaches and incorporate good features of each.

CURRENT STATUS, DEGRADATION WORLDWIDE

Human settlements are generally located on large bodies of fresh water, either rivers or lakes. At the beginning of the 21st century, people on all continents continue to migrate to such locales, and especially to coastal zones that contain supplies of fresh water.

For centuries, modernization of fish harvesting, processing and marketing when combined with modernization of economic development on the adjoining terrestrial parts of a watershed has caused the degradation of fish associations and their habitats. The closer a locale is downstream from a large human settlement, the more intense the degradation. Even large coastal seas downstream from large industrialized conurbations have been exhibiting increasingly intense debasement.

Some degraded fresh waters and their fish associations have been a focus for costly efforts toward rehabilitation. The Thames, Rhine and St. Lawrence/Great Lakes watersheds are examples in which some rehabilitative success is now apparent. But with each of these, the improved quality of the fish and their habitat does not imply a return to an earlier pristine state. These aquatic systems have been changed in many ways, and are continuing to be changed permanently in new ways. One of the latter includes the introduction of non-native species, for example, through release of ballast water containing live organisms from ocean-going ships. Thus what kind of fish association to expect with respect to particular species in a particular watershed will remain unpredictable.

Generally, the goals of such rehabilitation appear to include a mix of healthy populations of desirable K-selected species of each of the white, gray and black ecological types. While some watersheds of badly industrialized parts of the world seem to be trending in that direction, many other watersheds in industrializing watersheds in other parts of the world are now degrading and are losing their valued K-selected species of all three types.

Global climate warming scenarios generally forecast much larger temperature increases at higher than at lower latitudes. At mid-latitudes the severity of effects is expected to be spotty, both longitudinally and latitudinally, with some regions more severely affected than others. With fish, both the temperature and the volume of water are important ecologically. In mid-latitude regions of the various continents, decreases in the amount of surface waters and thus of aquatic habitat would result in reductions in the abundance and diversity of fish, with extinctions of local fish populations where the waters dry out seasonally. (In some cases a species may exist only as one population, and thus the whole species would be rendered extinct.) Temperature increases will also occur to various extents regionally at mid-latitudes and more generally at high latitudes. Where aquatic habitats and interconnections will persist, especially as in rivers flowing towards regions of colder temperatures, e.g., down the MacKenzie toward the Arctic Ocean, fish that are genetically programmed for warm water will likely migrate and there displace the species that are limited to cold water habitats. At high latitudes, new cold water habitat may emerge with melting of permafrost and longer open water seasons. Where north–south connections of aquatic habitats will not exist, local extinctions of species can be expected to occur at lower latitudes, with species associations of low diversity at higher latitudes above such habitat discontinuities. Humans may intervene to transport fish species across such discontinuities, as a mitigative measure.

G

Gaia

Gaia: The Earth seen as (or the view of the Earth as) a system that possesses at least some emergent properties typical of living organisms. The defining characteristics of Gaian organization (which could, in principle, be found elsewhere in the solar system or in other planetary systems) are postulated to be.

- Stabilization of the global environment by the biota, analogous to the self-regulatory processes that lead to homeostasis of the internal environment in many animal species.
- profound modification of the chemical composition of the planetary atmosphere away from the composition predicted by equilibrium thermodynamics.

This latter feature provides a potential basis for the detection of Gaian systems by space exploration. According to the Gaia theory, both of these properties arise because of the existence of tightly coupled mutual interactions, both within the collectivity of the global biota (symbioses) and between the global biota and their inorganic environment. Gaia (Mother Earth in Greek mythology) was proposed as a name for the Earth-as-organism by James Lovelock based on a suggestion from Nobel Prize winning novelist William Golding.

Generic Decomposition and Yield (G'DAY): A Model of Global Change Impacts on Plant and Soil

Ross E McMurtrie

University of New South Wales, Sydney, Australia

The effects of climate change on plant growth are complex, including direct instantaneous effects on numerous plant physiological processes, and indirect plant and soil feedbacks that act on time scales ranging from a few days to centuries. Consequently, predicting the responses of vegetation to environmental change presents a formidable scienti c challenge. One approach is through experiments that manipulate environmental conditions. However, this approach has practical limitations for predicting long-term responses. For long-term predictions the primary scienti c

tools are ecosystem models based on an understanding of the processes involved. One such model is G'DAY (Comins and McMurtrie, 1993).

G'DAY simulates the cycling of carbon, nitrogen and water in plant and soil. The plant sub-model simulates the carbon and nitrogen contents of leaves, fine roots, and wood. The soil sub-model predicts carbon and nitrogen in plant litter and soil organic matter pools (as in the CENTURY model; see *CENTURY Ecosystem Model, Volume 2) and water storage in the rooting zone. Processes represented include plant photosynthesis and respiration, plant water and nitrogen uptake, tissue growth and senescence, litter and soil decomposition, net soil nitrogen mineralization, nitrogen input by atmospheric deposition and biological fixation, and nitrogen loss by leaching and gaseous emission. Photosynthetic rates depend on [CO_2] and temperature, respiration depends on temperature, and decomposition depends on soil temperature and moisture content. G'DAY has been used to investigate effects of altered climate and land use on forest ecosystems in tropical, temperate, Mediterranean and boreal environments and on temperate grasses.*

G'DAY can be operated using either observed daily weather data or constant, mean annual weather. The daily version is used where the purpose is to simulate relatively short-term plant experiments, while the version with mean annual climate is used for investigating longer-term global change impacts.

DAILY VERSION OF G'DAY

G'DAY simulates the cycling of carbon (C), nitrogen (N) and water in plant and soil. The model's general structure is shown in Figure 1. A simulation with daily weather data is shown in Figure 2 for a water-limited stand of *Pinus radiata* growing near Canberra, Australia. The figure illustrates simulations of soil water storage over a four-year period at ambient (350 μmol mol^{-1}) and double ambient (700 μmol mol^{-1}) concentrations of atmospheric carbon dioxide. The simulation at 350 μmol mol^{-1} agrees closely with measured soil moisture (circles in Figure 2). For this water-limited site, G'DAY predicts wetter soils at elevated [CO_2]. This prediction is a consequence of improved water use efficiency at high [CO_2]. Wetter soils enhance plant growth because of an extended growing season and increased soil nitrogen availability.

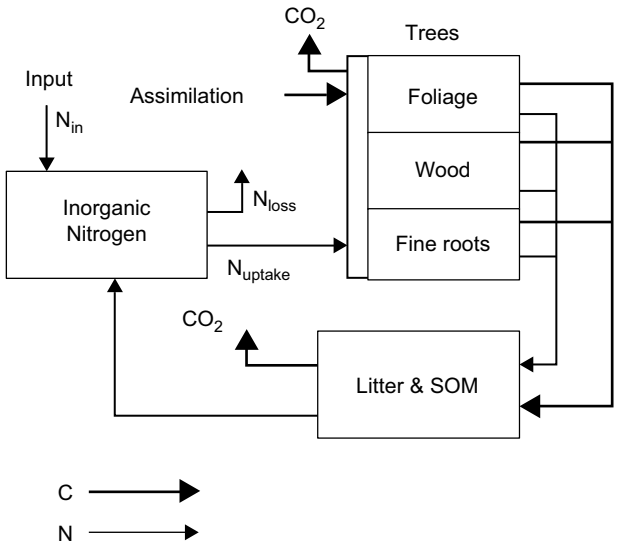

Figure 1 Pools and fluxes of carbon and nitrogen in G'DAY

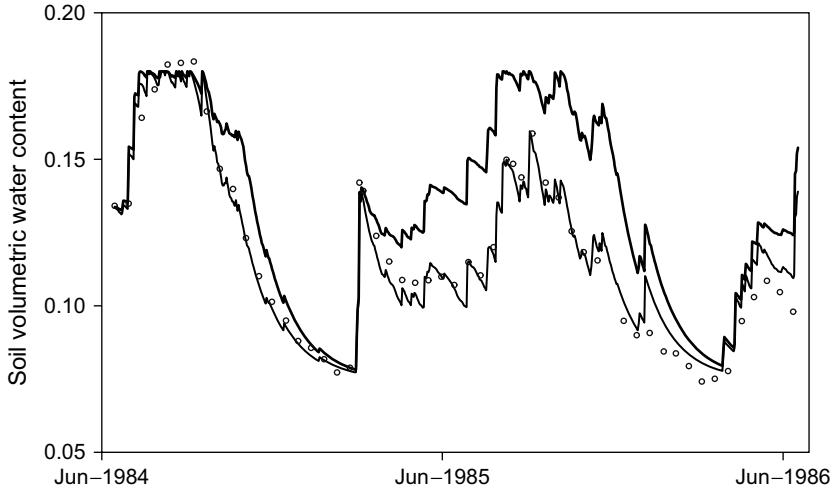

Figure 2 Simulated soil moisture contents to a depth of 2 m for a stand of *Pinus radiata* at ambient (350 μmol mol^{-1}) and double ambient (700 μmol mol^{-1}) [CO_2] concentrations (thin and thick lines, respectively). Measured soil moisture contents at current [CO_2] are also shown (circles)

G'DAY WITH SIMPLE CLIMATE

The daily version of G'DAY is appropriate for applications to short-duration experiments and for investigating short-term response to environmental change. But the daily model has limitations for investigating longer-term impacts. One limitation is that large daily and seasonal fluctuations in model output can make it difficult to ascertain why the model responds in a particular way. In simulations with a simple climate, that task is much easier, as illustrated in Figure 3 where G'DAY is applied to simulate the impact of gradual climate change on a stand of Norway spruce at Flakaliden, northern Sweden. This site is nitrogen-limited, but not water-limited. All simulations were initiated by running G'DAY to equilibrium under the baseline climate at Flakaliden, and then imposing gradual increases in temperature ($+0.03\,^{\circ}\mathrm{C\,year^{-1}}$) and $[CO_2]$ ($+3\,\mu\mathrm{mol\,mol^{-1}\,year^{-1}}$) which, when applied together, approximate the Intergovernmental Panel on Climate Change (IPCC) climate change scenario IS92a (IPCC – WG 1, Vol. 5). Model outputs shown in Figure 3 are net primary production (NPP), and net carbon dioxide exchange by the ecosystem (= NPP minus decomposition of litter and soil organic matter), which is known as the C sink or *net ecosystem production* (NEP). Under increasing $[CO_2]$ NPP increases but tends to decelerate. The carbon sink reaches a peak of approximately $9.3\,\mathrm{g\,C\,m^{-2}\,year^{-1}}$ after 20 years followed by a gradual decline. The carbon sink declines for a variety of reasons, including saturation of the photosynthetic carbon dioxide response, and increased decomposition because litter and soil carbon gradually accumulate. However, according to G'DAY the rate of decline is highly sensitive to parameters describing the flexibility of soil

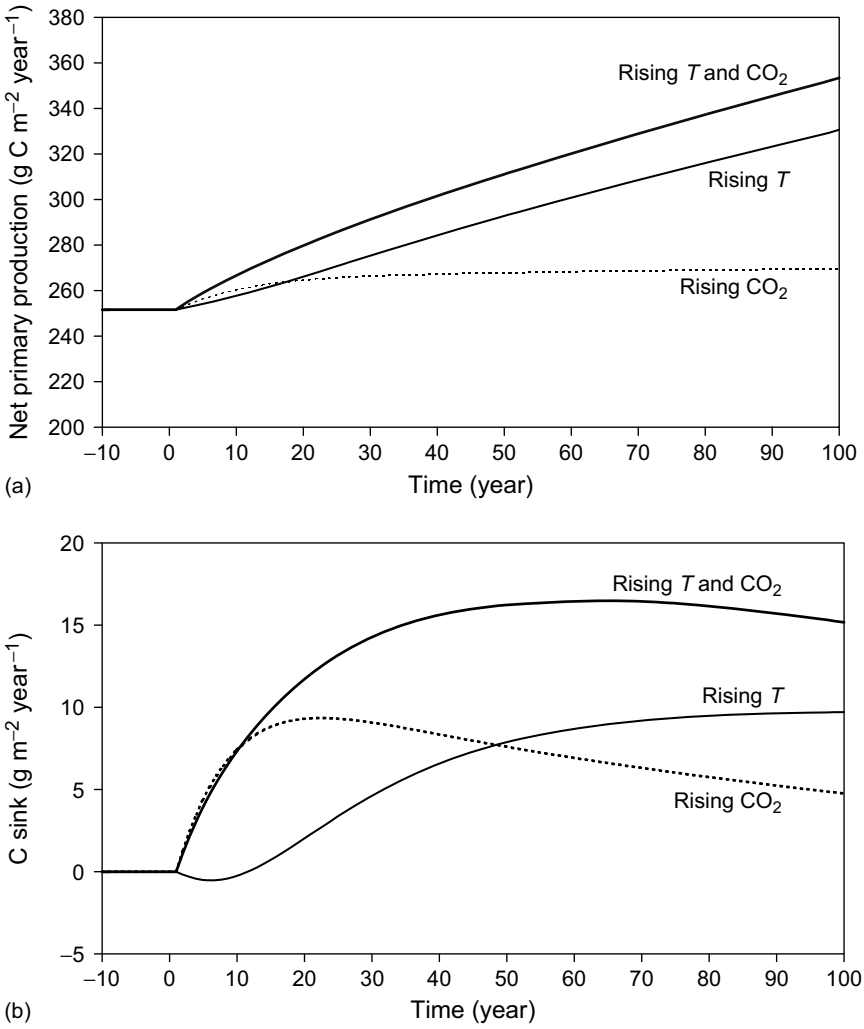

Figure 3 Simulated responses of G'DAY to gradual increases in $[CO_2]$ of $+3\,\mu\mathrm{mol\,mol^{-1}\,year^{-1}}$ alone (dashes), temperature of $+0.03\,^{\circ}\mathrm{C\,year^{-1}}$ alone (thin solid line) and both $[CO_2]$ and temperature (thick solid line). (a) NPP and (b) the ecosystem carbon sink. Each simulation was initiated by running G'DAY to equilibrium at current T

nitrogen: carbon ratios at high [CO_2], and the primary control over the carbon sink is soil nitrogen availability. The carbon sink declines under rising [CO_2] due to nitrogen immobilization in accumulating soil organic matter.

Figure 3 also illustrates simulations of NPP and the carbon sink with temperature increasing gradually at a constant rate of $0.03\,^{\circ}\mathrm{C\,year^{-1}}$. NPP increases steadily throughout the simulation. The carbon sink is negative for an initial transient period, after which it increases steadily to a peak value of approximately 9.7 g carbon $\mathrm{m^{-2}\,year^{-1}}$. The explanation for this temperature response is that warming stimulates soil decomposition causing a release of soil nitrogen, which promotes NPP. Unlike the high carbon dioxide simulation, there is no tendency for the carbon sink to decline over time. The simulation with gradual increases of both temperature and [CO_2] indicates a sustained positive carbon sink over the next 100 years. G'DAY's prediction of a strong and continuing carbon sink under increasing [CO_2] and temperature contrasts with claims that saturation of the carbon dioxide response together with increasing soil decomposition due to rising temperatures will cause a reduction in the sink (e.g., Pearce, 1999). Those claims are based largely on short-term experimental evidence that the temperature response of soil decomposition is steeper than the temperature response of photosynthesis. However, this argument ignores plant–soil feedbacks that are not evident in short-term experimental data (McMurtrie *et al.*, 2001).

MATHEMATICAL ANALYSIS OF G'DAY

Much of the research with G'DAY has been based on a mathematical technique called *two-timing* or quasi-equilibrium analysis. That analysis exploits the fact that ecosystems are made up of plant and soil pools with widely differing turnover times. For instance, leaves and fine roots have faster turnover times than stemwood. Thus, on a specified time scale, the system may be separated into fast and slow turnover pools, where fast pools are in approximate (or quasi-) equilibrium and slow pools are effectively constant. At quasi-equilibrium the total ux of carbon into the fast pools is equal to the total ef ux of carbon (and similarly for nitrogen). The carbon and nitrogen ux equilibria of the fast pools lead to an enormous simplification of G'DAY which gives powerful insight into the model's behavior. The quasi-equilibrium analysis can be represented graphically in terms of two relationships between NPP and leaf nitrogen : carbon ratio: (1) the photosynthetic constraint to production (corresponding to the quasi-equilibrium carbon balance of the fast pools); and (2) the nitrogen availability constraint to production (corresponding to the quasi-equilibrium nitrogen balance of the fast pools). NPP on the specified time scale is then represented by the intersection of the two constraint curves (Comins and McMurtrie, 1993). Responses to rising [CO_2] and temperature can be evaluated from how the intersection shifts on different time scales. Because the analysis leads to explicit equations for the two constraint functions as functions of [CO_2] and temperature, it can explain in graphical fashion how the response to climate change depends on all model parameters. The analysis has been applied to evaluate the response of NPP, the carbon sink, and ecosystem carbon storage, to rising [CO_2] and temperature for both nitrogen- and water-limited ecosystems, and has been used to identify key model parameters in u-encing responses on differing time scales (e.g., McMurtrie and Comins, 1996; Medlyn *et al.*, 2000; McMurtrie *et al.*, 2000).

Global Ocean Observing System (GOOS)

Colin Summerhayes
UNESCO, Paris, France

GOOS is designed to provide information to a wide range of users about the present and future states of the ocean and its resources on both short and long time scales. It will help to improve forecasts of weather and climate, and to enable the safe and sustainable management of coastal seas and their living resources.

Safe navigation, the sustainable exploitation of marine resources, the safeguarding of marine environments, and the forecasting of climate for the suppliers of food, water and energy increasingly depend on a greatly enhanced ow of information about seas and oceans and about their roles in climate change. Provision of this operationally useful information about the present state of the sea, and about its future states for as far ahead as possible, for a wide range of users and customers, comes from operational oceanography, comprising systematic and routine observations, forecasts, services and products to meet users' needs.

Because even local patches of ocean are affected by the transport of heat and energy from far away by currents, waves, winds and tides, the predictability of local conditions is improved by the use of regional and global observations and forecasting models. Operational oceanography is being developed at the regional and global scale through GOOS, which is sponsored by three United Nations (UN) agencies including the Intergovernmental Oceanographic Commission (IOC) of the UN Educational, Scientific and Cultural Organisation, the World Meteorological Organisation and the UN Environment Programme along with the International Council for Science. GOOS is not solely operational, but includes work to convert research understanding into operational tools. It will enable nations to convert research results into useful products to meet societal needs.

A good example of GOOS operating at the basin-scale is the Pacific Ocean system for observing El Nino events. It integrates a network of buoys along the equator measuring surface winds and temperature, and subsurface temperature and salinity, sea-level measurements made on Pacific coasts and islands, subsurface temperature measurements made from cargo vessels on trade routes, measurements of current speed and direction made by drifting buoys, and measurements from satellites of the height and temperature of the sea surface. Numerical models use these data to forecast El Nino events for as much as 9–12 months ahead, helping countries to plan to reduce the impact of those events, which recur every four years or so, causing ooding in some places and droughts in other places, as well as damaging the fishing industry.

GOOS implementation will be incremental, following tests of the system through pilot projects, and should be complete by 2010–2020. Much of its success will depend on remote sensing from outer space, key requirements being the continuity of observations from one satellite mission to the next, as well as a sufficient number of similar sensors being own at the same time. These must be matched by a fully global network of data from within the body of the ocean. To provide comprehensive global coverage of upper ocean properties for the first time, GOOS scientists are planning the Argo Pilot Project, which will seed the ocean with 3000 profiling oats to collect profiles of temperature and salinity globally over a long time period. Added to satellite data from the ocean surface, these profiles will underpin models of ocean behavior and of climate.

Ultimately, the development of GOOS will depend on commitments to GOOS plans and funding from national governments.

Global Terrestrial Observing System (GTOS)

James R Gosz
University of New Mexico, Albuquerque, NM, USA

GTOS is a dedicated long-term, integrated, user-driven observing system for monitoring the extent, form and function of terrestrial ecosystems. This includes managed lands and the detection and measurement of alterations in them resulting from climate changes, changes in human activities such as land use and industrial development, and changes from other causes such as tectonic activities (http://www.fao.org/gtos). This is accomplished through the development of partnerships between data generators and users that meet both the short-term needs of national governments and the longer-term needs of the global research and policy community.

Within the last decade, with rapid evolution of environmental monitoring technologies and political acceptance of the importance of global environmental problems, a set of Global Observing Systems (Global Ocean Observing System, Global Climate Observing System, and GTOS), integrating *in situ* and remotely sensed data, have been established, each focusing on a major component of the biosphere. Each of these observing systems relies on existing global data centers and networks to provide a global picture of the state of the environment of the planet Earth. The observing systems are sponsored by a number of international organizations – the Food and Agriculture Organization (FAO), the International Council for Science, the United Nations Educational, Scientific and Cultural Organisation, the United Nations Environmental Programme and the World Meteorological Organization.

GTOS addresses the total terrestrial ecosystem complex, including coastal systems, and thus considers biological, chemical and physical properties as well as terrestrial, oceanic, hydrological and atmospheric processes.

GTOS has five key global change issues that are its priority action areas:

- land-use and land-cover change, including land degradation and the sustainability of managed ecosystems;
- water resources management;
- loss of biodiversity;
- climate change;
- pollution and toxicity.

The issues are along thematic lines because of a focus on generating products aimed at specific users and their needs. In general, the issues are concerned with anthropogenic impacts on terrestrial ecosystems. Thus, GTOS is helping to obtain better understanding of some of the basic issues confronting sustainable human development: food and food availability; freshwater supply and demand; changes in terrestrial ecosystems and their life support capacities; changing biological diversity; and exposure of people and other life forms to toxic and hazardous substances.

The emphasis throughout GTOS is on the production of high quality, reliable information and data obtained in a harmonized cost-effective manner. The products are intended to answer specific questions posed by users such as experts in modeling as well as senior policy makers who participate in negotiations related to the implementation of global environmental agreements.

The Global Terrestrial Observing Network seeks to link existing terrestrial observing networks in a hierarchical structure in order to improve data exchange and access to information. These networks are a combination of national networks and thematic ones (e.g., permafrost, hydrology). The Terrestrial Carbon Initiative is a global effort that coordinates a wide array of scientific partners to obtain a better understanding of the pools and uxes of terrestrial carbon that are a central part of the Framework Convention on Climate Change and the Kyoto Protocol.

A number of projects have been initiated that will utilize the information from sites/networks to develop global patterns of plant productivity from satellite imagery, a global terrestrial carbon cycle, and relationships between ecosystem processes and biodiversity. GTOS is working closely with the earth observation and *in situ* scientific communities, both for purposes of validation of regional and global products, as well as the generation of new data and information. The Integrated Global Observing Strategy Partners is an active forum where this coordination takes place.

A metadata base – Terrestrial Ecosystem Monitoring Sites – is available on the internet and allows access to information on the terrestrial observation and monitoring stations (http://www.fao.org/gtos/pages/tems.htm). A secretariat for GTOS is provided by FAO and located in Viale delle Terme di Caracalla, 1-00100 Rome, Italy.

Habitat

Habitat describes the physical and environmental conditions within which a given species or group is able to live (e.g., northern boreal forest, swamp, grassland, etc., although narrower definitions may be appropriate). The habitat of an organism should not be confused with its niche (*see* **Niche**, Volume 2) which describes not only the physical and environmental habitat but also the intimate physical and biological relationships of the species with all other kinds of organisms that also occupy its habitat, and which may limit its range within its habitat.

Halophyte/Halophobe

Halophytes are plants that can survive in or benefit from an environment with a high level of salt (i.e., sodium chloride), as in saline soils and seawater. *Halophobes* cannot endure such high levels of salt, which has serious deleterious effects on protoplasmal organization. The Greek root suggests that halophytes love salt, but the situation is not so simple. Halophytes are often merely salt-tolerant plants, and would grow better in a low salt environment. However, they do not compete well with halophobic species in low salt conditions, so they can survive and grow only in saline regions where halophobes cannot grow.

While salt (or rather, sodium) is an essential nutrient in very small quantities for most species of plants, some halophytes require and benefit from a high salt environment. Those plants that absorb and store large amounts of salt have a much lower osmotic potential in their cells (i.e., higher osmotic pressure) which enables them to absorb water readily from a saline environment, and also to withstand more extreme cold. Such plants include species that tolerate desert conditions. Other halophytes survive in salty conditions because they have avoidance mechanisms that prevent the uptake of salt or transport it rapidly to glands in the leaves where it is stored out of harm's way or excreted, so that it does not disrupt the physiological functions of the plant.

Halophytic species, either natural or produced by genetic manipulation, are most important in increasing agricultural production by making possible the cultivation of saline soils and the use of salt water for irrigation.

Holdridge Life Zone Classi cation

Many ecologists are interested in the effect that climate warming might have on shifting the positions of the world's vegetation zones. One approach is to seek an

empirical relation between the current positions of the main vegetation belts and the current mean values of the main climatic elements (temperature and precipitation) in these belts. A shift in temperature and/or precipitation in a climate-warmed Earth could then be used to estimate the shifts that might take place in the positions of the world's vegetation zones. The search for such relations is assisted by taking account of latitude, elevation above sea level and proximity to bodies of water, although these factors are reflected in the temperature and precipitation values themselves.

A number of climate/vegetation classification schemes have been proposed beginning at the time of Pythagoras in the 6th century BC (Sanderson, 1999) and continuing more recently through Köppen (1918), Holdridge (1947), Penman (1948), to Thornthwaite (1948). One of the more popular approaches with ecologists has been that of Holdridge (1947), perhaps because he was a botanist and he had actually undertaken field studies of the rich variety of vegetation types in a mountainous area (Haiti).

The Holdridge classification is in the form of quite a simple nomogram. The horizontal axis is scaled in millimeters of mean annual precipitation, ranging from less than 125 mm (desert) on the left to more than 8000 mm (rain forest) on the right. The vertical axis is scaled in terms of mean annual temperature, ranging from the tropics to the poles (on the left) and from sea level to alpine and mountain top (on the right). This leads to a differentiation of world vegetation into 100 types. Holdridge also sketched in some tentative lines of equal evaporation but he remarks that "No data are available to support his suggestions regarding evaporation".

The Holdridge nomogram has been used by ecologists (see, for example, Solomon and Leemans (1990) and Yates *et al.* (2000)) to provide a first estimate of how the world's vegetation belts would respond to climate warming simulations as obtained from the atmospheric general circulation models.

Holling, C S

(1930–)

Crawford (Buzz) Holling, ecologist, Canadian citizen, recipient of the Austrian Cross of Honour for Arts and Science, Fellow of the Royal Society of Canada, Director of the International Institute for Applied Systems Analysis (1981–1984), and occupant of the University of Florida's Arthur R. Marshall Jr Chair in Ecological Sciences (now retired), has furthered human understanding of, and approaches to policy development for, global environmental change (Jansson, 1996).

Shortly after his PhD (1957, University of British Columbia (UBC)), Holling (1963) worked with the Canadian Forest Service in Sault Ste. Marie developing Experimental Component Analysis. Through this approach, the variability of a complex population process is explained by dissecting the process into its components and investigating how those components occurring universally interact with the variation in subsidiary components. This approach was particularly effective in relating predator hunting success to prey density and resulted in the Holling functional response equations which are ubiquitously employed in ecological population models involving predation.

Later, while directing UBC's Institute of Resource Ecology, Holling (1973) published his concept of (ecological) resilience, a holistic system property which determines how much disruption a system can experience before losing its integrity. By contrast, stability is a property of an equilibrium condition which determines how quickly the system recovers after a small temporary disturbance. Holling (1987) reasoned that real ecosystems are sustained by renewal cycles encompassing multiple equilibria and that some instability in the form of temporal and spatial variability is needed to maintain the cycles and hence the system's resilience.

Holling cautioned that humans typically reduce variability (and inadvertently, ecosystem resilience) to sustain high yields. With his colleagues (Holling, 1978), he proposed an alternative approach, adaptive management, which uses monitoring and large scale experiments involving abrupt changes in human impacts to learn about, and thus develop policies respectful of, an ecosystem's renewal cycles.

Holling also published a more mechanistic underpinning for resilience (Holling, 1992). He demonstrated that the ecological world is lumpy: body sizes, patch geometries, and ecosystem dynamics occur at discrete time and space scales determined by a few key processes. It is the diversity of functional and species relationships within and across scales that maintain renewal cycles and thus generate ecosystem resilience.

Hutchinson, G Evelyn

(1903–1991)

Evelyn Hutchinson was renowned for his syntheses in the fields of ecology, biogeochemistry, and limnology. He was one of the pioneers in the introduction of quantitative methods in ecology, in an era which still relied primarily on verbal descriptions. Quantification of the regular changes in various ecosystems allowed him to discover the methane cycle. It also permitted a rigorous approach to the long-standing question of why there are so many species. The concept of the *niche* (*see* **Niche**, Volume 2) as a hyper-dimensional space unique to each species is largely associated with his name, and this led to the development of a host of studies on species interactions and distributions.

His major research falls into three distinct categories: studies of the biogeochemistry of atmospheric and aquatic systems; biogeography and systematics of invertebrates, particularly Hemiptera; chemical stratification, metabolism and morphology of lakes; and (in the early part of his life) studies of lakes at high altitudes. The first of these culminated in the creation of a distinct field of science, for which his monumental treatise on biogeochemistry still serves as the principal text, while his systematic and biogeographic work, both directly and through the activities of his students, added whole new families to the zoological nomenclature. His limnologic work was original in its conception of lakes as parts of interacting systems, and continues to excite research to the present day.

What made Hutchinson stand apart from his contemporaries, however, was not merely his own research, but his embodiment of the Renaissance Man. His encyclopedic knowledge and breadth, is nowhere better revealed than in the column, *Marginalia*, which was for many years a mainstay of the prestigious journal, *American Scientist* and in which he anticipated such major findings as the significance of bacterial transformation, or the importance of elements such as aluminum to the biogeochemistry of the earth. His other publications spanned subjects from art to psychiatry, although his single most important work is his treatise on biogeochemistry.

While the measure of a scientist's importance may be thought to be the number of articles published, to academicians what counts more is the number of prominent

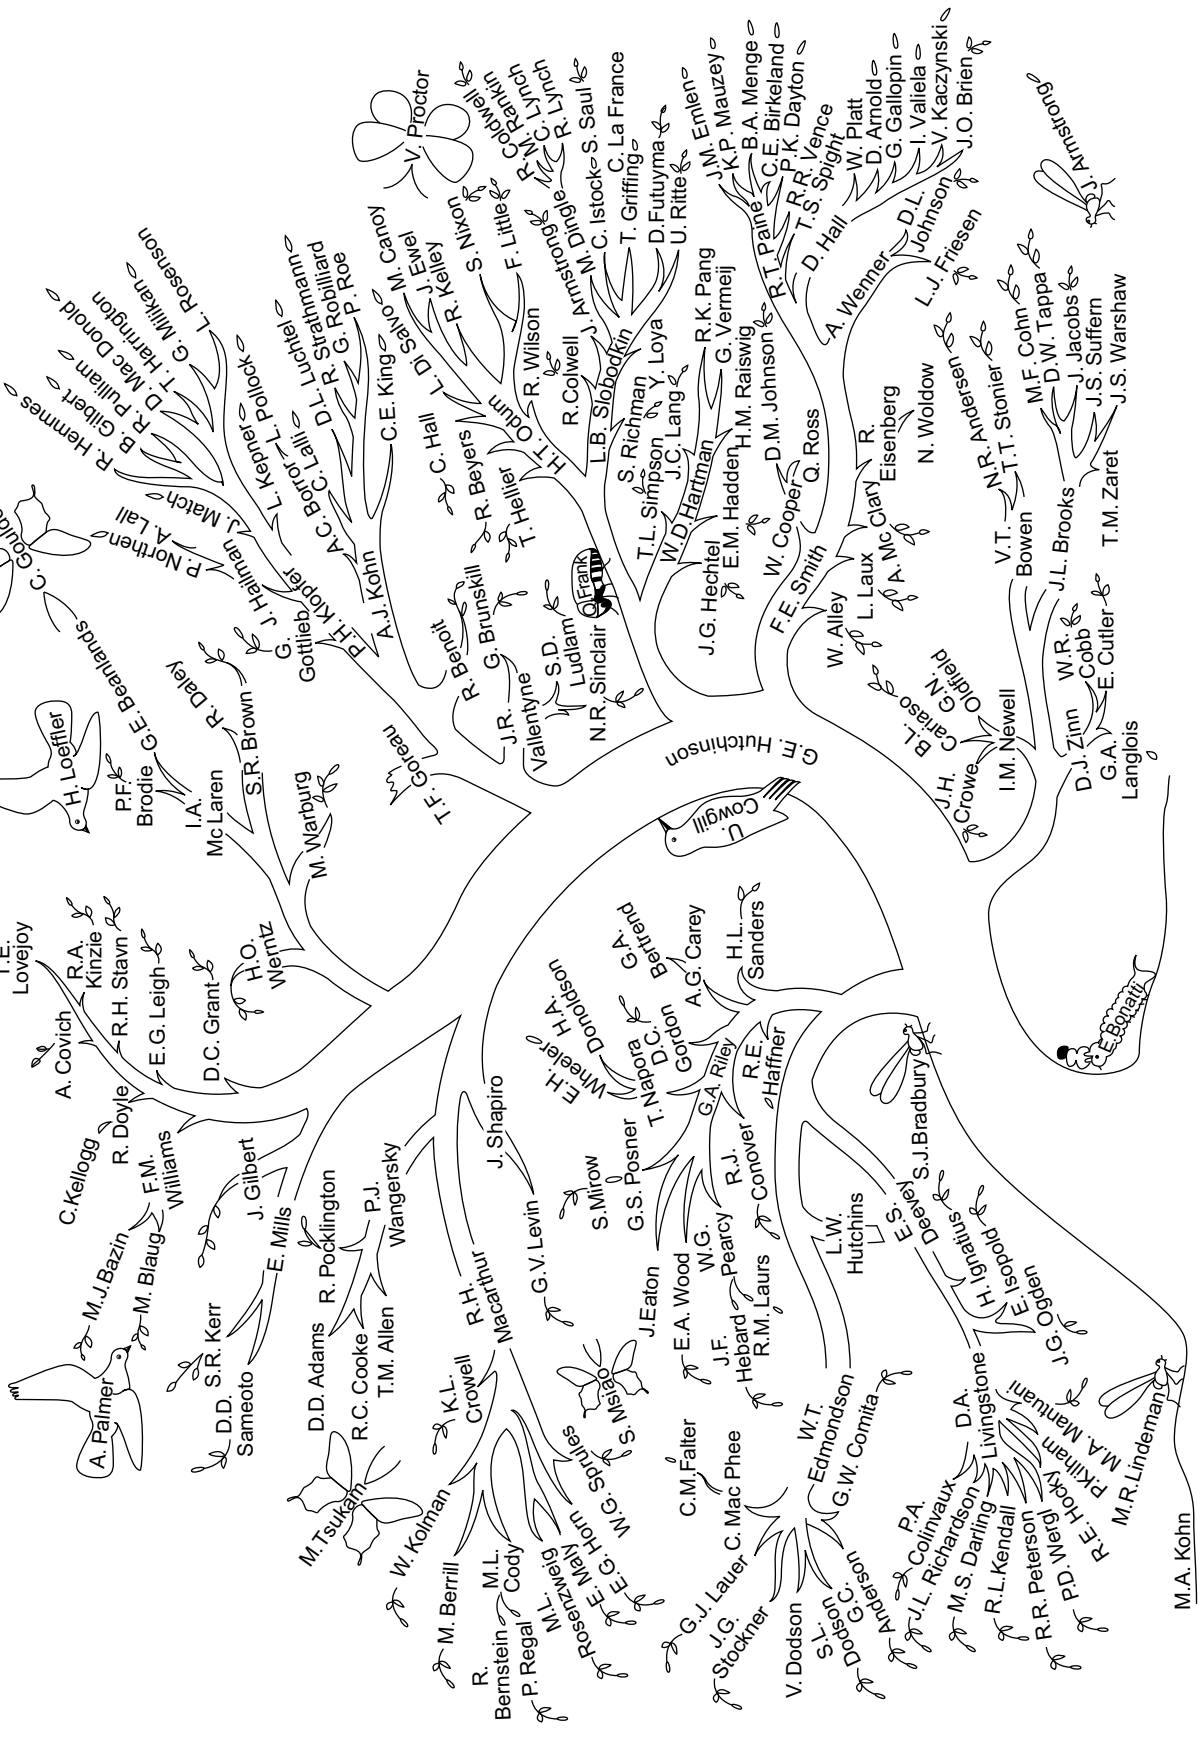

Figure 1 The GEH tree, original drawing by Yvette Edmondson. (Reproduced from Kohn (1971) by permission of the American Society of Limnology and Oceanography)

colleagues who trace their intellectual origins to that single source. In 1971, a celebratory issue of *Limnology and Oceanography* (vol. 16) in honor of Hutchinson appeared, with an analysis of his "phylogeny and biogeography" (Kohn, 197l). Already by that date, it was apparent that the ideas of a majority of contemporary ecologists could be traced to Hutchinson. This trend has continued at an accelerated pace. More significant is the prominence within ecology and behavioral ecology of these offspring: it is a fair estimate that over half of the tenured professors in these fields trace their intellectual origins to Hutchinson (Figure 1). They are responsible for major studies of pleistocene climatic changes in Africa, the history and dynamics of lakes in all parts of the globe, impressive systematic studies of molluscs and arthropods, current theories of biogeography, and a great variety of other studies ranging from animal behavior to zoological history.

Hutchinson's 1979 memoir, *The Kindly Fruits of the Earth*, describes much of his early life, which commenced with his birth in Cambridge, England, in 1903. The family were scientifically inclined, his father a mineralogist at Cambridge University. It was at Emmanuel College, Cambridge, that Hutchinson received his formal training. After a short stint at the zoological station in Naples, he took his first position in South Africa at the University of Witwatersrand. From there, through misadventure he came to the Osborne Zoology Labs at Yale University. Several versions of this tale are in circulation: the one current during my student years was that he blandly cabled Yale that he was available, but whatever the details, he was appointed to the faculty, eventually becoming Sterling Professor. He had no advanced degree at that time, other than a Masters, which Cambridge more or less automatically granted all its graduates after a 2- or 3-year interval on the sound theory that a Cambridge BA would certainly in that time have produced work worthy of an MA. In this case, the assumption was valid.

His first marriage to the renowned zoologist, Grace Evelyn Pickford, was contracted, both claimed, in order that Grace might engage in fieldwork, which was forbidden to unwed women. They were amicably divorced soon after, and remained colleagues and friends. Soon after, in 1933, he married Margaret Seal, and this more romantic relationship lasted until her death half a century later. He married once more, to Anne Twitty Goldsby, who assisted him until her death in 1990. He himself died soon after, in London, 17, May, 1991, aged 88.

Hydrology

John Roberts
Centre for Ecology and Hydrology, Wallingford, UK

The hydrological sciences deal with the study of the waters of the earth. In its broadest sense, hydrology includes the study of the occurrence, the movement, and the physical and chemical characteristics of water in all its forms within the hydrosphere of the earth. Hydrology is primarily concerned with water on or near the land surface, dealing with that part of the hydrological cycle from the arrival of water at the land surface as precipitation to its eventual loss from the land either by evaporation or transpiration back into the atmosphere or by flow at the surface or subsurface to the sea. There are very strong links between the land surface hydrology and studies of the water in the atmosphere and in the oceans. These are the subject of atmospheric sciences and oceanography, respectively.

The hydrologic cycle is the most fundamental aspect of hydrology. Water evaporates from the oceans and the land surface, is carried over the earth in atmospheric circulation as water vapor, precipitates again as rain or snow, is intercepted by trees and vegetation, provides runoff on the land surface, infiltrates into soils (from where it can be exploited by plants), recharges groundwater, discharges into streams, and ultimately, flows into the oceans, from which it will eventually evaporate again. This immense engine fuelled by solar energy, driven by gravity, proceeds endlessly with or without the activity of humans. Through evaporation and precipitation, water transfers much of the heat energy received by the earth from the tropics to the poles. Annual availability of water on land is the single

most important factor that determines the growth of plants (Kramer, 1982).

GLOBAL HYDROLOGY

The amounts of water in the global hydrologic cycle are so large that it is normal to quantify the compartments and transfers between them in units of km^3 ($1\,km^3 = 10^{12}$ liters $= 10^{15}$ g; see Figure 1). Not surprisingly, the oceans form the dominant component in the global water cycle. Seawater composes 97% of all the water at the surface of the earth. The next biggest store is the water in the polar ice caps and in glaciers. Soils contain 121 800 km^3 of water, of which about 58 100 km^3 is in the root zone of plants (Webb *et al.*, 1993). The poorest estimate of one of the components in the global water cycle is that of the groundwater, but without the influence of human activities, that water would interact little with the biosphere. In relation to other parts of the hydrological cycle, the amount of water in the atmosphere is very small, equivalent to about 30 mm if it were spread evenly over the globe, but enormous quantities of water move through the atmosphere each year (see Table 1).

Evaporation removes about 425 000 km^3 of water from the world's oceans each year. Thus, the mean residence time of ocean water with respect to the atmosphere is about 3100 years. Only about 385 000 $km^3\,year^{-1}$ of the water returns to the oceans as rainfall; the rest contributes to precipitation on land which amounts to 111 000 $km^3\,year^{-1}$. Plant transpiration and evaporation from soils return 71 000 $km^3\,year^{-1}$ to the atmosphere. Thus, with respect to precipitation inputs or evapotranspiration losses, the mean residence time of soil water is about one year. Owing to the excess of precipitation over evapotranspiration on land, about 40 000 $km^3\,year^{-1}$ becomes runoff.

Global averages obscure large regional differences in the water cycle. Evaporation from the oceans is not uniform, but ranges from $4\,mm\,day^{-1}$ in tropical latitudes to $<1\,mm\,day^{-1}$ at the poles (Mitchell, 1983). Although much precipitation falls at tropical latitudes, an excess of evaporation over precipitation in the tropics provides a net regional flux of water vapor to the atmosphere. Net evaporative loss accounts for the high salinity in tropical oceans, and the movement of water vapor in the atmosphere carries latent heat to polar regions (Vonder Haar and Oort, 1973).

On land, the relative balance of precipitation and evaporation differs strongly between regions. In tropical rainforests, precipitation may greatly exceed evapotranspiration. Shuttleworth (1988) calculates that half of the rainfall becomes runoff in the forested region of the Amazon basin. In desert regions, precipitation and evapotranspiration are more or less equal with limited recharge of groundwater.

The sources of water contributing to precipitation also differ greatly in different regions of the Earth. Nearly all the rainfall over the oceans is derived from the oceans. On land in maritime and monsoonal regions, much of the rainfall is also derived from evaporation from the sea. In contrast, up to 50% of the water falling in the Amazon Basin is derived from evaporation within the basin itself, the remainder coming from long-distance atmospheric transport (Salati and Vose, 1984; Eltahir and Bras, 1994).

Most recent estimates assume global river flow is about 40 000 km^3 year^{-1} (Schlesinger, 1997) but the distribution of flow among rivers is highly skewed. The 50 largest rivers carry about 43% of the total river flow; therefore calculations of global transport of dissolved and suspended materials can be estimated from data on a few large rivers. Because of the positions of the continents and their surface topography relative to global climatic patterns, there are large differences regionally in runoff to the sea and associated transport of materials. For example, there is a large contrast between the runoff from North America ($\sim$320 mm year^{-1}) compared to Australia; with a considerable area of dry regions and internal drainage, the annual runoff from Australia is $\sim$40 mm year^{-1} (Tamrazyn, 1989). In the Northern Hemisphere, 77% of the water flow to the oceans comes from rivers that have been regulated by dams or manipulated in some way by human agency. This will have a major impact on the transport of sediment to the oceans. For example, Humborg *et al.* (1997) showed that damming of the River Danube, and subsequent reduction of silicate flow in to the Black Sea, has had an impact on the composition of phytoplankton species in the sea. The shift has been from siliceous diatoms to non-siliceous coccolithophores and flagellates. It is calculated (Postel *et al.*, 1996) that over 50% of the volume of rivers is now used by human activities, particularly irrigated agriculture. Although there is interchange of waters between different oceans, differences in salinity do occur. Despite the considerable input of fresh water from the Amazon basin, the greater evaporation from the Atlantic Ocean than fresh water input means that it is more saline than other oceans.

RIVER BASIN HYDROLOGY

The drainage basin (the term *drainage basin* is synonymous with *catchment* or *watershed* which is commonly used in the US) provides the natural unit for the generation of river flow. As such, it is widely recognized also as the logical unit for water management and for the scientific study of hydrological processes and responses. Within a catchment, runoff is determined by the overall water balance of the catchment:

$$\text{Runoff} = \text{Precipitation} - \text{Evaporation} \pm \Delta\text{Storage}$$

where evaporation includes rainfall intercepted by vegetation canopies and evaporated back into the atmosphere, evaporation from bare soil surfaces and transpiration from plants. ΔStorage is the change in the amount of water stored in soils or rocks. Traditionally, water balances are calculated over 12 month periods but evaluations over shorter periods are equally valuable, but constrained by the resolution of the different components of the water balance especially over short time periods. The water balance may also be calculated for a fraction of the catchment or for a plot.

Precipitation (rain, snow, hail and dew) is an input to the catchment, hillside or plot, but traditional methods only make point measurements. Apart from the problems of acquiring representative values because of the spatial variation in precipitation, particularly in hilly areas, there are technical problems associated with precipitation measurement, which include air turbulence around the rain gauge, evaporation prior to measurement and wetting errors. There are additional problems in estimating snow deposition in

a representative way. A full discussion of the pitfalls associated with rainfall measurement is given by Jones (1997).

In some situations, plant, rock or soil surfaces can collect water directly from the air, bypassing the normal precipitation process and in some cases this may be a very important contribution of water to the soil and subsequently the stream or ground water. There are two processes involved: impaction of cloud or mist droplets on obstructing surfaces, tree crowns are particularly effective in this respect; and radiational cooling of surfaces at night, which might cause condensation of water vapor as dew. The best examples of cloud water deposition are to be found in the cloud forests of tropical mountains where there is substantial evidence that up to nearly half of the stream flow might be a result of trees scavenging water from the clouds.

Evaporation from the land surface involves three main processes: (i) evaporation of rainfall (or snow) intercepted by the vegetation canopies; (ii) transpiration, water taken up from the soil by plants and lost as vapor from pores (the stomata) in their leaves; and (iii) evaporation from the soil surface.

Leaves and branches intercept precipitation before it reaches the ground, and a certain amount can be retained on the canopy from where it is evaporated. This evaporation process, leading to the rainfall interception loss, is most effective in tall, rough canopies, well ventilated by wind, e.g., woodlands and forests. In extreme cases, the rainfall interception losses from forests can reach up to 40% of gross rainfall. An important feature of vegetation predominantly composed of trees and shrubs is that rainfall reaching the ground as throughfall can, in some cases, be preferentially concentrated close to the trunk because of *stemflow*. This is rainfall that is caught on the canopy and directed downwards and inwards towards the trunk by the funneling action of the branches.

Transpiration is controlled by many variables because it depends upon the many dynamic aspects of plant activity. (1) Different plant species can transpire very different amounts depending on the amount of foliage and the stomatal conductance, the sizes and changes of opening of pores in the leaf surfaces through which water vapor passes but which plants can close to control water loss; (2) seasonal changes include variations in radiation, temperature and humidity that influence evaporative demand, as well as phenological changes in the vegetation that control the amount of foliage cover; (3) time of day changes the radiation balance, photosynthesis and growth rates and stomatal activity; (4) meteorological factors such as light levels, wind and humidity deficit can control stomatal opening and influence transpiration; (5) the amount and distribution of water in soil influences its availability for plant roots which affects plant transpiration.

Soil evaporation occurs most readily when the soil surface has been recently wetted by rain and sufficient energy reaches the soil surface to sustain evaporation. Therefore, the highest amounts of soil evaporation will be observed in situations where vegetation cover is absent or very sparse and rainfall events frequently wet the soil surface. Evaporation decreases sharply after rainfall as the surface water content falls, until, with a dry surface, it becomes zero. Without plant roots, the upward movement of water to the soil surface from the wet layers beneath is controlled by capillarity and will, therefore, tend to differ with the texture of the soil. In fine-textured soils, with small pores between the soil particles, capillary movement may only occur over a meter or so but this distance will be much less, $\sim$ a few centimeters, in coarse textured soils.

When water from a rainstorm or melting snow reaches the ground, some or all of it will infiltrate into the soil. The rate of infiltration depends on the intensity of the input, the initial moisture content of the surface layers of the soil and the hydraulic characteristics of the soil. Infiltration will be retarded by compaction of the soil layers by any means and enhanced by the presence of small or large pores such as worm burrows or channels previously occupied by roots. Water in excess of the infiltration capacity of the soil will flow overland as surface runoff once the minor undulations in the soil surface (the depression storage) have been filled. Apart from built and other impermeable surfaces, such runoff occurs most frequently on bare soils and in areas subject to high rainfall intensities. In many environments, rainfall intensities rarely exceed the infiltration capacities of vegetated soil surfaces. The occurrence of surface runoff is then more likely to occur when rain falls on soil that is completely saturated.

The soil provides a major reservoir for water within a catchment. Soil moisture levels increase when there is sufficient rainfall to exceed losses by evaporation or drainage to streams or groundwater. Soils are depleted of water in seasons when evaporation is high and perhaps rainfall is also low or absent. Levels of soil moisture are important for plant and crop growth, soil erosion, and stability of slopes. The rate at which water flows through the soil is dependent on the gradient of hydraulic potential and the physical properties of the soil, expressed in terms of hydraulic conductivity, which varies with soil moisture in a non-linear way.

Runoff is the downward movement of surface water under gravity, in channels ranging in size from small rills to large rivers. Flow in channels can be *ephemeral*, flowing intermittently after periods of rainfall or snow melt (*see also* **Wadi**, Volume 3), while some watercourses are *perennial*, i.e., flowing all the time. Surface waters provide the majority of the water utilized by humans. Stream discharge is normally expressed in units of volume per unit time (e.g.,

cubic meters per second). There are a number of techniques for measuring stream discharge. Measurements of velocities using current meters or ultrasonic devices can be multiplied by the cross-sectional area of the stream channel. Weirs of different types are frequently used to measure discharge. These are constructed so as to give a unique relationship between water level and stream discharge. Water levels can then be measured continuously, usually with a float recorder to construct a record of discharge over time – the *stream hydrograph*. Analysis of the response of the stream hydrograph to rainfall can reveal a great deal about the nature and responses of the catchment and its hydrological functioning.

Many of the components of the water balance can be quantified from measurements made at a wide variety of scales, ranging, for example, from measurements of transpiration from individual plant leaves or changes in moisture content at single points in the soil to measurements made at much larger scales, such as the whole catchment. Details of measurement techniques relevant to different components of the water balance and for different scales will be found in texts such as Maidment (1992) and American Society of Civil Engineers (1996).

Measuring evaporation on a routine basis is not yet a practicable option other than for detailed research studies. For routine operational purposes, e.g., for scheduling irrigation, evaporation is usually estimated by formulae that utilize routinely measured climatic variables. Methods based on only a few variables, e.g., temperature alone are usually highly empirical. These formulae typically make no distinction between transpiration and interception losses from the vegetation. Formulae containing the most realistic physical and physiological descriptions of the evaporation processes require a large amount of information about the environment and the vegetation. Therefore, these formulae are unlikely to be used in practical operational applications, e.g., irrigation scheduling.

Modeling of evaporation losses from vegetation is only one aspect of the physical modeling of the hydrological behavior of a catchment. Comprehensive modeling of all aspects of the hydrological functioning of a catchment of typical complexity is an ideal that is never likely to be achieved. A major problem is to incorporate all the variation due to variations in slope, aspect, vegetation, soils and geology. Not only will it be unlikely that all key descriptions of these elements of the catchment will be available but also that some processes may still be inadequately understood. A description of some of the approaches to the hydrological modeling of rainfall-runoff relationships of catchments is given by Jones (1997). One of the most commonly used approaches is a statistical one, which relates rainfall to runoff, based on data records available over a sufficiently long period. This approach plays a key role in the forecasting of floods, which represent an important form of extreme event in rainfall–runoff relationships.

Extremes in hydrology take many forms, from extremes of magnitude to extremes of duration or both. By definition, an extreme event must be rare and unusual, but there is no sudden break or gap between extreme events and normal ones, and all hydrological events must be viewed as part of a continuous series. The fact that floods and droughts are different from common events by degree rather than of nature is of considerable importance for understanding and predicting their occurrence. Gumbel's (1941) extreme value analysis uses the concept that extreme events can be estimated from observing the magnitude-frequency distribution of more ordinary and not so severe events.

In the past, water planning and management relied on the assumption that future climatic conditions would be well represented by past conditions, and all water supply systems were designed on this basis. The design of dams and reservoirs are based on existing flows in rivers, and the size and frequency of expected floods and droughts. Reservoirs are operated for a variety of purposes using the past hydrologic record to guide decisions. Irrigation systems are designed using historical information on climatic conditions, water availability and soil water requirements. Because of climate warming expected in the next 100 years, however, this reliance on the past record may lead to faulty and possibly dangerous or expensive decisions. Because of those threats, it would be prudent to try both to understand what will be the consequences of climatic change for water resources and to initiate plans to accommodate those changes.

LAND USE AND WATER RESOURCES

Important differences in evaporation from different vegetation covers affect the runoff (stream flow) from catchment areas. Both the transpiration and interception components of evaporation contribute to differences in evaporation. Deep-rooted vegetation, especially forests, can sustain transpiration during long dry periods during which deeper soil water reserves are available to forests but not to shallow-rooted vegetation such as cereals and grass. There will also be greater interception losses from forests because their taller rougher canopies facilitate drying during and after rainstorms. Removal of forests can increase the amount of stream flow, but also there is the prospect that the timing and intensity of peak flows may be altered also. Forest logging often involves road construction and use of heavy machinery that can compact soils stimulating more rapid runoff. There will also be major implications for water quality.

Apart from the now well-documented cases of cloud forests producing rain, the notion that forests might cause

an increase in rainfall needs to be treated cautiously. General circulation models that incorporate substantial land cover changes over considerable areas, e.g., removal of the Amazon forest or major reductions in tree cover in the Sahel, have shown links to rainfall. However, at much smaller scales, the evidence that changes in land cover, such as afforestation, have an effect on rainfall is virtually non-existent. Nevertheless, there is evidence from studies in St Louis, US that the development of extensive urbanization and the heat island effect can be related to increased rainfall (Chagnon *et al.*, 1991).

WATER QUALITY

Water quality is a term covering a wide range of aspects of water and depends on the use to which the water will be put. Common aspects of water quality are physical characteristics such as color, temperature, taste and smell, as well as chemical characteristics such as acidity, hardness and the concentration of various other chemicals such as nitrates, sulfates, phosphates and dissolved oxygen and man-made pollutants including pesticides and herbicides. Deteriorating water quality is a threat to water resources and wildlife in many parts of the world. Much of the problem has been generated by industrialization and urbanization, from atmospheric and water pollution. More recently, agriculture has become a major pollutant source. Attempts to control agricultural sources require basin-wide attention. Particularly, there is concern about the quantities of nitrogen being deposited into the environment as fertilizer and as gases from industry and motor vehicles. Some of the consequences of overfertilization with nitrogen are (Munn *et al.*, 1999):

1. eutrophication of inland lakes and rivers, caused by run-off of nitrogen compounds;
2. development of coastal algal blooms;
3. creation of mineral deficiencies in forest soils caused by leaching;
4. loss of biodiversity in prairie grasslands.

Although some early agricultural activities, such as forest clearance, may have changed water quality, the major sources of pollution in the early industrial era were sewage and chemical pollution especially in urban areas, i.e., point source pollution. However, since World War II there has been a rapid rise in non-point sources of pollution, which enters groundwater and stream/river networks over a broad area.

An issue with the assessment of water quality is the restricted value of simple chemical analyses. In-stream devices are now available that can provide frequent measurements of key parameters of water quality. These might provide valuable information for the purposes of evaluating drinking water quality, for example, but have drawbacks in the evaluation of a suitable habitat for diverse stream biota. Measurements of the chemical properties of stream water provide no guidance towards defining the suitability of a habitat for animals and plants. Biological indicators are being developed to assess the quality of running waters; key indicators are the macroinvertebrates that inhabit streams. Their diversity and numbers in a particular stream are compared with the population in pristine waters in the same region.

IGBP (International Geosphere-Biosphere Programme)

This Programme, founded in 1986 under the auspices of the International Council for Science (ICSU), has as its objective:

> to describe and understand the interactive physical, chemical and biological processes that regulate the total Earth system, the unique environment that it provides for life, the changes that are occurring in this system, and the manner in which they are influenced by human actions.

Priority is placed on those areas that deal with key interactions and significant changes on time scales of decades to centuries, that most affect the biosphere, that are most susceptible to human perturbation, and which will most likely lead to a practical predictive capacity.

More than 70 countries have national IGBP committees, which facilitate the national coordination of research projects that are consistent with the IGBP research plan. These bodies are important in garnering national funding both for IGBP-related research and the international coordinating function of the program.

Since its inception, the IGBP has evolved a set of research projects and framework activities on data, modeling and regional research facilities. Research emphasis has been focused on six questions, and from these a set of research projects has been initiated. These include the International Global Atmospheric Chemistry Project (IGAC), Global Change and Terrestrial Ecosystems (GCTE), Land-Use/Land Cover Change (LUCC), Biospheric Aspects of the Hydrological Cycle (BAHC), Land–Ocean Interactions in the Coastal Zone (LOICZ), Joint Ocean Flux Study (JGOFS), Global Ocean Ecosystem Dynamics (GLOBEC), and Past Global Changes (PAGES). Two of these projects are overseen jointly with other international bodies. JGOFS planning and administration is shared with ICSU's Scientific Committee on Oceanic Research. Similarly, LUCC planning and administration is shared with the International Human Dimensions Programme (IHDP) on Global Environmental Change.

The crosscutting framework activities of IGBP include a Data and Information System (DIS), a task force on Global Analysis, Interpretation and Modeling (GAIM), and a Global System for Analysis, Research, and Training (START). This last activity addresses regional research initiatives and needs, and is co-sponsored with the IHDP and the World Climate Research Programme.

A scientific committee governs the planning and implementation of IGBP. Members include the chairs of each of the projects and framework activities and additional members appointed by ICSU. Every third year a scientific advisory council is convened to review the progress of the IGBP with representatives of national committees and various related ICSU bodies.

Since its inception, the Royal Swedish Academy of Sciences has hosted the secretariat for the IGBP, with generous

support from both the Academy and the government of Sweden. Similarly, the coordinating offices for the various projects are hosted by individual nations.

Science and implementation plans for IGBP projects are published in an IGBP Report Series. In addition, the secretariat publishes a quarterly newsletter. While most of the research products of IGBP projects appear regularly in relevant scientific journals, an IGBP Book Series covers advances in synthesis, some of which arise from IGBP scientific symposia.

Further information on the IGBP can be obtained from: IGBP Secretariat, The Royal Swedish Academy of Sciences, Lilla Frescativägen 4, Box 50005, S-104 05 Stockholm Sweden, Telephone (+46-8) 16 64 48, Fax 16 64 05, http//www.igbp.kva.se.

JAMES McCARTHY *USA*

IGBP-DIS (International Geosphere-Biosphere Program Data and Information System)

The role of the IGBP–DIS project is to assist IGBP core projects in the development of their individual data system plans; help provide an overall data system plan for IGBP; carry out activities leading directly to the generation of data sets; ensure the development of effective data management systems and act, where appropriate, to ensure the meeting of the data and information needs of IGBP through international and national organizations and agencies.

The need for a crosscutting, data-focused activity within IGBP was recognized during the programme's early planning phase. The subsequent development and implementation of IGBP–DIS has been achieved through workshops, scientific collaborations, and other activities of the IGBP–DIS standing committee and its office. Most workshops have been held jointly with one or more IGBP core projects, or with the GAIM task force.

The main aim of IGBP–DIS is to improve the supply, management and use of the data and information that are needed to attain IGBP's scientific goals.

Component objectives are to:

- carry out activities directly leading to the generation of relevant data sets and other data system components for IGBP;
- ensure the development of effective data and information management systems for IGBP, including the preparation and implementation of a programme-wide data system plan, and assisting IGBP core projects in the development of their individual data system plans;
- assist in meeting the data and information needs of IGBP through partnerships and collaborations with other organizations and agencies.

A suite of activities and tasks has been defined to achieve these objectives. An IGBP-wide data system plan is currently being developed that will deal with data management and exchange policies; partnerships and collaborations; and interoperability and standards.

Further information may be obtained from IGBP–DIS Office, CNRM – 42 Av G Coriolis, 31057 Toulouse cedex, France, Tel.: +(33) 5 61 07 85 81, Fax: +(33) 5 61 07 85 89.

JOHN S PERRY *USA*

IGBP Terrestrial Transects

Will Steffen

IGBP Secretariat Royal Swedish Academy of Sciences, Stockholm, Sweden

Global change research has prompted the development of new scientific research tools and the modification of existing ones. Ecologists have long used gradients of various types and scales to understand the influence of underlying environment factors in key system processes and characteristics. Global change research has adapted this approach to address some key questions about the interaction of the Earth's land surface with global change phenomena. The result has been the formation of a set of continental scale transect studies, the International Geosphere–Biosphere Program (IGBP) Terrestrial Transects (Koch, 1995b). The original aim of the transects was to determine how underlying 'global change gradients'–changes in temperature, precipitation and land use – affect terrestrial biogeochemical cycling, and what will be the consequent feedbacks to the Earth system. The original concept has been expanding beyond biogeochemistry to including other important global processes, such as the hydrological cycle, especially water and energy exchange between the land surface and the atmosphere.

DESCRIPTION

The IGBP Terrestrial Transects are best conceptualized when a linear or quasi-linear variation in an underlying environmental variable provides the organizing principle for the study. For example, the moisture gradient in northern Australia from the coast to the interior decreases virtually linearly for 1500 km, providing an ideal gradient on which to base a transect study. The temperature gradient from north to south in the Arctic-boreal region provides another such gradient. In addition to these biophysical gradients, some of the transects are organized around land use change 'intensity' as a gradient. These transects are more difficult to visualize in physical space, as they consist of a network of sites scattered through a biome (e.g., humid tropical forests) and organized into a gradient in an analytical sense rather than a physical one.

In scale, the transects are normally of order 1000–2000 km in length and a few hundred kilometres wide. This is important to facilitate the scale transitions discussed below. Also, the transects should be long enough to encompass a major ecotone between biomes – e.g., the tundra-boreal forest ecotone or the temperate forest – grassland ecotone – as well as the biomes on either side.

The generic transect design is shown in Figure 1. The backbone of the transect infrastructure would be a small number (normally 3–5) of field research stations where intensive observational or experimental work would be carried out. For example, eddy correlation observations of water, energy and carbon exchange would be established at such stations. In addition, a number of less intensive sampling sites would be established to explore sub-gradients, such as soil type or land use change intensity (for transects where a biophysical gradient is the predominant one) or to explore various stages in the successional dynamics of the ecosystem.

RATIONALE

Global Change Gradients

The fundamental rationale for the IGBP Terrestrial Transects is that key ecosystem properties and processes are controlled by environmental factors, which will change

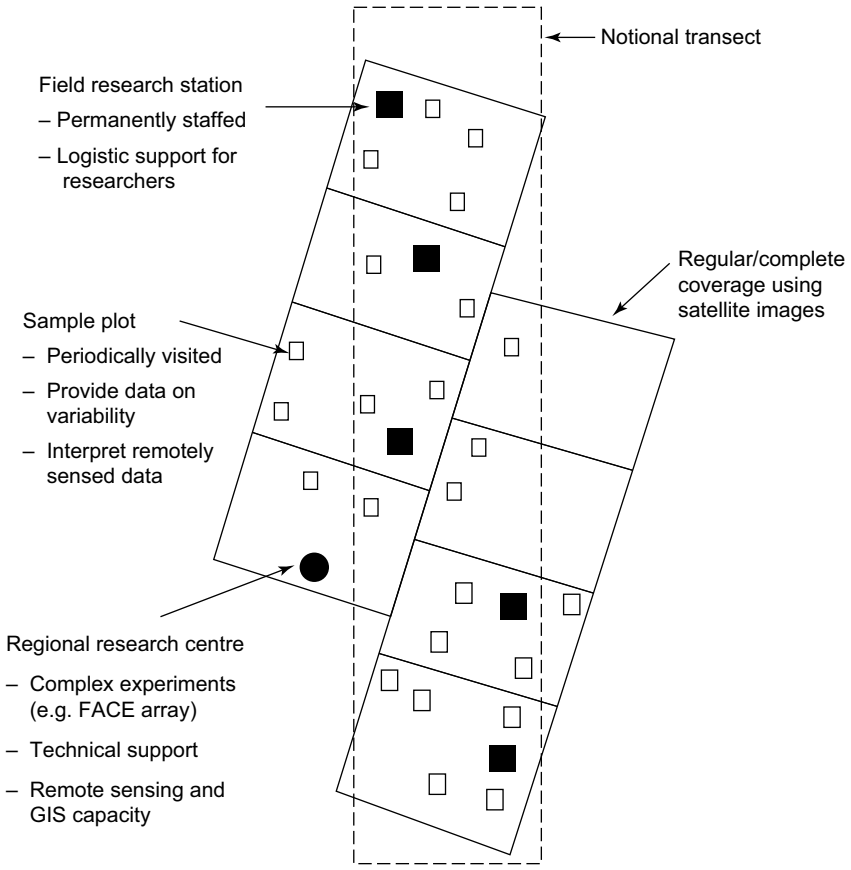

Figure 1 Idealized design of an IGBP Terrestrial Transect. The notional transect is about 1000 km long and a few hundred km wide (Koch *et al.*, 1995a, The IGBP Terrestrial Transects: Science Plan. IGBP Report No. 36. IGBP Secretariat: Stockholm, Sweden, 61)

under global change, and understanding how ecosystems might respond to such changes is best studied using a gradient approach. Examples of key ecosystem properties which are correlated to environmental gradients are: (1) leaf-area index and above – ground biomass related to precipitation in semi-arid savannas; (2) maximum rooting depth and soil moisture in grasslands. Examples of gradient-driven processes include (3) net primary production and temperature in the high latitudes; (4) flow of water through a catchment (gravity-driven); (5) movement of cattle and people along a moisture gradient in West Africa (Menaut *et al.*, 1995).

Thresholds along a Continuum

Transects are probably the only feasible approach, apart from modeling, that can identify thresholds along a continuum. Simple networks cannot do this. The threshold concept is particularly important for global change research, in which an increasingly important paradigm is that of a stress on a system reaching a critical threshold, causing a change of state of the system, rather than a simple cause-and-effect (or dose-response) approach. Examples of thresholds in global change ecological research include (a) an abrupt change in leaf area index along the Northern Australia Tropical Transect (NATT) in response to a smooth gradient in precipitation, and (b) an abrupt change from nutrient – rich to nutrient – poor tree leaves on savanna trees in response to a smooth precipitation gradient on the Kalahari Transect in southern Africa (Steffen *et al.*, 1999).

Facilitation of Interdisciplinary Research

Although not one of the original rationales for the establishment of the IGBP Terrestrial Transects, the enhancement of collaboration across disciplines has grown in importance. For example, the emission of trace gases from soils (atmospheric chemistry community), the exchange of water and energy between the land surface, both soil and vegetation, and the atmosphere (climatologists and hydrologists), the uptake and metabolism of carbon dioxide (CO_2), water and soil nutrients (ecosystem physiologists), and changes to the structure and composition of ecosystems (ecosystem dynamics) are all interlocking and closely related processes. In addition, human activities, especially land use and land cover change, are increasingly affecting these basic ecological processes. Encouraging the co-location of these studies at the same sites along the same gradient is a good way to facilitate the difficult process of building truly interdisciplinary research.

Scale Transitions

Global change research is often confronted with the challenge of scaling up results and understanding from process studies at small scales up to the global. This is particularly true for terrestrial ecosystems, where much process – level work is done on small, homogeneous patches of an ecosystem. The key question is: when can such process–level understanding be scaled up directly to the globe, and when must processes which emerge at intervening scales (e.g., the landscape scale) be taken into account in the extrapolation process. The transects are designed so that the transition from patch to landscape to region can be made taking appropriate account of scale-emergent properties and processes. In this regard, remote sensing plays a key role in the scale-up process, and all of the transects employ remote sensing techniques to a greater or lesser extent in the scale-up process.

DESCRIPTION OF INDIVIDUAL TRANSECTS

The locations of the current suite of IGBP Terrestrial Transects are shown in Figure 2. More details of the transects can be found in Steffen *et al.* (1999) and Walker *et al.* (1999) and references therein.

High Latitude

The high latitude transects are based on a north–south temperature gradient and encompass the tundra and boreal forest biomes and the transition between them. The long-term carbon dynamics of these systems is a crucial research and policy question.

Alaska

This interdisciplinary study builds on the work of the United States Arctic System Science Study, and is focused largely on two long-term ecological research stations north of the Brooks Range. The work includes studies on ecosystem physiology, hydrology, trace gas emissions and biodiversity. A Geographic Information System (GIS) database for the region is well established and many types of modeling tools are employed.

Canada

The Boreal–Forest Transect Case Study (BFTCS) extends along a southwest to northeast axis from the wheat belt of the Canadian prairies through extensive stands of boreal forest to a small area of tundra along Hudson Bay. Work in BFTCS concentrates on the long-term changes to the structure and carbon dynamics of the forests due to logging and natural disturbances – fire and insect outbreaks. Work along the BFTCS and across Canada as a whole has demonstrated the important influence of disturbance in long-term carbon dynamics (*see* **Boreal Ecosystem–Atmosphere Study (BOREAS)**, Volume 2) (Kurz *et al.*, 1995).

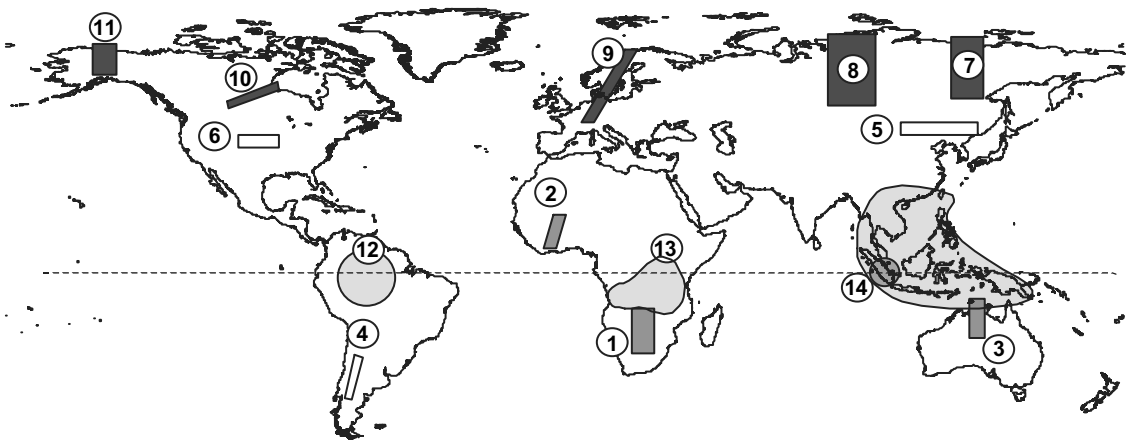

Figure 2 Locations of the existing IGBP Terrestrial Transects and those in the advanced planning phase (from Steffen *et al.*, 1999)

Siberia

Two transects have been established as part of the broader IGBP Northern Eurasia Study (Steffen and Shvidenko, 1996). The Central Siberian transect basically follows the Yenesei River from the Arctic Ocean south to near Krasnoyarsk. The river forms a boundary between the low-lying forests and wetlands to the west, dominated by pine and spruce species, and the higher, colder, drier forests to the east, dominated by larch. Considerable work, ranging from ongoing flux measurement stations to tree-ring studies, has already been established along the transect. The Far East Siberian Transect follows the Lena River basin from Tiksi in the north through Yakutsk and then extends south to the Khabarovsk region. Larch is the dominant tree species of the extensive forests along much of this transect, and the interplay of fire and permafrost in controlling the dynamics of these forests is a key research question.

Scandinavia

A recent initiative called DART (Dynamics of the Arctic Treeline), supported by the European Union (EU), could form the backbone of a Scandinavian high latitude transect. The present research design is focused on ecosystem dynamics but physiological studies co-located at the DART sites could enhance the value of this developing transect (B Huntley, personal communication). There has also been some planning under the SCANTRAN (Scandinavian Transect) initiative (OW Heal, personal communication).

Mid-latitude

These transects cover the temperate forest and grassland biomes and are heavily dominated by land use change. Two of the world's major agricultural areas – the USA grain belt in the middle of the continent and the north China agricultural belt – are encompassed in these transects. The underlying biophysical gradient is moisture.

NECT (North East China Transect)

This transect runs along an east–west axis from the temperate conifer – broadleaf mixed forests along the east coast, through meadow steppes and agricultural land in the middle, to steppes and desert grasslands in the west. The transect has recently been extended into Mongolia. The major issue along the NECT is land use change. Food demand is growing strongly in north China, and a combination of intensification and extensification of agriculture is likely. Previous extension of agriculture has led to large-scale land degradation in some areas of the transect. Avoiding such problems in future is a high priority.

USA Prairies

As for NECT, the USA Prairies transect is an east–west gradient dominated by land use change. In fact, the temperate forests which potentially occur at the eastern end of the transect (the states of Illinois and Indiana) have been almost completely cleared and converted to agriculture. A

large amount of research has already been carried out on this transect in various studies, but a co-ordinated effort is required to assess the relevant data and adapt it to the transect approach.

Argentina

This transect follows the moisture gradient through the western areas of Argentina. An interesting ecological question is why the entire transect is covered by grassland, whereas precipitation is sufficient on the northern end of the transect to support forest. Much of the work to date on the transect has focused on soil structure and dynamics, including estimates of rooting depth.

Savannas

Like the mid-latitude transects, these are based on moisture gradients. However, the evaporative demand is much higher in these areas, and the ecosystems are dominated by savannas, grading into dry or humid tropical forests at one end and into desert at the other. The contrast among the three transects described below in terms of the importance of land use change is striking, and offers an excellent opportunity to use the suite of transects in a comparative way to quantify this important biogeochemistry factor.

NATT (Northern Australia Tropical Transect)

The NATT extends from the dry tropical forests around Darwin (1500 mm annual precipitation) to the arid woodlands and desert near Alice Springs (300 mm annual precipitation). Much of the region is lightly grazed, population density is low, and tourism is a growing industry. Much of the vegetation is close to its potential structure, and its dynamics is strongly influenced by disturbance regime (fire) and grazing pressure. Currently much of the work along NATT is oriented towards ecosystem dynamics, but the transect is also ideally placed to support research on trace gas emissions and water and energy exchange.

SALT (Savannas in the Long-term)

A companion transect to NATT, SALT is organized along a West African gradient extending north from the edge of the humid coastal forest for 2000 km into the semi-desert on the boundary between the Sahel and the Sahara Desert. These West African savannas have been largely modified by intense human pressure, which is likely to increase even more. SALT is a well established transect which has produced a large amount of understanding of the human-natural linked dynamics that operate in this region (e.g., Valentin, 1996). One of the early land-surface experiments – HAPEX (hydrologic atmospheric pilot experiment) – SAHEL – was located at a site along the SALT transect.

The Kalahari Transect

The Kalahari Transect is midway between NATT and SALT in terms of the dominance of human pressure on the structure and functioning of the ecosystems along the transect. In addition, the transect is largely located on the Kalahari sandy soils, and thus largely eliminates soil type as another environmental variable. Current work on this transect is focused both on the ecosystem interaction with the strong biophysical gradient and on the growing likelihood of significant human influence from population growth and economic change. The current dominant land use is cattle grazing, but this is under pressure from conversion to more intensive agriculture (i.e., cultivation) in some places and broadening to multi-species systems in others.

Humid Tropics

In these regions the dominant global change driver is land use change, and the transects are ‘conceptual’ ones, in that the sites are not organized along a line in physical space but rather along a conceptual gradient of land use change intensity (see Steffen *et al.*, 1999).

LBA (Large-scale Biosphere- Atmosphere experiment in Amazonia)

This is perhaps the largest of the regional global change studies yet undertaken, and aims to determine how Amazonia as a region functions as part of the Earth system and how human modification of Amazonia might affect that functioning (LBA Science Planning Group, 1996). LBA is organized along two sets of gradients, one a biophysical moisture gradient from humid tropical forests through dry tropical forests and into savanna; and the other a conceptual land use change intensity gradient, as described above. The study has been carefully planned around an integrated set of climate, hydrological, biogeochemical, ecological and land use change components (*see* **Large Scale Biosphere–Atmosphere Experiment in Amazonia (LBA)**, Volume 2).

Southeast Asia

The land use change intensity/biogeochemistry work is part of a larger study, the Southeast Asian Integrated Study (Lebel and Steffen, 1998), which has a strong focus on the human dimensions of global environmental change. Southeast Asia provides an interesting contrast to Amazonia. Whereas the latter is a large continental land mass in which land use change can significantly affect the regional climate, Southeast Asia is an archipelago of islands and peninsulas whose climate is dominated by the surrounding oceans, and the Asian monsoon. In addition, land use change patterns and driving forces contrast sharply between the two regions.

Central Africa

This transect is in the very early discussion and development phase. There is an existing regional global change study in central/southern Africa, the Miombo Woodlands Network, which could also be adapted to a transect approach based on a land use change intensity gradient. The focus of the Miombo work is on dry tropical forests.

Altitudinal Gradients

A series of altitudinal gradient studies to be undertaken as part of a mountains research initiative associated with IGBP are complementary to the set of transects described. Insofar as these altitudinal gradient studies are based on temperature gradients, they will provide an interesting comparison to the high-latitude transects.

THE TRANSECTS IN ACTION

Although much remains to be done to reach the full potential of the transects as a global change research tool, there have already been some notable successes in terms of application of the transect approach to global change problems. For example, the concept of a land use intensity gradient has been successfully applied to a study of deforestation in Jambi Province, Sumatra, Indonesia (M van Noordwijk, personal communication). In that work sites have been stratified according to their degree of agricultural management, in effect, land use change intensity. Interestingly, the degree of ecological disturbance is strongly correlated with this gradient, and the loss of biodiversity is inversely related to the gradient. In additional to these biophysical parameters, a number of socio-economic variables also correlate with the land use intensity gradient when plotted against total net output of the economic system in US$/ha. These include the 'actors', who benefit from the economic activity (e.g., small – hold farmers or government supported trans-migrants); the current development trajectory with time; and the possible new variations of development trajectories.

A second example of the gradient approach, with more direct management applications, comes from the SALT transect in West Africa. Along much of that transect the vegetation grows in a banded pattern, with strips of woody vegetation interspersed with barren areas. This pattern is formed by a complex interaction of rainfall, runoff and evapotranspiration. The pattern can only be understood by considering two opposing gradients, over a long spatial scale. Early attempts to manage this system, based on local understanding only, were spectacular failures and led to significant degradation of the system as a whole. It was only when the transect approach was adopted, and the complex dynamics of the banded vegetation pattern understood, that the management regime was modified to maintain the productivity of the woody strips (Valentin, 1996).

The most comprehensive attempt to use the IGBP Terrestrial Transects as a global set was the regional – scale analysis of global change impacts undertaken as part of the GCTE (Global Change and Terrestrial Ecosystems) synthesis (Walker *et al.*, 1999). In that study two Dynamic Global Vegetation Models (DGVMs) were applied to two transects in each set-high latitude, mid-latitude, and semi-arid tropical savannas. In addition, a global vegetation model that incorporates projections of land use change was also applied to the transects in a 100 year run into the future. Furthermore, 'expert knowledge' was obtained from the transect co-ordinators; this latter approach was also applied to two of the humid tropical land use change intensity transects. The results were fascinating in that much of the 'expert knowledge' did not agree with the projections of the global models. There could be many reasons for this, two of which are that (1) the global models might be missing key processes, and (2) the 'expert knowledge' is simplistic and is missing critical interactions and feedbacks that can be simulated in a mathematical modeling approach. An urgent challenge is therefore to develop a suite of finer scaled models of ecosystem dynamics and ecosystem processes for each transect which can then be compared more directly with the global models.

FUTURE CHALLENGES

The transects described above all have regional objectives and priorities as their primary focus. This has strengths in that it enhances the prospects for national and regional funding and promotes the application of results from global change research to more immediate management goals. From the perspective of global change research, however, the growing emphasis on the regional perspective is presenting a considerable challenge to using the transects as a co-ordinated international set to answer global questions. To reach the full potential of the IGBP Terrestrial Transects as a global change research tool, the following key activities have been identified (Steffen *et al.*, 1999):

- Creation of consistent basic GIS datasets for each transect, incorporating information such as soil type and characteristics, vegetation composition, climate (present and future scenarios) and land cover and use.
- Agreement on common experimental protocols and observational regimes to facilitate truly comparative research across the transects.
- Intercomparison of experimental results and model simulations, and periodic synthesis and integration activities.

Infectious Diseases

Paul R Epstein
Harvard Medical School, Boston, MA, USA

Climate constrains the range of infectious diseases, while weather affects the timing and intensity of them. Global warming has helped extend the geographic range of several infections (Epstein et al.*, 1998) and extreme weather events (EWEs) spawn clusters of diseases (Epstein, 1999). Synergistic impacts of warming and increased climate variability have also produced several surprises. While economic inequities and ecological disruption are key determinants of disease susceptibility and transmission, an unstable climate is playing an ever-increasing role in driving the global emergence, resurgence and redistribution of infectious disease (Patz* et al.*, 1996; McMichael* et al.*, 1996).*

Since 1976, over 30 diseases have emerged that are new to medicine (World Health Organization, 1996). Of equal concern is the resurgence of old diseases once thought under control. Some infections – like tuberculosis – are transmitted person to person, and their resurgence primarily reflects

social disruption and poor public health infrastructures. Infectious diseases involving two or more species – mosquitoes, ticks, deer, rodents and humans – however, also respond to environmental factors.

HISTORICAL BACKGROUND

Pandemics – epidemics spanning multiple continents – have often been associated with social transitions and have stimulated social change. Declining living conditions and overtaxed infrastructures set the stage for two plague pandemics: the Plague of Justinian of 541 AD (apparently *Yersinia pestis*, by clinical description), and the Black Death (also bubonic plague), emerging from the overcrowded urban conditions of the Middle Ages (1346 AD). These two pandemics, in turn, altered settlement and labor patterns for the centuries after.

Another upsurge of epidemic disease, more akin to today's, had a more positive outcome. In the early 1800s, growth of national wealth in Europe, and decline in infectious disease, was matched by deterioration in the quality of life. By the 1830s, water and sanitation, workhouse and factory conditions reached critical thresholds, the Dickensian conditions proving ideal breeding grounds for cholera, smallpox and tuberculosis.

This time underlying conditions and growing contagion sparked protests and constructive responses. In England, the Sanitary and Environmental Reform Movements were born (1842–1854), and epidemiology (beginning with disease mapping) ushered in modern public health principles and later a national health program. The epidemics abated over several decades, before the discoveries of Pasteur and Koch, and three-quarters of a century before the advent of anti-microbials.

In the mid-1970s, a similar threshold was reached. Today, the exhaustion of finite resources, generation of wastes, and climatic change compound increasing poverty. Together social and environmental instability are creating conditions vulnerable to the global emergence, resurgence and redistribution of infectious disease.

Infections involve a disease agent (a pathogen), host(s) and the environment, and some require vectors (or carriers). Climate can influence pathogen and vector populations, alter host defenses, change the migration patterns and food sources, and can radically alter habitat.

Mosquitoes, in particular, are highly sensitive to climate, being hot weather insects with fixed thresholds for survival. The relationship between mosquito-borne diseases and climate was described as early as 1920 (Gill, 1920) and the dependency on temperature quantified in the 1950s (McArthur, 1972). *Anopheline* spp. mosquitoes can transmit falciparum malaria parasites, for example, when temperatures remain above 16 °C (Martens *et al.*, 1997; Patz *et al.*, 1996), while the mosquitoes that transmit dengue fever, *Aedes aegypti*, are restricted by the 10 °C winter isotherm, as freezing kills the eggs, larvae and adults (Martens *et al.*, 1997). Within their survivable range, warmth accelerates biting and parasite and viral maturation within mosquitoes. Malarial protozoa, for example, mature in 26 days at 20 °C and just 13 days at 25 °C (McArthur, 1972). *Anopheline* mosquitoes live but several weeks, thus warmer temperatures accelerate development allowing for two crucial blood meals: one from an infected person and a second for transmission.

Warm nights and warm winters, i.e., high minimum temperatures (TMINs) are particularly favorable to the insect activity. Fossils from the end of the last Ice Age (about 10 000 years ago) demonstrate that changes in TMINs were correlated with geographic shifts of beetles. Insects are thus superb paleothermometers, shifting latitude and altitude in response to temperature regime shifts ahead of grasses, shrubs, trees and large animals.

Natural Regulatory Systems

Antibodies that stun or kill pathogen invaders and phagocytes that consume them are part of the arsenal of animal defense systems. Natural systems have also coevolved functional groups like predators and prey, competitors and recyclers, that help regulate the populations of nuisance organisms. Wide swings in weather and other disturbances can disarm bodily defenses, and several features of global environmental change may harm predators disproportionately, releasing prey from natural biological controls. Among these are habitat loss and monocultures, excessive chemical use (harming friendly insects, birds and amphibians), increased ultraviolet radiation, and changes in seasonal climate.

CLIMATE AND INFECTIOUS DISEASES

Data on global warming are well established (Mann *et al.*, 1998), and several physical aspects of climate change are especially pertinent to the biological responses. Global warming is not uniform; warming is occurring disproportionately at high latitudes, high elevations, and during the nighttime and the winter (IPCC, 1996). Since 1950, springs begin almost a week earlier, on average, and fall a week later, and TMINs over land areas have risen twice as fast as overall warming (Easterling *et al.*, 1997). Less precipitation falls as winter snow and many biological systems on land and at sea are responding to the combined changes. Growing zones are shifting, but not as rapidly as the pests that prey upon nutritional staples – corn, soybean, wheat – and cotton.

Extreme events (droughts, floods, storms, severe winds) are intensifying (Karl *et al.*, 1995). A warmer atmosphere

also holds more vapor (6% more for each 1 °C warming), enhancing evaporation and the hydrological cycle. As the ocean warms, sea ice melts and atmospheric water vapor rises. Heat accumulating in the ocean (Levitus *et al.*, 2000) thus increases clouds, humidity and heat indices, contributes to warm nights and tropical-like downpours, fuels hurricanes, and alters ocean and air currents that influence weather patterns globally.

VECTOR-BORNE DISEASES

Hot, humid weather and absent relief at nighttime, directly challenge human (and livestock) health. These conditions also promote mosquito-borne diseases.

One-half of the world's population is exposed to malaria on a daily basis. In the 1990s, worldwide incidence of malaria increased dramatically. While poverty, deforestation and drug resistance all contributed, a warmer climate provided conditions conducive to increased transmission in temperate zones and highland regions. Models based on climate parameters and transmission dynamics project that the warming accompanying doubling of atmospheric carbon dioxide (CO_2) will increase vectoral capacity 100-fold in temperate zones, and extend the area capable of sustaining transmission from that containing 45% of the world's population of 60% (Martens *et al.*, 1997). A statistical model projects less of a change (Rogers and Randolph, 2000). But all the analyses to date are based on projected changes in average temperatures, rather than the more rapid changes in minimum temperatures being observed; and thus may underestimate the biological responses.

Evidence suggests the projected changes are underway. *Anopheline* mosquitoes are present in the US, and, earlier this century, malaria was prevalent, and control went along with advances in social development. In the 1990s, however, small outbreaks of locally transmitted malaria (not surrounding airports or imported) (see Zucker, 1996) have occurred during hot spells in Texas in 1994, Michigan in 1995, Georgia in 1996, Florida, New Jersey in 1995 (Zucker, 1996), New York and Toronto (see Epstein *et al.*, 1998), and in California, where transmission occurred in the 1980s. Malaria has extended its latitudinal range in South Africa, while dengue fever has spread into Northern Australia and into Argentina. Swedish research has demonstrated that warm winters facilitate northern migration of ticks carrying Lyme disease (Lindgren and Gustafson, 2001) – the most important vector-borne diseases in the US.

These changes are consistent with projections, but high altitude changes are most telling because of the emerging global pattern and the consistency with data from other fields.

Changes at High Elevations

Insects and insect-borne diseases (including malaria and dengue fever) are today being reported at high elevations in Africa, Asia, and Latin America (see Epstein *et al.*, 1998). Malaria is now prevalent in Central African highlands, affecting high elevation urban centers like Nairobi, and rural highland areas of Papua New Guinea. Once limited by temperature to 1000 m, *Aedes aegypti* (vectors of dengue and yellow fevers) are found at 2200 m in the Colombian Andes and India. Displacement of plants to higher elevations has also been documented in the European Alps, and reported in Alaska, the US Sierra Nevada and in New Zealand. (A plant shift of 500 m in elevation is equivalent to a 300 km shift in latitude (Peters, 1991).)

These insect and botanical trends, indicative of gradual, systematic warming, have been accompanied by another widespread physical phenomenon: Montane glaciers are in retreat in Argentina, Peru, Alaska, Iceland, Norway, the Swiss Alps, Kenya, the Himalayas, Indonesia, and New Zealand. Some may soon disappear.

Polar researchers suspect that melting at the base of the Greenland ice sheet may be sculpting fault lines that could diminish its stability (Krabill *et al.*, 1999). Shrinking of Earth's ice cover (cryosphere) has implications for water (agriculture, hydropower, and for albedo [reflectivity]), thus climate stability.

Finally, since 1970, the level at which freezing occurs has climbed about 160 m higher, corresponding to a 1 °C warming (Diaz and Graham, 1996). Thus, mountain regions – where biological, glacial and isotherm shifts are especially apparent – provide sentinel sites for monitoring the consequences of climate change.

EXTREME WEATHER EVENTS (EWEs) AND EPIDEMICS

A significant trend linked to heat buildup in the atmosphere and oceans is the alteration of EWEs (Intergovernmental Panel on Climate Change, 2001). Shifts in climatic norms alter the frequency and intensity of individual events, as well as their temporal and spatial patterns (Karl *et al.*, 1995). Storms and other extreme events are exacting a severe toll on public health and public health infrastructures worldwide (Epstein, 1999).

Since the 1970s, EWEs have increased in the continental US and elsewhere. Periods of drought have become longer as warming dries soils, and bursts of tropical-like precipitation (>5 cm over 24 hours) occur more frequently (Karl *et al.*, 1995).

Extreme disturbances favor nuisance organisms. Prolonged droughts, that fuel fires, haze and respiratory ailments, also support population explosions of insects and rodents, when punctuated by heavy rains. Floods foster

fungal growth, can create insect breeding sites, and flush microorganisms, chemicals and nutrients into waterways, triggering harmful algal blooms.

Intense rains and flash flooding, plus animal husbandry practices, can breach sanitation and water systems, and precipitate water-borne disease outbreaks of *Cryptosporidium parvum* protozoa and others.

The relationships between El Niño/southern oscillation (ENSO) events and disease outbreaks have been well studied (Bouma *et al.*, 1997). Analyses of multiple time series demonstrate associations between these climatic events, the accompanying anomalous weather, and outbreaks of vector-, water- and rodent- borne disease. Other climate signals – the North Atlantic Oscillation and regional sea surface temperatures (as with Rift Valley fever in West Africa) – are also drivers of conditions conducive to disease outbreaks.

The 1990s: A Decade of Extremes

In the mid-1970s the pattern of ENSO events quickened from the 4.2-year periodicity since 1877 (Trenberth, 1999). In the 1990s, the pattern changed again, each year of the decade experiencing an El Niño or a La Niña event. Build up of heat in the ocean may be altering the natural ENSO mode (Timmermann *et al.*, 1999), carrying profound implications for disease patterns. The largest El Niño of the past century – 1997/1998 – and the La Niña of 1998/2000 – spawned weather anomalies and associated disease clusters across the globe (Epstein, 1999).

EWEs have a profound impact on public health, particularly in developing countries, and the aftershocks can ripple through economies (International Federation of Red Cross and Red Crescent Societies, 1999). Hurricane Mitch, for example, nourished by a warmed Caribbean, hit Central America in November 1998, killing over 11 000 people and causing damages exceeding $5 billion. The intense precipitation and flooding associated with the hurricane spawned a cluster of disease outbreaks, including cholera (30 000 cases), and malaria and dengue fever (30 000 and 1000 cases, respectively) (Epstein, 1999).

In the summer of 1999, the drought affecting US Atlantic coastal states brought several health-related surprises to New York State. On July 6th, the power demands of the heat wave caused a blackout on New York City's upper west side, and, when backup diesel generators at two Columbia Medical School buildings failed, years of biomedical research were lost. The event affected the medical, scientific and financial world, highlighting the need for off the grid energy sources, like fuel cells, that are nearly 100% reliable.

At summer's end (August 26th), torrential rains drove farm waste into an upstate underground aquifer supplying the Washington County Fair. Over 1000 people fell ill from toxic *Escherichia coli*, some with hemolytic uremic syndrome and there were several deaths.

The third surprise for New York in 1999 was the appearance of the mosquito-borne West Nile Virus (WNV) (discussed later).

EWEs (winds, storms, droughts and fires) and sea level rise are taking an increasing toll on habitat itself, with implications for species diversity and disease. Habitat modification from abrupt climate change is considered the leading cause of four of the five mass extinctions of the past 440 million years. In Honduras, drought-sustained wildfires consumed 11 000 km^2 of forest during the summer preceding Mitch, widening the ongoing deforestation and magnifying the flooding and devastation (Epstein, 1999).

Sequential Extremes, Synergies and Surprises

In 1992, the US Institute of Medicine, in the first major report published on emerging infectious diseases, predicted that conditions in the US were ripe for the emergence of a new disease. What they did not foresee was that climate was to play a significant role in the emergence, amplification and transmission of two of this decade's surprises: the hantavirus pulmonary syndrome (HPS) in the Southwest and the WNV in New York City. Sudden weather changes and sequential extremes can decouple ecological rhythms and yield biological surprises.

HPS

The diversity of rodent predators provides insurance when some decline. The prolonged California and US southwest drought from 1987 to 1992 reduced raptors, coyotes and snakes. And when drought yielded to intense rains in 1993 (the year of the Mississippi flood), grasshoppers and piñon nuts on which rodents feed flourished. The resulting 10-fold increase in mice populations by June 1993, led to the emergence of a new disease: HPS (Epstein, 1995). The virus may have been present, but dormant. Altered predation and habitat associated with changing meteorological conditions provided the conditions allowing its amplification and transmission. By summer's end predators returned and the outbreak abated, demonstrating the resilience ecosystems retain. Subsequent episodes in the US have been limited with the aid of early warnings, but HPS has appeared in several Latin American nations, with about 50% mortality and several cases of person to person transmission.

WNV

While the introduction of the WNV into the US remains a mystery (through migrating birds, humans or airline-transported mosquitoes), conditions favoring diseases that

cycle among birds, urban mosquitoes and humans – like St. Louis encephalitis (SLE) and WNV – are well known. They are warm winters and hot, dry summers, conditions associated with climate change in the Northeast US The first recorded outbreak of SLE in the US occurred around St. Louis in 1933 during the dust bowl and the hottest summer to date, for the century. Most urban SLE outbreaks from 1933 to 1974 were preceded by multimonth droughts (unpublished data).

The precise mechanisms are matters for conjecture. Mild winters and dry summers favor breeding of city-dwelling mosquitoes (*Culex pipiens*), while their predators decline with drought. Birds may have congregated about shrinking water sites during the July 1999 heat wave, favoring viral amplification among birds and mosquitoes; the heat accelerating viral maturation. Finally, torrential rains in late August unleashed a crop of *Aedes* spp. mosquitoes that may have acted as an additional bridge vector to humans (Epstein, 2000).

Against this is the background of generalists – crows, Canada Geese and gulls – out-competing specialist avians, the specialists losing ecological niches and refuges. Generalists, with wide ranging diets, may, in general, be more tolerant of disease agents, thus more apt to maintain blood levels that favor disease transmission. In this case, WNV may have recently evolved in strength, as it took an unusual toll on birds. The importation of WNV highlights the potential spread of agents evolving in association with social and environmental change anywhere on the globe.

COSTS

The economic impacts of diseases of humans, livestock, and food crops can be far-reaching (Daszak *et al.*, 2000). White flies, whose numbers swell when there is drought, are injecting at least 18 types of Geminiviruses into tomato, squash, and bean plants throughout Latin America, threatening regional food security (Anderson and Morales, 1993).

The 1991 cholera epidemic cost Peru over $1 billion in seafood exports and tourist income, while international airline and hotel industries lost from $2 to $5 billion from the 1994 Indian plague, and cruise boats avoid islands affected by dengue fever, coral diseases and harmful algal blooms (Harvell *et al.*, 1999).

Prolonged anomalous conditions of the sort that applied in 1990–1995 can have cumulative biological consequences. In New Orleans, for example, five years without a killing frost fostered an explosion of mosquitoes, cockroaches and termites in summer 1995. Termites persisted inside trees during subsequent cold winters and threaten stands of New Orleans' mighty oaks.

If more frequent and intense EWEs continue to be a primary manifestation of climate change, we have begun to experience the true social and economic costs of an unstable climate. Viewed as a symptom, the resurgence of infectious disease across a wide taxonomic range suggests that we may be vastly underestimating the true costs of business-as-usual.

The International Federation of the Red Cross and Red Crescent Societies (1999) reports that developing nations are experiencing 96% of the impacts of climate change. In the last several years, however, Hurricane Floyd in North Carolina, fires in Florida and California, WNV in New York City, and the December 1999 $4 billion wind storms across Europe indicate the costs of climate change will borne by all.

CONCLUSIONS

We are changing the chemistry of the air, and in the process altering the Earth's heat budget. Global environmental change, climate change, stratospheric ozone depletion, excessive use of chemicals, urbanization and land cover change constitute a destabilizing array of forcing factors. The resurgence of infectious disease at the close of the 20th century is one of several symptoms of global change, which includes the amphibian decline on six continents and the proliferation of harmful algal blooms along coastlines globally. The decline in one type of specialist – pollinators, such as bees, birds, bats, butterflies, and beetles – threatens flowering plants, including crops.

There may be positive impacts, such as a drop in schistosomiasis in regions too warm to sustain snail hosts and lower winter mortality (Martens *et al.*, 1997). However, the respiratory, and injury, impacts of wide swings in weather (e.g., warm winter rains interrupted by sudden cold snaps) may overshadow the health gains of warmer winters.

Global warming is not linear. North Polar and Greenland ice sheet melting in the Northern Atlantic, plus cold upwelling in the Pacific (La Niña conditions), may usher in cold weather across Europe. Thus the greatest threat of climate change lies, not with individual diseases, but with the impacts on ecosystems, water quality and quantity, soils, crops and marine life – the life support systems that underpin our health and well-being.

RECOMMENDATIONS

Solutions may be divided into three levels. First-level solutions are improved surveillance and response capability, including vaccine and drug development, and more widespread support for public health infrastructures.

The second level – ecological epidemiology – involves integrating health surveillance and environmental monitoring. Greater use of satellite imaging and climate forecasts

can complement field work to produce health early warning systems and facilitate timely, less costly, environmentally-friendly public health interventions (Colwell, 1996; Epstein, 1999).

The third level is prevention: addressing the underlying social and environmental practices. Population stabilization is essential and World Bank figures confirm that a society's ability to stabilize its population is directly related to its income equity.

Addressing the economic, ecological and climatic conditions converge upon a central question: the mode of development and how it is powered. Use of non-polluting, clean energy sources is essential as is the maintenance of forests and wetlands that buffer climatic extremes and control the proliferation of opportunists and diseases they carry.

Addressing all levels requires resources and financial incentives. Adoption of the Montreal Protocol on stratospheric ozone-depleting chemicals, also driven by health concerns, depended upon establishing a fund for technology development and transfer.

Funds are needed for basic public health measures, electricity (for refrigeration) and clean water, and these will require clean energy sources. Indeed the looming water crisis may help drive the energy transition, for clean sources to pump and purify water, power irrigation and desalinate the rising seas. The Fund for HIV/AIDS, TB and malaria is a major step forward and an important precedent.

The global environment is most at risk from climate change certain to accompany fossil fuel combustion, compounding the direct health hazards of air pollution and the ecological damages due to their mining, refining and transport.

Systems can be restabilized. Just as the body heals after illness and lungs can recover with cessation of smoking (if the assault is time limited and has surpassed a threshold of irreparable damage), resilience allows ecosystems to re-establish new (dynamically) stable states. The climate system can also be restabilized, but only if the rate of forcing factors is slowed. Greenhouse gas emissions must be reduced by 60% according to the Intergovernmental Panel on Climate Change (1996) to stabilize atmospheric concentrations. Implementing the United Nations-sponsored Framework Convention on Climate is an essential first step.

Fortunately, values can also change rapidly, sometimes more rapidly than the natural systems we depend upon. Perhaps we are underestimating the economic opportunities waiting if we use resources efficiently, generate energy cleanly, and restore essential functions of the natural environment. Curbing our unhealthy addiction to fossil fuels may be the lever that opens the portal to a productive and healthy future.

Inter American Institute for Global Change (IAIGC)

Diana Liverman
University of Arizona, Tucson, AZ, USA

The Inter American Institute for Global Change (IAI) is an intergovernmental institution dedicated to the better understanding of global environmental change (e.g., climate variability, comparative studies of ecosystems, water and land use, air pollution, integrated assessment and human dimensions) in North and South America through collaborative research, networks of scientists, education, training, and free and open exchange of relevant data.

The IAI is an intergovernmental institution, established in 1992, dedicated to the better understanding of global environmental change in North and South America through collaborative research, networks of scientists, education, training, and free and open exchange of relevant data. As of 2000, the IAI had 18 member countries and had provided almost $20 m in grants for workshops, projects, networks, and training to scientists in the region. The majority of these grants are targeted at activities involving scientists from at least four member countries and with substantial education and training components that would build scientific capacity, especially in Latin America.

The IAI is managed by a small directorate, based in São José dos Campos, Brazil, advised by a 10-member scientific advisory committee, and reporting to an executive council and conference of parties consisting of representatives of member governments. Financial support has included contributions from member governments and national science foundations, and a training grant from the Global Environment Facility. The current members of the IAI are Argentina, Bolivia, Brazil, Canada, Chile, Colombia, Costa Rica, Cuba, Ecuador, Guatemala, Jamaica, Mexico, Panama, Paraguay, Peru, Dominican Republic, United States, Uruguay, and Venezuela.

The IAI science agenda focuses on major regional environmental issues including: (1) understanding climate variability associated with ocean–land–atmosphere interactions; (2) comparative studies of ecosystems, biodiversity, land use and water resources from the tropics to temperate and cold latitudes, including terrestrial, coastal and oceanic environments; (3) changes in the composition of the atmosphere including greenhouse gas emissions, ozone depletion and regional air pollution; and (4) integrated assessments, human dimensions and applications to decision making and policy. For example, several projects and networks of scientists are focusing on understanding and predicting climate variability associated with El Niño, and others seek to understand the impacts of land use change on biogeochemistry, ecosystems, and water quality. Other networks are reconstructing the environmental history of the Americas through dendrochronology, monitoring and analyzing ultraviolet radiation and its impacts, and focusing on understanding the climate of specific regions such as the Caribbean and South Atlantic. Of direct relevance to policy are projects that examine vulnerability and responses to climatic disasters, climate and health, fisheries dynamics, and the socioeconomic drivers of land use change.

Challenges facing the IAI include the establishment of a sustainable and diverse financial base, enhancing capacity in countries with smaller scientific communities, and the more effective integration of social science and policy into activities and projects. The IAI is making progress in establishing networks of researchers conducting multinational, collaborative research and in building a regional community of scientists who can contribute to international assessments of global change and advise policy makers in individual countries.

The IAI web site (http://www.iai.int) provides further information and updates on the IAI, including copies of

newsletters, lists of projects and publications, and contact information.

International Biosphere Program (IBP) - a Foundation for Global Studies

Frank B Golley
University of Georgia, Athens, GA, USA

IBP was launched in 1964, with the aim of contributing to the optimal exploitation, on a global basis, of the biological resources on which humans are dependent for food and other products. The IBP was sponsored by the International Council for Science, and planned to terminate in 1972 but continued until 1974.

While the IBP initially had broad intentions, it developed into a largely ecological project. Its scientific director, Barton Worthington (1975, pg. 64), commented "it is the ecosystem approach which distinguishes much of the IBP research from what dominated ecology before …. The application of system analysis to biological systems has been one of the major innovations developed during the IBP. Some would go further and say that it has been one of the IBP's major accomplishments".

Given the knowledge of ecology at the time, several steps were required to organize a global project. First, the Earth's terrestrial surface was divided into geographical units, such as habitats or biomes. Next, sites representing the average condition of these biomes were identified and studied intensively. The intensive studies proceeded in two directions. First, one could treat the site as an ecosystem and measure the productivity of the vegetation and herbivore, carnivore and decomposer subsystems. The performances of these linked units were integrated using ecosystem models and were extrapolated to the entire biome. Alternatively, one could begin with the biological species encountered at the representative site, study their feeding relationships and organize them into food webs. Ultimately the food webs were assembled into subsystems or representative ecosystems. Both approaches were employed in IBP.

The ecosystem studies were most highly developed in the US where teams of researchers studied biological productivity and factors promoting or controlling production at representative locations. Variation across the biomes was determined by taking measurements at other sites. The biome program combined terrestrial and aquatic studies and used ecological modeling. Biome studies were carried out in the tundra, taiga, grasslands, coniferous forests, deciduous forests and deserts. A tropical biome was never successfully organized, although tropical projects were carried out in Malaysia, India, Ivory Coast and Senegal.

The species-focused IBP projects were classical biological investigations and tapped into the wealth of information on such groups as small mammals, social insects, granivorous birds and soil organisms. These studies were located at study sites representing different habitats, Traditional biologists felt more comfortable in carrying out comparative studies across habitats, using familiar biological categories. Eventually the species-oriented studies were assembled into whole systems so that both approaches were brought together into what was called the IBP biome program. However, these were not the only IBP projects. Other IBP efforts considered conservation, human adaptation to extreme environments, islands, marine upwellings and freshwater ecology.

The IBP was extended for two years and ended in 1974. Over 2000 scientists were involved. They produced an enormous literature, which has never been fully catalogued. In most countries IBP work disappeared when IBP ended. However, in a few countries, such as the US, IBP was reorganized and research was continued. In the US, biome studies were relabeled as ecosystem studies, and were formally made a program of the Division of Environmental Biology of the US National Science Foundation (NSF). In 1979 a Long-Term Ecological Research Program was initiated by NSF, which incorporated several IBP sites into a national program of ecosystem research.

Summarizing: IBP resulted in a substantial increase in our understanding of the geographical pattern of ecological productivity. It also developed a global network of scientists experienced in cooperative international work. IBP studies contributed to the development of hierarchy theory, landscape ecology, global biogeochemistry, and long-term ecological research.

Intertidal Zones

Virginia Burkett
US Geological Survey, Lafayette, LA, USA

The intertidal zone occurs within the range of high and low tides along the shorelines of coastal landforms and estuaries. The intertidal zone is a physically dynamic zone that is exposed to alternate flooding and drying, heat from the sun, wind, waves and currents. Organisms that inhabit intertidal systems are uniquely adapted to environmental conditions that occur along the energy, salinity and moisture gradients that extend from the subtidal region to the top of the intertidal zone. In contrast to terrestrial systems, which have physical gradients that can stretch over 10s or 1000s of km, intertidal gradients are relatively short, particularly along rocky shores (Raffaelli et al.*, 1991). The intensely specialized and often crowded intertidal environment is considered more fragile than many other ecosystem types.*

The intertidal zone may include coastal marshes, sand and gravel beaches, estuaries, mangrove swamps, algal beds, unvegetated mud and sand flats, and rocky shorelines that are periodically flooded by tidal waters. Coral and oyster reefs that are subtidal, irregularly exposed and regularly or irregularly flooded, are also generally considered intertidal ecosystems. Environmental gradients that typify intertidal zones are responsible for their high biodiversity, due to different species tolerances for the physical forces that structure intertidal plant and animal communities (Day et al.*, 1989). In most regions, intertidal zones are subject to bi-directional flooding about twice every day, which is one of the most striking physical attributes of these systems, and one that influences both their biotic and abiotic structure (Wiegert and Freeman, 1990). At high latitudes, ice cover may last for several months, creating relatively harsh intertidal environments with unique faunal assemblages.*

There are many classifications of intertidal zones based on their biota, substrate and ecosystem type (bay and estuary, open coast). At the simplest level, however, intertidal zones are generally classified as upper, middle and lower.

UPPER

The upper part of an intertidal ecosystem is the least exposed to water. It is only inundated by the highest tides or it may receive moisture primarily from sea spray or wave splash. Some classification schemes include beaches in this zone, but generally the upper part includes only the more frequently wetted regions that lie between the mean flood of the highest tides and slightly below mean sea level. In general, the upper intertidal zone is above the mussel beds that are common on many coasts. Organisms that inhabit the upper zone include barnacles and other animals accustomed to tolerating more air than water (Ricketts *et al.*, 1968).

The upper intertidal zone on rocky shores is often call the *littorinid* zone because it is commonly populated with snails of the genus *Littorina* (Latin for shore-dweller) and a wide variety of other gastropods, flatworms and crustaceans that stay close enough to the sea to receive the occasional moisture needed for their survival (Ricketts *et al.*, 1968). Adaptations that prevent desiccation of animals living in this zone include thick mucous coverings, shells and hard exoskeletons.

Algal species in the upper intertidal zone may be perennial or seasonal, responding to ever-changing tide levels. Mangroves (halophytic trees and shrubs) and salt marsh grasses (halophytic grasses, rushes and sedges) commonly occur in the upper to upper–middle intertidal zones. Tidal fresh marshes are considered upper intertidal plant communities. Mangroves dominate intertidal subtropical and tropical estuaries between 25 °N and 25 °S latitude, and salt marshes dominate the mid to upper intertidal areas of more temperate coastlines (Keannish, 1986). Black lichens are common in upper intertidal sandy shores in some regions (Raffaelli *et al.*, 1991).

MIDDLE

The middle intertidal zone is usually inundated during high tides and exposed during low tides. On the west coast of North America this zone is typically populated with mussels

that are either attached to the substrate or to each other by abyssal threads. The mussels themselves create a unique substrate that provides food and shelter for other organisms. Many species of crabs, barnacles and tiny crustaceans can be found in the middle intertidal zone, depending upon wave energy, substrate, temperature and other factors. In rocky substrates, sea anemones are common, as well as many barnacle species. Numerous species of limpets, seastars, hermit crabs, nudibranchs (shell-less snails), chitons, hydroids, and roundworms are also common among middle intertidal rocks and pools in warm to temperate waters (Ricketts *et al.*, 1968).

Tidal flats along coastlines dominated by unconsolidated sediments are commonly classified within the middle intertidal zone. They support rich benthic communities and serve as a nursery ground for many species of fish and shellfish. These unvegetated portions of sounds, lagoons, estuaries and river mouths, and shorelines that lie between the high and low tide mark are also critical habitats for many bird species. Tidal flats receive and transform relatively large amounts of organic detritus from the land and sea, which accounts for their high productivity and important function within the coastal food chain (Reise, 1985). Microalgal mats, filamentous algae, bacteria and fungi of tidal flats play an important role in the dynamics of estuarine systems by converting energy bound up in detritus to forms that are usable to consumer organisms (Peterson and Peterson, 1979).

Macrophtyes may also be found in the middle intertidal zone, including mangroves and the more salt tolerant marsh grasses. Along some low energy coastlines, eelgrass (*Zostera*) flats may be frequently exposed during low tide.

LOWER

The lower intertidal zone, covered by tides nearly all of the time, often supports large brown algae in temperate regions, and red algae in warm–temperate regions (Raffaelli *et al.*, 1991). Few of the organisms found in this zone can tolerate long exposure out of water. They are generally bared only by lower-than-average low tides (*minus tides*) and therefore infrequently if not rarely exposed to wave action, direct solar radiation and wind. Low intertidal pools of the US Pacific coastline are often populated by molting dungeness crabs (in Oregon and Washington) and spiny lobsters (in California). Oyster and coral reefs that are exposed during the lowest tides are also considered intertidal. Although seagrasses are generally considered subtidal, their light requirements place them at the deep edge of the lower intertidal zone.

Fish that are commonly found in this zone include mature forms as well as a wide range of juvenile pelagic species that seek shelter, food and other accommodations found in this environment. Bottom dwellers, such as the Atlantic flounder, are common in low intertidal waters of the Gulf of Mexico and temperate to warm Atlantic coastlines.

Occurring along the narrow border between inland and marine ecosystems, the intertidal zone is considered highly vulnerable to the effects of human development activities, sea level rise and changes in climate. Although coastal areas comprise only about 5% of the world's surface, it is estimated that 50–70% of the global human population lives in the coastal zone (Intergovernmental Panel on Climate Change (IPCC), 1995). For example, approximately 53% of the total population of the US lives in 17% of the land area considered coastal (Culliton, 1998). Along heavily developed shorelines, seawalls, jetties, levees and navigation channels have disrupted water circulation patterns; altered salinity levels; and changed freshwater, sediment and nutrient delivery. The loss of plant and animal communities due to pollution, overharvesting and a variety of other stresses is also common along developed coastlines.

Over 90% of the intertidal wetlands in California have been lost as a result of human development activity (Watzin and Gosselink, 1992). Large areas of intertidal marsh and mangroves swamps have been impounded and converted to shrimp farms in Honduras, Bangladesh, and Mexico. Human-induced environmental change is subtler in areas that are impacted by discharges from sewage and industrial plants, agricultural runoff, and invasive species. An estimated 40% of US estuaries are impaired by some form of pollution or habitat degradation (EPA, 1996). Nutrient enrichment associated with agricultural runoff can result in estuarine hypoxia, harmful algal blooms and fish kills.

Climate variability and change can also alter the structure and ecological function of intertidal systems. Rapid changes can occur when storms produce catastrophic waves that reshape the sea/land boundary. Natural multi-year climate/ocean regime shifts such as the El Niño/Southern Oscillation (ENSO) and the Pacific Decadal Oscillation can also modify intertidal ecosystems. On the Pacific coast of North America, the prolonged El Niño of 1982–1983 and 1997–1998 brought winter storms farther south, causing extensive coastal erosion and much higher than average tide levels (Field *et al.*, in press).

Longer-term climatic change associated with global warming could also have significant, and possibly serious, effects on most intertidal systems. The IPCC Third Assessment Report (McLean *et al.*, in review) suggests key changes to the ocean environment that portend large-scale changes of the world's intertidal zones:

- increases in sea-surface temperature, sea level and coastal inundation;
- decreases in sea-ice cover;
- changes in salinity, alkalinity, wave action and circulation.

Sea-level rise is regarded as one of the more certain consequences of increased global temperature. Average global sea level rose between 4–9 inches (10–25 cm) during the past 100 years (IPCC, 1995) and this average rate is projected to accelerate two to five-fold over the next 100 years (IPCC, 1998). Increased sea level rise can lead to permanent inundation of coastal marshes and other intertidal habitats that cannot migrate inland or accrete sediment vertically at a rate that equals or exceeds sea level rise (Cahoon *et al.*, 1998). Low-lying wetlands that are subsiding, receiving inadequate sediment or freshwater supply, or stressed by salt-water intrusion (another impact associated with sea level rise) are particularly vulnerable (Burkett and Kusler, 2000).

Man's development activities can also affect the survival of intertidal systems as sea level rises (Figure 1). Levees, seawalls, roads and other development can prevent the inland migration of seagrass, beaches, wetlands and other coastal features as sea level rises.

Countries that have established various forms of managed retreat requirements to prevent intertidal and other coastal ecosystems from being squeezed between development and the advancing sea include Barbados, Sri Lanka and the UK (McLean *et al.*, in review).

Sea-level rise will increase tidal flushing in estuaries and will also increase storm surges over coastal landforms. Both average and peak salinity levels will increase in estuaries and adjacent habitats, thereby altering the zonation of vegetation and other biota. Increased storm surge and mean tide levels will also alter the disturbance regime in shallow coastal waters, thereby influencing the composition and productivity of seagrasses (Short and Neckles, 1999) and benthic fauna that are vulnerable to changes in sedimentation patterns, current velocity, and turbidity. The production of estuarine-dependent fish and shellfish will likely decline in regions where wetlands, seagrasses and other elements of the intertidal food chain are adversely impacted.

An analysis of approximately five million ocean temperature profiles taken over the past 55 years by Levitus *et al.* (2000) indicates that the mean temperature of the oceans between 0–300 m increased by 0.31 °C during that same period. Although this increase cannot be linked conclusively with global climate change, the increase is in line with land-based global temperature trends. Increased ocean temperature, most evident in shallow waters, can change the structure and productivity of intertidal ecosystems by directly altering the metabolic rates and phenology

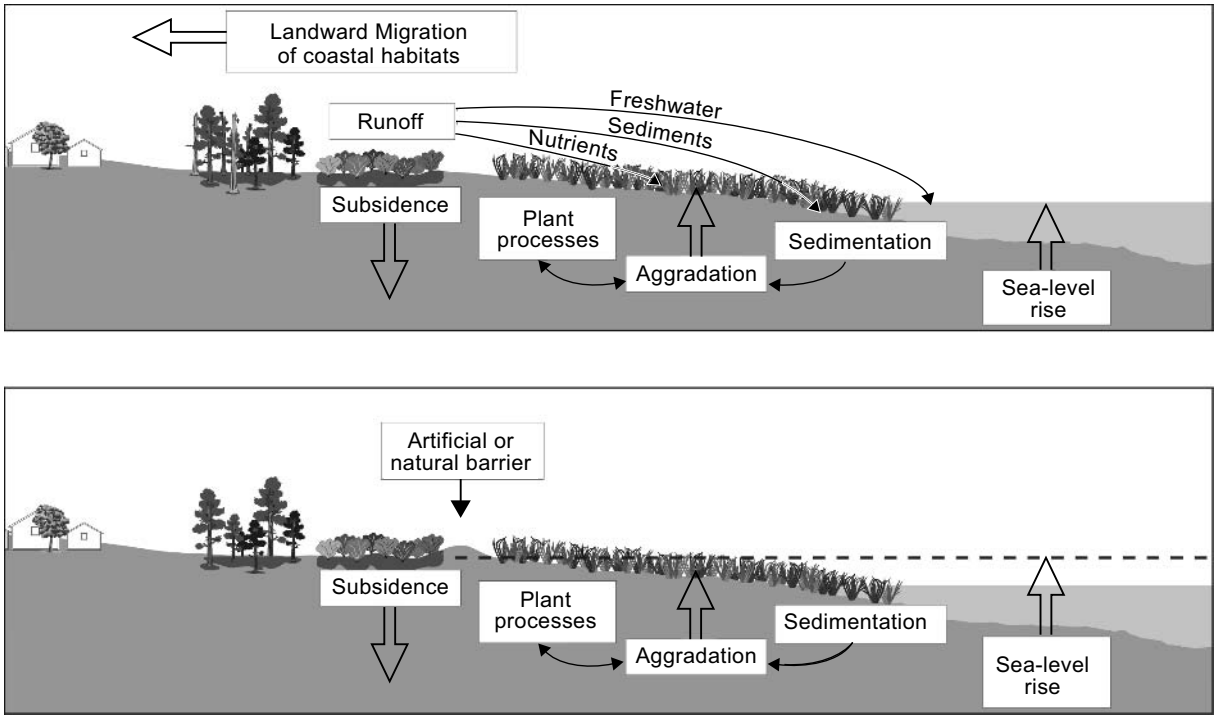

Figure 1 Through the accretion of organic and inorganic sediments, many vegetated coastal wetlands have the capacity to maintain their elevation as sea-level rises. Thresholds at which sea-level rise results in wetland loss varies among coastal regions due to differences in sediment accretion rates, subsidence and other factors (e.g., tectonism and isostacy) that affect the elevation of the land surface. If the rate of vertical marsh movement does not keep pace with sea-level rise, coastal wetlands will either be submerged or displaced landward. Natural or arti cial barriers can prevent the landward migration of coastal habitats

of organisms. Indirectly, increased ocean temperature can impact intertidal ecosystem productivity by altering water column stratification, circulation and mixing patterns, nutrient cycling and many other coastal processes.

Increases in hurricane wind strength could result from future elevated sea surface temperatures over the next 50–100 years. A recent model investigation shows that increases in hurricane wind strength of 5–10% are possible with a sea surface warming of 2.2 °C (Knutson, 1998). Other research supports the possibility that tropical cyclones could become more intense or more frequent (Raper, 1993; Kerr, 1999). For a moderate hurricane, a 5–10% increase in wind strength would translate into approximately a 25% increase in the destructive power of the winds; the resulting increase in wave action and storm surge would be greater than the percentage increase in wind speed. Similarly, wave height and storm surge would have a greater percentage increase than wind speed, potentially yielding increased impacts to coasts (Field *et al.*, in press).

Some recent global climate model investigations have shown that ENSO extremes could become more frequent with increasing greenhouse gas concentrations. For example, Timmerman *et al.* (1999) suggest that the tropical Pacific is likely to shift to a state corresponding to present-day El Niño conditions. Since fewer hurricanes occur in the Atlantic during El Niño years, Atlantic hurricanes will likely decrease in frequency. However, while prolonged El Niño conditions could decrease the occurrence of hurricanes in the Atlantic, they would likely enhance coastal impacts by winter storms on the Pacific coasts of Latin and North America.

Hydrological cycles are fundamental components of climate, and climate change is likely to affect freshwater runoff to the intertidal environment. In general, the consensus is that the hydrologic cycle will become more intense, with average precipitation increasing, especially at high latitudes (Field *et al.*, in press). The effects of these alterations in runoff to coastal zones and estuaries may include changes in freshwater and sediment inflows, water quality (particularly salinity and nutrient loading) and frequency of coastal flooding.

Iron Cycle

Keith A Hunter

University of Otago, Dunedin, New Zealand

The importance of iron as an essential chemical element in a wide range of biological processes is well known. Iron is the key component of many enzymes, as well as being the central ingredient of the oxygen-carrying protein, hemoglobin, in human blood. Yet despite being one of the most abundant chemical elements in the Earth's crust, iron is present at only trace levels in the oceans, the original birthplace of all biological systems.

There is now mounting scientific evidence that low iron availability in the global oceans is one of the most important factors controlling the growth rate of oceanic phytoplankton. These primary organisms not only represent the base of the marine food chain, but also act as an important control on the distribution of the greenhouse gas, carbon dioxide (CO_2), between the atmosphere and the ocean. Since the ocean is the dominant reservoir of carbon, changes in the availability of iron to phytoplankton within it may be quickly reflected in the Earth's climate. Indeed, there is compelling indirect evidence that during glacial times, an increased supply of iron to the ocean surface from increased weathering and transport of terrestrial dust (a rich source of iron) may have stimulated additional uptake of CO_2 by phytoplankton. This, in turn, would have the effect of bringing down atmospheric CO_2 levels, thus diminishing the greenhouse effect and contributing to the colder temperatures characteristic of glacial periods.

Not surprisingly, there has been vigorous scientific activity in this interesting field over the last two decades. However, many of the key features of the role of iron in controlling climate remain elusive, mainly because of the complexity of both its chemical behavior and the biological processes in which it is involved. Nonetheless, the evidence assembled so far points towards iron being a key component in the complex network of controls on global climate contained in the Earth's ocean–atmosphere system.

THE CLIMATE CHEMISTRY OF THE OCEAN

The importance of iron in global climate change derives from its ability to influence and control key processes in the global carbon (C) cycle (Figure 1). The level of atmospheric carbon dioxide (CO_2) determines, through greenhouse warming, the net radiation balance and therefore temperature of the atmosphere. However, as Figure 1 demonstrates, atmospheric CO_2 is dynamically linked, by rapid air–sea exchange, to a much greater reservoir of carbon dissolved in the oceans. As a result, long-term changes in atmospheric CO_2 are thought to result primarily from changes in the CO_2 chemistry of the oceans.

These changes are, however, slow. Most of the ocean's volume (about 95%) consists of very cold, deep water that spends on average 1000–2000 years circulating in the deep ocean basins out of contact with the atmosphere. As a result, the comparatively rapid introduction of fossil fuel carbon into the system means there has not yet been enough time for the extra CO_2 to be absorbed into this deep ocean reservoir, causing atmospheric CO_2 levels to rise over the last 200 years.

Lying above most of the deep ocean is a thin stable layer of warm water that is heated by the atmosphere. Only at the highest latitudes does the cold, deep water come into direct contact with the atmosphere. In these surface waters, the primary organisms of the marine biota, known as phytoplankton, convert CO_2 into organic tissue using sunlight energy in the process of photosynthesis. As well as requiring CO_2 and sunlight, photosynthesis also requires a whole raft of essential chemical ingredients that must be present in the seawater. These include nitrate and other forms of nitrogen (used, for example, in amino acids), phosphate (used for phosphate esters such as adenosine triphosphate), silicon (used for structural components of diatoms), iron (various iron-based enzymes) and other metals. These ingredients are usually termed nutrients.

Figure 1 shows that of the 50 Gt year^{-1} of carbon (1 Gt = 1 gigaton or 1 billion metric tons of carbon) taken up by photosynthesis into the marine biota, 40 Gt or 80% is put back directly into the surface waters by respiration. This process, which is just the reversal of photosynthesis,

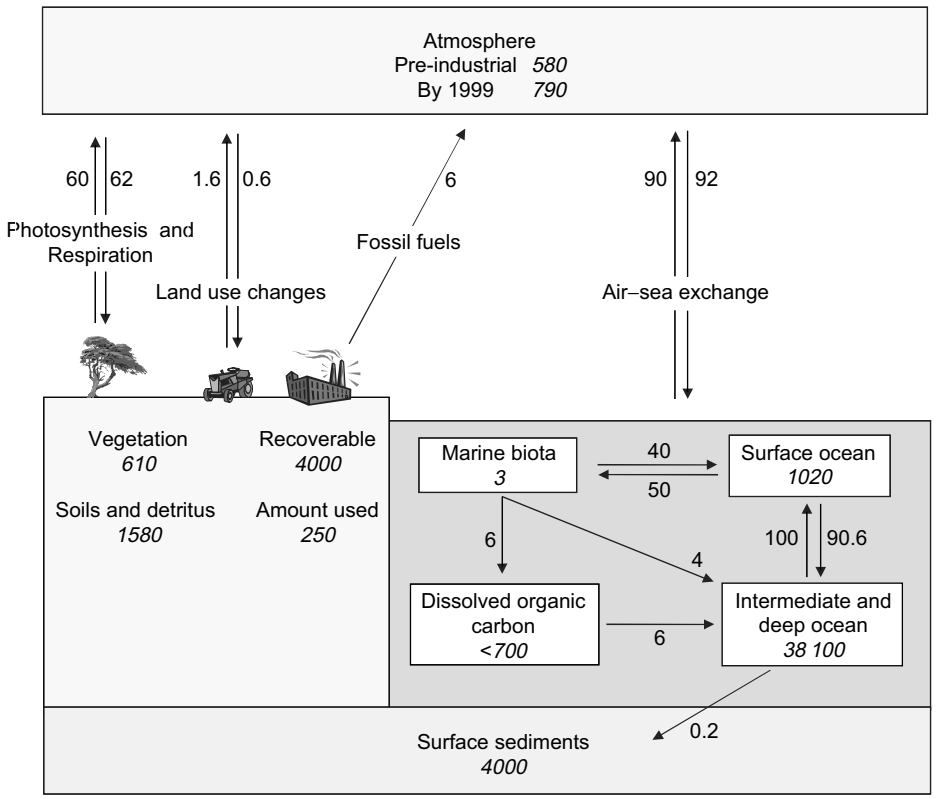

Figure 1 Global cycle of CO_2 in the ocean-atmosphere system representative of the present day. Fluxes between reservoirs are expressed in terms of gigatonnes of carbon per year (Gt C year^{-1}, 1 Gt being 1×10^9 tonnes or 1×10^{15} g of CO_2 expressed as carbon). Quantities in each reservoir are shown in Gt C as italicized numbers. Adapted from the IPCC document (Houghton *et al.*, 1996) by adding additional estimates of fossil fuel reservoirs and consumption, and by augmenting the original atmospheric inventory from 750 to 790 Gt assuming an annual growth of 3.3 Gt year^{-1} since the mid-1980s. Fluxes of CO_2 within the ocean have been modified from IPCC estimates to give balanced fluxes and a better match to measurements of the CO_2 increase in surface waters

occurs mainly through consumption by microscopic animals known as zooplankton, and through bacteria that feed on organic tissue. As a result of respiration, 80% of the nutrients needed for further photosynthesis are recycled within the surface waters.

THE BIOLOGICAL PUMP

The remaining 20% of carbon is transferred into the deep ocean as rapidly-settling particles comprising dead cells, fecal matter and other biological detritus. There, it eventually undergoes respiration, both directly and through the intermediate formation of breakdown products known as dissolved organic carbon. However, the slow circulation of the deep ocean means that recycling of the carbon and nutrients back to the surface takes thousands of years.

This process represents a biological pump through which deep water becomes enriched in carbon and nutrients and surface water becomes depleted. The overall distribution of the different chemical ingredients depends on the balance between the biological pump and the physical pump represented by the circulation system. Figure 1 shows that for carbon, the physical pump brings into the deep layer 90.6 Gt year^{-1}, or about 90% of the 100 Gt year^{-1} it pumps back to the surface. The balance of 10% is the carbon supplied by biological pumping.

This differential pumping has important consequences for atmospheric CO_2. Because of it, the total carbon content of the surface ocean is depleted by about 10%. In addition, because of the pH changes associated with photosynthesis, its pH is about 0.3 units higher than that of deep waters. The combined effect of these two factors means that if the biological pump were to cease, atmospheric CO_2 levels would increase to 2–3 times greater than they are now, precipitating a super-greenhouse effect. This underlines how the Earth's climate system is dynamically controlled, over short time scales, by the biological pump.

WHAT CONTROLS THE BIOLOGICAL PUMP?

Most of the plankton growth in the surface ocean is driven by locally recycled carbon and nutrients. However, the

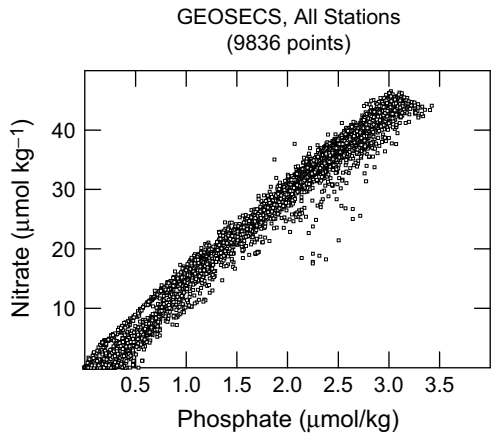

Figure 2 Relationship between measured concentrations of nitrate and phosphate in the global ocean. Drawn using data gathered during the GEOSECS programme

biological pump is driven only by the carbon and nutrients recycled into the surface layer from the deep ocean. This represents only a fraction of the total growth rate, and is often termed new production. Although there is agreement on what the concept of new production means, a variety of conflicting methods have been used to measure it, the details of which are beyond the scope of this article.

Since the surface water concentration of carbon is only depleted by about 10%, photosynthesis is not limited by the supply of carbon. In regions of high latitude, a lack of sunlight may be a limiting factor for part of the year, but throughout much of the global ocean, new production seems to be co-limited by the availability of the nutrients nitrate and phosphate. Throughout the mid-latitude range, between approximately 45 °S and 45 °N in the main ocean basins, levels of both phosphate and nitrate in surface waters are essentially zero compared to deep waters. More importantly, the concentrations of these two substances are closely correlated with each other throughout the ocean, as shown in Figure 2. The remarkable consistency of this correlation points to closely regulated, parallel controls on the availability of both nutrients by phytoplankton. This implies that the biological pump has stripped surface waters of nitrate and phosphate until both are depleted to near zero levels. At this point, new production will be small and limited by the resupply of these substances from deep waters. This nitrate-phosphate limitation is one of the central paradigms of oceanography.

ANOMALOUS REGIONS OF THE OCEAN

However, some regions of the global ocean do not conform to this picture. These are where high residual levels of nutrients remain at the surface, but phytoplankton growth rates remain low, as evidenced by low concentrations of the plant pigment chlorophyll, which is characteristic of the abundance of photosynthesizing organisms. The advantage of using chlorophyll is that its concentration can be indirectly sensed using a satellite image of ocean color. Such areas are termed high-nitrate, low-chlorophyll (HNLC) areas and they defy the nitrate–phosphate paradigm.

The main HNLC regions are located in the equatorial Pacific Ocean, in the Pacific Ocean at high latitudes (sub-Arctic Pacific), and in the Southern Ocean at latitudes greater than 50 °S. All are recognized as areas of upwelling, where the nutrient-rich deep waters spill upwards to reach the surface. Therefore, they should be particularly favored regions for nitrate-supported new production.

Clearly, another key ingredient for photosynthesis is missing in HNLC waters. Satellite images of ocean color reveal that in these regions, the highest levels of chlorophyll pigments are consistently found in areas close to landmasses, or in the downstream influence of landmasses. This implies that the missing nutrient is one that is particularly abundant in the terrestrial environment.

IRON - IS IT THE MISSING INGREDIENT?

From the 1980s, mainly through the pioneering efforts of the late John Martin of Moss Landing Laboratories, CA, and amid much scientific controversy, the element iron has become recognized as an important nutrient responsible for most, if not all, the control on phytoplankton new productivity in HNLC areas.

Early experiments involved inoculating small bottles (1–30 l) of seawater taken from HNLC regions with a small amount of iron, and observing the effects of iron addition on growth rates and nutrient uptake. These were carried out on board ship immediately after collection of the water. The main finding was a dramatic increase in the growth rate of primary organisms, particularly phytoplankton having larger cells such as diatoms. The stimulation of production was not immediate, but became apparent only after a time lag of several days. A change in ecosystem structure was also observed, from primary producers utilizing largely ammonium as a nitrogen source to one with an increased demand for nitrate. Consequently, the originally high nitrate levels in the water decreased as production developed.

These bottle incubation experiments were strongly criticized because they do not accurately reproduce the ecological conditions in the actual surface ocean. Specifically, taking a small volume of seawater does not include a statistically significant concentration of the much less abundant zooplankton that graze on phytoplankton. Thus, the observed increases in growth rate may have resulted from a lack of grazing pressure. Another criticism is that the

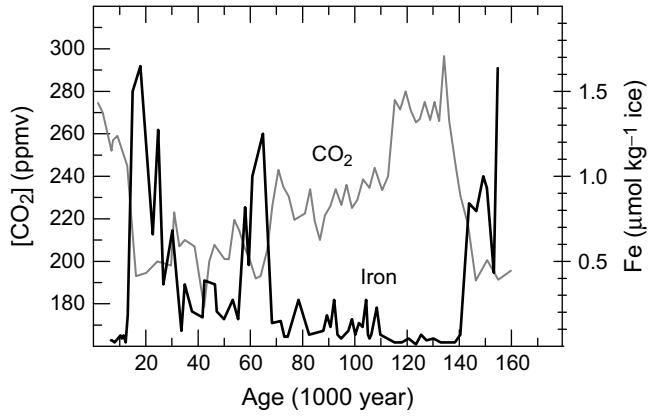

Figure 3 Comparison between CO_2 concentrations measured in air bubbles trapped in layers of ice taken from the Vostok core, East Antarctica (Barnola *et al.*, 1987) with iron concentrations derived from measurements of dust concentration in the same core (De Angelis *et al.*, 1987). The horizontal age scale is based on ice stratigraphy

walls of the bottle may provide an ecological niche that artificially enhances the growth rates of some species of phytoplankton.

In spite of these objections, the concept that iron may control phytoplankton growth in HNLC regions has intriguing implications for global climate change. John Martin was quick to point out that the periods of lowest CO_2 concentration during the last glacial period corresponded to periods of very high dust input because of larger arid regions (Figure 3). He suggested that iron-containing dust fertilized the glacial ocean, enhancing the uptake of carbon by the biological pump. However, this view is still hotly debated.

IRON CHEMISTRY AND ITS UPTAKE BY PHYTOPLANKTON

Iron is essential for the growth and metabolism of all organisms. It occurs in cytochromes and in proteins involved in key metabolic processes, e.g., photosynthetic and respiratory electron transport, nitrate and nitrite reduction, N_2 fixation, and sulfate reduction. Iron, therefore, has a wide variety of potentially important roles in marine phytoplankton, most of which are catalytic in nature, rather than being structural components of the cell. As a result, low iron availability should have its greatest influence on rates of metabolism and cell growth.

Phytoplankton that assimilate nitrate as their nitrogen source, such as diatoms, require nitrate reductase, an iron-containing enzyme. This explains in part why diatoms dominate after iron is added to iron-depleted waters. By contrast, the smaller organisms that are capable of assimilating reduced forms of nitrogen, such as ammonia, are more viable than diatoms under low iron conditions.

The chemistry of iron in seawater poses major problems for organisms requiring it for growth. Most iron in seawater is present in the oxidation state Fe (III), which in the alkaline conditions of seawater should readily form insoluble iron oxides. Calculations of the solubility of iron oxides suggest that the maximum concentration of Fe (III) should be less than 0.2 nM ($1\,nM = 10^{-9}\,mol\,l^{-1}$). In fact, throughout most of the ocean, measured Fe (III) concentrations are significantly higher (0.3–0.6 nM, with higher values in coastal waters). We now know that this superabundance is caused by the binding of Fe (III) to highly specific organic compounds that appear to be of biological origin. Indeed, we can speculate that if it were not for this organic binding, all of the ocean would be iron-limited. Thus, phytoplankton may have actually evolved to generate this iron-binding organic matter to create the conditions they require for growth!

It is not well understood how phytoplankton take up this organically bound iron from seawater. It seems clear that the bound iron is not itself biologically available, but first has to be released from its binding agent. This release may be the factor limiting the rate of iron uptake, and hence the rate of metabolism in iron-depleted regions. One mechanism for release is the action of sunlight on the iron-organic complex, which is known to generate Fe (II), which although unstable in seawater, may exist long enough to be assimilated by cells. An alternative mechanism involves the use of binding agents on the cell surface that assist in removing the iron from its complex. Although much is known about these mechanisms in other environments, e.g., soils, the very low levels of iron in the ocean make the study of its uptake extremely difficult. Therefore, much of our understanding at present is based on analogy rather than hard scientific evidence.

Experiments in the laboratory suggest that even coastal phytoplankton, which are usually not iron-limited, appear to be assimilating iron at optimal rates, given the constraints mentioned in the previous paragraph. Oceanic phytoplankton have, therefore, had to evolve strategies for achieving the same metabolic rates with a reduced iron supply. However, their flexibility is demonstrated by the fact that they can take advantage of variations in the iron supply, and go on an iron spending spree. This implies that they have alternative genetic pathways for synthesizing enzymes that depend on the local iron availability.

LARGE-SCALE IRON FERTILIZATION EXPERIMENTS

Due to the many objections to bottle-scale iron fertilization experiments mentioned earlier, much larger-scale experiments were advocated, in which a patch of surface water of the order of 10×10 km in size would be inoculated with iron. Over this distance scale, both grazing and

wall-effect anomalies would be absent. What made these experiments possible was the development of methods that would allow the location of a fertilized patch of water to be traced over a period of many days. This involved the addition of sulfur hexafluoride (SF_6), a harmless but readily-measured substance along with the iron. To date, three of these (very expensive!) experiments have been conducted.

The first two experiments, termed IRONEX I and II, took place in the equatorial Pacific Ocean (Martin *et al.*, 1994; Coale *et al.*, 1996). In both cases, a ~10 km-sized region of surface water was dosed with iron and the changes inside this region compared with control stations outside it for a period of 1–2 weeks. In IRONEX I, iron was added in a single addition, while in IRONEX II a similar total amount was added in three separate additions at three-day intervals with the aim of more nearly simulating a continuous supply from a natural source.

In both experiments, a significant increase in light energy consumption by the phytoplankton was measured within hours of iron addition, indicating new photosynthesis stimulated by the extra iron. Over the first few days, chlorophyll levels also increased significantly, and CO_2 levels began to decline. At the same time, significant levels of dimethylsulfide (DMS), an indirect product of phytoplankton growth, were observed (*see* **Dimethylsulfide (DMS)**, Volume 1).

However, after three days, the courses of the two experiments diverged. In IRONEX I, CO_2 levels in the fertilized patch did not decline further after the first two days. This shows that carbon was no longer being exported from the patch by the biological pump, implying that the grazing zooplankton responded rapidly to consume the enhanced phytoplankton growth. Moreover, organisms with larger cells such as diatoms, which are not as efficiently removed by grazing, did not have long enough to become dominant because the enhanced iron levels had decreased rapidly over the three-day period.

However, in IRONEX II, the same amount of iron was added in three separate doses, each three days apart, allowing the larger-celled diatom species to become dominant and eventually to form a bloom. This resulted in much more dramatic, and prolonged, decreases in CO_2 levels within the patch, indicating carbon export from the surface layer. Again, nitrate levels decreased significantly through this period, but did not reach zero. Instead, the ultimate limiting factor of the iron-stimulated patch appeared to be the diminished availability of silicate needed for diatom growth.

The third iron fertilization experiment (Southern Ocean Iron Release Experiment, SOIREE) was undertaken by a joint group from New Zealand, the United Kingdom and the Netherlands in early 1999 in the Southern Ocean, with additional dramatic results (Boyd *et al.*, 2000). A multiple dose of iron was used, as in IRONEX II, resulting in similar effects in terms of stimulated growth rates, nitrate uptake, decrease in CO_2 and DMS production. It was found, with great surprise, that although the added iron decreased in concentration over the first few days, afterwards it remained quite high throughout the experiment, contrary to expectations based on the known chemistry of iron. More significantly, satellite imagery indicated that the resultant bloom persisted for at least 55 days! In this case, it appears that the bloom did not run out of silicate because of the nature of the water movements adjacent to the patch that provided a re-supply of silicate as it was consumed by the diatom bloom.

IS IRON FERTILIZATION A FEASIBLE SOLUTION TO GLOBAL WARMING?

The realization that large areas of the global ocean were iron-limited quickly gave rise to the notion that it might be possible to fertilize HNLC areas with iron in order to bring down the concentration of CO_2 in the atmosphere. Calculations based on the amount of iron needed to stimulate new production of the required amount of carbon suggested that it might be economically sound. Iron is vastly abundant in the Earth's crust, and one of the cheapest mineral materials.

However, prudent examination suggests that such schemes would probably not work. The problem is to keep iron in the surface layer long enough to stimulate a reasonable amount of new production before it precipitates as iron oxide particles, but ensure that the newly-produced carbon sinks out of the surface layer. Clearly these two requirements are mutually exclusive. Indeed, detailed calculations suggest that the practical outcomes of iron fertilization would not be worth the trouble and expense in terms of the total amount of CO_2 that could be removed.

More importantly, it is probably extremely unwise to risk all of the unknown ecological and climate changes that might result from large-scale iron fertilization of the ocean (Chisholm, 2000). In terms of human influences on the global climate system, this might be the time to say enough is enough.

CONCLUSIONS

The last 10 years have seen the emergence of a fascinating new paradigm involving the importance of iron as a factor controlling the productivity of the global ocean. This involves the intriguing notion that phytoplankton have created the chemical conditions in the ocean that best suit them, in the process taking control of the global carbon cycle, with all that this implies for global climate change. There are many gaps in the picture, and future research will no doubt reveal even more subtle detail in this fascinating story.

Keystone Species

As the name implies, *keystone species* play such important and unique roles in the structure and functioning of an ecosystem that the ecosystem would be very different without them. Some keystone species help to maintain local diversity within an ecosystem by controlling populations of species that would otherwise dominate. For instance, the predatory starfish *Pisaster ochraceus* is considered a keystone species in the rocky marine intertidal of North America's Northwest Coast. By feeding on and thus suppressing populations of the mussel *Mytilus californianus*, the starfish maintains much of the local species diversity. Removal of the starfish in small-scale experiments has allowed mussel populations to increase so rapidly in size and spread so densely over the intertidal rocks within experimental enclosures that other species could find no space to gain a foothold. The starfish, however, has little overall effect on some other ecosystems in which it occurs and this shows that keystone status depends at least partly on the nature of the ecosystem.

Other keystone species help to maintain local species diversity by providing critical resources for a wide range of species. For instance, beaver are often thought of as keystone species in North America because the ponds behind the dams they build provide unique habitat for many amphibians, aquatic species, and water birds. Particular species (e.g., nodulated, nitrogen fixing plants) that carry out a crucial function for the rest of the ecosystem are also considered to be keystone species. Another example is the fig trees in the rain forests of South America and Borneo because they often bear fruit all year and thus provide a reliable food source for many mammals and birds during periods of scarcity.

Lakes and Rivers

John J Magnuson
University of Wisconsin-Madison, Madison, WI, USA

Lakes and rivers cover a tiny fraction of the earth's surface, but these ecosystems and the resources they contain are essential to human survival. Many of the ecosystem services they provide are under-valued. As ecosystems, lakes

and rivers cannot be understood, managed or conserved without including the interactions with their shorelines, their watersheds and their climates. Thus, their functioning in terms of biogeochemical cycling, productivity, and biodiversity habitat are influenced by anthropogenic changes not only to the waters themselves, but also to the land, the air and the climate.

Inland aquatic environments are relatively rare environments. Water covers about 75% of the earth's surface, but inland waters only constitute 0.0171% of the earth's surface waters by volume (0.0091% are freshwater). This contrasts with the 0.5% for groundwater, 2.2% for ice and the massive 97.3% for oceans (Cole, 1994).

Lakes and rivers are ecosystems – interacting physical and biological systems somewhat independent from adjacent lands and atmosphere. Rivers and streams are the arteries of our continents; and lakes, rivers and wetlands integrate the activities and events in their watersheds (Naiman *et al.*, 1995). They have their own biota, physics, and chemistry; their own processes and behavior, yet both are so dependent on their surrounding catchments or watersheds, their airsheds, and climate, that their behavior can be neither understood nor predicted without considering these external influences. The link to the watershed is so strong that an inland water ecosystem often is defined to be the water body plus its drainage system.

The science of inland waters is called *limnology*, the sister science to oceanography or marine science. Limnology includes the biology, physics, chemistry and ecology of all waters on continents and islands. Thus, limnology includes wetlands, groundwater, ponds and springs. Not all who study inland waters call themselves limnologists; some think of themselves, e.g., as aquatic ecologists, hydrologists, water chemists or wetland scientists. Somewhat counter to intuition, limnology is not the science of freshwaters, *per se*; some inland waters are more saline than the ocean, e.g., the Caspian Sea, the Dead Sea in the Middle East and Salt Creek in Death Valley, CA.

Lakes (Figure 1) and streams (Figure 2) provide many products and services for humankind (Naiman *et al.*, 1995; Postel and Carpenter, 1997). These include the direct uses of inland waters, products harvested from them, and a long list of often unappreciated or under-valued services (Table 1).

Recent general books on limnology include Cole (1994); Horn and Goldman (1994); Lampert and Sommer (1997); Brönmark and Hansson (1998); Giller and Malmqvist (1998); Moss (1998); Boulton and Brock (1999).

LAKE AND RIVER TYPOLOGIES

The classic distinction between lakes and rivers is that lakes are *lentic* (still waters) while rivers and streams are *lotic* (moving waters). Rivers have a shorter water residence time than lakes. All gradations between the two occur

and we often refer to wide sections of rivers as lakes, e.g., Lake Pepin as part of the Mississippi River. Streams and rivers tend to have a dominating, unidirectional or downstream flow and lakes do not. Lakes, however, are not still waters; wind-driven currents, waves, and mixing typify their physical behavior.

No single or exclusive set of designations characterizes types of lakes or rivers. They can be classified by location, size, chemical and physical features, productivity, shoreline or watershed features, use or modification by humans, position in the landscape, or even the geological processes of formation. Many types are largely self-evident but useful in the eye of the beholder – large or small, tropical or arctic, urban or forested, clear or dark water, bass or trout, etc.

Some classification requires more explanation. *Eutrophic* lakes, owing to high supply rates of essential nutrients, are productive and green with anoxic (without dissolved oxygen) deep waters; *oligotrophic* lakes, owing to low supply rates of at least one major nutrient such as phosphorus (P) or nitrogen (N), are unproductive and clear (Horn and Goldman, 1994). *Mesotrophic* lakes are intermediate. *Dystrophic* lakes are not productive and have stained brown waters owing to the dissolved organic materials from decaying aquatic vegetation in the watershed. Streams have similar differences, but suspended solids often reduce clarity as well.

Rivers are typically viewed in the context of their flow path from headwater streams to the floodplains in the lowlands nearer the ocean (Hauer and Lamberti, 1996). These are often classified into stream orders where the headwater stream is first-order; a stream formed from two first-order streams is second-order; one formed from two second-order streams is third-order. The Mississippi at New Orleans is by this system a 13th order stream. Lakes can also be classified in a similar way (Magnuson and Kratz, 2000).

HABITATS IN LAKES AND RIVERS

Geomorphology provides the basic basin structure for lakes and rivers. Additionally, there is an internal structure based on water temperature and light intensity as well as water flow for streams.

The immediate shoreline, the *riparian* zone, is proportionately longer for streams than lakes when considered relative to the surface water area. Additionally, the *floodplain* is considered part of the riparian zone for streams (Jones and Mulholland, 2000); lakes typically have little floodplain compared to large rivers. Not surprisingly, while important to both lakes and streams, ecological interactions between the riparian and a water body are given more emphasis in stream ecology than in lake ecology. For example, living trees can shade much of a small stream, not so for lakes. Coarse woody debris and fallen dead trees provide structure and habitat for aquatic life but are relatively more significant in streams than lakes.

Lakes contain a number of habitats. The *littoral zone* of lakes is the interface between the shoreline and the open water. It extends from the splash zone on shore, offshore to the depth at which light is still sufficient for growth of rooted aquatic plants and bottom-living algae (Wetzel, 1975). Emergent plants such as reeds and cattails live nearest to the shore; submergent plants live farther offshore; and bottom living algae are at the greatest depths of the littoral zone. The size of the littoral is determined by basin shape as well as by suspended sediments, dissolved color, and dense algal populations in the water column that reduce light penetration and thus the maximum depth of plant growth. Offshore are the open water or *pelagic zone* and the *profundal* or deep bottom water habitat. *Benthic* habitats are the bottom substrate environments in all locations.

Lakes tend to thermally stratify while rivers tend not to. Turbulent flow usually mixes rivers from top to bottom; the work of the wind is responsible for mixing in lakes but often mixing does not extend to the bottom. In summer many lakes thermally stratify into an upper warmer, less dense layer or *epilimnion*; a *thermocline layer* or *metalimnion*; and a deeper cooler, denser layer or *hypolimnion*. A rule of thumb for defining the depth of the thermocline is where temperature changes $>1\,^{\circ}\mathrm{C\,m^{-1}}$ depth in the water column. If a lake becomes ice covered in winter, stratification again occurs but in this case the coldest water floats over less cold water. Winter stratification takes place because the maximum density of fresh water is $4\,^{\circ}\mathrm{C}$. Between summer and winter stratification, lakes mix from top to bottom (turnover). This seasonal pattern of stratification is for a temperate-zone lake; tropical lakes tend to remain stratified all year; Arctic lakes tend not to stratify in summer.

Stream drainage networks are hierarchically nested into valley segments, stream reaches, and channel geomorphic units (Hauer and Lamberti, 1996). Valley segments include colluvial, alluvial and bedrock. Valley sediments in colluvial segments derive from organic and inorganic materials eroded from the adjacent hillslopes. In alluvial valleys, sediments derive from upstream sources and currents are insufficient to scour the valley to bedrock. Bedrock valleys usually have confined valleys and little fill materials. The channel is V-shaped in relatively young mountain catchments with considerable erosive influence while stream channels in the alluvial or deposited terraces of floodplains are complex. Channel reaches in alluvial valleys can be cascades, braids, step pools, plane beds, pool riffles and low gradient meanders. Channel geomorphic units are initially classified by fast water (turbulent and non-turbulent) and slow water (scour pools and dammed pools). Many sub-units exist such as falls, cascade, rapids, riffle and chute for turbulent fast water; sheet and run for non-turbulent fast water; eddy, trench, mid-channel, convergence, lateral and plunge for scour pools; and debris, beaver, landslide, backwater and abandoned channel for dammed pools.

In streams, and lakes as well, a distinctive biota lives in the zone below and adjacent to open waters where mixtures of ground and surface water occur (Cole, 1994; Hauer and Lamberti, 1996). For streams, this hyporheic zone is an important habitat for organisms and for hydrologic interactions with the surface stream with complex influences on nutrient cycling. The psammolittoral zone of lakes exists in the interstitial waters within sand beaches.

BIOTA IN LAKES AND RIVERS

Biota of lakes and rivers occur in and on the bottom or benthic zone, in the water column, floating on the surface, and in the hyporheic and psammolittoral zones. Primary producers make new organic carbon; they include phytoplankton suspended in the water column, macrophytes and benthic algae in the littoral zone, and chemosynthetic and photosynthetic bacteria. Many bacterial groups are involved in biochemical transformations of nitrogen, sulfur (S), and other elements (*see* **Biogeochemical Cycle**, Volume 2). Primary consumers include many invertebrate taxa, such as microscopic crustaceans like water fleas, immature aquatic insects and snails, plus some vertebrates. Secondary consumers are dominated by fishes, but include other vertebrates such as birds and many invertebrates such as immature and adult aquatic insects. Tertiary consumers are typically large piscivorous fishes, but include birds and mammals such as bears. Humans sit at the top of many inland water food webs.

Aquatic organisms often are treated as functional groups or guilds owing not only to their role in ecosystems, but also to their high species diversity, the taxonomic complexity of food webs, and an inability to identify and count all players. In forest streams, animals are considered by

their source of food and feeding mode. Scrapers – scrape algae and other organisms from the surfaces of rocks and dead wood; shredders – shred fallen tree leaves, rich with bacteria and fungi, leaving only the veins of the leaf and fine particulate material; gatherers – gather the fine particulates, and predators eat the scrapers, shredders and gatherers. In the open waters of lakes and ponds, organisms are grouped by life style and strength of swimming. *Phytoplankton* are small unicellular plants suspended in the water column; *zooplankton* are small weak-swimming animals carried by the currents; *nekton* are the strong swimming fishes, birds, and reptiles; and *neuston* are the diverse organisms living on the water surface film. Fishes can be *herbivores*, *zooplanktivores*, *zoobenthivores*, and *piscivores*. Nitrogen-fixing algae convert dissolved nitrogen gas (N_2) into usable nitrates; denitrifying bacteria convert nitrate back to nitrogen gas. Aquatic plants are grouped into emergent, submergent, and floating groups, each with different sets of adaptations and ecological roles.

CONCEPTS OF LAKE AND RIVER STRUCTURE AND FUNCTION

Biogeochemical Cycling

Biogeochemical cycling includes the major elements such as the important nutrients, phosphorus and nitrogen, and industrial chemicals such as polychlorinated biphenyls (PCBs), and biocides such as dichlordiphenyltrichloromethane (DDT). Compounds are transformed by biological and chemical processes, transported by movement of water and biota, deposited or stored in sediments. Some such as DDT and PCBs accumulate in food webs with harmful biological effects.

Major biogeochemical cycles are greatly influenced by whether dissolved oxygen is present and by pH or acidity. These conditions affect solubility of compounds and thus biotic availability; they also determine which biochemical processes can occur. Below, we consider phosphorus, nitrogen, and mercury (Hg).

In anoxic sediments, hyporheic zones, or hypolimnia, iron phosphates are soluble and the phosphorus can be recycled back into the biota. If dissolved oxygen is present, then the iron phosphates are insoluble, precipitate, and accumulate in the sediments. This process can intensify the negative influence of excess production, because excess production leads to anoxic conditions and the release of phosphorus that, in turn, can lead to more production.

Cycling of nitrogen by bacteria goes from nitrite to nitrate in oxygenated conditions, but from nitrate to nitrite in anoxic conditions and ultimately to nitrogen gas. In river floodplains, water covered sediments become anoxic and nitrate is transformed to nitrogen gas and released to the atmosphere. If the sediments are dry or oxygenated, nitrates persist and are available for transport downstream and increased biological productivity during a flood event. This process contributes to the movement of nitrate from major floodplain rivers to coastal marine waters where excess production and anoxia can occur owing to these transported nutrients (Naiman *et al.*, 1995; Turner and Rabalais, 1994).

Biogeochemical cycling of nutrients is conceptualized as nutrient cycling in lakes and nutrient spiraling in streams (Wetzel, 1975; Allen, 1995; Essington and Carpenter, 2000). In lakes, nutrients cycle between the biota and the water and can accumulate in bottom sediments. In streams, nutrients cycle from the biota to the water, but in so doing move progressively downstream with each exchange; thus there is a visual analogy of a nutrient spiraling downstream. Differences in the export rates of a nutrient to the sediments of lakes or downstream in streams helps conceptualize the importance of export in determining productivity in the two systems. In lakes the number of times a nutrient molecule is sequestered by producers before export is governed by processes that promote mineralization (*see also* **Nitrogen Mineralization**, Volume 2) and retard particulate sedimentation; in streams it is governed by processes that promote uptake and retard downstream loss of dissolved nutrients.

Mercury is deposited on the surface of the waters by atmospheric deposition (Porcella *et al.*, 1995). About half of this mercury is from the burning of coal. The form of mercury taken up by the food web is methyl mercury (CH_3Hg^+). Bacterial processes that form methyl mercury thrive in more acidic waters of pristine headwater lakes where contamination of fishes reaches levels unhealthy to humans.

Contaminants such as PCBs and DDT that are soluble in lipids bioaccumulate in food webs by about a factor of 10 for each step upwards. Concentrations in the apex predators such as fishes are thus greatly biomagnified over levels in water (Stow *et al.*, 1995).

Productivity

Productivity of lakes and streams has long been of interest because people use these systems for food and fiber on the one hand and because high productivity produces limnological conditions judged to be unfavorable to humans on the other hand. Freshwater and inland fisheries yielded 7.7 million metric tonnes of fishes, amphibians, crustaceans, and mollusks in 1997 (FAO, 1999). Another 17.7 million tonnes came from aquaculture, much of which also comes from inland waters. Eutrophic lakes have noxious algal growths that not only are unsightly and smell bad, but also result in the loss of dissolved oxygen needed for the survival of coldwater fishes in the hypolimnia of lakes. Excessive nutrient from sewage, or agriculture and industrial inputs to rivers also produce putrefaction, loss of dissolved oxygen, and loss of fishes.

Productivity varies greatly among waters, depending on morphometric (size and depth), edaphic (watershed soil and nutrients), climatic (precipitation and temperature), and anthropogenic (fertilization and runoff) factors. Primary production in lakes generally increases with nutrient input or loading and decreases with increased depth (Horn and Goldman, 1994). With the same input of nutrients, deeper lakes tend to be more oligotrophic in character than shallower lakes. This is because dilution is greater in larger lakes, and because a greater store of oxygen exists in the large hypolimnion that is less likely to be depleted by the decomposition of phytoplankton as they sink and die.

In inland waters, primary productivity is usually limited by phosphorus (Horn and Goldman, 1994). However, in some regions where phosphorus is naturally abundant or where phosphorus is a major pollutant, limitation by nitrogen is common. In a lake, silicon (Si) usually becomes limiting for diatom growth by mid-summer because sinking diatoms with their heavy siliceous frustules have sunk into the hypolimnion carrying their silicon with them. In some systems even rare elements like molybdenum can limit productivity through their influence on nitrogen fixation by plants in the watershed. Production of benthic algae in some streams can be patchy owing to the patchy nature of nutrient upwelling from the hyporheic zone (Jones and Mulholland, 2000).

Consumer Driven Dynamics

While food webs and productivity are driven by nutrient and food resources, the influence of consumer-driven processes is equally important (Carpenter, 1988; Carpenter and Kitchell, 1988; Allen, 1995). In lakes, about half of the interannual variability in phytoplankton production is attributable to variation in nutrient availability and the other half to variability in the abundance of consumers. Herbivorous zooplankton can graze on and deplete the phytoplankton. Zooplanktivorous fishes can feed on and deplete the zooplankton. As a consequence, the presence of zooplanktivorous fishes in floodplain ponds can result in green water, the absence of fish to clear water. Alewife in small lakes can result in the loss of large zooplankton and the replacement with small zooplankton that are less effective herbivores on the phytoplankton. The visible influence of consumers on their prey is lessened in streams where prey immigration rates are high.

Consumer-driven changes are perhaps most apparent when a large change in abundance of a consumer is brought about by stocking of game fishes, the invasion of an exotic species, or by the catastrophic loss of fishes such as with summerkill or winterkill events resulting from low dissolved oxygen. Biomanipulation (Hansson *et al.*, 1998) is the developing management practice of reducing excess phytoplankton by stocking predaceous fishes that reduce the abundance of zooplanktivorous fishes that, in turn, increases the abundance of zooplankton that eat phytoplankton. Similarly, invasions or introductions of exotic crayfish can forage on and eliminate many macrophytes; invading zebra mussels can filter massive quantities of water and reduce the abundance of small phytoplankton and indirectly cause noxious blue/green algal blooms; predaceous fishes can eliminate smaller species of fishes. The perceived value of such changes ranges from positive to negatively catastrophic.

Commercial, artisanal, and recreational fishers can overfish lake and river populations. Over-fishing as a consumer-driven process, results in a reduction in the abundance of targeted fish species and a reduction in their average body size with subsequent reverberations down the food web. Additionally, fisheries increase the probability of introductions of harvested or exotic species by fish managers and escapees from aquaculture, bait production, and the aquarium trade.

Climate

The balance between precipitation and evapotranspiration determines the very existence of inland water ecosystems. Where evaporation greatly exceeds precipitation, saline waters form in lowland areas. Dilute waters characterize upland areas when precipitation exceeds evapotranspiration. The flow of water in streams, the annual flood and drought, and contributions of ground water are determined by the climate acting on the local landscape and geomorphology.

Lakes and streams are warmed by solar radiation and warmed and cooled by heat transfer by thermal conduction, evaporation, and hydrologic flow. Winds drive internal dynamics of physical mixing working against the density gradients resulting from heating near the surface. Cloudiness can shade the waters from direct sun.

Lakes and streams are highly responsive to climatic variability and warming (Arnell *et al.*, 1996; Cushing, 1997). As a class of ecosystems, they are vulnerable to climate change (Gitay *et al.*, 2001). The most vulnerable components are the loss of lake and river ice, habitat loss for cold-water fishes, increases in poleward invasions and subsequent extinctions of biota, and the exacerbation of existing problems with eutrophication, toxic pollutants, and water use.

Regional Ecology

Lakes appear as patches, and streams as dendritic patterns on the landscape. The heterogeneity among lakes and among stream reaches is organized across the landscape in respect to the hydrologic flow path. The basic idea, and a tenet from landscape ecology, is that position matters.

For streams, the stream continuum concept portrays changes in the dominance of particular ecological processes

from the headwaters downstream to the large floodplain rivers (Vannote *et al.*, 1980; Johnson *et al.*, 1995). In headwaters of a forested stream, for example, structure and function are dominated by groundwater inputs and shading by riparian trees; the food web is driven by organic inputs of leaves and branches from the riparian vegetation. Thus, upstream waters are cooler than lower reaches, terrestrial primary production controls stream productivity, and a food web dominated by shredders and gatherers exists. In mid-reaches, streams widen and the shallow flowing waters are increasingly energized directly by the sun as the canopy opens. Thus, waters warm and instream primary production from benthic algae and macrophytes and consumption by herbivores dominate. In the lower reaches of large rivers, fine organic particulates and sediments enter from the floodplain. The waters warm; sunlight for instream photosynthesis is low because the stream is deeper and the light is absorbed and scattered by suspended materials. Gatherers and filterers dominate the primary consumption in the food web. Thus, there is a continuum of energy inputs and a continuum of energy processing from *heterotrophic* in the headwaters, to *autotrophic* in mid-reaches, to heterotrophic again in the lower reaches.

Viewing a river ecosystem in the continuum context provides a concept of the whole and helps eliminate a road bridge view of how rivers function. Additionally, it emphasizes the importance of upstream and lateral influences.

For lakes, the concept of position in the landscape portrays a sequence of structure and function with clear analogies to the stream continuum (Magnuson and Kratz, 2000; Riera *et al.*, 2000). Headwater lakes tend to be small and have greater inputs of rainwater relative to groundwater or overland flow, while lakes lower in the flow system tend to be large and have more inputs from ground water and tributary streams. Thus, upland lakes tend to have lower concentrations of dissolved ions and lower species richness of fishes. In some regions, many other characteristics map on this template such as human dwellings, lake shape, invertebrate distribution, chlorophyll concentrations, etc.

Other landscape considerations important to lakes and streams include interaction with the watershed, the flood pulse concept, ecological interactions that cross the boundary between lakes and streams, and island biogeography (Magnuson and Kratz, 2000). Considering a lake or stream interacting with its catchment is clearly a landscape approach that recognizes the strong interaction between two major dissimilar patches on the landscape – water body and adjacent land. Owing to changes in land use, this is a particularly significant consideration in any discussion of future global environmental changes of lakes and streams.

In flood plain rivers, the flood pulse onto the land is incorporated into the functioning of river ecosystems and constitutes an important land-water interaction (Bayley, 1995). In this sense, the flood is not a disturbance to a river ecosystem, but a process that contributes to productivity in the river and its floodplain. Organisms and biogeochemical cycles are adapted to the progressive advance and retreat of the waters. For example, young and adult fishes disperse onto the floodplain to utilize rich foraging areas where a progression of nutrient inputs, production of aquatic and terrestrial plants, and decomposition of this production occurs over the flood pulse. River channels are dynamic, and primary succession and agriculture occur on recently deposited sediments.

Biodiversity

Biodiversity of inland waters is high. For example, of the more than 28 000 known fish species, 41% are freshwater and 58% marine (Moyle and Cech, 1996), even though the oceans are much larger – about 70 times by area and 10 000 times by volume. In lakes formed in ancient times, species flocks of fishes, algae, and many invertebrates have evolved with many endemic species unique to that particular water. Individual rift valley lakes in East Africa contain species flocks of almost 250 cichlid species. In Lake Baikal in Russia 35% of the plants and 65% of the animals are endemic (Burgis and Morris, 1987). Individual streams have high species diversity; the Breitenbach, a small German stream has at least 1044 invertebrate species, including 476 dipteran species, 125 nematodes, and 106 rotatorians (Allen, 1995). As many as 250 species of diatoms are known from individual species-rich streams in the US.

Isolation of lakes and headwater streams is a primary explanation of the high diversity both in individual waters and across a region. Species composition depends on a range of regional to local factors (Tonn *et al.*, 1990). The number of species increases with the area of a lake (Barbour and Brown, 1974) and the drainage basin area of streams (Sepkoski and Rex, 1974), largely owing to the increase in habitat diversity in larger systems. The number of species is difficult to determine and numbers found is greatly dependent on sample size (Arnott *et al.*, 1998).

Because humans have increased both invasion and extinction rates, the species turnover rates of inland waters have apparently increased (Magnuson, 1976). Species composition and richness in more isolated waters may be more controlled by adaptive radiation and local extinction than by invasion. The more isolated a water body is from invading colonists, the more endemism will result for older lakes and streams. More relic flora and fauna will persist in more isolated waters as dispersal brings warmer-loving colonists poleward. In more open or connected waters, species composition and richness may be controlled more by invaders and their interactions with native organisms. Invasion rates, owing to transplantation by humans, have been occurring at a rapid rate and floras and faunas are tending towards spatial homogeneity (Rahel, 2000).

THREATS IN A CHANGING GLOBE

Both the functioning of lake and stream ecosystems and the supply of human products and services are sensitive to anthropogenic change. Responses will not only come from direct changes to the waters themselves, but also from changes to the riparian zone and the watersheds as well as the air and climate. Effects of global environmental change on land will be accentuated downward across the landscape in lakes and streams. Many of these systems are already damaged with present levels of population and development.

Changes of concern to the function and value of lakes and streams include increases or changes in land use, climate (e.g., falling lake levels), biological invasion rates, toxic and nutrient release or redistribution, food production and aquaculture, hydrologic engineering structures for water regulation, and energy production and use. Each of these general topics includes a rich array of concerns. Land use, for example, includes changes in agricultural lands and practices, urbanization and suburbanization, shoreline modification, and altered vegetative cover. Hydrologic engineering structures include dams, dykes, channelization, instream flow regulation structures, bulkheads, pilings and walls.

Change will occur. Not all will negatively influence lakes and streams, many will. A key is to understand how these changes will influence the functioning of inland aquatic ecosystems and the products and services they provide. There is also an increasing awareness that restoration or rehabilitation of ecosystem functions can help maintain and recover the function and the goods and services that inland waters can provide.

Landscape Ecology

Traditionally, ecologists have focused on the study of individual ecosystems. *Landscape ecology* is the study of the ecology of a large geographic area (or landscape) as a unit. The focus is on the spatial arrangement of different kinds of ecosystems (e.g., swamps, fields, ponds, roads, and woods) and how these arrangements affect the movement of animals, plants, nutrients, and energy across landscapes. Landscape ecologists look at the spatial structure of diverse ecosystems, their function and interaction, and how they change over time.

Landscape ecology moves beyond measures that represent averages over the many different patches in an area and considers where patches are located relative to one another and how particular variables differ in value from one specific location to another. Landscapes are distinguished by properties of their constituent patches (i.e., patch quality) and by how their constituent patches interact. These interactions depend not only on the spatial arrangement of the patches, but also on the behavioral responses of organisms to landscape structure, or the properties of spatial flows of materials and spread of disturbances (e.g., fire, insect outbreaks, disease epidemics) through landscapes. Both landscape pattern and the reaction of organisms or physical processes to it depend on spatial scale, so spatial scale is important. The appropriate scales at which to study landscapes depend on the causal mechanisms behind the reactions of organisms or systems to landscape structure. Natural resource management has usually concentrated on particular blocks of habitat or species of interest, and management practices have been conducted on the hectare-to-kilometer scales corresponding to human land use. Landscape ecology stresses the need to consider entire landscape mosaics over a broad range of scales to gain a fuller understanding of how spatial patterns and processes interact to produce ecological dynamics.

Large Scale Biosphere-Atmosphere Experiment in Amazonia (LBA)

Diane E Wickland[1], Michael Keller[2], Carlos Nobre[3], and Pavel Kabat[4]

[1] *National Aeronautics and Space Administration, Washington, DC, USA*
[2] *United States Forest Service, USA*
[3] *Brazilian Space Research Institute, Brazil*
[4] *Wageningen University and Research Centre, The Netherlands*

The Brazil-led LBA is an international, interdisciplinary research program designed to address the climatological, ecological, biogeochemical, and hydrological functioning of

Amazonia, the impact of land use change on these functions, and the interactions between Amazonia and the entire Earth System. LBA's key questions are:

- *How does Amazonia currently function as a regional entity?*
- *How will changes in land use and climate affect the biological, chemical and physical functions of Amazonia, including the sustainability of development in the region and the influence of Amazonia on global climate?*

Tropical forests in Amazonia are being cleared and developed for agriculture at unprecedented rates. Road building, followed by immigration of farmers and fiscal incentives in Brazil for cattle ranching, resulted in this sharp increase in deforestation. Deforestation and agricultural land use are changing the cycling of water, energy, carbon, and nutrients and are expected to have climatic and environmental consequences at local to global scales. Further, some agricultural practices have not succeeded, and the long-term sustainability of development in Amazonia is a concern. To understand the consequences, to plan mitigation efforts, and to predict future conditions and the fate of agricultural development, enhanced knowledge is needed of Amazonian system functioning.

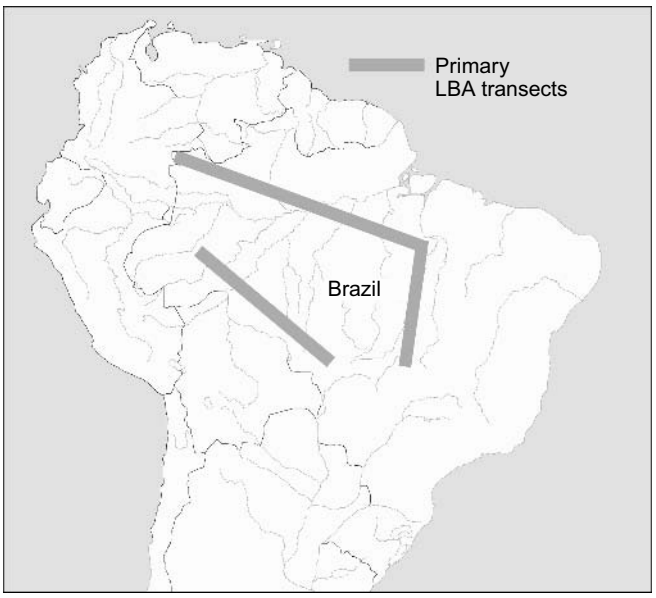

Figure 1 The two LBA transects are delineated on this map of Northern South America. Amazonia lies predominantly within Brazil, under the direct in uence of the Amazon and Tocantins Rivers, but includes portions of Bolivia, Peru, Ecuador, Columbia, Venezuela, Guyana, Surinam, and French Guiana

The LBA's biological and ecological research focuses on the effects of tropical forest conversion, regrowth, and selective logging on carbon storage, nutrient dynamics, trace gas fluxes, and the prospect for sustainable land use in Amazonia (Houghton, 1997; Fernandes *et al.*, 1997; Richey *et al.*, 1997; Keller *et al.*, 1997; Nepstad *et al.*, 1997). Conversion of undisturbed tropical forests to agriculture or to regrowth, combined with the effects of fire and selective logging, are studied in relation to their effects on biogeochemical cycles. Quantifying Amazonia's carbon balance, nutrient pools and trace gas fluxes is emphasized. Land use is studied in the context of both its biophysical and its socioeconomic causes, and land cover changes throughout Amazonia are documented.

LBA employs a multi-scale approach that considers the effects of forest conversion at scales ranging from the local site-level scale, to that of the entire Amazonian region. It started in 1998 and will continue till 2003, with observations running for 3–5 years to capture seasonal and interannual variations. Its field research is carried out along two transects (Figure 1), spanning gradients from wet, aseasonal forests to relatively dry and seasonal forests or savannas. Continuous or periodic observations of a core set of measurements (e.g., carbon dioxide, water, and trace gas fluxes; trace gas concentrations; micrometeorological conditions; vegetation and soil properties) are made along the transects in predominant land uses for that location. Time series of remote sensing observations are compiled for past and current satellite sensors. The local-scale measurements and results of process studies are combined with the remotely sensed data and other geographically extensive data sets to derive regional-scale understanding. Models play a key role in testing understanding, extending it across scales, and predicting future responses.

If the past is a guide, pressures to provide for a growing human population and plans for expanded commerce will spur future development that will lead to increasing deforestation and a continuing search for options for sustainable land use. LBA has a substantial education and training component dedicated to building local capacity, fully engaging Amazonian scientists in LBA research, and training people within the region to be prepared to address such global change challenges.

[2] *Norwegian Institute for Nature Research, Trondheim, Norway and Coastal Oregon Marine Experiment Station, Oregon State University, Newport, OR, USA*

Although no generally agreed definition of life exists, various processes associated with living organisms often help distinguish them from inert matter. These processes include growth, or its potential; reaction to stimuli in the immediate environment; passive or active movement; metabolism through which matter and energy are transformed into the organization of organic compounds unique to each individual; and reproduction.

As organisms grow and age, most go through various developmental stages in which some of these processes, or certain aspects of them, are particularly emphasized. For instance, a butterfly began life as an egg and later emerged as a larva, the eating-for-growth stage. The larva eventually pupated and underwent metamorphosis before emerging as a butterfly. Only as a butterfly can the insect mate, reproduce, and thus complete its life cycle. A species' life cycle is thus the sequence of developmental stages that individuals pass through, going from the start of one stage to the start of that same stage in the next generation.

Animals and many simple organisms complete their life cycle in a single generation. For instance, individuals of various species of protists (microorganisms which have both plant and animal characteristics) and bacteria originate from the fission of a single existing individual, grow to maturity, and then complete their life cycle by dividing into two new individuals. In more 'advanced' animal species, the individual originates from the fusion of male and female sex cells (gametes), grows to reproductive maturity, produces gametes, and then completes the life cycle through successful mating.

Most plants, and some fungi and protists, have life cycles with alternating generations. Individuals originate from germinating spores, which grow into gamete-producing organisms. Fertilized gametes can grow into spore-producing organisms. Spore germination completes the life cycle.

Life cycles provide frameworks for exploring how different species might cope with global change. Global change is occurring because the scale of human activities now exceeds that of all other species and affects biospheric fluxes of matter and energy. Global change encompasses the direct and indirect effects of changes in atmospheric composition, biological diversity, land use, and climate. Since different stages of a life cycle often have different functions (e.g., growth, reproduction), and requirements (e.g., temperature, habitat, food) to fulfil those functions, different aspects of global change will likely have different, possibly even compensatory, impacts over a complete life cycle. Thus, one needs to consider how each component of global change might affect each life stage in forecasting how a species might respond to global change as a whole. This approach is illustrated with three very different life forms: the spruce budworm, a naturally outbreaking forest insect; wild salmon, a group of fishes which spend parts of their life cycle in freshwater and parts in saltwater; and black spruce, an ubiquitous tree species of North America's boreal forest.

RESPONSES OF THE SPRUCE BUDWORM TO GLOBAL CHANGE

The spruce budworm, *Choristoneura fumiferana* (Lepidoptera: Tortricidae), the dominant insect defoliator of North America's coniferous forests, has been outbreaking on a roughly 35 year cycle since before the first Europeans arrived on the continent. Its outbreaks last 10–15 years and during outbreaks spruce (*Picea* species) and balsam fir (*Abies balsamea*) are often killed over vast areas. In its life cycle (Figure 1), the spruce budworm has one generation a year. In mid-August, 2–3 weeks after the eggs are laid and most adult moths have died, the first instar (stage immediately prior to shedding the first skin) larvae hatch and move to overwintering sites on the branches. They overwinter as small, second instar larva and become active again in early May. Then they pass through four heavily feeding instars before pupating in late June. In July, emerged moths mate, disperse, and lay eggs. The spruce budworm's potential for causing tree mortality stems from its rapid growth and high fecundity (realized fertility) of 170–200 eggs per female. A mature sixth instar larva weighs approximately 100 mg (fresh weight) and is roughly 20–30 mm long. This is about 1500 times larger than it was as a second instar larva just 6–9 weeks earlier.

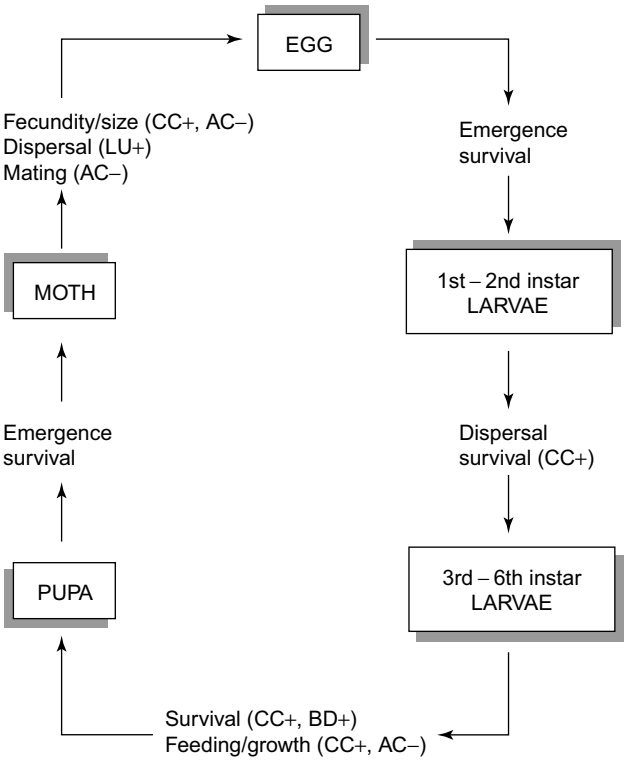

Figure 1 Generalized life cycle of the spruce budworm. Boxes enclose the major stages. The principal functions and processes needed to progress from stage to stage are designated by phrases interrupting the directing arrows. Letters in parentheses indicate components of global change: AC, atmospheric chemistry; BD, biodiversity; CC, climate change; or LU, land use, which the text describes as potentially in uencing the function or process. A plus or minus indicates whether the in uence is expected to be largely positive or negative for the insect

Global change, particularly climate change, may affect insect populations directly through their *per capita* growth rates or indirectly through interactions and feedbacks with other species and abiotic components of the environment. These interactions and feedbacks often depend on delicately tuned phenological relationships. For instance, the spruce budworm, like many other herbivores, has synchronized its greatest nutritional demand (the heavily feeding larval stages) with the time when developing, rather then mature, host plant foliage is most available. Developing is often better for herbivores than mature plant tissue because it is lower in fibre (which can limit digestibility), higher in nitrogen (nutritional value), and lower in secondary metabolites (defensive chemicals). In a warmer climate, foliage is generally expected to develop more quickly, thus diminishing the time interval when herbivores can find the best foliage. Since cold-blooded animals such as insects also develop faster and feed more actively at higher temperatures, however, the net effect is uncertain. Many insect herbivores may remain well synchronized in phenological development with that of their host plants' foliage, even in changing climates. On the other hand, increased atmospheric CO_2 concentrations may allow host plant foliage to accumulate secondary metabolites fast enough that herbivory becomes inhibited relatively earlier in development, and this may work against some insects.

Under climate change, the southwestern part of the spruce budworm's range can expect drier conditions with the increasing likelihood of drought. Warmer, drier conditions directly increase spruce budworm reproductivity and larval survival. Indirect effects are also important. The vulnerable larval stages can escape many natural enemies (e.g., the fungal pathogen *Erynia (Zoophthora) radicans*) because larvae develop faster at high temperatures than at normal temperatures, and this reduces the length of their exposure. Furthermore, larvae develop more quickly at high temperatures than many of their natural enemies. As many of these natural enemies have alternate hosts, they are less closely synchronized phenologically with the spruce budworm than is the budworm with its host trees. Hence, some phenological de-synchronization of the spruce budworm with its natural enemies is expected as climate change progresses. In summary, warmer, drier conditions tend to weaken the regulating effects of natural enemies and simultaneously increase reproductivity and larval survival. Thus, the expectation for longer or more frequent outbreaks in warmer, drier climates.

Protracted trends toward warmer climates will allow many successive generations of directed natural selection, particularly for organisms like some insects (e.g., aphids) with many generations per year. (Increased climatic variability may disrupt this process frequently for short periods but seems unlikely to forestall it over the long term). Consequently, genotypes best suited to warmer environments are expected to become increasingly common, resulting in genetically adapted populations. Experimental and observational evidence suggests that such adaptations may produce increases in the rates of phenological development; increases in the number of generations per year; shifts in geographical and also possibly host range; changes in morphology, physiology, and reproductive strategy; and possibly even speciation or extinction.

Other aspects of global change could affect spruce budworm outbreak patterns but these are more speculative. For instance, biodiversity loss manifested as a lack of suitable plant habitat or lack of alternate hosts could have serious consequences for certain natural enemies. Up to a point, this loss may be compensated by other natural enemies so that there is little overall effect on the spruce budworm's outbreak cycle. In central parts of the range, land use changes, manifested as increased wildfire control and harvesting, allow the spruce budworm's host tree species to capture ever increasing proportions of the forest. The resulting increase in feeding and egg-laying sites

lends itself toward larger scale, and possibly more intense, outbreaks. In contrast, experiments suggest that elevated atmospheric CO_2 concentrations can impede the chemical communication systems that many insects use for finding mates and food sources. The prevalence and importance of this impedance in the wild is unknown.

Figure 1 summarizes this discussion. Climate change has a more pervasive influence throughout the life cycle of the spruce budworm than other components of global change, and will likely benefit spruce budworm populations. Biodiversity loss and land use change are also represented as having net positive influences for the spruce budworm. The only negative aspects of global change diagrammed in Figure 1 are associated with elevated atmospheric CO_2 concentrations. The large scale consequences of other changes in atmospheric composition are even less certain.

RESPONSES OF SALMON TO GLOBAL CHANGE

Wild salmon populations, *Oncorhynchus* and *Salmo* species, are declining globally: populations of Atlantic salmon are declining or have been extirpated in two-thirds of their native range, hundreds of Pacific salmon populations have gone extinct during the past century and hundreds more are at risk. The cause of these declines is multifaceted, and the relative contributions of human-induced changes, natural climatic events and other abiotic and biotic factors have not been firmly established. Unquestionably, however, human impact has been substantial.

The spatial scale at which human-induced changes affect wild salmon varies through the course of their life history, with localized impacts predominating in fresh water and global impacts predominating in oceanic environments (Figure 2). In fresh water, habitat degradation, pollution and introductions of exotic species represent the main human-induced impacts. Logging, agricultural, urban and resource extraction activities may all degrade habitat (e.g., sedimentation, channelization, flow conditions, removal of bank vegetation and fragmentation) and water quality (e.g., temperature, dissolved oxygen, nutrients and pollution). The effects of pollution also occur at large scales: acid rain is blamed for losses of Atlantic salmon populations in Europe and North America. Introduction of cultured salmon, exotic fishes and other aquatic organisms generally have localized impacts in fresh water. Escape of aquacultured salmon and stocking of hatchery salmon pose ecological (e.g., resource competition), genetic (e.g., loss of diversity), and disease threats to wild populations. In Norway, such practices have introduced and spread the parasite *Gyrodactulus salaris* which has almost eradicated 40 salmon populations.

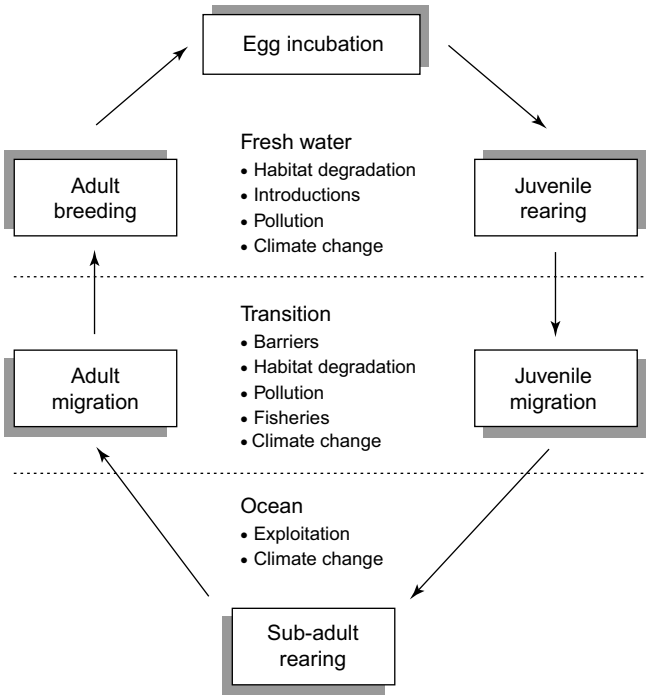

Figure 2 Principal impacts of global change during the life cycle of anadromous salmon, from egg incubation through juvenile freshwater and sub-adult oceanic rearing to adult freshwater breeding. Three critical stages are depicted: (1) fresh water; (2) the transition between fresh and salt water; and (3) ocean

The transition stage is also affected at predominately local scales. The major cause of salmon extirpations is blockage of their upstream migration routes, particularly by hydropower dams. Fortunately, the importance of this is declining. Effective fish passage mechanisms have been developed, inefficient dams removed, and with few hydropower opportunities remaining, dam construction is falling. Habitat degradation and pollution affect the energetic costs, susceptibility to predation, physiological state and ultimately, survival of salmon during migration. Over-fishing can also severely depress target populations and contribute to their risk of extirpation.

Oceanic impacts on wild salmon occur mainly at large scales, reflecting the vastness of this domain. Particularly important are climatic changes (*see* **Fisheries: Effects of Climate Change on the Life Cycles of Salmon**, Volume 3) and exploitation. It has been predicted that modest rises in sea surface temperatures due to climate change could result in salmon disappearing from large areas because of their narrow thermal limits during winter and early spring. Warmer sea surface temperatures may also interact with currents to alter the location and availability of food for salmon, which current evidence suggests will cause a reduction in salmon body size. Exploitation effects occur both directly (from salmon fisheries

[discussed above] and incidental catches during other fisheries), and indirectly (e.g., industrial fisheries competition of salmon with forage fish such as capelin and sand lance).

This analysis shows that most human impacts on Atlantic salmon are intensifying throughout the lifecycle, that they are predominantly negative, and that they are interacting in complex ways. Sustainability of wild salmon thus depends on forecasting and minimizing these impacts. The latter depends on maintaining a diversity of gene pools and population structures to provide evolutionary flexibility for salmon in response to an uncertain future.

RESPONSES OF BLACK SPRUCE TO GLOBAL CHANGE

Trees are amongst the longest-lived organisms on earth; several decades are usually required to reach sexual maturity or full fecundity, and generation times are often 50–200 years. Adaptations and changes in forest tree composition in response to global change will largely reflect the competitive abilities and ecological tolerances of existing ecotypes rather than the rapid evolution of new ecotypes. As the main structural component of forested landscapes, trees are the primary providers of habitat for many terrestrial organisms, and changes in the overstory resulting from global change will have wide-ranging repercussions.

Black spruce, *Picea mariana*, is an abundant, evergreen conifer found throughout the North American boreal forest. It has the most northerly range of any tree species on the continent, extending to the tree line, and is commonly found as far south as the temperate forests of the Great Lakes region. This slow-growing tree reaches heights of 15–25 m and ages exceeding 200 years on productive sites, but assumes a more shrub-like stature on very poor sites or in extreme climates. Over much of its southern and central range, it forms dense stands of considerable standing biomass, either by itself on wetter sites, or in combination with other species on well-drained sites. In northern locations, stands are more open and growth is reduced; at its southern limits, this species is confined to cold, wet, or shallow-soiled sites.

Black spruce seed and pollen cones emerge in the spring, and fertilized seeds mature by fall of the same year. Cones continue to disperse seed for several years after ripening. Seed production occurs regularly in stands over 25 years old, and peaks in stands between 50 and 150 years of age. Seed fall is accelerated for 2–3 years after wildfire. Seeds are commonly dispersed 100–200 m from stand edges, but individual seeds can achieve much greater dispersal distances, particularly during high winds or on crusted snow. Black spruce also reproduces vegetatively from lower living branches, which become partially buried by organic debris. This form of reproduction is common in open-grown stands, particularly in the far north where successful pollination and subsequent seed germination are restricted.

Climate change could have large direct impacts on the range, abundance and vigour of virtually all forest trees, including black spruce. Warmer temperatures should improve seed production and germination at higher latitudes and may allow considerable extension of black spruce beyond the current tree line. In contrast, the forecasted northerly extension of the western Canadian prairies would greatly reduce the southern extent of the species' range in western Canada. The direct effects of changes in precipitation patterns are less predictable. Black spruce is well adapted to drier upland sites as well as wetter lowland sites, both in the colder continental climates of northwestern North America, and in the cool, more humid climates to the east. However, drier conditions combined with warmer temperatures may restrict germination, limit seedling establishment, and increase drought stress in established stands. Increased temperatures and CO_2 levels will improve tree growth, but may put black spruce at a competitive disadvantage on sites which provide suitable habitat for competitors such as white pine (*Pinus strobus*), jack pine (*Pinus banksiana*) and oak (*Quercus*) species which have greater temperature or CO_2 growth responses.

In the southeastern portion of its range, climate change effects on black spruce populations may be manifested largely through alterations in competitive relationships with other species. Longevity, conservative resource requirements and broad ecological tolerances suggest that established black spruce trees and stands may not be greatly affected by the forecasted changes in climate. Increased competition from faster growing and/or more shade tolerant competitors, however, is likely to reduce seedling establishment and sapling vigour.

Climate change influences on the frequency and intensity of rarely occurring, catastrophic events (e.g., wildfire, insect outbreaks, storms, severe frosts) are equally as important to forest trees as the direct effects of incremental changes in climate averages. Like most boreal species, black spruce is adapted to and dependent upon infrequent wildfires, which destroy existing stands but produce dense, vigorous new stands of the same species. Increased fire frequencies (i.e., within every 30–40 years) could reduce black spruce abundance by burning many stands before most trees reach full fecundity. In contrast, substantial reductions in fire frequency could permit the incursion of faster-growing or more shade-tolerant competitors which are less fire-adapted but better resource competitors than black spruce. Feedback between changes in stand composition and fire frequency are also likely. Large increases in broad-leaved species will reduce fuel availability and perhaps fire frequency.

Insect epidemics affect individual tree species directly through herbivory, and indirectly by altering competitive

relationships with other plants. Outbreaks of the major insect pest of black spruce, the spruce budworm, reduce stand vigour and destroy current seed production, but cause little long-term damage to black spruce. This reflects the phenological development of feeding larvae, which is synchronized with vegetative bud flush and foliar development in balsam fir and white spruce, the spruce budworm's principal host species. Vegetative bud flush in black spruce usually occurs 10–14 days later. Differential effects of climate change on herbivore-host phenology could either reduce or greatly increase defoliation of black spruce by altering the synchrony of bud flush and budworm larval feeding. Climate-induced changes in the frequency and severity of insect outbreaks on associated species (e.g., forest tent caterpillar on trembling aspen and spruce budworm on balsam fir) could alter the competitive position of black spruce.

Other facets of global change which have widespread implications for forest trees include logging, deforestation and afforestation. Most of the land base currently occupied by black spruce has little agricultural value because of climate and soil limitations, and more land suitable for black spruce is currently reverting from agriculture to forests than *vice versa*. In contrast, logging activities have had large and sustained negative impacts on the representation of black spruce on the landscape. Black spruce is highly valued for pulpwood and saw timber, and has been logged extensively throughout the southern boreal. Typically, on peatland sites, black spruce remains the predominant species in second growth stands, although there may be regeneration delays and reductions in stand densities. Without planting and stand tending, many areas on upland sites revert from black spruce-dominated to mixed-wood forests with black spruce a minor component. The widespread establishment of black spruce plantations has maintained this species on other parts of the landscape, but often at reduced densities and with different stand compositions and structures than are found in stands of wildfire origin.

CONCLUSION

The life cycles of three very different species have provided analytic frameworks for developing a qualitative understanding of how each species is likely to react to global change. Global change will affect some stages of a life cycle more than others, and certain aspects of global change, either individually or interactively, are more important than others at these particularly vulnerable stages. To establish in a new area or persist in its current habitat, a species must be able to complete its life cycle. By identifying the most vulnerable stages, life cycle analyses can provide a focus for management efforts ranging from repelling invading species to protecting endangered ones (*see* **Integrated Pest Management (IPM) in an Era of Global Environmental Change**, Volume 4).

LOICZ (Land-Ocean Interactions in the Coastal Zone)

The LOICZ project is one of the program elements of the International Geosphere–Biosphere Programme (IGBP). As

its name implies, LOICZ focuses on the area of the Earth's surface where land, ocean and atmosphere meet and interact. The overall goal of this project is to: determine the nature of that dynamic interaction at regional and global scales; determine how changes in various compartments of the Earth system are affecting coastal zones and altering their role in global cycles; assess how future changes in these areas will affect their use by people; and provide a sound scientific basis for future integrated management of coastal areas on a sustainable basis.

Unlike many of the other core projects of the IGBP, LOICZ deals with a specific, spatially heterogeneous domain rather than a process. To achieve the overall goals and objectives, a global network of coastal scientists must be developed. While LOICZ does not directly address coastal zone management, it does seek to provide a sound scientific basis for the future sustainable use and integrated management of coastal environments under conditions of global change.

LOICZ includes three classes of research projects: core, regional, and relevant. These classes are distinguished on the basis of geographic extent, scientific contribution to LOICZ global research, and commitment to the project.

Reports and data collections are being produced, and a newsletter is regularly published.

Further information may be obtained from: LOICZ International Project Office, Netherlands Institute for Sea Research (NIOZ), PO Box 59, 1790 AB Den Burg, Texel, The Netherlands, Tel.: +31-222 369404, Fax: +31-222 369430, E-mail: loicz@nioz.nl, WWW home page: http://www.nioz.nl/loicz/.

JOHN S PERRY *USA*

Long-term Ecological Research (LTER) System

James R Gosz
University of New Mexico, Albuquerque, NM, USA

The concept of long-term research sites dedicated to collaborative research was developed in the US during a series of three workshops sponsored by the National Science Foundation (NSF) from 1977–1979. At these workshops, the philosophy of collaborative research was emphasized and a centralized working hypothesis approach proposed to facilitate collaboration. Five core areas of research were defined to orient LTER projects toward question/hypothesis formulation and resolution. The core research areas common to all LTER sites in the US are:

- *pattern and control of primary production;*
- *spatial and temporal distribution of populations selected to represent trophic structure;*
- *pattern and control of organic matter accumulation in surface layers and sediments;*
- *patterns of inorganic inputs and movements of nutrients through soils, groundwater and surface waters;*
- *patterns and frequency of site disturbances.*

These areas are basic to all ecosystems and are required to understand patterns, processes, and relationship to change. They also require participation by different disciplines that form the basis for collaborative interactions.

General Details

The first six site awards were initiated in 1980 and as of 2000, 24 sites had LTER awards based on competitions that evaluated research excellence, quality and duration of existing data sets, and strength of the commitment to long-term research and site security (Figure 1). As part of their commitment to the LTER program, each site conducts a series of measurements and experiments directed towards the understanding of the five core areas and studies addressing ecological issues specific to the site. The most common scientific approaches include observation, experimentation,

comparative analysis, retrospective study and modeling, although emphases differ among sites.

The LTER sites comprise a broad array of ecosystems ranging from tropical rain forest in Puerto Rico to polar desert oases at McMurdo Station, Antarctica (Table 1). Collectively, the sites provide opportunities to contrast marine, coastal, and continental regions, the full range of climatic gradients existing in North America, and aquatic and terrestrial habitats in a range of ecosystem types. All sites are sufficiently large to incorporate moderate to large landscape mosaics, and most sites include human-manipulated as well as natural ecosystems. Most sites embody considerable within-site variability in habitats and ecosystem processes and attempt to characterize this variability in the context of broad regional gradients covering hundreds of kilometers.

LTER Network

The 24 sites are now organized into a LTER Network representing a wide variety of research emphases and approaches with over 1200 scientists and graduate students involved. The mission of the LTER Network is to conduct and nurture ecological research by:

1. understanding general ecological phenomena that occur over longer temporal and large spatial scales;
2. creating a legacy of well designed and documented long-term experiments and observations for the use of future generations;
3. conducting major synthetic and theoretical efforts; and
4. providing information for the identification and solution of societal problems.

Over time (i.e., since 1980) the focus of research efforts has shifted from a concentration on individual site research to a broader synthetic viewpoint. Expectations for results from the research programs now include not only the individual and site-based products, but also cross-site, network-wide, and international collaborative studies. There are many examples of the value of information developed at LTER sites. Long-term research is crucial in understanding issues like climate change, effects of pollution, and biodiversity and in contributing to management decisions.

The range of locations provides an understanding of the diversity of regional patterns of the effects of climate change. For example, McMurdo Dry Valley in the Antarctic has demonstrated an increase in glacier mass since 1993 which coincides with a period of cooler than normal summers and more than average snowfall. The larger glaciers seem to be advancing, primarily a legacy of past climate, roughly 103 years before present. In contrast, the Bonanza Creek and Toolik Lake sites in Alaska have recorded a warming period unprecedented in the past 200 years. Warmer air and soil temperatures and drought are associated with increased melting of ice-rich permafrost, fire, insect outbreaks, reduced growth and seed production in dominant tree species, extensive grassland development following disturbance, reduction in moss abundance and increased shrub and birch densities in the far north. Increased warming is associated with changed dominance of grass species in the Short Grass Steppe in Colorado while the Sevilleta site in central New Mexico had increased tree growth during the wet period of the 1980s–early 1990s, unprecedented in the past 500 years.

Nitrogen deposition effects have been identified through long-term watershed studies on biogeochemical cycles, especially at Coweeta Hydrological Laboratory, Harvard Forest and the Hubbard Brook Experimental Forest, producing evidence of nitrogen saturation associated with forest maturation and increased nitrogen deposition over time. Forests influenced by management and natural disturbance (e.g., hurricanes, insect outbreaks) exhibit more advanced stages of nitrogen saturation. At Cedar Creek, increased nitrogen deposition is linked to increased carbon sequestration, but also loss of plant diversity and increased growth of weedy, non-native plant species.

Biodiversity research results range from the effects of climate change and pollution as described above to the influence of management. Research at the Konza tall grass prairie site has demonstrated that re-establishing grazing by native ungulates (bison) in combination with burning enhances productivity and biodiversity. Agricultural research at the Kellogg Biological Station shows that although agricultural management decreases plant diversity

in cropping systems, different management strategies can be developed that promote different assemblages of species which have important implications for ecosystem services such as protection from insect pests and nutrient conservation associated with species considered to be weeds. Results show that rotation of crops in conventionally managed systems does not increase the diversity or composition of the weed community that emerges, whereas under biological management, the composition of the weed community changes markedly with crop rotation. These sorts of results are key to creating designer weed communities that provide ecosystem services without competing with the crop for limited resources.

In aquatic systems, such as the Northern Temperate Lakes site, long-term data have revealed time lags in effects of invaders and disturbance on lake communities. Species such as the Lake Cisco went extinct 16 years after a smelt invasion and in Trout Lake the loss in aquatic plant diversity was delayed as long as 20 years after a Rusty Crawfish invasion. Biological recovery from an effect such as lake acidification was shown to lag behind chemical recovery. These results are critical to developing management programs.

Perhaps the best way of documenting the value of LTER research is by the way it has influenced management. In Puerto Rico, the Luquillo LTER demonstrated that dams obstruct migrations of fish and freshwater shrimp; and water abstraction at low flows can completely obliterate downstream migration of juveniles and damage estuaries below by removing all incoming freshwater. As a result local water authorities changed the design of a new water filtration plant to maintain minimum stream flows. At Toolik Lake, long-term experiments of removing top predators from the food web of lakes showed dramatic alterations of lake populations of small fish and zooplankton. As a result, the Alaska Fish and Game Department has instituted a catch-and-release law in northern Alaska to preserve the population structure of lakes. At the Virginia Coast Reserve, repeated surveys have documented major island-scale geomorphic adjustments as result of storms. Hundreds of meters of shoreline retreat and hundreds of square meters of destruction of major dune environments can occur as evidenced by the major storms of early 1998. Studies of these island adjustments are critical in human occupation of coastal areas. Research on the Short Grass Steppe in Colorado has demonstrated that livestock grazing has only limited impacts on the Short Grass Steppe ecosystem structure and function, likely due to a long evolutionary history of grazing by bison and other large herbivores. Research demonstrated that the plant community has a high degree of tolerance to both grazing pressure and yearly fluctuations in precipitation. Cultivation in this system, however, was shown to have strong impacts on ecosystem structure and function and a strong forcing function on regional climate. Regional land use patterns appear to have a larger impact on regional climate than does the signal from global greenhouse-induced climate change. In New Mexico, LTER research on small mammal populations is successfully predicting rodent increases and the potential for increased zoonotic diseases such as Hantavirus and bubonic plague. This ability to forecast based on El Niño predictions is being used to increase scientific awareness and public health awareness through media communication with the public. In Oregon, the Andrews Forest LTER program has had long, strong links with natural resource policy and management. Basic understanding of forest–stream interactions, characteristics of old-growth forests, roles of woody debris in temperate forest ecosystems, invertebrate biodiversity and ecosystem function have been incorporated in management guidelines, plans and regulations for public and private lands throughout the Pacific Northwest. For example, the riparian management guidelines for the Willamette National Forest, where the Andrews Forest is located, became the cornerstone concepts of forest–stream interactions used in President Clinton's Northwest Forest Plan for the region. Later they were used in similar ways for the state of Minnesota and translated into Japanese to be used to increase environmental sensitivity in management of rivers in Japan.

Many other examples of the value of LTER research are available. Access to the science at all of the sites is available through the LTER web site (http://www.lternet.edu).

Information Management

Information management is crucial to the success of the long-term research programs and the development of comparable data sets, and a Network Information System (NIS) to set standards in information management is actively facilitated by information management professionals at each site. There is a continuous effort to develop standards for equipment and methodology for commonly collected data (e.g., climate measurements) and to develop tools to access and analyze data sets existing in the distributed Network environment. The NIS sets standards in information management sufficient to achieve network-wide data integration. The goal of NIS is to facilitate seamless data exchange and synthesis within the LTER Network and to make data collected at LTER sites available to scientists worldwide. The goal is accomplished through the use of the latest advances in World Wide Web database interfaces, that provide access to network-side data sets through a single point of entry.

Management

The management of the US LTER Network is led by a coordinating committee comprised of representatives of all 24

sites. This group meets twice a year to plan LTER activities. An Executive Committee meets more frequently and is empowered to act on behalf of the Network in routine matters. Eight standing committees help to coordinate specific LTER activities; collection and synthesis of climate data, education, social and economic science collaboration, publications, information management, graduate student participation, research synthesis and technology. The members of these committees are drawn from the LTER community at large. The activities of the standing committees include the development of network-wide policies and initiatives, preparation of proposals and interactions with private and public institutions as well as other segments of the scientific community. In 1983, NSF established the LTER Network Office under the direction of the LTER Coordinating Committee Chair and Executive Committees. The goals of the Network Office are:

- to facilitate communication among the LTER sites and between the LTER program and other scientific communities;
- to support the planning and conduct of collaborative research efforts, including provision of some technical support services;
- to facilitate intersite scientific activities;
- to provide a focal point and collective representation of the LTER Network in its external relationships;
- to develop linkages with other relevant long-term research programs, site networks, and science and technology centers.

US Partnerships/Collaboration Among Networks

Strong partnerships have developed between the academic research programs that represent LTER awards and the US federal and state agency research programs at many sites. Most of the LTER sites are on federal property (e.g., Forest Service Experimental Forests, Agriculture Research Service Experiment Stations, National Wildlife Refuges, National Parks) and involve collaborative efforts between federal and academic researchers. The LTER Network continues to develop interactions with federal network programs such as those of National Aeronautics and Space Administration (NASA) (e.g., Mission to Planet Earth, AErosol RObotic NETwork (AERONET), Oak Ridge Distributed Active Archive Center), National Resource and Conservation Service (e.g., soil mapping), United States Department of Agriculture (USDA) (National UVB Radiation Monitoring National Network), and National Oceanic and Atmospheric Administration (NOAA) (e.g., National Estuarine Research Reserves). Personnel from the LTER Network Office actively cooperate with several national agency/interagency efforts to assure interoperability between the LTER Network and the greater scientific community (e.g., National Biological Information Infrastructure (NBII) metamaker project, US National Committee for Committee on Data for Science and Technology (CODATA).

International Networking

Since the first exploratory discussions with other countries in 1993, LTER programs have developed rapidly, based on experiences in the US. At that time an International LTER (ILTER) Network was formed with a mission to facilitate international cooperation among scientists engaged in LTER. Subsequently, the ILTER Network Committee established the following mission statements:

- to promote and enhance the understanding of long-term ecological phenomena across national and regional boundaries;
- to promote comparative analysis and synthesis across sites;
- to facilitate interaction among participating scientists across disciplines and sites;
- to promote comparability of observations and experiments, integration of research and monitoring, and encourage data exchange;
- to enhance training and education in comparative LTER and its relevant technologies;
- to contribute to the scientific basis for ecosystem management;
- to facilitate international collaboration among comprehensive, site-based, long-term, ecological research programs;
- to facilitate development of such programs in regions where they currently do not exist.

Each country must assess its own needs and resources if it wishes to develop a national LTER program and involve itself in an ILTER program. Each nation will have a unique set of opportunities and limitations that are best evaluated by the scientists and policy makers of that country. The typical procedure is for the scientists and funding agencies of that country to decide whether to endorse the premise that ecology and environmental management are significantly benefited by long-term, integrated studies over broad spatial scales. A plan is then developed that establishes the context and mission for such studies, and sites and programs are identified that will contribute to this mission. Typically, support is obtained from within that country and/or international organizations for implementation and continued maintenance. The models developed by most countries are similar to that in the US; however, the core areas that focus research efforts across sites can vary. Many countries add biodiversity, agriculture, and anthropogenic effects to the core research areas. The requirement for joining the ILTER Network is formal recognition by a national-level organization that a national network of long-term research sites has been established for that country. It is anticipated that

Table 2 Countries participating in the International LTER Network (2000)

Australia
Brazil
Canada
People's Republic of China
Taiwan, China
Colombia
Costa Rica
Czech Republic
Hungary
Israel
Korea
Mongolia
Namibia
Poland
Slovakia
Switzerland
Ukraine
UK
US
Uruguay
Venezuela
We anticipate the following countries to be added by the end of 2001
France
Mexico
South Africa
Other countries are in the process of developing national LTER programs

each country's program will be part of a global network of scientists and of scientific information that will advance our understanding of not only local and regional, but also global issues and provide solutions to environmental problems at these scales.

Currently (2000), there are 21 countries with LTER programs (Table 2) and additional countries in the process of establishing such programs. A more recent development is the formation of Regional LTER Networks. Because neighboring countries often have similar issues, there are increased opportunities for collaboration and support. At this point, regional organizations exist for the East Asian Regional LTER Network, the North American Regional LTER Network, the Central and Eastern Europe Regional Network, the Middle East Regional Network, and the Latin American Regional Network. The various sites within a national network to those in regional national networks to the entire international LTER Network all contribute to the vision of integration and collaboration needed for modern, global science.

LTER sites in the countries of the ILTER Network can provide unparalleled opportunities for cross-site and comparative research efforts on many of the world's ecosystems. Just as with focused site research described earlier for the US, these global LTER sites lead to interdisciplinary research at broader scales that can provide the scientific basis for management and policy decisions. The ILTER Network is now well positioned to interact with other international activities such as the International Geosphere Biosphere Programme (IGBP), the Global Terrestrial Observing System (GTOS), and the United Nations Educational, Scientific and Cultural Organization (UNESCO) Man and the Biosphere (MAB) program. We anticipate rapid progress in these interactions in addition to continued expansion of the ILTER Network.

Mangrove Ecosystems

Robert R Twilley

University of Louisiana at Lafayette, Lafayette, LA, USA

Mangroves are forested wetlands that are salt tolerant and dominate the land- sea interface of warm tropical environments. These tropical forests are unique communities of diverse biological organization that offer scientists and resource managers insights into how ecosystems can respond to a variety of ever-changing environmental conditions. The plant physiologist nds it remarkable that a tree that has its roots surrounded by salt water (which can be considered an osmotic desert) can transport a parcel of water to a leaf that is up to 40 m above the ground (over 120 ft). Population and community ecologists marvel at the biodiversity and associated mutualistic interactions that result in a most productive ecosystem even along a salinity spectrum from nearly freshwater (oligohaline) to marine (euhaline) conditions. The ecosystem ecologist and coastal geomorphologist can together catalogue mangroves into schemes that describe nearly every type of coastal formation from riverine deltas to oceanic reefs - another example of the tremendous biodiversity of mangrove ecosystems. And the coevolution of geological and biological processes of these ecosystems over the last several interglacial periods has produced an intriguing ecological landscape.

Mangroves truly represent an ecosystem that we can use to monitor several dimensions of global environmental change (Figure 1). Mangroves also demonstrate the importance of understanding the relative impacts of global environmental change on ecosystem goods and services along with socioeconomic decisions of regional land use development (Figure 2). The coupling of mangroves to coastal waters is considered to be the most important link in the sustainability of subsistence, commercial and recreational fisheries associated with estuaries and related nearshore marine habitats. In addition, mangrove plantations have historically promoted sustainable use of forest products such as timber, fuelwood, tannins, pulpwood, and charcoal throughout the tropics. Mangroves also play a major role in maintaining water quality and shoreline stability, by controlling nutrient and sediment distributions in estuarine waters. However, there are several examples of how regional land use decisions have resulted in negative feedback effects on sustaining these ecosystem goods and services. Recent forms of direct exploitation include the destruction of biodiversity by land uses such as aquaculture (shrimp ponds), agriculture (rice and salt ponds), urban development, and forest clearfelling. Indirect loss of mangrove ecosystems has resulted from human alterations of upland watersheds causing diversion of freshwater (dams and canals) and deterioration of water quality (nutrients, heavy metals, oil spills, pesticides). Projections of how mangroves will respond to global environmental change will have to be considered along with these human impacts to the coastal landscape, coupled with impacts to upland tropical watersheds (Figure 2).

The environmental settings of mangroves are a complex behavior of regional climate, river discharge, tides, wind, and oceanographic currents (Figure 1). There are about $240 \times 10^3\,\mathrm{km}^2$ of mangroves that dominate tropical continental margins from river deltas, lagoons and estuarine complexes, developed from terrigenous sediments to carbonate deposits. In addition, mangroves colonize shorelines and islands in oceanic formations (non-continental) formed principally from carbonate sediments. These geomorphologically distinct landscapes have local variations in topography and hydrology that result in the evolution of distinct ecological types of mangroves such as riverine, fringe, inland, and scrub forests. These ecological types of mangroves have specific structural characteristics and ecological

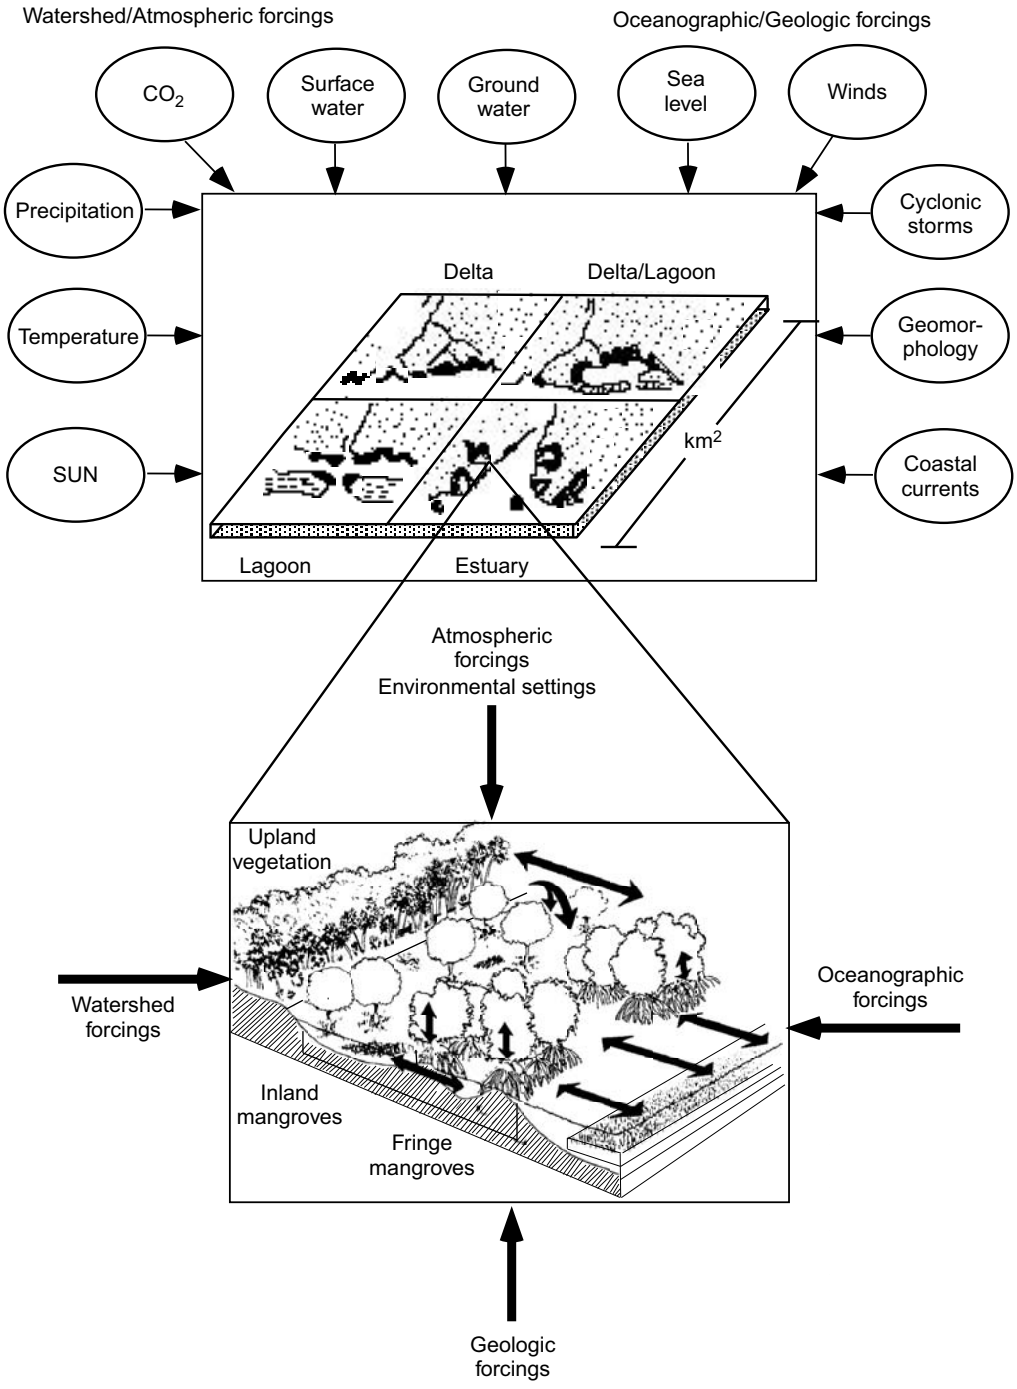

Figure 1 Classification system to describe how the relative strength of different forcings across different types of environmental settings control the spatial distribution of various ecological types of mangroves across the coastal landscape

functions. Although there are relatively few species of mangrove trees (54 true species), mangrove ecosystems are nevertheless diverse because mangroves in the coastal environment support a disproportionately rich diversity of fauna. The unique location of these tropical forests along the sea combines the diversity of terrestrial and marine ecosystems into one of the more diverse ecosystems among coastal habitats.

There is evidence that mangrove biodiversity is intricately linked to ecosystem function. Mangrove ecosystems

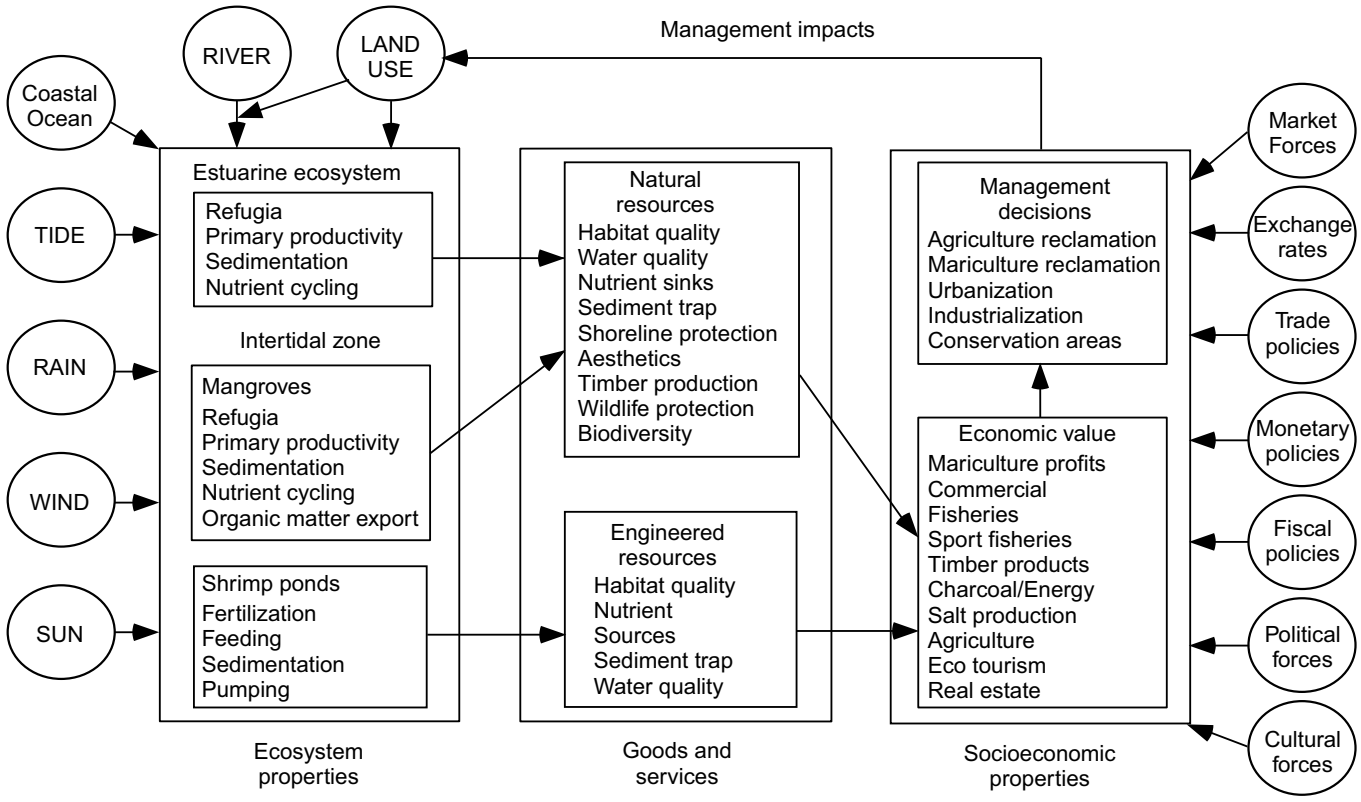

Figure 2 Diagram of how both environmental forcings (left side of the diagram) and social constraints (right side of diagram) control ecosystem and socioeconomic properties of mangrove ecosystems; including feedback effects of human utilization on ecosystem properties

support a variety of marine and estuarine food webs involving an extraordinarily large number of animal species and complex heterotrophic microbial food webs (Figure 3). Extensive surveys of marine fauna have found 26–114 species of fish and more than 100 species of macroinvertebrates that exert control of community dynamics in fringe mangrove zones. One of the best examples is the mangrove crab fauna that is considered a keystone guild in these forested wetlands. The genus *Sesarma* accounts for over 60 species of crabs predominantly associated with mangroves with many functions, such as contributing to plant zonation by differential seed predation, to litter dynamics by transporting leaves into burrows, and to nutrient dynamics by aerating otherwise anaerobic soils. Sponges, tunicates, and a variety of other forms of epibionts on prop roots are equally diverse and may be sources of nutrition for higher-level predators, as well as providing nutrients to fringe mangrove forests.

In addition to the marine and estuarine food webs and associated species, there are a relatively large number and variety of animals from inland habitats, such as insects and birds, that live in and/or that feed directly on mangrove vegetation. These include arboreal feeders such as foliovores and frugivores, and ground-level seed predators. Over 200 species of insects have been documented in mangroves such as in the Caribbean. In Belize, wood boring insects in mangroves are important to the formation of gaps and the specific architecture of mangrove trees. Also, the diverse avifauna, mainly those that use mangroves for rookeries, control nutrient levels and foliage dynamics through nesting and the associated herbivory. These keystone guilds have disproportionate effects on ecological processes of mangrove ecosystems, and represent the importance of biodiversity in ecosystem functioning.

Mangroves occupy a transitional zone from land to ocean, and such ecotones (*see* Ecotones, Volume 2) illustrate ecosystems that are particularly sensitive to environmental change. There is often a distinct elevation gradient from the water's edge (lower intertidal zone) to the terrestrial transition zone (supratidal zone). Mangroves are taller in the lower intertidal zone, where they are inundated nearly daily by tides, known as *fringe mangroves*. Lower intertidal zones with more in uence from rivers than tides have a greater supply of sediments and nutrients, and lower salinities. Mangroves in this zone are even more robust and are known as *riverine mangroves*. Farther inland to the mid and upper intertidal zone, there

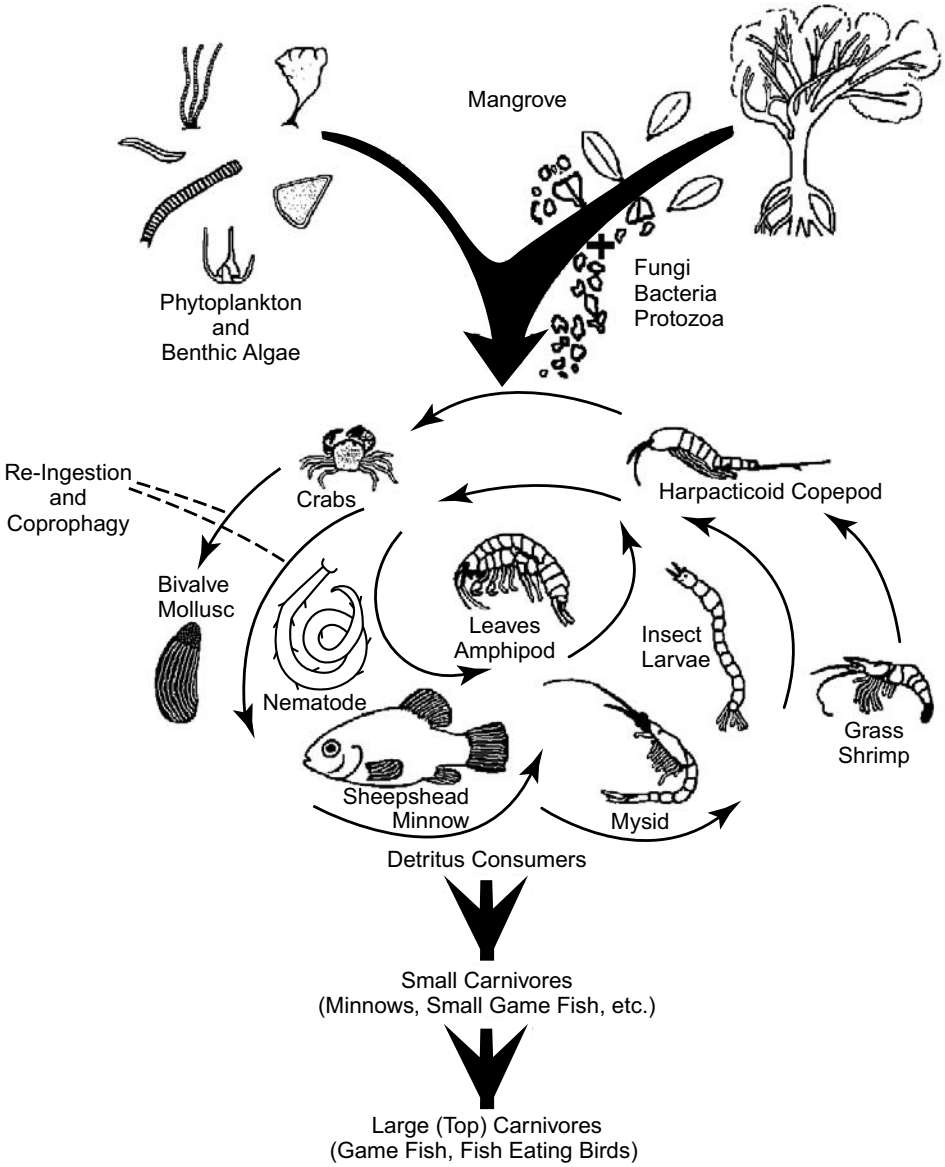

Figure 3 Conceptual diagram describing the fate of mangrove leaf litter in the food chain of an estuary in south Florida determined by William Odum and Eric Heald

is unique *inland mangrove* vegetation whose stature is more dependent on local climate and upland freshwater discharge. Even farther away from shore in the supratidal region, mangroves are at the edge of optimum growth conditions, and together with competition from upland vegetation, they usually have restricted growth and are known as *scrub mangroves*.

The diverse patterns in species composition of mangrove trees in these different zones (riverine, fringe, inland and scrub), along with distinct patterns of forest structure and productivity, reveal the response of mangroves to a variety of environmental gradients in resources and regulators. These gradients are associated with the relative strength of environmental drivers (e.g., temperature, tidal amplitude and river ow) across the coastal landscape (Figure 1). These spatial patterns in response to environmental gradients may also provide insights as to how these ecosystems will respond to global environmental change in time.

The predominate forcings from the ocean include tides and sea level change, oceanographic currents, and the source of salinity that represents one of the major stressors in mangrove habitats. Atmospheric forcings include wind (including cyclonic disturbances), precipitation, relative humidity, and temperature; the latter two components determine regional loss of water by

evapotranspiration. The watershed provides both surface and subsurface freshwater discharge that potentially transports sediments and nutrients to the coast. This forcing can determine the type and fertility of the estuarine environment. The magnitude and distribution of these forcings across the landscape topography determines the patterns of hydroperiod, soil nutrients, and pore water salinity that largely control zones of mangrove vegetation. Environmental changes associated with either the oceanic, atmospheric, or watershed forcings will change the species composition, structure, and function of mangrove ecosystems.

Accelerated rates in sea level rise have been speculated as the most critical environmental change affecting the continued existence of mangrove ecosystems. Numerous processes contribute to vertical accretion of mangroves at a rate that balances the increase in regional sea level rise. Critical rates in sea level rise have been estimated above which there is a projected collapse of mangrove ecosystems. While some speculation suggests that mangroves cannot sustain existence at sea level rise $>1.2-2.3\,\mathrm{mm\,year^{-1}}$, there is evidence that mangroves existed through periods of accelerated rates of sea level rise above these critical rates in particular environmental settings. Mangroves in the south Alligator tidal river in Australia can keep pace with changes in sea level rise with rates ranging from $0.2-6\,\mathrm{mm\,year^{-1}}$. Mangrove forests in many estuaries in northern Australia tolerated sea level rise of $8-10\,\mathrm{mm\,year^{-1}}$ in the early Holocene. These rates are higher than many projections of accelerated rates of sea level rise associated with global climate change. Many of these mangroves receive terrigenous sediments and exist in macrotidal environments, with critical rates that are much different than for mangroves in microtidal and oligotrophic (carbonate) environments. However, given projected rates of accelerated sea level rise of $10-20\,\mathrm{mm\,year^{-1}}$, most mangrove wetlands will collapse as viable coastal ecosystems.

Mangrove areas can be sustained along the coastline by migrating inland under conditions of increased sea level rise. However, this inland migration will depend on whether suitable inshore landscapes are available. Coastal landscapes with steep topographic gradients resulting from regional geologic and oceanographic processes may limit inland migrations; but the most significant recent restriction to mangrove colonization is human land use of available landscapes. At the oceanic edge of mangroves, mineral accumulation is enhanced by mangrove prop roots and pneumatophores, which trap sediments suspended in the water column during low-velocity flooding. Coastal forested wetlands thereby enrich intertidal soils and retard the forces of erosion along the shoreline. This process has led to a significant expansion of mangrove shorelines in several regions and is considered a very important service in protecting shorelines from erosion. Accelerated sea level rise is projected to increase coastal erosion and destabilize shorelines presently colonized by mangroves.

The tropical nature of mangrove forests constrains their latitudinal distribution depending on the frequency, duration and/or severity of freezing temperatures. Red mangrove seedlings are more severely impacted by low temperatures among three Caribbean mangrove species due to their inability to resprout following foliar damage from freezing temperatures. The greater resprouting ability of black mangroves results in better recovery from freeze damage, resulting in the distribution of this species into Texas, Louisiana and Mississippi. Global warming will result in potential spread of mangroves into higher latitudes. On many coastlines, however, the latitudinal extension of mangroves is either restricted by cold oceanographic currents (such as along the Pacific coast of South America), or has expanded into subtropical latitudes by warm water flowing away from the equator (Atlantic coast of North and South America). Changes in ocean temperatures and currents will influence the latitudinal distribution of heat along tropical coastlines and influence the latitudinal distribution of selected mangrove species.

Warmer ocean temperatures could increase the intensity and/or the frequency of cyclonic storms. For those mangroves distributed in latitudes where the frequency of hurricanes is high (such as the Caribbean), the frequency of cyclonic disturbances can restrict forest development (i.e., forest structure, species composition, etc.) and community dynamics. Damage by hurricanes is more severe on large trees, where tree mortality of 36% can represent 68% of the basal area of a preexisting stand. Species attributes and availability of propagules are important factors, along with the severity of storm and sediment disturbance, in projecting recovery patterns. Frequent storm disturbance tends to favor species capable of constant or timely flowering, abundant seedling or sprouting, fast growth in open conditions, and early reproductive maturity. Although mangrove trees show these traits, it is important to consider the cumulative impact of human activities on these ecosystems, in conjunction with the complex natural cycle of regeneration and growth of mangrove forests. Cyclonic disturbance in areas with higher rates of sea level rise have been demonstrated to cause sediment collapse (drop in surface elevation), which reduces the ability of mangroves to recolonize disturbed areas. The loss of above-ground biomass following disturbance reduces below-ground productivity, which is critical to continued soil formation and accretion. Thus, the increased frequency of tropical disturbances, together with accelerated sea level rise, could expand the loss of mangrove ecosystems along coastlines susceptible to both types of environmental change.

Atmospheric forcings in the upper intertidal and supratidal ecotones, where tides are less frequent, control the moisture content of intertidal soils by the balance of rainfall and evapotranspiration. Evapotranspiration is linked to seasonal patterns of temperature and relative humidity, and together with rainfall, determine dry or humid life zones. In dry climates with little freshwater discharge from the estuarine watershed, an imbalance of soil moisture in these zones, even though infrequently ooded by tides, can result in salinities over three times that of the ocean. As a result, scrub mangroves occupy these hypersaline soils and *salinas* (zones void of vegetation) are common in the supratidal region. Scrub mangroves may also occur in the upper intertidal zone of moist environments in response to oligotrophic soils or long hydroperiods rather than high salinity. In these moist environments, the scrub zone is inhabited by different species composition competing with freshwater marsh or forested wetland vegetation. In dry coastal tropical regions where precipitation deficits occur, limits to mangrove zonation and forest structure can be negated by the presence of freshwater inputs (surface or subsurface) to the coast from upland watersheds. Thus, the amount of moisture in mangrove soils is a complex interaction of regional climate and hydrology, including upland freshwater input. Some mangroves may be located in a dry climatic zone, but they may have the characteristic zonation of mangroves in humid coastal environmental settings due to the presence of freshwater inputs. These freshwater subsides from upland watersheds increase the moisture of mangrove soils and in uence the functional ecology of mangroves.

River (and surface runoff) diversions that deprive tropical coastal deltas of freshwater and silt result in losses of mangrove species diversity and organic production, and alter the terrestrial and aquatic food webs that mangrove ecosystems support. Freshwater diversion of the Indus River to agriculture in Sind Province over the last several hundred years has reduced the once species-rich Indus River delta to a sparse community dominated by *Avicennia marina* (*see* Indus Basin: a Case Study in Water Management, Volume 3). It is also responsible for causing significant erosion of the seafront due to sediment starvation and the silting-in of the abandoned spill rivers. A similar phenomenon has been observed in southwestern Bangladesh following natural changes in river channels of the Ganges and the construction of the Farakka barrage that reduced the dry season ow of freshwater into the mangrove-dominated western Sundarbans. Freshwater starvation, both natural and human-induced, has had negative impacts on the biodiversity of mangroves in the Ganges River delta, as well along the dry coastal life zone of Colombia (the C enaga Grande de Santa Marta lagoon). The effects of human land use change of tropical watersheds are not only important regionally, but they have significant impact on biodiversity and ecosystem goods and services of coastal systems down stream. Mangroves and estuaries are important nurseries because of the dependence of marine organisms on estuarine conditions during the juvenile or adult stages of their life cycle. Many organisms migrate from either freshwater habitats upstream or marine habitats offshore to mangrove refugia during critical stages of their life cycle. The fragmentation of mangrove-dominated landscapes may create the same types of problems for estuarine-dependent organisms that are associated with the fragmentation of upland tropical forests.

Another significant type of global environmental change is the recent rise in atmospheric concentrations of carbon dioxide (CO_2), which along with other greenhouse gases, is the precursor to many of the environmental changes described above. Mangroves may respond directly to this increase in atmospheric CO_2 by increasing rates of carbon assimilation, growth and biomass allocation. Greenhouse studies have shown an increase in the amount of root productivity relative to allocation to above-ground biomass, which may be important with respect to soil formation and accretion relative to accelerated sea level rise. These responses depend on local conditions of soil salinity, which will control species-specific responses to increased CO_2 concentrations. However, in those environments where water use efficiency may be limiting mangrove growth, increased CO_2 will most likely enhance mangrove productivity.

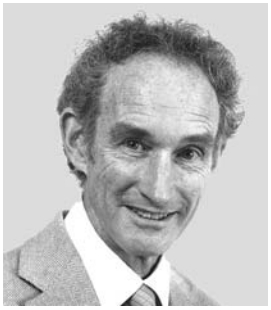
Mangroves are arguably an excellent indicator of how ecosystems will respond to the manifold impacts of global environmental change. The unique position of these forested wetlands along the continental margins of tropical environments integrates the combined effects of oceanic, atmospheric, and watershed forcings on ecosystem structure and function. Some scenarios of global environmental change will restrict mangrove ecosystems, such as increased erosion along the ocean margin, increased frequency and magnitude of cyclonic disturbances, and decreased moisture along the terrestrial ecotone. Other scenarios may expand mangrove-type habitats such as warmer environments at the latitudinal edges of mangrove global distribution, and increased CO_2 concentration. All of these environmental changes have to be considered in concert with human land use change both on the coast and in upland watersheds. The balance of energy and water between the ocean, atmosphere and watershed components of the Earth System will change several forcings that control the distribution, biodiversity, and function of mangrove ecosystems. Given present patterns, the combined effects of climate and land-use change will be noticeably evident in reduced goods and services to human systems throughout the tropics in this century.

Margalef, Ramon

(1919-)

Ramon Margalef, born in Barcelona, Spain, in 1919, an early self-taught naturalist, had to serve 6 years in the Army due to the Spanish Civil War. In 1944, his work on freshwater phytoplankton with a self-made microscope, while working as a clerk in an insurance company, attracted the interest of some naturalists. He received a grant and, in just two years, completed his secondary education with the highest score, then a degree in Natural Sciences at the University of Barcelona and a PhD (1951) with a thesis on *Temperature and Morphology of Living Things*. In 1952, he obtained a post as a researcher of the Consejo Superior de Investigaciones Cient ficas (CSIC) at the Instituto de Investigaciones Pesqueras (IIP, now Instituto de Ciencias del Mar), Barcelona, where he served as Director 1965–1967, launching many international contacts and programs. He became the first full professor in Ecology in Spain, at the University of Barcelona, but continued his research at the IIP until 1977. Since the late 1950s, he has contributed to theoretical developments in ecology, and his work has had an international impact. The most relevant of his contributions is in the application of Information Theory to the analysis of diversity in natural communities, and in the application of thermodynamic general principles to the understanding of succession and of ecosystems organization. As a limnologist, he recognized his debt to the ideas of A Thieneman and his friendship with V Tonolli and L Tonolli. He had many contacts within the ecology community, such as G E Hutchinson, R H MacArthur, E Odum and H Odum. His ideas on relationships between ecology and evolution, organizational patterns in the biosphere, the use of macroscopic parameters to study ecosystems and the need for a physical, rather than a mathematical approach to ecological understanding, have had a strong in uence on ecological theorists. Only a few of his synthesis books have been published in English (for instance, *Perspectives in Ecological Theory*, 1968; *Our Biosphere*, 1997). *Ecolog´a* (1974) and *Limnolog´a* (1983) are two monumental works that have been essential reading for Spanish ecologists, and the same is true for *Biosfera, Entre la Termodinámica y el Juego* (1980) and *Teor´a de los Sistemas Ecológicos* (1991), two beautiful theoretical synthesis. But he has also published an enormous amount of specific research, around 400 scientific papers and books mainly on oceanography and limnology. Even in retirement, he is still active. For some years, he has been the most quoted Spanish scientist in any topic. His work has been recognized with many national and international prizes (including the Huntsman Oceanography Award 1980, Premio S. Ramon y Cajal 1984, Italgas Prize 1989, Humboldt Award 1990, Naumann-Thieneman Medal 1989, Ecology Institute Prize 1995, several *Honoris Causa* doctorates and honorable memberships of the British Ecological Society and the Ecological Society of America, among others). Married in 1952, Professor Margalef has two sons and two daughters.

JAUME TERRADAS *Spain*



May, Robert, M

(1936-)

Robert McCredie May is a mathematical biologist. No aspect of global change is more prominent than the wholesale transformation of once species-rich ecological communities to depauperate ecosystems, and no single individual has contributed more to understanding this change than Sir Robert May. These ubiquitous changes in the earth's biota consist of extinctions and changes in species composition caused either by the substitution of native communities for managed ones such as farms or plantations or by the introduction of exotic species. Before the 1930s, the focus of ecology was on documenting natural history and chronicling patterns in the distribution and abundance of organisms. A J Lotka and V Volterra then provided a mathematical framework for understanding how such patterns may be generated by dynamic ecological processes. R H MacArthur dramatically extended their approach, providing elegant models that highlighted the ecological importance of structure and composition in communities. MacArthur in uenced many ecological and environmental biologists, including May, who led the way in restructuring ecology from a science that primarily described the earth's biota to one that predicts the causes and consequences of its change.

May's contributions are fivefold, all of which have and continue to contribute to every major area in global change ecology. These are the relationship between the

stability of ecological systems and its biological complexity (May, 1974), patterns in distribution and abundance (May, 1975), non-linear or chaotic dynamics in ecological systems (May, 1976), disease dynamics (May, 1977), and patterns in global extinctions (May, 1988). May has written hundreds of scientific and popular publications both individually and in collaboration with leading ecologists. The central theme of May's extraordinarily broad and diverse work is that the dynamics of the earth's biota, although seemingly complex beyond comprehension, are fundamentally understandable. Even the apparently chaotic dynamics and sometimes rapidly shifting compositions of biological communities we sometimes observe in nature can be understood by the theory May developed. This work provides the foundation for quantifying, modeling, and predicting the potential environmental consequences of anthropogenic impacts on populations, communities, and ecosystems.

His in uential contributions have been internationally recognized. May was elected to the American Academy of Arts and Sciences (1977), the Royal Society (1979), the Australian Academy of Sciences (1991), the US National Academy of Sciences (foreign member 1992) and to the Academia Europaea (1994). His contributions have earned him numerous honorary degrees around the globe, including England, Scotland, Sweden, the United States, and Australia. He was awarded the Royal Swedish Academy of Science's Crafoord Prize (1996) and the 1998 Balzan Prize for his contributions to the mathematical analysis of biodiversity. He was knighted in 1996 and awarded the Companion of the Order of Australia in 1998. Numerous awards preceded these honors, including the MacArthur Award by the Ecological Society of America (1984), the Croonian Lectureship of the Royal Society of London (1985), the Linnean Society's Zoological Medal (1991), and the Zoological Society's first Marsh Award for Conservation Science (1992) and its Frink Medal (1996).

May has and continues to serve on numerous key scientific and governmental boards. These positions have included those with the Natural History Museum, London; the Nuffield Foundation; the Royal Botanic Gardens, Kew; the Joint Nature Conservancy Councils; and as Chief Scientific Advisor to the UK Government and Head of UK Office of Science and Technology. Most recently he has been elected President of the United Kingdom's Royal Society. His insightful scientific contributions, of theory informed by data, continue to inspire the field of global environmental change.

Mercury in the Environment

Arne Jernelöv

International Institute for Applied Systems Analysis, Laxenburg, Austria

Environmental problems associated with mercury can be said to consist of several only weakly connected parts.

The one that was rst identi ed to be of environmental concern was the use of methyl mercury as a seed-dressing agent. It caused mortality and population decline among seed-eating and predatory birds in Sweden in the 1950s and 1960s. Human consumption of methyl mercury (CH_3Hg^+) dressed seed also resulted in the largest mercury-related catastrophe hitherto in Iraq, 1971- 1972. Its use ended in the 1970s.

Industrial use of mercury (Hg) and handicraft applications have for a long time been an occupational health concern. In the 1960s, it was also recognized that industrial discharge of mercury to nearby water courses resulted after bio-conversion in locally elevated areas of methyl mercury in larger predatory shes and a toxic risk to sh consumers. The Minamata catastrophe in the 1950s is the largest tragedy to humans from this type of mercury use. Industrial use and release of mercury has been drastically reduced in the last three decades following environmental concerns and governmental restrictions.

A technology with its roots in Roman times and one that was heavily used by the conquistadors in South America came back in large scale in the mid-1980s. Amalgamation as an extraction method of gold and silver replaced gold panning and resulted in extensive use of mercury in small-scale gold mining from the early 1980s to the late 1990s, predominantly in tropical countries. The mercury came to a large extent from inventories of the chemical industry in the

Organization for Economic Cooperation and Development (OECD) countries and the former Soviet Union. Following the fall in gold price, this practice has almost disappeared during the last few years.

A very large source of anthropogenic mercury is releases to the atmosphere from coal combustion and increased evaporation following land use changes. Those emissions have, together with atmospheric discharges from industrial uses, doubled mercury concentrations in the air and may have contributed to elevated concentrations in marine top predators. The current and forecast future trend for mercury release from these sources is upward.

Mercury as an environmental pollutant interacts with many other contaminants, e.g., eutrophication, acidi cation, and ground-level ozone. Thus acidi cation partly caused by sulfur emissions from coal combustion has led to an increase in methyl mercury concentrations in fresh water sh.

PHYSICAL PROPERTIES OF MERCURY AND GENERAL OCCURRENCE

Mercury (Hg) belongs to the metal group of basic elements. Within the group it is unique in that it is in liquid form and has a vapor pressure that results in evaporation at room temperature. Mercury has a high density ($13.7\,g\,ml^{-1}$) and surface tension and rare dielectric properties. From the elementary (metal) stage it can be oxidized to mono- or divalent form of which the latter is most common and it forms ions and salts (Turner, 1987).

Mercury in its divalent form binds very strongly to sulfide and selenide and forms salts with extremely low solubility (10^{-53} for mercuric sulfide). It also forms complex ions like HgS_2^{2-} and $HgCl_4^{2-}$.

In organisms, divalent mercury tends to bind to sulfur groups in proteins. Most of its toxic properties are associated with protein denaturation following such bindings. Higher organisms like mammalians have barrier-like blood/brain and placenta barriers that prevent divalent mercury from reaching the most sensitive places, the central nervous system and the fetus. Mercury also forms organic compounds through covalent bindings to carbon (C). Methyl mercury (CH_3Hg^+) is formed biochemically in nature and that compound, as well as many other organo-mercurials, is synthesized. Organo-mercurials like methyl mercury readily pass the protective barriers of the mammalian body and can thereby cause brain damage and harm to the fetus.

Dimethyl mercury ($(CH_3)_2Hg$) is highly volatile. In nature, mercury occurs predominantly as a mineral in the form of oxide (cinnabar) or sulfide.

Metallic mercury forms mutual solutions with many other metals like zinc or gold. These are called amalgams.

MERCURY USAGE FROM ROMAN DAYS TO CURRENT PRACTICE

The many unique properties of mercury have resulted in a very wide range of applications. Already, 2000 years ago, it was a well-known element and around the Mediterranean there were several established mercury mines. One of them – Almaden in Spain – has survived to the present day.

Those mines were based on cinnabar deposits where a proportion of the mercury occurred in elementary/metallic forms and frequently would bleed out of the rocks in liquid form. Consequently, the air in the mines would contain high concentrations of mercury from evaporation. High mortality from mercury poisoning among slave miners contributed to the relatively high cost of mercury in Roman days. The dominating uses at the time were two: metallurgic and pharmaceutical. In metallurgy, mercury was used to extract gold and silver from grained minerals in the form of amalgams. Later the amalgams were heated and the gold or silver retrieved. This technique was also used by the conquistadors in Latin America and again came into use in small-scale gold mining in the late 20th century.

The toxic properties of mercury were used early on in various pharmaceutical applications against a large number of diseases and illnesses. After the discovery of the Americas and the introduction of syphilis in Europe, mercury became a well-known standard treatment of that disease. Some scholars argue that some of the classical symptoms of syphilis are very much like those of mercury poisoning and could indeed be the result of the treatment rather than of the disease.

Mercury as mercuric chloride ($C_7H_{14}ClHg$) or sublimate was also a popular poison for many countries as humans cannot smell or taste it and it therefore was regarded as undetectable. Among widespread historic uses was also the mixing of mercury salts into starch for uses in wet weather or under damp conditions, e.g., on top hats where the starched clothing would otherwise quickly mould. Mercury poisoning therefore became a widespread occupational risk for people in that trade and the mad hatter as in *Alice in Wonderland* became a well known phenomenon.

With industrialization and electrification, mercury found a large number of new applications. The specific electric properties gave rise to many functions in electrical applications such as switches, batteries, light bulbs and tubes. For some of these, it has been especially difficult to find substitutes with similar performance. Other uses were as catalyst in industrial syntheses such as formaldehyde (CH_2O) and acetaldehyde (C_2H_4O) or as electrolyte in the chlor-alkali process when common salt (NaCl) is converted to alkali (NaOH) and chlorine gas (Cl_2).

The mercury inventory in chlor-alkali plants has frequently been very high, often in the range of several hundred tons in a single room. Spillage of mercury often impregnated oors and walls and resulted in high ambient

air concentrations with subsequent exposure of workers. Medical symptoms of mercury intoxication were common in chlor-alkali plants for many decades.

Industrially produced organo-mercurials found uses as seed-dressing agents for fungi-control (methyl-mercury) or as a slimecide in pulp and paper industry (phenyl-mercury).

Mercury is mined predominately from two types of deposits:

1. Cinnabar ores where mercury is the direct target of the mining process; and
2. sulfide ores with a variety of metals where some other – often copper – is the main product and mercury only the by-product.

Global mercury production peaked at some 10 000 tons annually around 1970 and has since fallen sharply as a consequence of the environmental and health concerns. Cinnabar-based mercury mines have been closed or nearly so and it is only the sulfide ore-based mines that continue to yield mercury at a rate of some 500 tons year^{-1}. As other forms of mercury mobilization by humans – most notably coal burning – release mercury at the rate of some 10 000 tons annually, mining is no longer a major source of anthropogenic mercury (Lindqvist *et al.*, 1984).

ENVIRONMENTAL CYCLING AND (BIO)CHEMICAL TRANSFORMATIONS

Mercury has several environmental cycles that are partly inter-linked and lack of which is based on biochemical or chemical transformations. One of the cycles is global or semi-global in nature and involves evaporation from land or sea of elementary mercury oxidation in the atmosphere to divalent mercury (H^{++}) and subsequent wash-out with precipitation. From both land and sea, mercury can then be either quickly re-emitted to the atmosphere or more permanently bound to organic or inorganic receptors. There is also an atmospheric cycle involving emissions of dimethyl mercury mostly formed in biochemical processes in the sea. In this case the main atmospheric conversion process is probably one involving ultraviolet (UV) light and/or acids (H^{++}) resulting in water soluble mono-methyl mercury (CH_3Hg^+) and subsequent washout with rainwater. In both cases, there is also dry deposition and re-emittance of unknown magnitude.

In aquatic systems, mercury also undergoes a cycling process. After introduction in a water course, mercury in divalent inorganic form binds to particles and through this attachment settle in sediment. While suspended in the water or placed in the upper part of the sediment, different types of microorganisms, both bacteria and fungi, may methylate mercury (Jensen and Jernelov, 1969). Depending on pH for example, the end product can be either mono- or dimethyl mercury. The process of biological methylation is especially fast in the low oxygen concentration range where sulfate-reducing bacteria thrive.

Some biochemical mechanisms for biological methylation of mercury have been described. Among them are methylcobalamin (B_{12}) mediated methylation in methanogenic bacteria and erroneous synthesis of methionin from homocystein when mercury binds to the target sulfur (S) group in Neurospora (Landner, 1971).

There are also bacteria that convert methyl mercury to inorganic mercury, as do seals and fish-eating birds. Dimethyl mercury largely evaporates into the atmosphere while mono-methyl mercury is readily picked up by living organisms. Through the food chain, a substantial fraction of the methyl mercury in for example a lake will find its way to fishes.

Although fishes have fairly efficient excretion mechanisms for inorganic mercury, they can neither excrete methyl mercury nor degrade it. Methyl mercury concentrations in individual fishes thus mostly increase with size and age. As a consequence, methyl mercury constitutes a large fraction of the total mercury body load of fishes – mostly over 90% (Bloom, 1992). In fish, most of the methyl mercury is bound to sulfur groups in muscle-proteins. Certain organs, especially the parapharyngeal or pseudo-bronchial one show extremely high methyl mercury concentrations such as two orders of magnitude more than the whole fish average.

Only in extreme situations with methyl mercury concentrations exceeding 20 parts per million (ppm) have fishes demonstrated symptoms of poisoning. Fish consumers are at risk much earlier. Most countries have health standards banning sale at 0.5 or 1 ppm. Fish disappear from acidifying lakes because of difficulties in reproduction. In some lakes whole age classes are missing.

HUMAN MERCURY TOXICOLOGY AND MASS MORTALITY FOLLOWING EXPOSURE TO METHYL MERCURY

The effects of mercury on humans as well as other mammalians or birds are highly dependent on the form of mercury and route of exposure. As noted above, mercury in the body binds predominantly to sulfur-groups in proteins; and effects, e.g., on enzymes, are most often associated with protein denaturalization. Inorganic divalent mercury does not pass the blood brain or placenta barriers. The cause of death when mercuric chloride was used as a poison in, for example, renaissance Venice, was due to damage to liver and kidney functions. Inorganic divalent mercury is excreted with urine with a half-life in the body of weeks.

The lungs effectively take up elementary mercury when inhaled while mostly passing through the intestinal tract if swallowed. After lung uptake, elementary mercury is

oxidized in the body to divalent mercury and thereafter behaves as such. Prior to oxidation, though, elementary mercury may pass the blood-brain barrier. Thus damage to the central nervous system is part of the symptom package associated with exposure to elementary mercury in air.

Methyl mercury is readily absorbed in the intestinal tract or through the skin if applied in solution, and via the lungs if present (as dimethyl mercury) in air. In methylated form, mercury easily passes all types of biological membranes and readily reaches the brain or fetus. In modeling methyl mercury, the body can be treated as one compartment due to the fast equilibration (Cox *et al.*, 1989).

Symptoms of methyl mercury poisoning are associated with damage to the central nervous system, as the effects here occur at much lower concentrations of mercury than those of other organs in the body. Especially sensitive is the brain of the fetus.

Methyl mercury is excreted with the bile but reabsorbed in the intestine. Excretion also occurs via milk in lactating females and through irreversible incorporation in hair and nails. The half-life in the human body is typically some months.

The first environmental catastrophe involving mercury and mass mortality among humans occurred in the 1950s in Minamata in Japan. Among the fishing population in the small town and around the bay, severe cases of central nervous system dysfunctioning including loss of balance, ataxia, cramps and blindness frequently resulting in death occurred from the mid-1950s. From observations of similar symptoms among domestic cats, it became clear that fish were the vehicles for the causative agent, but it took until 1959 before it was concluded that methyl mercury was the cause of the poisoning.

Several hundred people were killed or permanently damaged. Some of them still live at a special local hospital. The mercury that contaminated fish and shellfish in Minamata Bay came from a chemical factory making acetaldehyde with mercury as a catalyst. Some of the mercury was chemically methylated in a holding pond where different ef uents were mixed before discharge to the bay. The exact level of mercury and methyl mercury in aquatic life in the bay at the time has been much debated since the colorimetric analytical method available at the time was not reliable. Concentrations well above 10 ppm were in all likelihood common. A similar case occurred at the same time in Niigata in Japan involving fewer cases.

In 1971/1972, the by far largest mercury catastrophe up until that time occurred in Iraq. After some years of bad harvests Iraq, in 1971, decided to import Green Revolution wheat from Mexico. To protect that seed from fungal attacks, it was dressed with methyl mercury. The distribution to the farmers took longer than planned so when the pink colored grain arrived, the sowing season was already over. The farmers were told not to eat the seed but the previous year's bad harvest and a general mistrust of governmental instructions caused many of them to try to feed chicken and sheep and sometimes cattle. When no short-term effects were seen, they progressed to feeding expendable family members like grandparents and soon whole families were eating pink bread.

By the time that humans started to show symptoms, many food products on the markets like meat, milk, cheese, chicken and egg were also contaminated. A strict governmental order was issued that all pink grain within a fortnight should be handed in to the storehouses where the farmers had obtained it. Failure to comply would be punished by death. But farmers only got the information after the death penalty had already come into force. Thus methyl mercury dressed seed was dumped in irrigation canals and along roadsides, which resulted in contamination also of fish and wild birds, which suddenly became easy to catch.

In total some 10 000 people died and maybe 100 000 were permanently injured. A secretive governmental policy lead to very limited publication of this catastrophe compared to the one in Minamata.

MERCURY IN TERRESTRIAL AND AQUATIC FOOD CHAINS

In the 1950s and early 1960s, methyl mercury was extensively used as a seed-dressing agent in Sweden. Environmental concerns arose when populations of yellow sparrow, pheasant and other seed-eating birds declined and individuals of the species were found unable to y, moving in circles or paralyzed. Predatory birds were also found dead without physical injury and populations were steadily shrinking. The cause was methyl mercury uptake from the dressed seed in the seed-eating birds and further food chain magnification. Similar patterns were found in a variety of aquatic environments from small lakes and rivers to marine bays and semi-enclosed seas to open ocean systems. In fact, methyl mercury in aquatic systems is one of the very best examples of bio-magnifications in food chains, as fish lack excretion mechanisms for methyl mercury. This is also the reason why other naturally occurring mercury forms do not show the same pattern.

The original studies of mercury in the environment were carried out in temperate systems in Scandinavia, Japan and North America, in the 1960s and 1970s. When mercury use and release started to expand in tropical and subtropical regions in connection with the use in small-scale gold mining, some reported analytical results did not match the established picture. An International Council of Scientific Unions/Scientific Committee on Problems of the Environment (ICSU/SCOPE) study was launched to look at the fate and effects of mercury in tropical systems. With regard to food chains, one structural difference between tropical and temperate ecosystems that significantly affect mercury

bio-magnification is that tropical predators frequently are specialists while those in temperate areas often are generalists. The latter results in relatively small differences in methyl mercury concentrations between individuals and between closely related species. In tropical systems with geographically specialized individuals and prey-specialized species, the variations in (methyl) mercury concentrations are much larger with consequences for required sample sizes for trend analyses and for establishment of statistical differences (Jernelov and Ramel, 1995).

In open ocean systems, large and long-lived top predators like swordfish, tuna and sharks have high concentrations of methyl mercury that frequently reach several ppm. Mediterranean fish show higher concentrations than their relatives from the Atlantic Ocean, which may re ect both a different size/age relationship depending on the more oligotrophic conditions in the Mediterranean and mercury rich geological strata in the region.

Seals also have high concentrations of mercury but practically all of it is in inorganic and selenium-bound form, despite the fact that the fish on which seals feed contain predominantly methyl mercury.

As already noted, methyl mercury differs significantly from inorganic forms of mercury with regard to bioaccumulation and food chain magnification. However, in fish where methyl mercury is the dominating form of mercury, current methods of mercury analysis (ameless atomic absorption) cannot distinguish between inorganic and methylated mercury. In other situations the analytical method used may blur the results and complicate interpretation as the proportion of methyl mercury in different samples remains unknown.

An illustration of the importance of the food chain is given by the situation in Scandinavian acidified lakes. As a rule of thumb it can be said that in a lake with pH below six, a 1 kg pike will have a mercury level above 1 ppm. Many factors of both chemical and biological nature contribute to this. The single most significant factor is that the food web is significantly altered when roach disappear as they are more acid sensitive, and pike start to feed mainly on perch, which through their feeding habits and growth rate have higher methyl mercury concentration than roach.

MERCURY IN SMALL-SCALE GOLD MINING

In the early 1980s, mercury had replaced the panning process for density-dependent separation in small-scale gold mining. Amalgamation allows capture of gold-containing particles in the dust – the very fine particles – that could never be gravimetrically separated in a pan, and thus the mercury process gives a substantially higher yield than panning. Sometimes, depending on local conditions, the increase in yields may be as high as ten-fold. Mercury and amalgamated gold is then separated by putting the mixture in a cloth and squeezing the mercury droplets out. The amalgam is then heated which evaporates the mercury leaving the gold (Kato and Pfeiffer, 1996).

Occupational mercury exposure occurs throughout the process but is especially pronounced when scraping gravel off the mercury bed or with a modified technique when gravel and mercury are mixed. Most of the immediate intoxication occurs in connection with heating the amalgam and evaporating the mercury as this is frequently done indoors while hiding to avoid robbery.

Environmental contamination occurs both through mercury spillage on the ground and in water courses, as riverbeds frequently are favored places for gravel extraction, and to the atmosphere through evaporation.

The practice started in the Amazon region in Brazil and quickly grew with regard to the number of practitioners and spread to neighboring countries in the region. In the late 1980s, several hundred thousand people in the Amazon region were using the technique.

In the early 1990s, the mercury technique spread to Africa, in particular Tanzania and Ghana. A little later, a boom came to South Africa when people re-extracted old tailings from gold mines with the technique.

The global spread continued to Asia, first to Vietnam and Indonesia and also reaching Papua, New Guinea.

In the mid-1990s, an estimated ten million people were earning their livelihood from small-scale gold extraction using the mercury method.

As gold production or mercury use figures from these mostly unauthorized activities is non-existent or non-reliable, the SCOPE group used an indirect method to access mercury use. Small-scale gold miners tend to get 15–25% of the world market price when they sell their unrefined gold. To cover their costs of living and support families they would in the Amazon region be required to produce one gram of gold per garrimpero per day. As the mercury requirement for gold production is 1.5–1, each miner would release 0.5 mg of mercury per year. Thus the mercury used in the trade globally is estimated to amount to 5000 tons annually in the mid-1990s.

In the late 1990s, the gold market collapsed and the small-scale miners were hit by a price drop of frequently 50%. This put most of them out of business and a rough guess is that today their number does not much exceed one million – most of them in Asia.

Another question that the SCOPE group studied was the source of the 20 000 tons or so of mercury that were used from the early 1980s to the late 1990s. The conclusion was that it came from industrial mercury inventories, first from OECD countries when, for example, their chlor-alkali plants shifted from mercury to other techniques for environmental reasons. Later the bulk of the mercury came from the inventories of Soviet industry through private profiteers (Jernelov and Ramel, 1997).

CURRENT SCIENTIFIC CONTROVERSIES

Effects on Humans of Long-term, Low-level Exposure from Marine Food

In connection with the mercury poisoning catastrophe in Iraq, it was observed that schoolchildren exposed to methyl mercury showed no apparent physical symptoms but they performed badly in school in the years following exposure. This and other indications together with more theoretical considerations based on mercury action in nerve cells have led to concern about developmental effects in children from long-term, low-level, methyl mercury exposure. A special focus has since been placed on populations with a high general intake of marine food products containing significant amounts of methyl mercury. Two large such studies have yielded con icting results.

One study was carried out in the Seychelles where tuna with methyl mercury concentrations of 1–3 ppm is the staple food for half the year. This study involved a large number of children who were followed from birth. Developmental indicators like age of walking were noted and the children were tested using a series of standard methods. No development effect significantly correlated to mercury exposure was found (Davidson *et al.*, 1995).

The other study was undertaken on the Faeroe Islands. Here traditional whaling in the bays provides a substantial part of the local diet, with most of the meat having high mercury concentrations. Also here, a group of children was followed from birth. Developmental indicators were noted and the children tested with especially developed or modified tests. This study reported that delayed development was correlated to mercury exposure (Budtz-Jorgensen *et al.*, 2000; Grandjean *et al.*, 1997).

The debate has focused on the sensitivity and reliability of the methods used to test the children. Much less attention has been given to the difference between tuna and whalemeat. The underlying sensitive question – both from an economic and a cultural point of view – is whether mercury concentrations in those traditional marine foods render them unsuitable as staples.

Resident Time of Mercury in the Atmosphere

The annual calculated anthropogenic mercury emission to the atmosphere plus the estimated natural degassing from the earth more or less correspond to the total amount of mercury present in the atmosphere. Thus the apparent resident time of mercury in the atmosphere should be in the order of one year. From this it follows that mercury in the atmosphere stays there long enough to have at least a hemispheric distribution bordering on a global one. Like carbon dioxide (CO_2), locations of emissions should thus be of little relevance for local and regional fall-out (Fitzgerald, 1986; Fitzgerald *et al.*, 1991).

Many studies over the years have on a smaller scale yielded results that fit poorly into this picture. Atmospheric emissions from chlor-alkali plants in Sweden were shown to contribute to locally elevated deposition. Mercury in rainwater falling on lakes was calculated to be re-emitted very quickly to a large extent. After closure of a major East German chemical industry after re-unification, mercury fall-out in Southern Sweden markedly decreased.

To reconcile those calculations and studies, a *ping pong ball model* was proposed. In this model, after emission to the atmosphere, mercury will have a resident-time much shorter than one year but will have a high probability of re-emission (to bounce back up) upon deposition. The picture prepared was one of ping pong balls on a stone oor with some soft carpets here and there. The calculated one-year residence-time would then be the average time the balls kept bouncing before coming to rest rather than the average time that the mercury on the average stayed in the air before hitting the oor (Jernelov, 2000).

The soft carpets in the real world would be, for example, acid lakes or arctic areas where chemistry and temperature reduce the probability of re-emission. They would accumulate mercury not because of a high fall-out but because of low re-emission. The two models obviously lead to very different results when assessing local and regional consequences of mercury discharges to the atmosphere, e.g., when preparing a formal environmental impact assessment (EIA). In addition, detailed analyses of wet and dry deposition and of (re)emission show that there are other measurable differences between the two models, sometimes referred to as the balloon (stay up a long time) and the ping pong ball (bounce back up):

- A much larger part of atmospheric mercury must consist of water soluble or reactive forms in the ping pong ball than in the balloon case.
- Reduced mercury use and emissions in recent decades should result in a steeper trend of decreasing mercury concentrations in fish in lakes close to industrial centers than far away in the ping pong ball case with little or no difference if the balloon model is valid.

Mercury Toxicity Risks with Dental Amalgam

Amalgam has been widely used for dental fillings on a large scale for more than a century. Numerous studies by national health authorities and international organizations have concluded that this practice is safe and that side effects are small and rare. During recent decades a growing number of dental patient associations have claimed the opposite, with the support of some scientists.

Recently the Swedish Counsel for Planning and Coordination of Research (FRN) was commissioned by the Swedish government to review the question once more (FRN, 1998). Among the conclusions from that study were

that documented individual variations, both in mercury leakage from amalgam-fillings (caused for example by saliva pH and grinding jaw movements) and sensitivity to mercury were larger than previously accounted for, and that the possibility of existence of a fairly large group of people with medical symptoms caused by amalgam fillings could not be ruled out. The Council also concluded that very different risk philosophies rule in the environmental domain where mercury bound to sulfur or as amalgam is not considered safe for storage above ground (also when cast in concrete) and the dental domain where amalgam in the mouth of most people is considered safe. Clearly from an environmental point of view, mercury emissions from crematoriums are an important anthropogenic mercury source.

Short Distance Air Transport

Several studies in the Amazon region have indicated or yielded results that have been interpreted to indicate a substantial degassing of mercury from rain forest soil and a subsequent trapping of that mercury in the foliage of the trees.

There are no supporting studies from other areas and the existence of a significant short air cycle is debated.

MERCURY TURNOVER AND GLOBAL ENVIRONMENTAL CHANGE

Mercury undergoes several environmental cycles involving various chemical transformations between elemental and oxidized stages and between inorganic methylated forms.

Obviously temperature is a rate determining factor for many of these processes. However, the complexity is such that no simple conclusions can be drawn. In very general terms, it can be said that a given amount of mercury tends to give rise to higher methyl mercury values in predatory fishes in cold and temperate climates than in tropical ones but compounding factors are many, e.g., nutrition and growth rate.

Globally, mercury cycling is thought to involve transport towards the polar regions. Warming could increase re-emission to the atmosphere of some of that mercury. Would it then just move a little farther north (and south) or would it expose ecosystems globally? Atmospheric/oceanic mercury exchange has been demonstrated to involve large local uxes, but these go both ways and upwelling may be a more important factor than temperature. Thus, if global change involves ocean circulation on a large scale it will in uence mercury cycling too, but it is too early to say how.

Acidification clearly has a strong effect on mercury turnover and resulting mercury levels in fish. More acidification means higher methyl mercury levels (in less fish). Acidification is caused by sulfur emissions, and is associated with coal burning; this may be further emphasized as coal burning today is a major source of anthropogenic mercury emissions. This could be the most direct link between other aspects of global environmental change and mercury. Increased emissions from coal burning is the causative agent behind many of them.

High mercury levels in open ocean top predators like swordfish, tuna and shark have long been seen as a natural phenomenon. Computations within the framework of the ICSU/SCOPE study indicate that anthropogenic emissions may have contributed by a factor two, not only to atmospheric concentrations but also to that of the upper layer of the oceans. Declining anthropogenic mercury emissions from industrial sources may, with a time delay of a decade or two, result in lower concentrations of methyl mercury in pelagic marine organisms – unless other emissions notably from coal burning increase correspondingly.

Besides the generally higher speed of biological and chemical processes associated with higher temperatures and the other factors discussed above, global climate change may affect mercury cycles in the following ways:

- Mercury methylation rates are frequently especially high in newly ooded areas.
- Increased ooding may therefore contribute to formation of more methyl mercury and thus to higher levels in fish. Increased UV-radiation may contribute to the oxidization of elementary mercury in the atmosphere thus shortening the residence time and speeding up washout.

Metadata

Jonathan M O Scurlock[1], Paul Kanciruk[1], Raymond A McCord[1], Richard J Olson[1], and William K Michener[2]

[1] *Oak Ridge National Laboratory, Oak Ridge, TN, USA*
[2] *University of New Mexico, Albuquerque, NM, USA*

Metadata (also written sometimes as meta-data or meta data) is information that enables data users to locate, acquire, understand, and apply or manipulate data. In other words, it documents data characteristics so that users can determine the tness of the data set for their purpose. A brief de nition of metadata is therefore data about data, or information about data. However, this encompasses a wide range of possibilities ranging from human-generated textual description of a resource to machine-generated information that may be useful only to computer software applications. Metadata describes the content, quality, condition, lineage, and other characteristics of data. Metadata makes it possible for data users to search, retrieve, and evaluate data set information from networks of databases by providing standardized data descriptions.

The term *metadata* may be interpreted in a number of ways. In its simplest and most restricted interpretation, metadata is the information necessary to locate data. This may be as simple as a unique resource locator (URL, or web address) where data may be found on the Internet, or it may comprise more detailed search and order criteria (e.g. spatial or temporal attributes, measurement characteristics or types, keywords). An analogy of this interpretation is the information contained in a library's card catalogue of books: author, title, subject, year published, publisher, etc. The generalized metadata standards developed by the Dublin Core Metadata Initiative are such an example. But although this information is effective in identifying the data of interest, it would be only marginally useful in understanding or interpreting the data. A more comprehensive interpretation of the term *metadata* includes all the information necessary not only to find the data of interest, but also to fully understand and effectively use these data. These include, for example, details of methods used to collect data, data formats and pointers to further information (references, etc.).

Metadata serve to describe data sets, databases, or information products (such as maps or technical reports) by documenting such things as subject matter, data set contents, context, quality, structure and accessibility. This includes the basic who, what, when, how, where (and sometimes why) of the data, their accuracy, and availability and distribution information. Metadata occur in layers with some parts being unique, and very intimately and specifically related to a measurement (e.g., the exact time and place of a single measurement). Other parts are more general and less directly connected to an individual measurement (e.g., a technical discussion of how the data-collecting instrument works). Other metadata may have intermittent and irregular interactions with the data (e.g., the effects of corrective maintenance activities).

Metadata is a term of relatively recent origin, probably first used during the 1980s. Over the past 15 years its usage has increased, and has become particularly common with the rising popularity of the World Wide Web. Until the mid-1990s, it was a term most prevalently used by communities involved with the management and interoperability of geospatial data, and with data management and systems design and maintenance in general. For these communities, *metadata* refers to a suite of industry or disciplinary

standards, as well as additional internal and external documentation and other data necessary for the identification, representation, interoperability, technical management, performance, and use of data contained in an information system. However, the underlying concepts have been in use for as long as collections of information have been organized. Library catalogs represent a well-established variety of metadata that have served for decades as collection management and resource discovery tools.

METADATA FOR GLOBAL CHANGE SCIENCE

Environmental monitoring and research programs depend on being able to store, retrieve, and understand data that are collected over long periods. Long-term accessibility of high-quality data is hindered by data entropy, the natural tendency for data to degrade in information content over time (*see* Data Banks: Archiving Ecological Data and Information, Volume 2 and references therein). In order to minimize data entropy, data require comprehensive documentation (i.e. metadata), as well as storage in secure data archives.

Investing adequate time and energy in metadata development is beneficial for several other reasons. Data sharing is facilitated; data previously collected for a different purpose can be mined to answer new questions. Descriptions of sampling and analytical procedures, data quality and data set structure, facilitate subsequent analyses and interpretations. Many of the questions now being addressed by environmental scientists require more data than could be realistically collected, managed and analyzed by a single individual.

Various groups of computerized data users are developing metadata standards to increase interoperability and efficiency within and between different information technology organizations, software products, etc. Industry groups, international standards organizations and new associations such as the World Wide Web Consortium (W3C) all have a stake in the setting of metadata standards, as well as those charged with the management of scientific, and, more specifically, environmental data (see Table 1).

Considerable resources have been devoted to developing, adopting and implementing spatial metadata standards. In 1994, the US Federal Geographic Data Committee published standards which were developed as part of the US National Biological Information Infrastructure, to standardize geographical data collected by the federal government. However, metadata standards for non-geospatial data typically do not exist in any accepted format beyond individual studies, projects or organizations. Environmental studies often require large amounts of diverse data related to the physical and chemical environment, as well as the organisms, populations, communities and ecosystems comprising the biotic portion of the environment. It is unlikely that a single metadata standard, no matter how comprehensive could encompass all environmental data: but some metadata guidelines have nevertheless been developed recently, as well as computer software tools for compiling and submitting metadata. Certain special metadata may be required which are peculiar to certain kinds of environmental data, e.g., consistent taxonomy and nomenclature for species, families, etc., whilst other environmental data will share metadata standards with other kinds of geospatial and technical data.

Metadata for environmental data include a particularly wide range of context information that helps to define the meaning of an environmental parameter. An example is provided here by temperature: the contextual information needed to correctly interpret this common parameter includes metadata about:

- what media (air, water, soil, etc.);
- what units (C, K, or F);
- where (latitude, longitude, height above or below the Earth's surface);
- who (name of observer, institution, storage location, etc.);
- when (integration interval, date and time);
- how (what measuring device, what precision);
- how good (methods of quality assurance, what precision, etc.).

This contextual information can be extended to include more detailed information about the primary metadata values (e.g., how was the location determined, what units are used for the coordinate system, whether time is given as local time, Greenwich Mean Time (GMT), Coordinated Universal Time (UCT) or possibly the proposed Universal Date and Time standard, what other parameters were measured at the same time and place, what other programs

are related to this research project, etc.). Context may be further expanded if the data represent results taken from a sample. In this case, information about sampling scheme, sample size, and sample preparation are also part of the metadata. Some parameters may even require other measurements as part of their metadata (e.g., dissolved oxygen is more meaningful when water temperature is also measured). The data themselves may even become metadata for some applications. For example, cloud cover is a characteristic of LANDSAT satellite images, but this information becomes a valid metadata variable itself when users want to select only those images that are cloud free.

The adequacy of metadata is determined ultimately by future data users. If they are familiar with the specific scientific discipline and/or the research project or investigator, the users can successfully guess the correct values for incompletely specified metadata. If the users are unfamiliar with the discipline, incomplete metadata will significantly limit the usefulness of the results. Good metadata will minimize user problems with undocumented or misunderstood data, incorrect linkage of data and metadata, as well as the increased effort required to make later corrections, and consequently wasted time in the user community. It will result in efficient data processing and communication with the data user, and improved information longevity. As information technology rapidly increases the ability to store, share, and process environmental information, all scientists that gather and record data should more rigorously challenge the sufficiency of their own metadata.

Metapopulations

Pablo A Marquet
P. Universidad Católica de Chile, Santiago, Chile

A metapopulation is an ensemble of interacting populations connected by dispersal of individuals among them. Many species exist as metapopulations, and more are expected to do so, considering that landscapes are becoming increasingly patchy through habitat loss, degradation, and fragmentation, one of the most important of the many interacting components of global change affecting ecological systems.

In this essay a broad overview of metapopulation models and theory, from an ecological point of view, is presented, with emphasis on those concepts and approaches most important to understand the consequences of changes in the global environment. Global change through fragmentation can increase metapopulation extinction by: (1) destroying key habitat patches, which albeit their low quality (sinks), may be essential to maintain the connectivity of the system or by destroying those of high quality (sources) that are important sources of new colonists; and (2) by altering the natural dynamic regimes of habitat patches within landscapes. The effects of these changes may be subtle, lagged in time, and usually with sharp threshold transitions. Hence it is essential to establish long-term landscape monitoring programs to ensure metapopulation persistence in the face of a global change in the environment.

INTRODUCTION

Individuals and the habitats they occupy are not homogeneously distributed in space. Population ecologists have recognized the importance of spatial heterogeneity for a long time (e.g., Gause, 1935). However, the study of temporal uctuations in the number of individuals within populations has historically received most attention from both theoretical and empirical ecologists, likely as a result of the complexity involved in the consideration of space in theoretical models and experiments. Researchers following this non-spatial approach pictured populations as closed systems that changed in size as a consequence of births and deaths that occurred locally. However, the observation that populations can go extinct at particular locations and later reappear owing to colonization events, or can persist even if additions of new individuals through births do not compensate for losses through death, pointed to the importance of considering the exchange of individuals among populations in order to account for their dynamics and persistence. Under this view, populations are open systems, not independent from nearby populations with which they interact through the exchange of individuals. This ensemble of interacting populations (Figure 1) is what is called a *metapopulation* or *population of populations* as epitomized by Richard Levins in two foundational papers (Levins, 1969, 1970). Under the metapopulation paradigm, in addition to the importance of local populations, there is an added emphasis on the dynamics of the ensemble of local populations and the way they interact through migration.

Many species exist as metapopulations, and more are expected to do so, considering that the distribution of habitats within landscapes is becoming increasingly patchy through habitat loss, degradation, and fragmentation. Fragmentation in particular is the largest, and one of the most important, of the many interacting components of global change affecting ecological systems (Vitousek, 1994). Recent analyses of global databases on human disturbance of natural habitats point out that the effects of these degradation processes are acute in different biomes (Groom and Schumaker, 1993; Hannah *et al.*, 1995). Major ecosystems have already been reduced to fragments and numerous species and genetically distinct populations have been lost in the process (Ehrlich and Wilson, 1991). The effects

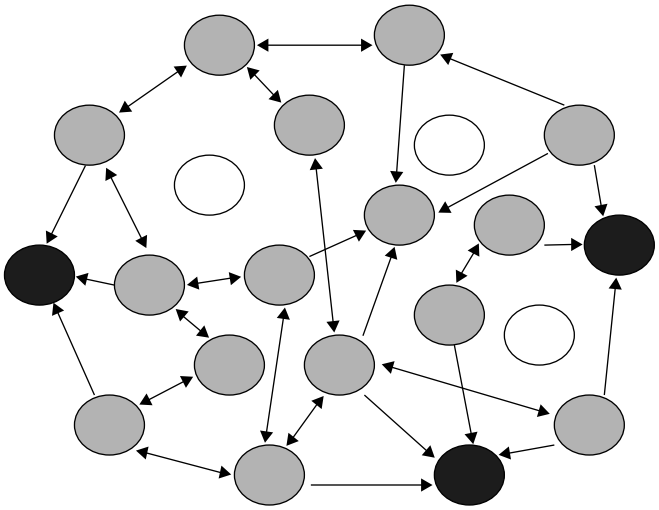

Figure 1 An ideal metapopulation composed of several local populations (or subpopulations) interacting through migration of individuals among them. Empty habitat patches, susceptible to be colonized from nearby local populations, are shown in white. Local populations whose persistence depends on immigration from nearby local populations (sink populations) are shown in black, while sources or immigrants (source populations) are shown in gray

of habitat loss and fragmentation are pervasive, featuring as the primary causes of endangerment of two-thirds of the world's vertebrates categorized as at risk of extinction (Prescott-Allen and Prescott-Allen, 1978) and of 82% of the endangered bird species (Temple, 1986).

Landscapes subjected to change through fragmentation represent one of the real world situations where metapopulation theory and models have been shown to be particularly suited to understand species persistence and population dynamics. The process of habitat fragmentation entails the creation of discrete habitat patches whose effect is that local populations interact with each other through the exchange of dispersing individuals, thus behaving as a metapopulation system (Hanski and Simberloff, 1997). In this essay I will present an overview of metapopulation models and theory from an ecological point of view, emphasizing those concepts and approaches deemed most useful to understand the consequences of changes in the global environment. A more in-depth treatment of metapopulation theory may be found in four recent books on the topic (Gilpin and Hanski, 1991; McCullough, 1996; Hanski and Gilpin, 1997; Hanski, 1999). It should be noted that population geneticists have been analyzing microevolutionary processes within metapopulations or spatially structured populations for a long time (Wright, 1931). The interested reader may refer to Hasting and Harrison (1994) and Harrison and Hastings (1996) for reviews.

METAPOPULATION MODELS AND THEORY

The pioneer of metapopulation models is that proposed by Levins (1969). This simple model assumes that N, the total number of available patches, is a constant. Let U and O denote the number of unoccupied and occupied patches, respectively. Levins' model assumes that instantly upon colonization of an empty patch, the organisms achieve their carrying capacity, thus reaching their demographic equilibrium within each patch. Assume that at this equilibrium, each individual in the patch produces a total of β propagules per unit time. Therefore, βO represents the total number of propagules produced by all the individuals in the occupied patches. These propagules find unoccupied patches at a rate proportional to their frequency U/N, thus unoccupied patches are lost to colonization at a rate $\beta OU/N$ per unit time, and occupied patches increase by the same number per unit time. If we assume that occupied patches become extinct at a rate e, then eO is the number of occupied patches that become extinct per unit time. Furthermore, this model assumes that occupied patches become unoccupied and immediately available for colonization at the same rate at which they become extinct, implying a closed system without an independent patch dynamics. The Equations that govern this system are:

$$\frac{d}{dt}O = \beta O\frac{U}{N} - eO$$
$$\frac{d}{dt}U = -\beta O\frac{U}{N} + eO$$

Dividing both Equations by N, defining $O/N = p$, and noting that $U/N = 1 - p$, then the Equations reduce to the Levins metapopulation model (Equation 1):

$$\frac{dp}{dt} = \beta p(1-p) - ep \qquad (1)$$

Because all patches and colonizing individuals are identical, one can dynamically follow the proportion of occupied patches instead of their actual numbers, and characterize the whole dynamics with two parameters: β and e. At equilibrium, the proportion of occupied patches is given by $p^* = 1 - e/\beta$, which is globally asymptotically stable, such that perturbations of this equilibrium as well as all initial conditions converge to this point.

In Levins' model, a positive proportion of occupied patches at equilibrium will exist whenever $\beta/e > 1$ (Figure 2). Taking into account that the average lifetime of an occupied patch is $1/e$, the above expression represents the total number of secondary colonizations produced by an occupied patch during its lifetime. This threshold parameter corresponds to the basic reproductive number used in epidemiology (usually denoted by the symbol R_0) which is a measure of the number of secondary infections that a single infectious individual produces when introduced

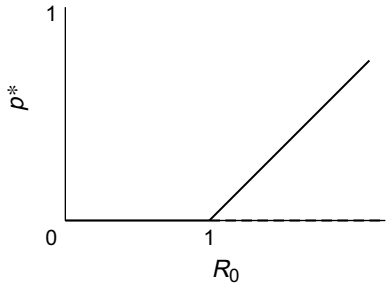

Figure 2 Bifurcation diagram for Levins' metapopulation model. For values of $R_0 < 1$ only the steady-state $p^* = 0$ exists and is stable. For $R_0 > 1$, a second steady-state appears. The other equilibrium still exists but is unstable. Note that the equilibrium proportion of occupied patches increases as R_0 increases. (Reproduced by permission of Sociedad de Biología de Chile in Marquet and Velasco-Hernández, 1997)

in a completely susceptible population (Diekman *et al.*, 1990; Hernandez-Suarez *et al.*, 1999). If this number is higher than one, the disease spreads in the host population. Otherwise, no epidemic outbreak ensues and the disease dies out. The basic reproductive number is therefore an invasion criterion: it determines if a pathogen will be able to survive in a host population once it is introduced. In a metapopulation context, it determines if a landscape composed of a set of empty patches will be successfully colonized, and also determines its long-term persistence (Marquet and Velasco-Hernandez, 1997). To appreciate the importance of R_0 in affecting metapopulation persistence, we can re-scale time in Equation (1) by taking as a unit the average time to extinction $1/e$. With this re-scaling, Levin's original model becomes (Hernandez-Suarez *et al.*, 1999):

$$\frac{dp}{d\tau} = R_0 p(1-p) - p \qquad (2)$$

where τ stands for the new re-scaled time. It is clear that if $R_0 < 1$, $p \to 0$ and if $R_0 > 1$, $p \to 1$.

This simple patch-occupancy metapopulation model provides a simple and fruitful way to understand the basic dynamical properties of metapopulations. Its success is re ected in its many subsequent modifications and applications to describe single species, two species, and multispecies interactions (Hanski, 1999). Although the many assumptions made by Levins' model limits its application to understand real world metapopulations, it has been of paramount importance to unveil the existence of important processes affecting species persistence in patchy environments. In retrospect, Levins' simple model is the ancestor of a plethora of more complicated models, some of which are described in Table 1. Among them, spatially explicit models have become very important in metapopulation theory (e.g., Keymer *et al.*, 1998) and well grounded in ecology (Durrett and Levin, 1994; Tilman and Kareiva, 1997; Dieckmann *et al.*, 2000). After all, metapopulations as well as ecological systems in general, are spatially extended systems whose dynamics are highly dependent on their topological arrangement, and neighborhood interactions. Two typical spatially explicit metapopulation models are presented in Figure 3. In the first model (Figure 3a) space is included as a regular lattice of patches that can be occupied by a species. However, most landscapes have a more complex spatial distribution of patches, which have different shapes and are located at different distances from each other. This complexity can be captured in spatially realistic models where a real landscape (in the form of a Geographical Information Systems (GIS) layer or a classified satellite image), instead of an arbitrary lattice, is used to run the model. Examples of this approach are the RAMAS-GIS model developed by Akcakaya (1995), and the PATCH model developed by Schumaker (1998). Figure 3(b) shows the metapopulation structure of the California spotted owl (*Strix occidentalis occidentalis*) in the Sierra Nevada and

Table 1 Different types of metapopulation models

Patch occupancy models or patch models
Models where the environment consists of an array of patches in two possible states, occupied or empty. They ignore attributes of local populations such as density and in most cases assume that all patches are equal. This type of model dynamically follows the proportion of patches in each state. Levins' model (Levins, 1969, 1970) is a patch-occupancy model
Structured metapopulation models
Structured metapopulation models explicitly include within-patch dynamics (modeling changes in local population sizes) and allow for the existence of differences in patch quality (reviewed by Gyllenberg *et al.*, 1997)
Spatially implicit metapopulation models
Models that ignore the spatial geometry or arrangement of patches, assuming that all are equally accessible and connected. Levins' model is spatially implicit
Spatially explicit metapopulation models
Models that include space explicitly, usually as a regular lattice of patches. Dispersal is restricted such that the dynamics of each patch in the lattice is a function of the state of the patches in its neighborhood. In this category are Cellular Automata models (e.g., Keymer *et al.*, 1998), coupled map lattice models (Hassell *et al.*, 1991), and interactive particle system models (Durrett and Levin, 1994)
Spatially realistic metapopulation models
These models are spatially explicit, where the lattice of patches is a real landscape (a GIS layer or a remote sensing image). This lattice preserves the relative position of patches, areas and other attributes of the real landscape (Keitt *et al.*, 1997; Schumaker, 1998)

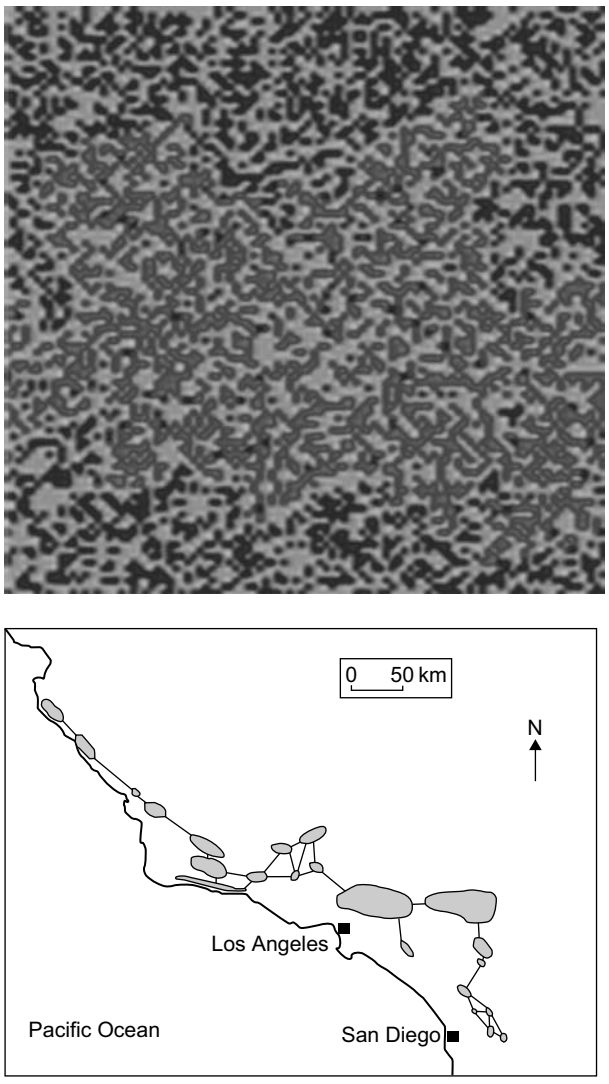

Figure 3 Two types of spatially explicit metapopulation models. (a) Space enters into the model as a regular lattice where each cell can be in a different state. (b) The metapopulation structure of the California spotted owl (*Strix occidentalis occidentalis*) is shown in the Sierra Nevada and in several isolated local populations in the mountains of southern California. (Reproduced with the permission of the British Ecological Society in Lahaye *et al.*, 1994)

in several isolated local populations in the mountains of southern California. A metapopulation model run on this patch network would be spatially realistic to the extent that the topology of the real system is preserved and affects its dynamics.

In Levins' patch occupancy model, the dynamics of the metapopulation is the result of the rate at which patches go extinct and the rate at which empty patches are colonized. However, by relaxing some of the assumptions about the source of the colonists, and the effect of migration between extant local populations, more complex and realistic scenarios can be analyzed.

SOME KEY METAPOPULATION CONCEPTS

Levins' model assumes that all colonists come from local populations within the system. However, there are other possible formulations (e.g., MacArthur and Wilson, 1967) with colonists coming from outside the system. In this scenario there is a propagule rain (a continuous source of migrants that could potentially colonize an empty site) which implies that the colonization rate depends, linearly on the fraction of empty patches only (Gotelli, 1991):

$$\frac{dp}{dt} = \beta(1-p) - ep \tag{3}$$

Examples of situations in which the assumption of propagule rain may be appropriate include:

1. a collection of forest fragments separated from a larger expanse of forest which serves as a source of colonizers;
2. an archipelago of islands near a continental source of propagules;
3. intertidal habitats with organisms that are sedentary as adults but have widely dispersed pelagic larvae.

Among metapopulation models that include the colonization process as a propagule rain are the so-called mainland-island metapopulations.

Individuals or propagules produced by a local population may either land in an empty habitat patch, an event that is called *colonization*, or in an occupied patch where there are already *conspeci c* individuals (i.e., that belong to the same species), in which case this event is called *immigration*. Immigration can be of great importance for the persistence of local populations, especially if the population receiving the immigrants is close to extinction. In this case, the genetic and demographic contribution of immigrant individuals may potentially rescue the population from extinction by increasing its population size, thus lowering the chances of disappearing because of demographic or genetic stochasticity. This concept named *rescue effect*, or the effect of immigration on extinction, was elegantly developed by Brown and Kodric-Brown (1977) in the context of the equilibrium theory of island biogeography (MacArthur and Wilson, 1967). It implicitly emphasizes the importance of connectivity among local populations and how this may potentially enhance metapopulation persistence. Clearly, this is of great importance to applied questions such as the maintenance of habitat corridors across landscapes.

Hanski (1982) was the first to include the rescue effect in a metapopulation model. This author reasoned that if

rescue effects are operating, then the extinction rate should decrease as the proportion of occupied habitat patches increases. This is because the probability of a local population being rescued from extinction increases as the numbers of potential sources of immigrants to any given local population increases. A simple way to include the rescue effect into Levin's model is (Hanski, 1982):

$$\frac{dp}{dt} = \beta p(1-p) - ep(1-p) \tag{4}$$

which reduces to:

$$\frac{dp}{dt} = \lambda p(1-p) \tag{5}$$

where $\lambda = \beta - e$. This model, which has a stable equilibrium at $p^* = 1$, gives rise to a bimodal distribution of occupied patches when λ is considered to be a random variable. In a multi-species case, this model predicts the existence of two types of species: those found in most of the habitat patches and those found in very few. This is what is known as the *core- satellite species hypothesis* (see Hanski, 1999 for a review and alternative models).

Source–Sink Dynamics

Landscapes are heterogeneous in time and space. Spatial heterogeneity is manifested, among other things, in differences in habitat quality such that the demographic rates of local populations are different in different patches. Extreme cases across a continuum of habitat-specific demographic rates are represented by source and sink populations (Pulliam, 1988, 1996). A *source population* is one where births exceed deaths and emigration exceeds immigration (Pulliam, 1988; see also Roughgarden and Iwasa, 1986). In other words, source populations are net exporters of individuals. In *sink populations*, on the other hand, deaths exceed births and immigration exceeds emigration. By definition, a sink population would not persist if immigration were impeded, because it has a negative rate of population increase (deaths outnumber births). Thus, rescue effects are essential for the persistence of sink populations. Clearly, sink populations will be found to the extent that there are source populations subsidizing them and engaged in source–sink dynamics. According to Pulliam's (1988) definition, real metapopulations should be composed of a mosaic of source and sink local populations. In practical terms, source populations are essential to metapopulation persistence and should be of great conservation concern. But why would some individuals immigrate into low quality patches inhabited by sink populations? There are at least two likely explanations (Dias, 1996). Individuals can occupy low-quality habitats as a result of interference competition whereby juvenile or subordinate individuals are forced to leave high quality (source) habitat patches, or because of passive dispersal as in plants and sessile invertebrates in intertidal habitats. A classical example of the first alternative is Carl's (1971) study on Arctic ground squirrels (*Spermophilus undulatus*). This species lives in breeding colonies where burrowing sites are limited and hence actively defended against conspecifics. Those individuals forced to ee the main breeding colonies occupy low quality (sink) habitat where mortality is high due to predation and environmental perturbations. Virtually all individuals in this population are immigrants in a low quality habitat. An example of a sink population maintained by passive dispersal is that described in Kadmon's (1993) study of the demography of the desert annual herb *Stipa capensis* in three habitats (slopes, depressions, and dry water course–*wadis*). Kadmon estimated that 75–99% of the seeds were produced in the depression and wadis, even though these two habitats represent less than 10% of the area occupied by the species. This evidence and previous results, which indicated that seeds produced in the wadis accounted for more than 90% of the abundance of *Stipa capensis* in the slope habitat, suggest that slope populations are maintained by immigration and correspond to sink populations. Typically sink populations are common at the border of geographic ranges of species. As noted by Lawton (1996), this fact may underlie the observed low success rate in species reintroduction programs at the edge of a species range in comparison with reintroductions in central areas (Griffith *et al.*, 1989).

Source–sink dynamics is an important metapopulation process with profound implications for species conservation in the face of global change. In the first place, it makes clear that the presence of a species in a given habitat is not proof that the habitat is suitable for its persistence or able to support a locally breeding population in the absence of immigration. Secondly, it suggests that the density of a species may be a misleading indicator of habitat suitability (Pulliam, 1996) because some species can maintain large populations in unsuitable (sink) habitats (Pulliam, 1988).

The previous discussion emphasized the importance of source populations for species persistence. However, sink populations can also be important on ecological and evolutionary grounds. Under some circumstances, sink populations can stabilize interactions between species, can foster coexistence in ecological systems (e.g., Holt, 1985; Loreau and DeAngelis, 1997), and can increase metapopulation persistence (Howe *et al.*, 1991; but see Marquet and Velasco-Hernandez, 1997) especially in variable environments (Jansen and Yoshimura, 1998). Sink populations in the periphery of the geographic ranges of species tend to be genetically divergent from central populations and potentially important for future speciation, especially if mutations of large effects on individual fitness occur in

these sink populations. If the mutations are large enough, they can overcome the selection bias toward increasing adaptation to source habitats, rather than to sinks (Holt and Gaines, 1992). Thus, under some circumstances peripheral sink populations can be of conservation value (Lesica and Allendorf, 1995), by keeping genetic variability that may be useful for future adaptation, especially in a climate change scenario.

GLOBAL ENVIRONMENTAL CHANGE AND METAPOPULATION EXTINCTION

Most species are spatially structured as metapopulations within their geographic ranges, and their global extinction is usually mediated through changes in metapopulation dynamics, as a consequence of habitat loss associated with human encroachment of natural habitats. How these events affect metapopulation extinction depends on three factors: (1) how many local populations or habitat patches are lost; (2) the quality of the remaining patches; and (3) the resulting changes in metapopulation connectivity.

The effect of habitat loss or destruction depends on how many local populations are required to ensure the long-term persistence of the metapopulation or its *minimum viable metapopulation size*. This is equivalent to one of the key concept in population and conservation biology – the *minimum viable population size*, i.e., the minimum number of individuals within an isolated population necessary to guarantee its long-term persistence (Schaffer, 1981). Until recently, this concept remained almost unexplored in a metapopulation context. Following the lead of Lande (1987), Nee and May (1992) proposed a general model that attempted to understand the effect of habitat destruction upon species interactions and persistence in patchy landscapes. By focusing on patch destruction, this model allows one to estimate the minimum number or fraction of habitable patches required for metapopulation persistence, also known as the *extinction threshold* (Lande, 1987; Lawton *et al.*, 1994; Hanski *et al.*, 1996; Hernandez-Suarez *et al.*, 1999). Conceptually, the extinction of a metapopulation following patch destruction is equivalent to the collapse of a disease epidemic following the removal of susceptible hosts (Lawton *et al.*, 1994). The process depends on the *eradication threshold* (Anderson and May, 1991), that is, on the minimum number of susceptible individuals that will enable the disease to persist.

To understand the effect of habitat destruction on metapopulation persistence we can use a simple model. Imagine a metapopulation composed of a finite number (N) of patches and suppose that D patches are destroyed. Now consider the question of how many patches can be destroyed without driving the situation to extinction? In this situation the number of suitable patches is $N - D$,

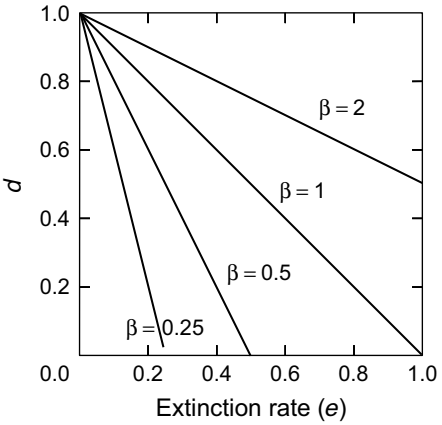

Figure 4 Changes in the critical amount of habitat destruction (d) needed to drive a metapopulation to extinction as a function of the species' extinction rate (e) and for species with different colonization rates (β). Notice that for the same extinction rate, species with higher colonization potential can withstand a higher proportion of habitat destruction before going extinct, and that this critical threshold decreases as extinction rates increases

which can be either occupied (O), or empty (U), such that $N - D = O + U$. Dividing by N, defining the proportion of occupied patches as $O/N = p$, the proportion of destroyed patches as $D/N = d$, the proportion of empty patches as $U/N = 1 - d - p$, and then replacing these terms in Equation (1), we arrive at a model equivalent to that proposed by Levins (1969) but now including habitat destruction:

$$\frac{dp}{dt} = \beta p(1 - d - p) - ep \tag{6}$$

In this model the proportion of occupied sites at equilibrium in the face of destruction (p_d^*) is:

$$p_d^* = 1 - \frac{e}{\beta} - d \tag{7}$$

Equation (7) has several implications. First, metapopulation extinction will occur ($p_d^* = 0$) if a critical proportion of habitat (d) is destroyed. This threshold corresponds to

$$d = 1 - \frac{e}{\beta} \tag{8}$$

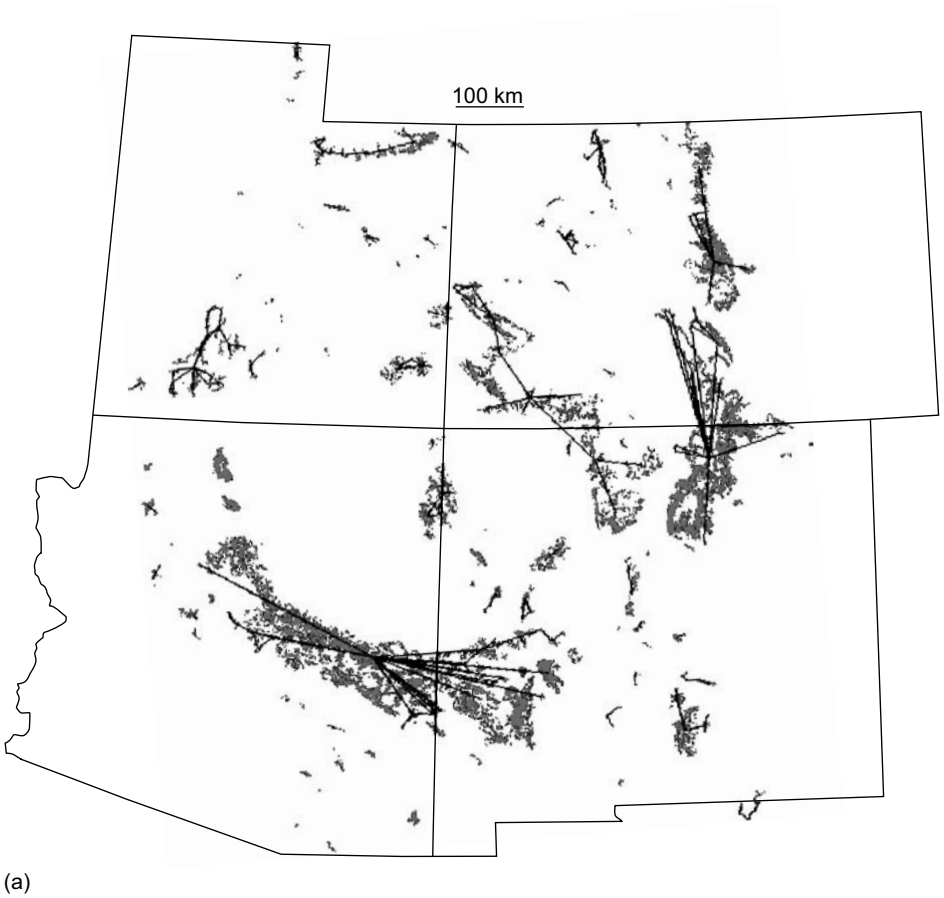
This implies that species with higher colonization rates or lower extinction rates can sustain higher amounts of habitat destruction (Figure 4). Interestingly, as noted by Tilman *et al.* (1997), this critical threshold corresponds to the equilibrium proportion of occupied patches in the absence of destruction such that a rule of thumb for metapopulation persistence is: A necessary and sufficient condition for metapopulation persistence is that the proportion of destroyed habitat patches should be less than the proportion originally occupied by the species in the

intact system. Thus, if a species in a pristine habitat occupied 25% of the available patches, then the random destruction of >25% of the patches will result in its extinction. Notice also that Equation (7) can be rearranged as

$$1 - d - p_d^* = \frac{e}{\beta} \tag{9}$$

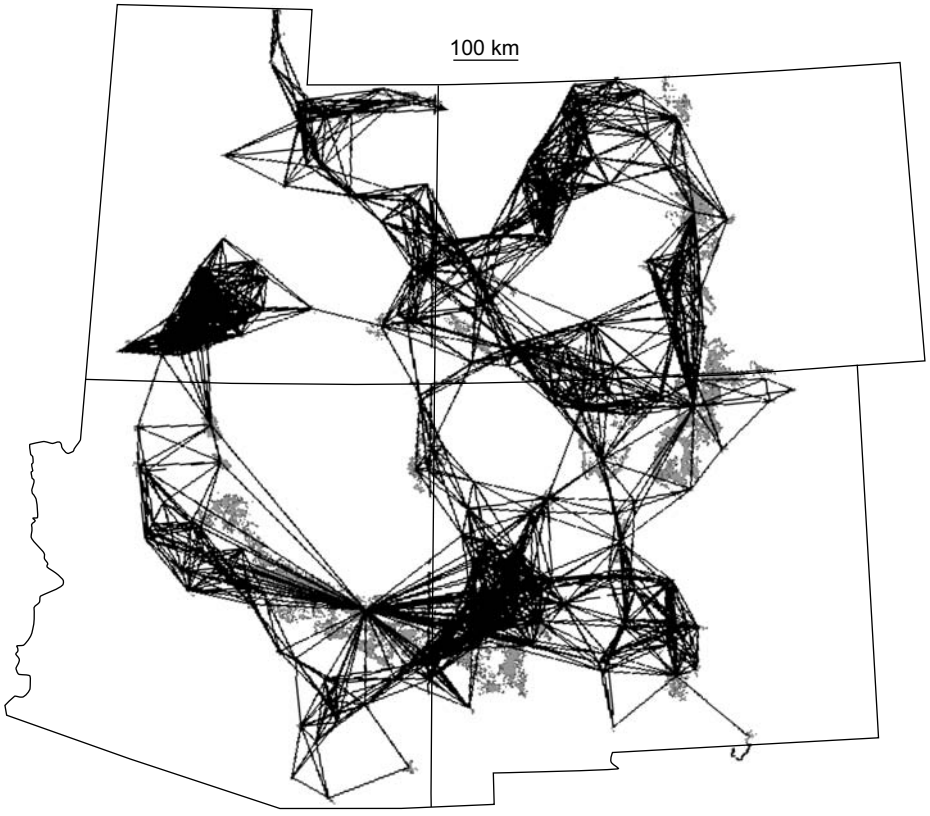
Noticing that $1 - d$ corresponds to the total amount of suitable habitat left after destruction, an equivalent rule of thumb (see Lawton *et al.*, 1994; Hanski *et al.*, 1996) can be formulated as: A metapopulation will persist if the proportion of suitable habitat patches after destruction exceeds the proportion of empty but suitable habitat patches in the intact system (i.e., $1 - d > e/\beta$). However, there are many other factors not captured by this simple model that can have an effect on metapopulation extinction.

A metapopulation may go extinct well before habitat destruction seriously threatens its persistence, as derived in the models above, because of stochasticity linked to a reduced number of local populations, such that a metapopulations can go extinct simply because all local populations happen to become extinct at the same time. This effect has been termed *extinction-colonization stochasticity* (Hanski, 1991) and is equivalent to the concept of demographic stochasticity for closed populations (May, 1973). But even if there is no habitat destruction and the metapopulation is large enough to escape extinction-colonization stochasticity, large-scale changes in the environment may tend to increase the correlation in local population dynamics, thus increasing the probability that all local populations become sinks, which can lead to metapopulation extinction. This effect has been termed *regional stochasticity* (Hanski, 1991) and is equivalent to the notion of environmental stochasticity in closed populations (May, 1973). To the extent that local populations are not correlated in their local



(a)

Figure 5 Digital cover map of the southwestern United States showing the spatial distribution of mixed-conifer and ponderosa pine habitat patches and the potential connection among them as a function of the scale at which organisms interact with the landscape pattern. In (a) black lines represent paths along which habitat patches are at a distance less than or equal to a threshold of 10 km, and thus organisms with a dispersal capability <10 km will perceive a highly fragmented landscape with many isolated patches. On the contrary, an organism capable of long distance dispersal [100 km as shown in (b)] will perceive a highly connected landscape. (Reproduced with permission of the Ecological Society of America in Keitt *et al.*, 1997)



(b)

Figure 5 (*Continued*)

dynamics, there will always be some local populations acting as sources (and rescue effects operating) to counteract local extinctions.

Finally, the quality of patches lost to destruction can make a big difference in terms of metapopulation persistence. Traditionally, the quality of patches has been assessed in relation to their suitability for population growth (with source and sink being extreme cases). In this context the destruction of a source patch has a higher impact on persistence than the destruction of a sink. However, patches of low quality for population growth can be of paramount importance in maintaining the connectivity of the system by acting as stepping stones between high quality patches; consequently their loss can have a tremendous impact on persistence. Thus, in terms of connectivity, source patches can be dependent on sink patches. Recently, Keitt *et al.* (1997) proposed a method to quantify habitat connectivity and to assign conservation priority to habitat patches based on their contribution to connectivity. Because connectivity of landscapes depends not only on the spatial configuration of habitat patches but also on the scale at which organisms interact with landscape pattern, e.g., Gardner *et al.* (1989), Keitt *et al.* (1997) quantified connectivity at different scales (Figure 5). Then, for each map, the authors removed patches (one at a time) and recorded the changes in landscape connectivity. This patch removal experiment allowed them to assess the importance of each patch in terms of landscape connectivity. Interestingly, after controlling by area, small patches had a very high contribution to connectivity, which suggest that they may be of high priority for conservation.

This is an important result, provided that small patches are more sensitive to environmental changes and may be the first to disappear. If this is the case, current environmental change may have a strong negative impact on metapopulation persistence even if source patches are not affected. The disappearance of sink populations may trigger a cascade of events such as disruption in connectivity, increase in isolation, limited rescue effects, and loss of useful genetic variability, thus increasing metapopulation extinction risk. Because these effects may be subtle, lagged in time (Tilman *et al.*, 1994), and usually with sharp threshold transitions (Bascompte and Sole, 1996; Keitt *et al.*, 1997), it is essential to establish long-term multiscale landscape monitoring programs to ensure metapopulation persistence in the face of a global change in the environment.

PATCH DYNAMICS

So far we have discussed the role of landscape pattern and the importance of particular patches for metapopulation persistence. However, Keymer *et al.* (2000) have shown that in addition to the pattern of *patch distribution*, *patch dynamics* (i.e., the creation of extinction and patches) greatly affects metapopulation persistence. Keymer *et al.* (2000) propose that metapopulation persistence is the result of the interaction between landscape pattern, patch dynamics, and species life history. The inclusion of patch dynamics in metapopulation theory underscores the importance of landscape monitoring, and the need for an adequate characterization of patch dynamic and disturbances regimes in order to gain insight and be able to predict species extinction. In particular, the establishment of monitoring program inside and outside protected areas would be desirable to understand the interaction between direct human impacts and environmental changes upon landscape pattern and dynamics, and how these affects metapopulation extinction.

The effects of global environmental changes upon ecological systems are complex and involve changes in landscape patterns and dynamics. In this context, metapopulation theory provides the theoretical and empirical framework needed to understand and foresee the potential consequences of these changes in the global environment.

ACKNOWLEDGMENTS

The author acknowledges support from grant FONDECYT 1990144. Special thanks to J Keymer, J Mena and J X Velasco-Hernandez, who provided stimulating discussions on metapopulations in recent years. M Lima and F Jaksic provided helpful comments on the manuscript. Figure 3(a) was kindly provided by J Keymer.

Microbial Diversity

James T Staley[1] and Jed Fuhrman[2]
[1]University of Washington, Seattle, WA, USA
[2]University of Southern California, Los Angeles, CA, USA

Microbial life has ourished on Earth for at least 3.8 Ga (Ga = 10^9 years) of its 4.5 Ga existence. In contrast, plant and animal life has been here for less than 600 million years. The early evolution of microorganisms (bacteria, archaea and eucaryotic microorganisms such as protists and fungi) and their long tenure on the planet have resulted in their occupation of every conceivable environment that is habitable. Thus, in addition to living in all ecosystems along with plants and animals, some live in boiling hot springs, sub-freezing sea ice, acidic mine waters, saturated salt waters and radioactive wastes that cannot be inhabited by plants and animals. During their long evolutionary history, they have evolved many biochemical capabilities that allow them to use a large variety of energy sources that are oxidized by unique mechanisms of respiration. For example, methane-producing (methanogenic) archaea cannot grow or respire in the presence of oxygen. Yet they are able to oxidize hydrogen gas as an energy source and respire with carbon dioxide that is xed into organic cell materials and methane gas.

Microorganisms formed the rst biosphere and continue to carry out a multitude of essential geochemical activities that prepared Earth for the eventual evolution of macroscopic life. Furthermore, microorganisms live in associations with all plants and animals and are responsible for their well-being. Thus, almost all animals have an intestinal tract lled with resident bacteria that help digest their food.

What is known about microbial life only scratches the surface of what still remains largely unexplored. This contribution discusses the diversity of microbial life, provides some examples of the important roles they play in ecosystem functions and introduces some of their major habitats.

MICROBIAL LIFE AND BIODIVERSITY

Until the last 10 to 15 years, biologists had difficulty in comprehending how plants and animals were related to microorganisms. Most biologists knew that microorganisms were simpler in their morphology, suggesting they had evolved early; however, there was no scientific information that would allow them to be satisfactorily classified with plants and animals which were more complex and whose evolution was partly known from the fossil record. Indeed, until the 1960s, fossils of microorganisms had not yet been discovered (Barghoorn and Tyler, 1965).

All of this has changed. Now, fossils of microorganisms are well known and some have been dated to about 3.5 Ga (Ga = 10^9 years) ago (Schopf, 1993). Likewise, geochemical evidence from early sedimentary deposits indicates that microbial life has existed on Earth for the past 3.8 Ga (Schidlowski, 1988).

But the fossil and chemical evidence provides little information on which microorganisms came first and how microorganisms are related to one another and to plants and animals. A major breakthrough in biology occurred when Carl Woese compared the sequence of a highly conserved ribosomal Ribonucleic acid (RNA) macromolecule found in all cellular organisms. From this he unveiled for the first time, a truly scientific *tree of life* containing the major groups of all living cellular organisms (Figure 1). It should be noted that viruses, which are not independent cellular organisms, do not fit on this tree because they do not have their own cellular machinery and rely on cellular hosts to reproduce.

The tree of life has three major branches, called *domains*, of organisms. One domain is called the *Bacteria*, another the *Archaea* and the final one the *Eucarya*. The most striking difference that distinguishes the eucarya from the bacteria and archaea is that their cells possess a membrane around their nucleus. Also, in contrast to the eucarya, the bacteria and archaea are *haploid*, that is, they have only one set of genes on an unpaired chromosome. The Domain Bacteria, contains the organisms we normally think of when we think of bacteria. With the exception of the planctomycetales group, the bacteria all contain a cell wall material called peptidoglycan consisting of amino sugars and short peptide chains, that makes them potentially sensitive to the antibiotic penicillin. None of the archaea contains peptidoglycan. Bacteria live in soils and aquatic environments and a few of them cause plant and animal diseases. It is interesting to note that photosynthesis appears to have evolved in the Domain Bacteria because several of the phyla have photosynthetic members including the proteobacteria, cyanobacteria, green sulfur bacteria, green filamentous bacteria and one of the gram positive phyla.

The members of the Domain Archaea are unusual in that some of them live in hot springs, others in saturated salt environments and others are responsible for production of methane gas. None of them is known to cause a plant or animal disease. Although we think of the archaea as being unusual in the habitats they occupy, many are also found in typical soil and aquatic habitats along with representatives of the bacteria and microbial eucarya.

The Domain Eucarya is also largely comprised of microorganisms. The cell of the eucarya is more complex than that of the bacteria and archaea. In fact, the eucaryotic cell

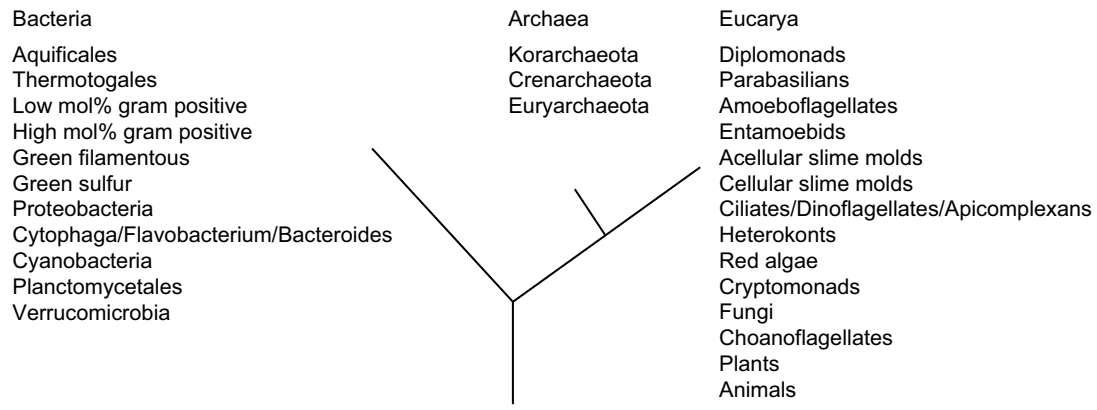

Figure 1 A diagram showing a rooted Tree of Life with its three major branches (domains), the Bacteria, Archaea and Eucarya based upon sequence analyses of the small sub-unit RNA from ribosomes. Under each domain is a listing of the major phylogenetic groups. Branching patterns are provided in some published trees (e.g., Woese *et al.*, 1990). Also, it should be noted that in addition to those sub-domain groups listed, the Bacteria are now known to contain a total of at least twice the number of major groups shown (more than 30 total), many from which no representatives have yet been cultivated (Hugenholz *et al.*, 1998)

actually contains organelles such as the mitochondrion that have evolved from intracellular symbiotic bacteria. Thus, the mitochondrion, which is responsible for aerobic respiration, has evolved from one of the members of the proteobacteria. Likewise, the chloroplast found in all photosynthetic members of the eucarya has evolved from the cyanobacteria. Most believe that the eucarya evolved from the bacteria and archaea, however; the details of how this has happened are still not clear. The eucarya group contains several microbial groups of single-celled organisms that are called *protists*, in addition to the fungi. And, finally in addition, it contains plants and animals.

What is abundantly clear from the tree of life is that most of the major branches and therefore most of the diversity of life on Earth is microbiological. To amplify on this point, it should be noted that many more major phylogenetic groups of microorganisms, particularly in the Domain Bacteria, are still being discovered. The tree shown in Figure 1 can now be updated to include a total of more than 30 major phyla of bacteria which are equivalent to the Animal or Plant Kingdoms by the earlier classifications (Hugenholz *et al.*, 1998). This view of diversity dramatically illustrates the genetic and evolutionary depth and variety of microbial life forms. Although there are only about 5000 different species of bacteria and archaea with formal Latin names, and these are biased towards those of medical or industrial significance, it is believed that the true number of different species probably falls in the millions. The large discrepancy derives from the general lack of morphological distinguishing features and the difficulty and cost in formally describing and naming a microorganism on the basis of biochemical and genetic characteristics.

Viruses

Viruses do not fit onto the tree of life because they are not independent organisms. Viruses consist of a nucleic acid genome (deoxyribonucleic acid (DNA) or RNA, single or double stranded) within a protein coat. They are obligate parasites that live by invading cells and using the cell's own machinery to reproduce, typically killing the host cell when viral progeny are released. Although it is not known for sure, it is thought that virtually all kinds of organisms (bacteria, archaea, and eucarya) are susceptible to viral infection. In general, a particular kind of virus usually can infect only one species or a closely related species (with a few well-known exceptions). Also, for the systems that have been examined closely (humans, farm animals, bacteria like *Escherichia coli*), one species of host may have dozens or hundreds of different viruses. This suggests that viruses are probably extremely diverse, more so than all other organisms combined.

FUNCTIONAL DIVERSITY OF MICROORGANISMS

What the tree of life does not show are the crucial roles that microorganisms play in the biosphere. They play critical roles in all ecosystems and all biogeochemical cycles.

Photosynthesis and Chemosynthesis in Carbon Dioxide Fixation

The oxygen we breathe is produced by photosynthetic microorganisms and plants. Interestingly, oxygen did not

exist on Earth when it was first formed because there was no photosynthesis. Indeed, until about 2.0–2.5 Ga ago, there was no oxygen in the atmosphere at all. As mentioned previously, many of the bacteria contain photosynthetic members. However, the first photosynthetic bacteria, which appear to have been members of the proteobacteria, did not produce oxygen in photosynthesis (Xiong *et al.*, 2000). Instead, they used reduced sulfur compounds such as hydrogen sulfide (H_2S) as the reductant in photosynthesis. Thus, carbon dioxide was reduced to organic carbon and H_2S was oxidized to sulfur and sulfate. However, one group of photosynthetic bacteria, the cyanobacteria, evolved to use water in place of H_2S and when this happened, oxygen was generated. The ubiquitous presence of water (especially as compared to H_2S) made this an incredibly valuable physiological trait, and the cyanobacteria became enormously successful. As that process evolved, oxygen began to oxidize reduced chemicals and eventually began to accumulate in the atmosphere. Because oxygen is essential for macroscopic life forms, its production provided conditions for the evolution of the Plant and Animal kingdoms. Moreover, the oxygen in the atmosphere enabled the development of a stratospheric ozone layer through photochemical reactions with oxygen. The ozone layer absorbs ultraviolet light, which, as a mutagenic agent, prevented the evolution of life on land. This example illustrates how important microbial life forms have been in setting the stage for the evolution and maintenance of plant and animal life. It also illustrates the power of microorganisms in affecting global change.

It is also noteworthy that some bacteria can gain energy for growth from the oxidation of reduced chemicals such as hydrogen gas (one example is the methanogens mentioned earlier), sulfur, ammonia and iron. Some of these organisms are able to carry out the fixation of carbon dioxide, just like plants, but in the absence of light. This process is referred to as *chemosynthesis*. Only certain members of the bacteria and archaea are able to do this, none of the eucarya. This, then is another example of how microbial life is capable of carrying out important, unique and remarkable biogeochemical processes that affect the carbon cycle, the sulfur cycle, the nitrogen cycle and the iron cycle.

Another Biogeochemical Cycle: Nitrogen

The nitrogen cycle also illustrates many unique roles of bacteria. The original atmosphere on Earth is thought to have contained reduced forms of nitrogen including nitrogen gas, N_2, which is quite inert chemically, and ammonia. The current nitrogen cycle consists of other inorganic forms including nitrite, nitrate as well as organic nitrogen produced by organisms. The most remarkable process in the nitrogen cycle is *nitrogen fixation*, the reduction of N_2 in the atmosphere by certain members of the archaea and the bacteria to form the amino group of nitrogen in their cells. Many of the bacteria which carry out this process live as free individuals or colonies in soil and water, but some grow symbiotically with plants such as peas, beans and other legumes as well as alder trees. Thus, the enzymes for nitrogen fixation, including the unique enzyme nitrogenase, are produced only by members of the bacteria and archaea (*see* Nitrogen Fixers, Volume 2).

Two other activities in the nitrogen cycle are carried out exclusively by bacteria. One is *nitrification*, the two-step oxidation of ammonia to nitrite (NO_2^{-1}) and nitrite to nitrate (NO_3^{-1}) by chemosynthetic bacteria. Ammonia, nitrite, and nitrate are fixed forms of nitrogen that can be used as nutrients for plants. The other bacterial process is *denitrification*, which as the name suggests, is simply the reverse of nitrification. Thus, nitrate or nitrite is used as an electron acceptor and reduced to produce, in some bacteria, ammonia and in others nitrogen gases including N_2O and N_2. This latter process is important agriculturally because it removes an essential fixed and therefore utilizable form of nitrogen for plants from soils and aquatic environments. If it were not for microbial nitrogen fixation, the loss of fixed nitrogen by denitrification would cause the biomass of life on Earth (dependent on nitrogen for protein) to dwindle without replacement. Therefore, it is widely thought that on pre-industrial Earth, nitrogen fixation generally balanced the loss of nitrogen by N_2 producing denitrification, on geological time scales. Man has altered this balance by artificially fixing large quantities of nitrogen for the production of fertilizer, among other potential perturbations. It should also be noted that N_2O is one of the potent greenhouse gases of major concern, and microbial processes are responsible for much of its production as well as removal.

These examples provide some sense of the types of processes that are carried out exclusively by microbial life forms, in particular by members of the bacteria and archaea domains. Many other examples exist and many processes are yet only poorly understood. *See also* Nitrogen Cycle, Volume 2.

SYMBIOTIC MICROORGANISMS AND VIRUSES

Many of us may be unaware of the importance of microorganisms to our personal wellbeing. Indeed, we carry billions of microorganisms, particularly bacteria, around with us every day. What is true for us is true for virtually all other animals: microorganisms live in our intestinal tract where they help us degrade the foods that we eat. In so doing, they help provide us with the amino acids and vitamins that are essential in our nutrition. Woe to the

person that is on extended antibiotic therapy, who has lost this essential group of microorganisms. It can be life threatening unless action is taken to replace the microbiota quickly.

Our skin and all of the orifices to our body are other places where microorganisms live. For the most part, they are benevolent organisms that live as *commensals*, neither harming nor necessarily helping us in our own lives. In most instances, they serve us well by preventing the colonization of other microorganisms that could be harmful.

What is true for animals is also true for plants. Microorganisms that grow profusely in the rhizosphere in association with plant roots are responsible for helping plants obtain nutrients for growth. Some, such as the nitrogen-fixing bacteria are confined to specialized tissues in the plants. Others have a less obligate type of symbiosis, but nonetheless still serve vital roles.

It has only been in recent years that it was recognized that viruses might play important roles in natural ecosystems. They are extremely abundant in nature, typically 10 times the numbers of bacteria, and they have relatively rapid turnover rates. In marine systems where they are best studied in this regard (see review by Fuhrman, 1999), it is thought that most viruses infect bacteria and are responsible for about 10–40% of the total bacterial mortality. However, they also infect algae and are thought to sometimes cause the crash of algal blooms. Because of their specificity, viruses may also be important agents in fostering biodiversity. This is because viral infection rates depend on the density of the host organisms. Therefore, when an organism becomes abundant due to superior competition, it also becomes susceptible to a viral epidemic.

MICROBES AND GLOBAL ENVIRONMENTAL CHANGE

Despite the diminutive size of individual microbial cells, the high abundance of microorganisms in virtually all habitats ensures that they contribute significantly to global biomass. It has been estimated recently that the carbon biomass of prokaryotic microbes is 60–100% of that thought to occur in plants worldwide, and microbial nitrogen and phosphorus biomass exceeds that of all other organisms (Whitman *et al.*, 1998). Because microbes are known to have potentially high metabolic and growth rates (in line with the general observation that physiological rates per unit mass tend to increase with decreasing size), it follows that microbial participation in global carbon, nitrogen, and phosphorus cycles is quite large. This includes a major component of global photosynthesis and respiration rates.

A big unanswered question is how microorganisms might respond to global environmental change. Because of their major roles in biogeochemical cycles, changes in the functioning of microbes can have global consequences. Will they buffer some of the changes (by negative feedback) or accentuate them? These are difficult questions to answer, especially given the great diversity of microorganisms and their geochemical functions. A simplistic view might examine a process such as microbial respiration (oxidation of organic carbon), which typically increases with increasing temperature. In a global warming scenario, one might imagine a transient burst of increased microbial respiration, especially in polar climates where permafrost can melt and suddenly make organic matter available for microbial consumption. This would cause a transient increase in CO_2, lasting until frozen substrates get depleted. However, it is only to the extent that respiration uses old organic matter that it would cause a net increase in CO_2, because respiration of newly fixed carbon does not lead to a net release of CO_2.

The ultimate effects of global change on microbial activities, and *vice versa*, often relate to the complex interplay between physical, chemical, and biological factors. For example, in the sea, increased temperatures could cause changes in circulation patterns and an increase in aquatic stratification that might lead to a decrease in aquatic production due to the reduced availability of nitrogen and phosphorus nutrients. This could lead to the rain of particulate organic matter from surface waters to the deep sea, the so-called biological pump of carbon. Thus, less carbon might be removed from the atmosphere by this mechanism, and this can be a positive feedback with regard to global warming. However, would increased winds or storms cause deeper mixing and reduction of the stratification? This could have the opposite effect.

Microorganisms carry out especially important roles in the biogeochemical cycling of two other greenhouse gases besides CO_2, namely methane and nitrous oxide. The biological production of these substances is microbial, with the methanogenic archaea producing methane and the denitrifying bacteria producing nitrous oxide. Both gases also have significant non-biological or anthropogenic sources as well. Interestingly, the biological removal of both of these gases is also microbiological. Methane is oxidized by specialized bacteria (called *methanotrophs*), organisms that live where they have a supply of methane (most often from an anoxic zone) and oxygen. Some methanotrophs live as symbionts in invertebrates near natural methane sources, such as methane seeps. Nitrous oxide can be reduced by denitrifying bacteria to N_2 gas under anoxic conditions. Although it is known that both methane and nitrous oxide are increasing in the atmosphere, there is still considerable uncertainty in the accounting of supply and removal processes and uncertainty about how much of the change

is due to biological processes. Therefore, it is difficult to make mechanistic predictions about how microorganisms might lead to or respond to future changes in these gases.

Another microbial process of note in this regard is the formation and removal of dimethyl sulfide (DMS) (*see* Dimethylsul de (DMS), Volume 1). This gas is an important regulator of climate because it leads to the production of sulfate aerosols that form nuclei necessary for cloud formation over much of the planet. Clouds affect re ection of sunlight into space and also the distribution of precipitation. DMS is formed from dimethylsulfonyl proprionate (DMSP), which is an osmotic regulator in certain groups of microscopic marine algae. DMSP is converted to DMS biologically by a variety of organisms (microbes and small herbivores). Its production and release to the atmosphere is controlled by the combined activities of these microbes and animals, as well as physical mixing and gas exchange (Kiene and Bates, 1990). We know very little about the details of what controls the biological component of this production. Therefore, it is extremely difficult to predict how global change will affect this important gas.

Ocean Iron Fertilization

The primary production of much of the open ocean is thought to be limited by the availability of iron. The connection is that iron is needed for the enzymes that are used to reduce nitrate (a common marine nitrogen source) and also for bacteria that fix N_2 gas. Iron arrives on airborne dust from remote arid regions, and a change in world climate and wind patterns can change how iron in dust is distributed, and therefore affect marine productivity (Falkowski *et al.*, 1998; Falkowski *et al.*, 2000).

Because iron limits primary productivity in some marine environments, proposals have been made to deliberately fertilize large tracts of the ocean with iron, in an attempt to stimulate production and draw CO_2 from the atmosphere. This approach would result in the human engineering of a planetary geochemical cycle, via microbes, on a massive scale. A few pilot research projects have shown that one can indeed stimulate productivity with iron additions (Boyd *et al.*, 2000). However, the long-term removal of CO_2 from the atmosphere is not a clear result from these projects, and there are major concerns that large-scale fertilization may cause greater warming or other problems in the long run from unplanned geochemical consequences of fertilization (Fuhrman and Capone, 1991). For example, because the idea is to permit the use of available nitrogen and therefore drive the nitrogen cycle faster, there are concerns that microbial nitrification and denitrification associated with the fertilization may cause the release of enough N_2O to cause greenhouse warming by itself. Similarly, the deep sea microbial respiration stimulated by iron fertilization may make extensive tracts of the deep sea anaerobic, killing most sea life in the area and altering geochemical cycles unpredictably. Effects on methane and DMS are also hard to predict. Therefore, the scientific basis of iron fertilization as a partial solution to global warming is lacking. Indeed, such fertilization might make matters much worse (*see also* Iron Cycle, Volume 2).

Monsi, Masami

(1914- 1997)

Masami Monsi, Japanese plant ecologist and environmental scientist, Professor of the University of Tokyo 1954–1975, started his career with studies on the regulation of stomatal opening and plant transpiration, but his most important and well known contribution to plant ecology is the functional analysis of canopy structure (Monsi and Saeki, 1953). Monsi developed his idea from P. Boysen Jensen's classical work *Die Stoffproduktion der P anzen* (1932). He paid particular attention to the light climate as a factor to determine the structure and function of plant canopies. He considered dry matter production to be the most important function of plant canopies and invented the stratified clipping method to determine the productive structure of a plant stand, which describes the vertical distribution of light climate, biomass and leaf area through the canopy. He first formulated the relationship between light climate (I) and cumulative leaf area index (F) as $I = I_0 e^{-kF}$, on which he built a mathematical model of canopy photosynthesis. The model predicted the optimal canopy architecture (leaf area index, leaf size and angle, and leaf distribution) to maximize canopy photosynthesis, which was later successfully applied to breed rice varieties to increase agricultural production. He further applied his theory for the analysis of plant succession after gap formation, with which he pioneered model simulation of vegetation dynamics (Monsi and Oshima, 1955). In 1960 he presented a comprehensive scheme to model growth and reproduction of plants with different life histories, based on photosynthesis in leaves and matter allocation to other organs (Monsi, 1960). From 1964 he was involved in organizing international programs such as the International Biological Program (IBP, International Council for Science (ICSU)) and Man and the Biosphere (MAB, United Nations Educational, Scientific and Cultural Organization (UNESCO)). He led the Research Group of Production Processes of IBP where his theory and model on dry matter production and plant growth were further developed and accepted internationally (Monsi, 1968; Monsi and Murata, 1971).

Mooney, Harold A

(1932-)

Harold A Mooney holds the Paul S Achilles Professorship in Environmental Biology at Stanford University. Born in 1932 in California, he received his PhD from Duke University in 1960. Mooney has made major contributions to plant and ecosystem ecology and environmental biology. A renowned international expert, he has been invited to advise governments on a variety of ecological issues such as the effects of global change on the terrestrial biosphere.

His research on the carbon balance of plants has provided a major theoretical framework for ecophysiological studies, and has been instrumental in the incorporation of physiological understanding to studies of ecosystem processes. This work has also led to several lines of research on the nature of interactions of plants with their biotic environment, and has provided an objective measure for evaluating many of the current theories of plant–animal interaction. He has demonstrated that convergent evolution takes place

in the properties of different ecosystems that are subject to comparable climates, and has pioneered in the study of the allocation of resources in plants. He has worked in many of Earth's diverse ecosystems, including the arctic alpine, the Mediterranean climate scrub and grasslands, tropical wet and dry forests, and the deserts of the world.

Mooney has been engaged for over a decade in the study of the impacts of global change on terrestrial ecosystems, with an emphasis in understanding processes that control uxes and their quantities in a changing environment. A second major emphasis has been on understanding the role of biotic assemblages and how they are affected by multiple stressors, and examining the factors that promote the invasions of non-indigenous plant species.

Mooney has been instrumental in developing the new global ecology as we know it today by being involved in the organization of international activities through which he has brought together scientists from many diverse disciplines to address topics that promise to contribute substantially to the advancement and integration of ecology. Mooney was deeply involved in the International Biosphere Programme (IBP), and he was instrumental in the development of the International Geosphere Biosphere Programme (IGBP) in the early 1990s, specifically with its core project Global Change and Terrestrial Ecosystems (GCTE) in which he served as a scientific adviser for many years. Most recently, Mooney was instrumental in the development of the new international program, the Global Invasive Strategies Program (GISP). He is also a force behind the International Biodiversity Observation Year (IBOY) to take place in 2001–2002. Currently he is serving as a panel co-chair for the Millennium Ecosystem Assessment, a program devoted to strengthening our capacity to manage ecosystems sustainably for human wellbeing. He is also Secretary General of the International Council of Scientific Unions (ICSU), now called International Council for Science, and was earlier Secretary General of SCOPE. Through these efforts and his lengthy publication record of over 400 scientific books, papers, and articles, he has developed bridges between physiological ecology and other areas of ecology, and he has explored the contributions that ecologists can make to resolving the growing problems of global habitability.

Mooney has served on many editorial boards for ecological journals, and on advisory committees of many funding agencies, universities, and national and international agencies. He served as President of the Ecological Society of America 1988–1989, President of the American Institute of Biological Sciences in 1993, Secretary General of Scientific Committee on Problems of the Environment, 1987–1988, and is currently Secretary General of the International Council for Science. He is an editor of *Flora*, *Trends in Ecology and Evolution*, *Tree Physiology*, *Environment and Pollution*, *Global Change Biology*, *Global Environmental Research*, *Ecosystems*, *Journal of Mediterranean Ecology*, and *Biological Invasions*, as well as series editor of *Physiological Ecology* (Academic Press), and *Ecological Studies* (Springer-Verlag).

Among his many honors, he was elected to the National Academy of Sciences, the American Academy of Arts and Sciences, and the American Philosophical Society. He has received the Eminent Ecologist Award and the Mercer Award of the Ecological Society of America, a Humboldt Senior Distinguished US Scientist Award, the Max Planck Research Award, the Ecology Institute Prize for Terrestrial Ecology and the Nevada Medal. He is a Fellow of the American Association for the Advancement of Science and a foreign member of the Russian Academy of Sciences. He worked in Chile and France as a National Science Foundation Senior Postdoctoral Fellow and in Australia and Africa as a Guggenheim Fellow.

Mooney is a person of exceptional modesty, enthusiasm, and never ending energy. Combined with his skills as an outstanding speaker and sincere commitment to science, he has inspired hundreds of scientists in the US and worldwide, and in uenced policy agencies and governments to shape a more environmentally sound and sustainable world.

Natural Capital

Natural capital is what nature provides: air to breathe, water to drink, food to eat, fiber, living space, waste disposal and other things. Traditionally, the word *capital* is thought of as a stock of materials such as tools, machinery or buildings that generate a flow of services more commonly known as profits. The tools, machinery or buildings are known as the manufactured capital. But there are other types of capital such as human capital, and natural capital. The essential feature of all forms of capital is that capital provides a capacity for excess production, that is, a capacity for growth. It is this feature that links the traditional forms of capital with human capital, cultural capital and natural capital.

Natural capital refers to that stock of materials provided to us by nature free of charge: ecosystems, soils, trees, air and water. The goods and ecosystem services provided by natural capital are vast in scale, and fundamental to human survival on the planet. As an example, consider the naturally fixed nitrogen in the soil and the ecosystem service of providing this critical component for plant growth. The cost of replacing the natural capital with artificial fertilizers is prohibitive. As yet, these ecosystem services are not fully captured in commercial markets or adequately quantified, so as they are often given too little weight in policy decisions involving natural resources and the environment. By attempting to price services such as water purification, pest control or climate amelioration, we can make quantitative estimates of what is lost when we degrade the free services that nature provides. Tailored to specific regions or watersheds, such information greatly improves our ability to take explicit account of the tradeoffs we make in the course of decisions about land use and development.

Economists have been trying for many years to put an economic value on natural capital. Costanza *et al.* (1997) estimated that the total value of all the Earth's ecosystem services stemming from natural capital totaled $33 trillion per year, a figure that exceeds the sum of the world's gross national products. Others have called the $33 trillion per year a serious underestimate of infinity, as without the services from natural capital, humans would not exist.

An alternative approach to valuing the ecosystem goods and services is to bring an ecosystem's natural capital to the market by some mechanism. One method is to evaluate the local ecosystems capacity for growth and to issue tradable permits for economic development appropriate to that growth potential. The marketplace will then value the reduction of the particular ecosystem's goods and services by the changing price of the tradable permits.

Niche

Each species in a community is a specific part of that community, and it occupies a specific place, or *niche*, in the structure of that community. The niche is far more than simply the physical or spatial location of each species in the ecosystem; in addition it expresses the concept of the functional role that each species has in the totality of the community. A species has a *fundamental niche*, which is the total environmental range that it is adapted to occupy, and a *realized niche*, which is that reduced portion of its fundamental niche that it is forced into by competition.

The niche occupied by some species may be very broad, encompassing a variety of habitats and food sources. Species occupying such broad niches are usually strongly dominant in the ecosystem. Other species may occupy a narrow or highly specialized niche. In either case the evolution of successful adaptations enables the species to compete successfully for the occupation of the niche. A niche is never occupied by more than one species, although some overlapping of ecologically adjacent niches may occur. As is the case for the diversity of species, the diversity of niches in an ecosystem is directly correlated with its stability and its ability to withstand environmental or climatic insult. A large number of narrow niches fosters community sharing rather than competition for its resources, which increases the efficiency of resource use. Agriculture, by introducing a small number of strongly dominant species occupying broad niches, greatly reduces the stability of an ecosystem, decreases its environmental tolerance, and ultimately leads to its deterioration. It may be of interest to note that the human species has evolved to occupy a broader niche with a greater degree of dominance than has ever occurred previously in the world ecosystem.

Nitrogen Cycle

Robert W Howarth
Environmental Defense, Boston, MA, USA

Nitrogen (N_2) is an element essential for all life and is the fourth most abundant element in living biomass, after hydrogen, carbon, and oxygen. Nitrogen is of central importance to the biogeochemistry of the earth, since compared to the needs of plants, it is frequently the most scarce of the essential elements. Thus, primary production is limited by nitrogen in most temperate and arctic terrestrial ecosystems and in most estuaries and coastal oceans (Vitousek and Howarth, 1991). Nitrogen, together with phosphorus, also co-limit primary production in many of the open ocean areas of the planet (National Research Council, 2000). Further, nitrogen availability is a key factor regulating the rate of decomposition of organic matter, so the nitrogen cycle is intimately tied to the sequestration of carbon dioxide (CO_2) in both the oceans and terrestrial ecosystems. Indeed, changes in the nitrogen cycle over the past decades may be responsible for increasing the storage of carbon in the world's forests to a globally significant extent. Nitrogen is therefore a major regulator of the CO_2 concentration in the atmosphere and of the rate of global warming (Vitousek et al.*, 1997).*

Of the major elements of biogeochemical importance, nitrogen is undergoing the most rapid change globally. Most nitrogen on Earth is present as gaseous, elemental N_2 that is largely unavailable to plants. A century or more ago, the only major mechanism whereby this molecular N_2 became available to most organisms was by bacterial nitrogen fixation, the conversion of element nitrogen into more reactive and biologically available forms However, several types of human activity also convert N_2 to more reactive and biologically available forms. Over the past few decades, these processes under human control have increased to the point that they have roughly doubled the biological availability of nitrogen on the land surfaces of the planet. That is, since the 1960s human activity has changed the nitrogen cycle from one that was primarily controlled by biological processes to one that is now dominated by human-generated pollution. Although nitrogen is essential to life, too much nitrogen is deleterious to life, just as consumption of too much food by humans leads to obesity.

The acceleration of the nitrogen cycle is leading to a large variety of very serious environmental consequences (Vitousek et al.*, 1997). Nitrogen pollution is now the major source of acid rain in developed countries, and perhaps globally. Nitrogen pollution in the atmosphere also contributes markedly to smog and ozone formation in the lower atmosphere, to the depletion of ozone in the ozone layer of the stratosphere, and to the formation of fine particles that diminish visibility and pose a serious public health hazard. One gaseous form of nitrogen pollution in the atmosphere contributes to greenhouse warming. Nitrogen is now the largest pollution problem in the coastal oceans of the US and perhaps worldwide, causing dead zones devoid of oxygen, increased blooms of toxic algae, and a loss of biodiversity. More than half of the coastal rivers and bays in the US are degraded from nitrogen pollution (National Research Council, 2000). Accelerated nitrogen cycling on land is also a major contributor to the loss of biotic diversity in terrestrial ecosystems, and in extreme cases, can lead to the dieback of forests (Vitousek* et al.*, 1997; Tartowski and Howarth, 2000).*

The vast majority of nitrogen on earth is present as elemental nitrogen (N_2), with most of this being in the atmosphere (3.9×10^{21} g) and some dissolved in the oceans. N_2 is the most abundant gas in the atmosphere and makes up 78% of its volume. Of all nitrogen on Earth, only 0.002% is present in living tissues and detrital organic matter on land and in the oceans (Schlesinger, 1997). Nonetheless, this small amount of organic nitrogen is critical to life, as its recycling supplies most of the nitrogen that supports plant growth. Elemental N_2 is quite unreactive because of the extreme strength of the chemical N−N bond. However, under appropriate conditions, N_2 can react with other elements such as oxygen, hydrogen and carbon to form a variety of compounds that are both more chemically reactive and more biologically available. The process of this conversion is called *nitrogen fixation* (*see* **Nitrogen Fixers**, Volume 2).

Prior to the disruption of the global nitrogen cycle by human activity, most nitrogen fixation on earth was biologically mediated through an enzymatic process catalyzed by bacteria that produces the reactive form ammonia (NH_3). Many different types of bacteria are capable of this process, including photosynthetic cyanobacteria and symbionts of some plants, but no higher forms of life are capable of nitrogen fixation without bacterial symbionts. Some nitrogen is also fixed naturally by lightning and by volcanic action; in this case, the element N_2 is converted to nitrate (NO_3^-), another biological form of nitrogen, as extreme heat catalyzes the reaction with atmospheric oxygen. Prior to large-scale alteration of the landscape by humans, bacterial nitrogen fixation on the land surface was probably in the range of 90–195 Tg N year^{-1} (Vitousek *et al.*, 1997; Cleveland *et al.*, 1999). An additional 200–300 Tg N year^{-1} is probably fixed by cyanobacteria in the oceans of the world, although there is much uncertainty associated with this estimate (Karl *et al.*, 2002). Thus, before humans began to alter the nitrogen cycle, nitrogen fixation by bacteria globally was probably in the range of 300–500 Tg N year^{-1}. Nitrogen fixation by lightning is much smaller, probably less than 10 Tg N year^{-1} globally. Given the tremendously large pool of elemental N_2 in the atmosphere and oceans, the conversion of N_2 to reactive forms through nitrogen fixation yields a turnover time of N_2 of approximately 10 million years.

Human activity has greatly altered the nitrogen cycle globally (Figure 1), with the single largest change resulting from the increased use of synthetic inorganic fertilizers in agriculture (Table 1). The process for making synthetic nitrogen fertilizer was invented during World War I by German chemist Fritz Haber, but the synthetic fertilizer was not used on a large scale until the 1950s. Use has increased greatly since then and is in large part responsible for the green revolution in agriculture that has reduced starvation

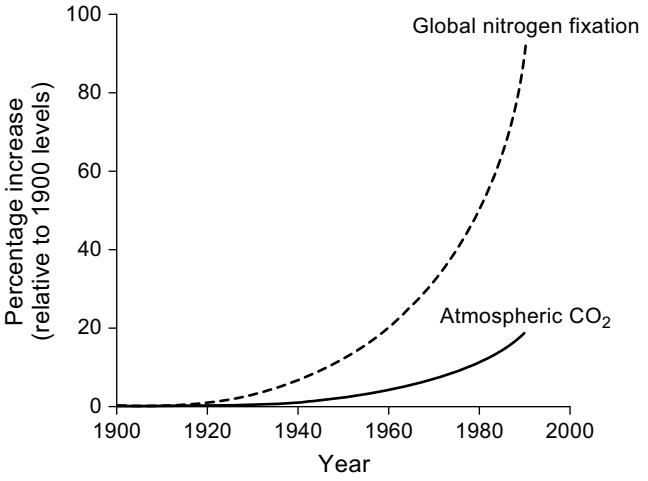

Figure 1 The relative change in the rate at which human activities have accelerated global nitrogen xation in comparison to the increase in atmospheric carbon dioxide since 1900. (Modi ed from Vitousek *et al.*, 1997)

Table 1 Best mean estimates for global rates of nitrogen xation on land (Tg N year^{-1})

	Before industrial revolution	Current
Natural terrestrial ecosystems	140	140
Lightning	5	5
Agricultural crops	0	40
Fertilizer production	0	83
Fossil fuel combustion	0	20
Total	145	288

and allowed the human population to grow so dramatically over the past few decades (Smil, 1997; *see* **Green Revolution**, Volume 3). As of 1996, the global use of inorganic nitrogen fertilizer was approximately 83 Tg N year^{-1}. The rate of growth in fertilizer use is so great that half of the inorganic nitrogen fertilizer that has ever been used on Earth has been applied during the last 15 years (National Research Council, 2000).

The application of nitrogen fertilizer is not uniform over the surface of the Earth. Use grew first in the US and other developed countries, but has been relatively constant since 1980. Globally, nitrogen fertilizer use decreased somewhat for a five-year period beginning in the later 1980s (Figure 2). This was a result of the collapse of the former Soviet Union, which led to widespread disruption of economic activity, including agriculture, in Russia and elsewhere in eastern Europe. The increase in fertilizer use in recent years has been driven largely by use in Asia. Today, China uses almost one-third of all inorganic nitrogen fertilizer produced on the planet.

Production of nitrogen fertilizer is the largest process whereby human activity has altered the global nitrogen cycle. However, other human-controlled processes, such as growing nitrogen-fixing crops in agriculture and the combustion of fossil fuels have also resulted in increased nitrogen fixation. Many agricultural crops such as soybeans, alfalfa, peas, and peanuts have symbiotic bacteria that fix nitrogen. Globally, this probably contributes some 40 Tg N year^{-1} of reactive, biologically available nitrogen (Vitousek *et al.*, 1997). The combustion of fossil fuels contributes another 20 Tg N year^{-1} to the global cycle

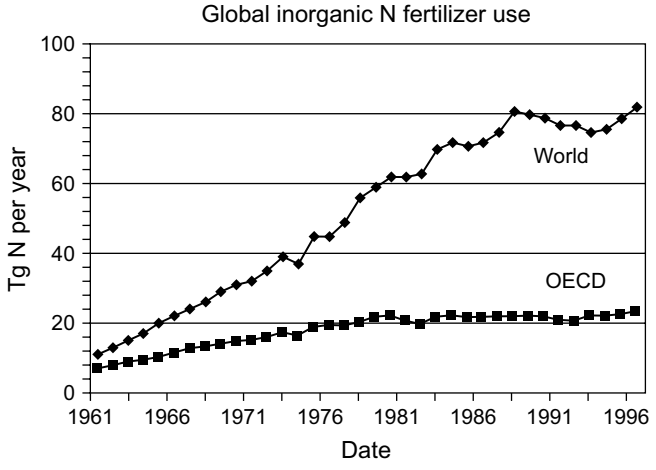

Figure 2 The global use of inorganic, synthetic nitrogen fertilizer since 1961 in the world as a whole and in the developed nations of the world (Organization for Economic Co-operation and Development - OECD), which include the US, Canada, western Europe, Japan and Korea. (Data are from the Food and Agricultural Organization [unpublished])

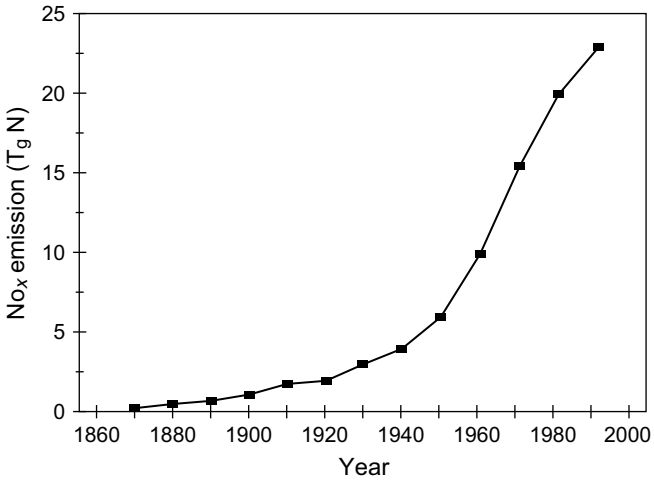

Figure 3 The global emission of NO_x to the atmosphere from human activities since 1860. (Estimates are from the World Meteorological Organization [unpublished])

of reactive nitrogen, and this too is increasing rapidly (Figure 3; Galloway *et al.*, 1995). Some of the nitrogen released from burning fossil fuels represents nitrogen contained in the fuels themselves, and some comes from the heat and pressure of combustion catalyzing the reaction between O_2 and N_2 in the atmosphere.

Collectively, the nitrogen fixation under control by humans now contributes some 140 Tg N year^{-1} world-wide. Given the estimates of natural nitrogen fixation by bacteria on the land surface of the Earth (90–195 Tg N year^{-1}, with a mean value of 140 Tg N year^{-1}), human activity has roughly doubled the availability of nitrogen to the terrestrial ecosystems of the planet. This nitrogen fixation through human activity increased by some two- to three-fold over the three decades between 1960 and 1990, and it continues to grow (Galloway *et al.*, 1995).

Although humans have altered the nitrogen cycle globally, the intensity of the alteration varies greatly among regions. This is because both combustion of fossil fuels and agricultural activity are most intense in developed countries and in Asia, and because most reactive nitrogen is not transported very far from where it is released. So far, the acceleration of the nitrogen cycle has been more pronounced in north temperate regions than in the tropics, since most industrial activity and agriculture have developed in the north temperate regions (Holland *et al.*, 1999). Further, the natural rates of biological nitrogen fixation on land are far greater in the tropics than in temperate-zone ecosystems (Cleveland *et al.*, 1999). One measure of how humans have altered the nitrogen cycle is the rate at which reactive forms of nitrogen are deposited onto the land surface from the atmosphere in rain, snow, and dry deposition (the process whereby gases and small particles leave the atmosphere). On average worldwide, nitrogen deposition

from the atmosphere has probably doubled in the tropics and increased more than six-fold in the north temperate zone because of human acceleration of nitrogen cycling (Holland *et al.*, 1999). On the other hand, human activity has had little effect on nitrogen deposition in the temperate zone of the Southern Hemisphere. The flux of nitrogen in large rivers provides another measure of how humans have altered the nitrogen cycle in particular regions. As of 1990, human activity had increased the nitrogen flux in the watershed of the North Sea in Europe by more than 10-fold, in the rivers of the northeastern US by some eight-fold, down the Mississippi River by more than four-fold, and not at all in the rivers in northern Canada (Figure 4; Howarth *et al.*, 1996). The flux of nitrogen from the watersheds of large regions is proportional to the use of nitrogen by humans in the landscape (Figure 5).

Despite the huge reservoir of elemental N_2 on Earth, the process of nitrogen fixation would eventually – over a time period of 10 million years – deplete this pool if it were not for the process of *denitrification*. Denitrification is the bacterial conversion of nitrate to elemental N_2. In this process, the bacteria use nitrate as an electron acceptor

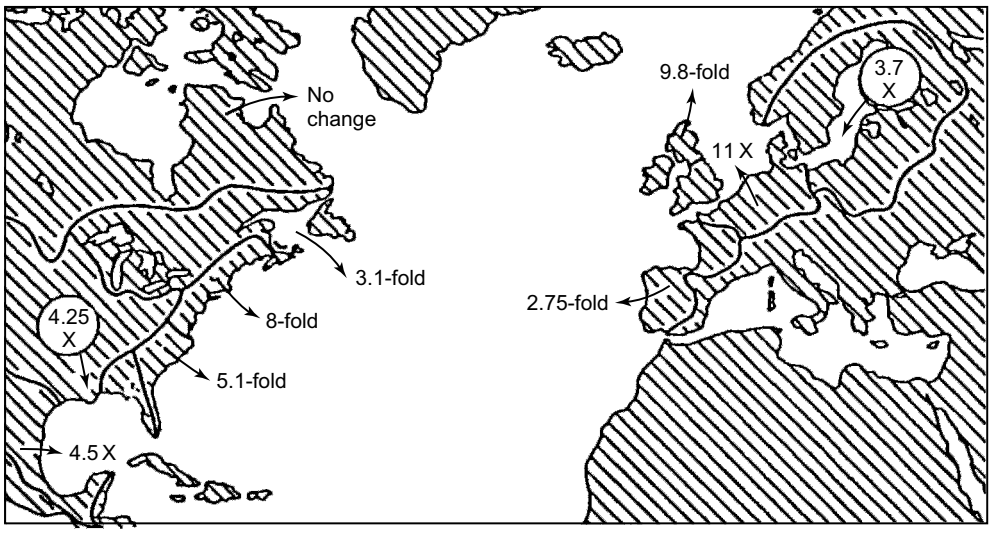

Figure 4 The extent to which human activity has altered the ux of nitrogen from the landscape to coastal waters. (Reprinted from Howarth *et al.*, 2000)

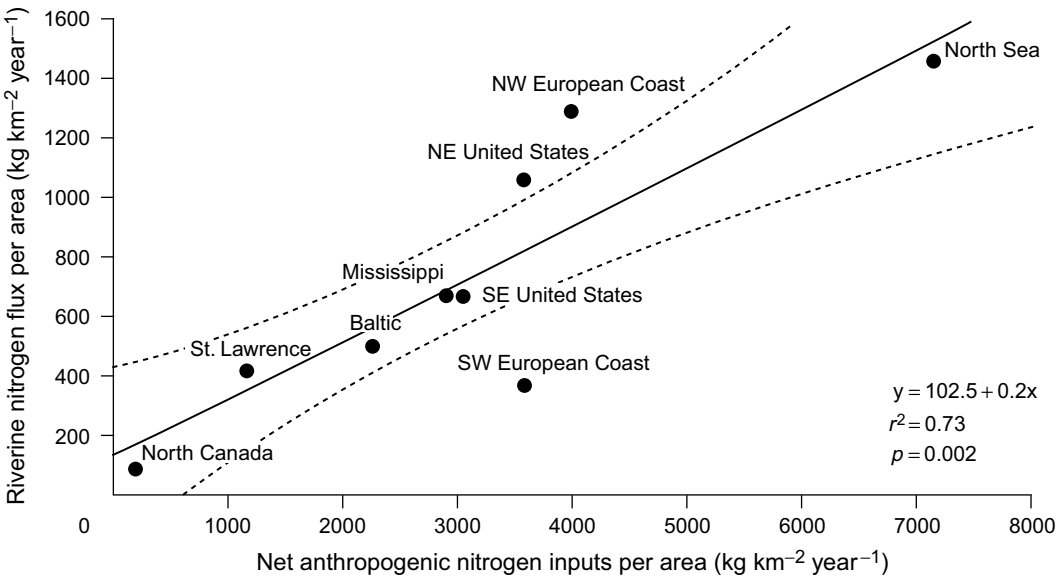

Figure 5 The export of nitrogen per area of watershed for different large regions surrounding the North Atlantic Ocean as a function of the inputs of nitrogen to those regions from various human activities. (Reprinted from Howarth *et al.*, 1996)

to support their respiration. Since this yields less energy to the bacteria than if they used O_2 as the electron acceptor, denitrification tends to occur only in environments where O_2 is absent, or where concentrations are low, such as in the sediments of wetlands, lakes, rivers, and coastal oceans. As human activity has increased the flux of reactive nitrogen through the landscape, rates of denitrification have increased in direct proportion (Nixon *et al.*, 1996; Howarth *et al.*, 1996).

Even to understand the nitrogen cycle in its simplest terms, we need to consider a few other processes (Figure 6). Plants and algae assimilate most of the nitrogen they need for growth as NH_3 or as nitrate. They convert this to the organic nitrogen that comprises their tissues. As this material is eaten by animals or decomposed by microorganisms, most of the organic nitrogen is recycled to the environment as ammonia. In the presence of O_2, certain types of bacteria

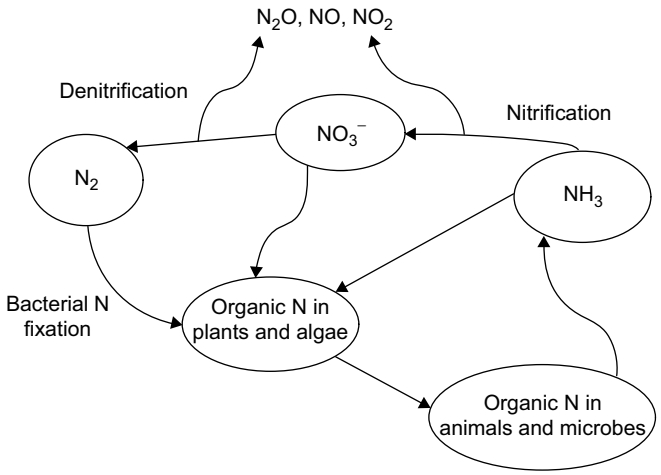

Figure 6 A simpli ed representation of the natural nitrogen cycle. Note that the atmospheric gases N_2O, NO, and NO_2 come from leakages from both the processes of nitri cation and denitri cation. A human acceleration of the nitrogen cycle increases these processes, resulting in greater uxes of these pollutant gases to the atmosphere

can oxidize the NH_3 to nitrate, and thereby gain energy to support their growth, in a process called *nitrification*. In many sediments, zones that are oxygen-free coexist in close proximity to zones that have oxygen, allowing NH_3 to be oxidized to nitrate and denitrified to N_2 in coupled processes in close proximity.

As nitrogen is converted by bacteria in the processes of nitrification and denitrification, some leaks to the environment as nitrous oxide (N_2O), and most of this probably diffuses to the atmosphere. Globally, the current flux of N_2O to the atmosphere is approximately 16 Tg N year^{-1} (Table 2; Schlesinger, 1997). The mean residence time of this gas in the atmosphere is relatively long, 120 years. This is of global significance, as N_2O is a major contributor to the destruction of ozone in the ozone layer of the stratosphere and is a potent greenhouse gas, some 300-fold more so than is CO_2 per molecule (Schlesinger, 1997). The mean concentration of N_2O in the atmosphere as of the 1990s was approximately 310 ppb, or some 1000-fold less than the concentration of CO_2. Currently, the concentration of N_2O in the atmosphere is increasing at a rate of 0.3% per year. Data from ice cores show that the concentration was lower and stable for the thousand or so years before the start of the Industrial Revolution, at approximately 280 ppb (Schlesinger, 1997). The increase is largely the result of the general human acceleration of the nitrogen cycle, which is increasing the processes of denitrification and nitrification in many different ecosystems globally, although some of the nitrous oxide comes directly as a byproduct of industrial activity, such as the synthesis of nylon (Vitousek *et al.*, 1997). Although many different types of ecosystems contribute to the flux of N_2O to the atmosphere, the fluxes are particularly high from coastal oceans and from tropical soils. The fluxes from tropical soils increase markedly in areas where forests are converted to agricultural lands and are fertilized (Schlesinger, 1997).

In addition to N_2O, the other major forms of reactive nitrogen gases in the atmosphere are nitric oxide (NO), nitrogen dioxide (NO_2), and NH_3. NO and NO_2 are

Table 2 Nitrogen gases in the atmosphere: uxes to the atmosphere under current and pristine conditions, and concentrations and residence times in the atmosphere[a]

	Flux before Industrial Revolution (Tg N year^{-1})	Current ux (Tg N year^{-1})	Concentration (ppb)	Residence time (years)
N_2[b]	−140	−283	780×10^6	10×10^6
N_2O	10	16	310	120
NO_x	12	36	<10	0.003
NH_3	15	46	<10	0.003

ppb, parts per billion.
[a] For nitrogen xation, the ux is from the atmosphere to the land surface, and so is indicated here as a negative ux.
[b] Considering only uptake by nitrogen xation on the land surface.

collectively referred to as NO_x. In contrast to N_2O, the concentrations for NO_x in the atmosphere are small, only 0.02–10 ppb, and the residence times are short, approximately one day (Schlesinger, 1997). NO_x gases are typical of polluted air, and they are instrumental in catalyzing the production of ozone pollution and smog in the troposphere. NO_x is oxidized to nitric acid in the atmosphere, and this nitric acid is a major contributor to acid rain. The other major contributor, sulfuric acid, has been more effectively controlled in developed countries over the past two decades, so that NO_x is increasingly becoming the dominant contributor to acid rain in the US and western Europe. The best current estimate is that the global flux of NO_x to the atmosphere is 36 Tg N year^{-1}, although there is considerable uncertainty associated with this estimate (Holland *et al.*, 1999). Most of this (20 Tg N year^{-1}) comes from the combustion of fossil fuels, with electric-power generating plants, cars, trucks, buses, and off-road vehicles all contributing. Other sources are lightning, biomass burning, and leakage from the microbial processes of nitrification and denitrification. Human activity has probably increased the total flux of NO_x to the atmosphere by some three-fold, with the largest increases being in the eastern US, in Europe, and increasingly, in east Asia (Holland *et al.*, 1999). The change has been recent, and rapid (Figure 3).

Human activity has also increased the flux of NH_3 to the atmosphere by three-fold or more globally (Table 2), although the emissions prior to human acceleration of the nitrogen cycle are poorly known. Currently, the flux is estimated as 45 Tg N year^{-1} or more (Holland *et al.*, 1999). As with NO_x, concentrations in the atmosphere are low, and the residence time is short. NH_3 is a base, and so unlike NO_x, it does not directly contribute to acid rain. However, if the NH_3 that is deposited onto the land or into a lake is nitrified to nitrate, 2 moles of protons are released for every mole of nitrogen oxidized. Thus, per atom of nitrogen, NH_3 actually has twice the capacity to contribute to lake and soil acidification as does nitric acid. NH_3 is also a major contributor to the creation of fine aerosol particles in the atmosphere, which reduce visibility and pose a public health threat to humans.

The flux of NH_3 from domestic animal wastes is the single largest source to the atmosphere, contributing roughly half of the global total. Other major sources are volatilization from inorganic nitrogen fertilizers, biomass burning, and the natural flux from upwelling zones of the ocean (Holland *et al.*, 1999). The past few decades have seen a remarkable increase in the production of domestic animal wastes, as the world population has grown and the *per capita* consumption of meat has increased (Figure 7; National Research Council, 2000). In developed countries, most crop production is fed to animals, and so large quantities of the inorganic nitrogen fertilizer applied to fields are processed through animal wastes. In North America, 15% of

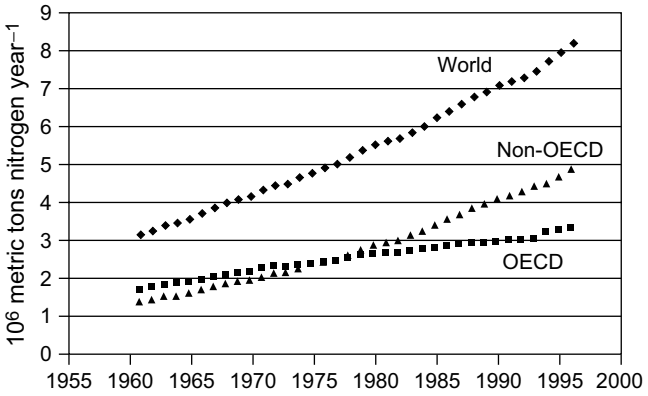

Figure 7 The increase in meat protein (expressed in terms of the nitrogen content of the meat) since 1961 globally, in the developed countries of the world (OECD), and in the developing countries (non-OECD). (Data are from the Food and Agricultural Organization [unpublished])

the inorganic nitrogen fertilizer that is used eventually ends up volatilized to the atmosphere as NH_3 (National Research Council, 2000). Globally, the figure is perhaps twice this high, due in part to the use of particularly volatile fertilizers in China (Holland *et al.*, 1999; National Research Council, 2000). The huge flux of NH_3 to the atmosphere is a very recent phenomenon, a direct result of the green revolution.

Nitrogen Deposition on Forests

Peter Högberg

Department of Forest Ecology, Umea, Sweden

Industrial fixation of nitrogen (N) in the production of fertilizer for agriculture and fixation of nitrogen in combustion processes in energy production, industry and transport now exceed natural biological N_2 fixation. Hence, the input of nitrogen to the Earth's ecosystem has doubled in a century. Simultaneously, nitrogen has turned from being a growth-limiting nutrient to a problematic pollutant. Problems of excess nitrogen are found in northern temperate forests close to major agricultural and industrial areas, in particular in central Europe and northeastern North America. At low levels, nitrogen deposition increases tree growth in initially nitrogen-limited forests. However, more sensitive plant species and other organisms can become negatively affected already at low levels of nitrogen deposition. Ultimately, high continuous supply of nitrogen leads to soil acidification, pollution of ground and surface waters by nitrate and inorganic aluminum (Al), changes in species composition, and can contribute to forest decline. Some of these adverse effects reverse rapidly if the nitrogen load is removed, while others will have a more lasting impact. It is difficult to reduce nitrogen emissions because of the tight coupling between the large nitrogen inputs to agriculture and the demand for food by a growing population, and also because of the increasing use of cars worldwide. It can be predicted that the problem of nitrogen deposition will increase for these reasons in the developing world, especially in East and Southeast Asia. This will be particularly serious in the tropics and sub-tropics, where natural ecosystems are often phosphorus (P) limited, and where available nitrogen is thus already present in excess of ecosystem demand.

INPUTS OF NITROGEN TO THE ECOSYSTEMS HAVE DOUBLED IN 100 YEARS!

Nitrogen (N) is the nutrient needed in largest quantities by plants, and the rate of nitrogen supply frequently limits plant production, especially in temperate ecosystems and in agriculture worldwide. Unlike other major nutrients, nitrogen is rarely released by weathering of minerals at rates needed to match plant demand (but see Dahlgren, 1994). The larger portion of the nitrogen in the biosphere was originally bound by N_2-fixing prokaryotic organisms, but some atmospheric N_2 has also been fixed in connection with lightning. The last hundred years the Haber–Bosch process (industrial N_2 fixation), which is used in the production of fertilizers for agriculture, in particular, increased use of N_2-fixing legumes in agriculture, and fixation of N_2 into oxidized forms, NO_x, in industrial combustion processes and in combustion engines in transport vehicles, have together doubled the input of nitrogen to the ecosystems of the Earth (Galloway *et al.*, 1995; Vitousek *et al.*, 1997). The rate of global natural N_2 fixation is estimated at $90–130\ \mathrm{Tg\ N\ year^{-1}}$, which compares with anthropogenic contributions from energy production, fertilizer production and cultivation of N_2-fixing crops, of 20, 80 and $40\ \mathrm{Tg\ N\ year^{-1}}$, respectively (Galloway *et al.*, 1995). In and close to densely populated areas of North America, Central and Northern Europe, and East Asia, nitrogen is added to ecosystems in excess of plant demand, and turns from being a good thing in great demand to a problematic pollutant. This article focuses on this new role of nitrogen in forest ecosystems, which has been a major concern the last 10–15 years (Nihlgård, 1985; Aber *et al.*, 1989, 1998).

Nitrogen, mainly as ammonium from agriculture or nitrate from energy production, industry and transport is a component of the acid rain affecting these forests. Sulfur (S), the other major component of acid rain, is largely

emitted from relatively few industrial and energy producing point sources burning fossil fuels, and also from transport vehicles, and it has been technically possible to greatly reduce the emissions by using oil products with lower sulfur content, catalytic processes, etc. In Europe, the emissions of sulfur went down by 50% between 1980 and 1995. To reduce the emissions of nitrogen is more problematic. Catalytic burners remove some NO_x from car exhausts, but nitrogen as ammonia (NH_3) is emitted from the activity of millions of animals, and from nitrogen-rich decaying plant residues on arable lands. Consequently, the emissions of nitrogen dioxide (NO_2) and NH_3 over Europe have decreased by not more than 10% between 1980 and 1995. Similarly, in the USA, the implementation of environmental policies has substantially reduced sulfur emissions, but has reduced nitrogen emissions only marginally (Aber *et al.*, 1998). Efforts continue to be made to reduce nitrogen emissions further, but in addition to technical problems, these efforts are also hampered by many socio-economic constraints. In the developing world, nitrogen emissions are increasing and can be expected to continue to do so because of increasing number of cars, and increased crop and animal production. It is expected that the rapid development in East and Southeast Asia will lead to large emissions of nitrogen. In fact, Galloway *et al.* (1995) predicted that by 2020, Asia will account for more than half of the global anthropogenic N_2 fixation.

NITROGEN DOSE- ECOSYSTEM RESPONSE RELATIONS

In Europe, where the nitrogen load over forests regionally is higher than elsewhere, the nitrogen load varies from a few $kg\,ha^{-1}\,year^{-1}$ in the far north, to between $50-100\,kg\,ha^{-1}\,year^{-1}$ in the worst affected parts in Central Europe, e.g., in the Netherlands (Dise and Wright, 1995). Deposition levels are lower in North America, but may reach $25\,kg\,N\,ha^{-1}\,year^{-1}$, e.g., in the densely populated areas of northeast and eastern central USA and in downwind areas in Canada (Fenn *et al.*, 1998). This compares with, and adds to, annual natural cycle rates between soils and trees, which are commonly of the order of $20-150\,kg\,N\,ha^{-1}\,year^{-1}$.

Nitrogen additions to initially nitrogen-limited forests first make the trees and other plants grow faster. Under continuous high nitrogen load, a point is ultimately reached, at which nitrogen additions do not increase tree growth any more. At this stage the biological demand for nitrogen is fulfilled and the biota is nitrogen saturated. Definitions of ecosystem nitrogen saturation vary (Skeffington and Wilson, 1988), a common being the one above. This definition is, however, not consistent with the use of the term *saturation* in chemistry, which more strictly would refer to a situation when losses of nitrogen from the ecosystem equal nitrogen inputs. Ultimately, under conditions of high nitrogen load, also this definition will become satisfied. However, long before this stage is reached, several processes and organism groups become affected. Aber *et al.* (1989, 1998) described four stages of forest ecosystem responses to increasing nitrogen supply:

1. nitrogen limiting of;
2. initial effects of chronic nitrogen deposition;
3. nitrogen saturation;
4. forest decline;

Nitrogen-Limited Forests

This is the normal condition in most temperate forests, while, e.g., many tropical lowland rain forests are phosphorus (P) limited (Vitousek, 1984). Nitrogen limitation is demonstrated in experiments, in which additions of nitrogen increase plant growth (Figure 1). As a consequence, fertilization with nitrogen is often a profitable practice in forestry. For example, in most of Sweden a single addition of $150\,kg\,N\,ha^{-1}$ increases forest production by around 30% over a period of five years (Binkley and Högberg, 1997). Typical of a nitrogen-limited ecosystem is low nitrogen concentrations of plant tissues and soils, and consequently a high carbon (C) to nitrogen (C/N) ratio of plants and soil organic matter. Nitrogen limitation typically occurs in young ecosystems (e.g., sand dunes, young volcanic soils and soils left bare after glacial recession). It also occurs in older ecosystems, where rates of nitrogen accretion (by, e.g., N_2 fixation) are low in relation to rates of nitrogen loss. This is typical for many northern temperate forests and for tropical savannas, in which considerable losses of nitrogen in wildfires are a recurrent phenomenon. Characteristic of forests in cold climates is also that the cycling rates of nitrogen and other elements are low due to the low temperatures. Nitrogen limitation controls not only plant growth, but also many organism interactions, notably interactions between trophic levels in ecosystems. In nitrogen-limited forests, leaching losses of nitrogen are minimal, and often, organic nitrogen compounds are a large component of the leachate reaching ground and surface waters. Mineralization of nitrogen (*see* **Nitrogen Mineralization**, Volume 2) results in immediate uptake by roots, often mycorrhizal roots, or uptake by microorganisms other than mycorrhizal fungi. It is, in fact, possible that organic compounds like amino acids are an important nitrogen source for plants, as they can be taken up directly without any prior mineralization, which may be especially important in cold climates (Näsholm *et al.*, 1998). Hence, concentrations of inorganic nitrogen in the soil are kept minimal, and especially nitrification is strongly limited by a low supply of ammonium and a low soil pH. Thus, there is little risk of production

Figure 1 The effect of fertilizer nitrogen addition on the growth of Norway spruce (*Picea abies*): control plots to the left, treated plots to the right (photo by P Högberg 1993). In this experiment at Strasan, Sweden (Tamm, 1991), which comprises 56 plots, tree growth was primarily limited by nitrogen. Once this limitation was removed by additions of nitrogen, there were secondary limitations imposed by the supply of phosphorus and other elements. The NPK treatment increased tree growth several-fold although it acidi ed the soil

(through nitrification) and leaching of the most mobile nitrogen species, nitrate.

Initial Effects of Chronic Nitrogen Deposition, and Dose Responses

The concentration of nitrogen in plants often increases a little, but more importantly, the biomass of foliage increases more significantly (Figure 1), when an initially nitrogen-limited forest is subjected to increased nitrogen inputs. Thus, the tree canopy will capture more light energy and will contain more of the CO_2-fixing enzyme RuBisCo, which leads to increased photosynthesis and, thereafter, increased growth. A portion of the nitrogen deposited is sequestered into wood. Despite the low concentration of nitrogen in wood, budget calculations do suggest that it can be regarded as an important sink for nitrogen at low rates of nitrogen deposition (Johnson, 1992).

With age, and especially under high continuous nitrogen supply, however, the tree canopy closes in the end. Fully closed tree stands with a sufficiently high foliar nitrogen concentration will not respond to further nitrogen additions, and are, therefore, in a biological sense, nitrogen saturated. Before this occurs, the closing canopy reduces the amount of light received by understory species, which will become light limited and display high nitrogen concentrations (Högbom and Högberg, 1991). Under the course of nitrogen loading, the trees will not show drastically elevated nitrogen concentrations to begin with because the nitrogen they take up will be diluted by growth. However, in more slow growing species, e.g., many ground mosses, like *Sphagnum* and *Racomitrium*, the increased nitrogen load has caused considerable increases in nitrogen concentrations of tissues even in open habitats (Baddeley *et al.*, 1994). *Sphagnum* is capable of assimilating nitrate to some extent, but continuous high loading leads to loss of plant nitrate reductase activity (Woodin *et al.*, 1985; Figure 2) and in the end degradation of the moss cover, and even erosion of peatlands.

Nitrogen loading not only promotes directly the growth of the potentially more fast growing plant species, but may also affect the plant species composition indirectly through complex plant–animal interactions. One of the best described examples of such interactions is the effect of nitrogen deposition on grazing by the heather beetle (*Lochmaea suturalis*) on heather (*Calluna vulgaris*) in Dutch heathlands. In the past this insect had outbreaks at return intervals of *ca.* 20 years, but since 1980, the return interval has been less than eight years (Bobbink *et al.*, 1998). Evidently, grazing by this beetle on heather correlates positively with the concentration of nitrogen in plant shoot tissue. Grazing leads to increased light interception by understory grasses like *Deschampsia flexuosa* and *Molinia caerulea*, which may thus become dominant. In boreal forest, a single addition of ammonium nitrate at 25 kg N ha^{-1} resulted in significantly increased damage

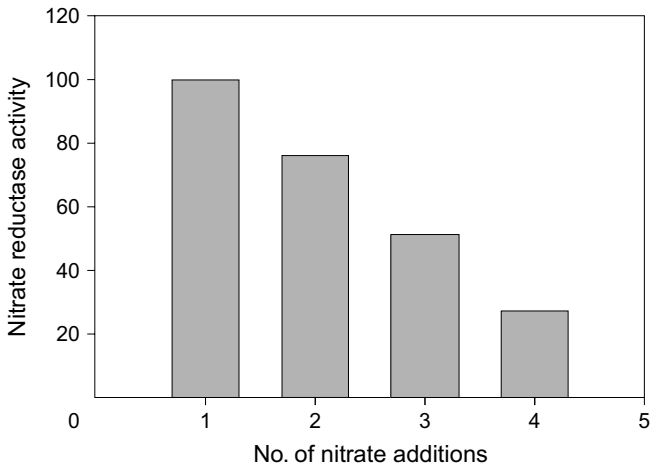

Figure 2 Effect of repeated additions of nitrate on nitrate reductase activity of the moss *Sphagnum fuscum* (calculated from data provided by Woodin *et al.*, 1985)

within two months, by two parasitic fungi and herbivory by insect larvae, on shoots of the dwarf shrub *Vaccinium myrtillus* (Nordin *et al.*, 1998). This effect of nitrogen can help to explain the increased growth of the grass *Deschampsia flexuosa*, which occurs together with *V. myrtillus* in this type of forest. Thus, deposition of nitrogen may influence the competition between plant species both directly, by increasing the growth of the more nitrogen-demanding species, and indirectly, by increasing grazing, fungal attack, frost damage, etc. on some species. In many northern temperate ecosystems this results in a loss of slow growing ericaceous dwarf shrubs and a dominance of faster growing grasses (Figure 3).

Despite the drastic local effects of air pollution, sometimes in combination with abrupt weather changes, notably in Central European mountains, where thousands of hectares of forests died in a few years in the late 1970s and early 1980s (the classical *Waldsterben* or forest decline, *see* **Waldsterben**, Volume 5), the overall trend of forest growth in Europe is increased productivity (Kauppi *et al.*, 1992; Spiecker *et al.*, 1996). Several factors could cause increased productivity, e.g., nitrogen deposition, increased concentration of atmospheric CO_2, higher temperatures (Cannell *et al.*, 1998), improved silvicultural practices, etc. This general increase in productivity, which has occurred despite increased soil acidity, and the growth responses in experimental acidifying nitrogen loading treatments, refute the idea that the acidity of the soil (expressed, e.g., as the calcium (Ca) to aluminum (Al) (Ca/Al) ratio) exerts an immediate control on tree growth (Binkley and Högberg, 1997). This is only likely under conditions of nitrogen saturation (see below). Clearly, in nitrogen-limited forests, the supply of nitrogen exerts a proximal control on tree growth.

The nitrogen input versus nitrogen output dose responses are relatively well established for northern temperate forest (Dise and Wright, 1995; cf. Figure 4; Fenn *et al.*, 1998). At deposition levels below $9\,kg\,N\,ha^{-1}\,year^{-1}$, the leaching of nitrogen is only a few $kg\,ha^{-1}\,year^{-1}$, deposited nitrogen is strongly retained by the system, and the ecosystem nitrogen capital is increasing. At intermediate levels of deposition, i.e., $9–25\,kg\,N\,ha^{-1}\,year^{-1}$, most forest ecosystems still have a tight nitrogen cycle with only

Figure 3 Grasses on the way to out-compete the dwarf shrub bilberry, *V. myrtillus*, in an area receiving high inputs of nitrogen and sulfur. Forest at Nacetin, Ore Mts., Czech Republic (photo by P Högberg, 1995)

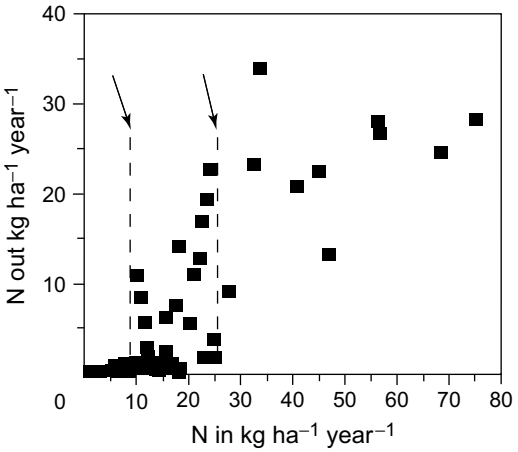

Figure 4 The relation between leaching of inorganic nitrogen (nitrogen out) and nitrogen deposition (nitrogen in) across forest ecosystems in Europe (Dise and Wright, 1995). (Reproduced by permission of Elsevier Science Ltd. from Dise and Wright, 1995)

small losses, but there are systems with considerable (>5 kg N ha^{-1} year^{-1}) nitrogen leakage. At a deposition of nitrogen above 25 kg ha^{-1} year^{-1}, virtually all forests leak significant amounts of nitrogen, especially as nitrate, and in some cases outputs rival inputs, and the systems are nitrogen saturated by any definition.

As for trees and other plants, the allocation of carbon to the root system is high under nitrogen limitation, but decreases when the nitrogen supply increases (Ericsson, 1995). The same dose response occurs for phosphorus and sulfur, but possibly not for potassium (K) and magnesium (Mg). Hence, nitrogen deposition could result in a lower biomass of active roots. There is also a mechanism of down-regulation of the root uptake capacity for, e.g., ammonium, when the supply exceeds the demand. It is thus possible that trees in nitrogen-loaded areas down-regulate both their root biomass and their specific uptake capacity for at least ammonium. However, they cannot effectively exclude all excess nitrogen by down-regulation of root uptake. Locally, there may be considerable foliar uptake of gaseous ammonia (Pearson and Stewart, 1993) from farmed animals, or of NO_x from traffic. Ammonia in high concentrations may even kill trees directly downwind of larger animal farms. Ammonia may also react with long-range transported sulfuric acid to form ammonium sulfate, leading to exceptionally high nitrogen and sulfur co-deposition locally (van Breemen *et al.*, 1982). Very high deposition is also encountered at forest edges, especially when located downwind of larger urban, industrial or agricultural areas. In conifers, excess nitrogen is often stored as the amino acid *arginine*, which thus is a good indicator of incipient nitrogen saturation (Näsholm *et al.*, 1997). As regards soil microorganisms, their capacity to retain nitrogen is strongly and directly related to the supply of available carbon. Moreover, long-term nitrogen retention is also strongly dependent on the overall presence of carbon compounds in the soil. Therefore, the soil C/N ratio is very often a useful indicator of the nitrogen retention capacity of soils (Dise *et al.*, 1998; Gundersen *et al.*, 1998). Below a C/N ratio of 15–20, the capacity of the soil to store additional nitrogen is usually marginal, and there is a greater risk of leaching of nitrate.

As northern temperate forests often are nitrogen-limited, it could be argued that, additions of nitrogen would increase the sequestration of carbon, and hence would reduce the greenhouse effect of atmospheric carbon dioxide (Schimel, 1995). It has thus been suggested that nitrogen deposition contributes to the missing sink for atmospheric carbon dioxide, which has been located in the terrestrial biomes of the north. However, most of the nitrogen deposition is on forests that are already, or will soon be, nitrogen saturated, e.g., forests in Central Europe. In theory, nitrogen fertilization of more nitrogen-limited forests could be used as a strategy to increase the carbon sink strength of forests, but this would not be a long-term solution given the trend of nitrogen eutrophication and associated problems.

Nitrogen Saturation and Forest Decline

When the combined biological demand for nitrogen by trees and other plants and microorganisms is exceeded by the nitrogen supply, the losses by leaching of nitrogen, primarily in the form of nitrate, will start to increase, and will ultimately reach the same level as the nitrogen inputs. This may cause serious nitrogen pollution of ground and surface waters, and may render them unsuitable for human consumption. Along with the nitrate anion, cations like calcium, magnesium and potassium, base cations in the first place, and subsequent inorganic aluminum species, are leached out. Some fish species are sensitive to inorganic aluminum, and soil acidification may thus cause fish death. The loss of base cations from the soil and the high nitrogen supply can cause nutrient imbalances in trees. The forest decline in the German Fichelgebirge was argued to be linked to a high N/Mg ratio in tree foliage (Schulze, 1989). Excess nitrogen in soils will also increase rates of denitrification, and hence the production of the greenhouse gas N_2O.

The ultimate stage of nitrogen saturation was described (Aber *et al.*, 1989, 1998) as forest decline. However, although excess nitrogen may certainly have been a contributing factor to forest decline in Central Europe, damaged forests occurred in areas with high concentrations also of sulfur dioxide (SO_2) and other gaseous pollutants, and it is difficult to identify the major cause of damage. When forest decline was first observed, the impact of SO_2 directly on the canopy was initially thought to be

the major cause. Later on, the effects of soil acidification, especially aluminum toxicity effects on tree roots was a major focus (Hüttermann and Ulrich, 1984). However, sensitivity to inorganic aluminum varies considerably amongst plants, and forest tree species like spruce and beech are among the more tolerant. It has, nevertheless, been argued that indicators of acidity such as soil solution Ca/Al ratios or base cation to aluminum ratios correlate negatively with tree growth (Cronan and Grigal, 1995; Sverdrup *et al.*, 1992). Critical points have been raised about the use of such ratios (e.g., Lökke *et al.*, 1996), and at present there is no consensus as regards their usefulness. Clearly, the Ca/Al ratio cannot have proximal control on tree growth when nitrogen is limiting.

How much nitrogen load can a forest then tolerate? This is probably highly variable and dependent on the availability of other nutrient elements. In areas with low background deposition levels, forests have been subjected to experimental additions of around $100\,\mathrm{kg\,N\,ha^{-1}\,year^{-1}}$ for 20 years without a significant increase in tree mortality despite serious soil acidification (Tamm, 1991; Binkley and Högberg, 1997). The treatment caused nutrient imbalances and deficiencies in the micronutrient boron (B), though. In other areas, with older and more leached soils, the forest may become negatively affected by additional nitrogen at lower rates (Aber *et al.*, 1998). The experimental evidence at hand does not point at a generally applicable lethal dose of nitrogen for trees. Many other species and ecosystem functions become affected long before serious damage is obvious in tree stands.

ARE THERE ANY REMEDIES?

As discussed below, reductions in nitrogen emissions lead to some immediate positive effects, e.g., improved quality of ground and surface waters. Reductions of emissions are, of course, also the necessary and ultimate effective long-term solution of the problem of excess nitrogen. However, the results of attempts to control nitrogen emissions are so far meagre.

Awaiting major reductions in emissions, a policy has been to reduce harmful effects of acid deposition. Nutrient imbalances in trees and soil acidification can be counteracted by so-called *vitality fertilization* or by liming. The conventional remedy against soil acidification, liming, may, however, have clear disadvantages, e.g., it may cause increased nitrification, and hence, increased leaching of nitrate along with negative effects on several groups of soil organisms (Kreutzer, 1995). Many forest ecosystems have naturally acid soils due to the presence of organic acids, and liming results in a larger perturbation of soil biota than when used in agriculture. There are cases however, where severely damaged forests have recovered after liming, e.g., in the French Ardennes (Bonneau *et al.*, 1990). In Germany, liming was tested experimentally many decades ago and before the forest decline (Waldsterben) in the 1980s; a reanalysis of those experiments showed positive results with regard to forest growth notably where dolomitic lime, containing both calcium and magnesium, was used, and on sites where a magnesium deficiency could have developed (Hüttl and Zöttl, 1993). In many cases, forest growth was not affected by liming.

Vitality fertilization aims at correcting nutrient imbalances in trees, which, for example, occur as a result of an excessive supply of nitrogen, rather than to counteract soil acidification *per se*. Commonly vitality fertilizers contain phosphorus, calcium, potassium, magnesium and some micronutrients. It is believed that such targeted additions will have less negative side effects than conventional liming.

WHAT HAPPENS IF THE NITROGEN LOAD IS SUSPENDED?

This question has been addressed most explicitly in experiments, where: (1) nitrogen-saturated forests in areas of high-nitrogen deposition have been sheltered by roof constructions (Figure 5) under which nitrogen-depleted rain water has been added (Boxman *et al.*, 1998); or where (2) continuous experimental nitrogen additions (started by C O Tamm, see bibliography) have been suspended on nitrogen-saturated plots (Quist *et al.*, 1999). These different approaches yield strikingly similar and most positive results; i.e., in both cases levels of available inorganic nitrogen decrease rapidly in the soil. In the case of roof experiments, the effect on leaching losses of inorganic nitrogen was a remarkable reduction from a rate of $50\,\mathrm{kg\,N\,ha^{-1}\,year^{-1}}$ to a few $\mathrm{kg\,N\,ha^{-1}\,year^{-1}}$ in a couple of years. The lesson from these experiments is that high concentrations of inorganic nitrogen in the soil cannot be maintained without high inputs. However, the negative effects of the previous nitrogen deposition on the base saturation of the soil may be much more lasting. Also the changes in plant community composition may last for many more years, because it is difficult for plants to invade closed vegetation communities.

CONCLUSIONS

High levels of nitrogen deposition are going to continue to be a major environmental problem, and will most likely soon be evident in areas of intense agricultural and industrial development other than densely populated areas of Europe and North America, e.g., in East and Southeast Asia. Although much of the focus in this context has been on the growth of forest trees, many other organisms are

Figure 5 The roof experiment at Klosterhede, Denmark (photo P Högberg, 1992). Throughfall deposition containing acidifying sulfur and nitrogen compounds is prevented from reaching the soil. Water with a salt composition of pre-industrial rain water is sprinkled under the roof

more sensitive, and we will continue to witness ecosystem nitrogen eutrophication resulting in shifts in species composition, along with soil acidification and aluminum and nitrate pollution of ground and surface waters. Thus, it is most important that emissions from transport, industry and agriculture be reduced substantially. This would result in an immediate reduction in the availability of inorganic nitrogen in forest soils, and hence in decreased leaching of nitrate and aluminum. As regards other ecosystem functions and species composition, the time needed to recover is not known.

Nitrogen Fixers

Jean-Francois Soussana
INRA, Clermont-Ferrand, France

Nitrogen (N_2) is critical for the growth of plants and animals and can be assimilated only in the form of ammonia. Biological nitrogen fixation, the reduction of N_2 to ammonia, is a process unique to bacteria, which occurs both in free-living autotrophs and heterotrophs and in associative or symbiotic organisms. The most efficient systems for N_2 fixation are those where the microorganisms are associated with a plant in differentiated organs (i.e., root nodules) to benefit crop productivity. Currently, biological nitrogen fixation would account for approximately two-thirds of the total inputs of combined nitrogen to the biosphere (Stewart, 1977), that is 160 million tons nitrogen per year. Pre-industrial biological nitrogen fixation on land is difficult to estimate but has been placed in the range of 90–130 million tons nitrogen per year (Galloway et al.*, 1995).*

Nitrogen limitation to production is a strong constraint on carbon storage in the biosphere and increased production under elevated carbon dioxide (CO_2) may decrease over time as nitrogen becomes more limiting due to increased growth. In this context, the activity

of nitrogen-fixing microorganisms may offer the unique possibility to give plants access to an unlimited nitrogen source from the atmosphere. Due to the intimate relationships between the carbon and nitrogen cycles in ecosystems, biological nitrogen fixation could account for a possible, CO_2 induced, increased nitrogen demand thereby favoring the sequestration of additional carbon into terrestrial ecosystems (Gifford et al.*, 1996).*

POSSIBLE EFFECTS OF ELEVATED ATMOSPHERIC CARBON DIOXIDE (CO_2) CONCENTRATIONS ON FREE-LIVING AND ASSOCIATIVE NITROGEN FIXERS

There are approximately 100 bacterial genus which are known to contain at least one nitrogen (N_2)-fixing species (Young *et al.*, 1992). With the exception of the nitrogen-fixing photosynthetic bacteria and cyanobacteria, most of the free-living nitrogen-fixing bacteria are heterotrophs requiring habitats like soils, capable of providing a source of utilizable carbon (C) substrates necessary to meet the energy demands for N_2 fixation. In general, in most natural habitats, N_2 fixation is limited by the availability of carbohydrates, which helps explain why typical soil free-living bacteria like *Azotobacter* spp. contribute less than 0.5 kg nitrogen $ha^{-1}\,yr^{-1}$ (Evans and Burris, 1992).

Despite a wealth of information on root associated nitrogen-fixing bacteria, there are so far no convincing data on significant nitrogen transfer to root colonized plants. This not only follows from extensive studies with ^{15}N isotope and nitrogen balance techniques but also can be deduced from the observation that none of the listed bacteria emits significant amounts of ammonia during nitrogen-fixing growth. For *Azospirillum*, the plant growth-promoting effect is clearly demonstrated but is mostly attributed to the bacterial synthesis of phytohormones (Vanderleyden, 1998).

The effects of elevated CO_2 on free-living and associative nitrogen-fixing bacteria would be mediated through plants, primarily by altering rhizodeposition (the release of cells, exudates, mucilages and other compounds into the rhizosphere by plant roots). Plants grown under elevated CO_2 generally increase the allocation of photosynthates to roots which increases the capacity and/or activity of below-ground carbon sinks, enhancing in some but not all systems root turnover and deposition of organic carbon into the soil (Rogers *et al.*, 1994). However, no experimental demonstration of an increased nitrogen-fixation by free-living or associative N_2 fixers has yet been reported for plant–soil systems grown under an elevated atmospheric CO_2 concentration.

DIRECT EFFECTS OF ELEVATED CO_2 ON SYMBIOTIC N_2 FIXATION

Two types of symbioses between nitrogen-fixing bacteria and higher plants are known where the bacteria are hosted in special organs, root nodules, that are formed by the host plants upon interaction with the microsymbionts. In one of these symbioses, the microsymbionts are rhizobia that interact with plants of the legume family or with one non-legume, *Parasponia* (*Ulmaceae*). In the other one, actinomycetes of the genus *Frankia* interact with plant species from eight different families, mostly woody shrubs.

It has long been known that elevated levels of atmospheric CO_2 concentration stimulate legume growth and N_2 fixation (Wilson *et al.*, 1933). In a wide range of plants, elevated CO_2 leads to an increase in nitrogenase activity within several days. The longer term increase of total nitrogenase activity under high CO_2 would be due to an increase in the number and in the individual weight of the nodules, but the nitrogenase activity per unit nodule dry weight is not greater than in the control (Norby *et al.*, 1987; Ryle *et al.*, 1992). Nevertheless, with *Gliricidia sepium*, a fast-growing woody legume, greater rates of carbon supply to nodules under elevated CO_2 did not affect nodule mass per plant but did increase specific nitrogenase activity (Tissue *et al.*, 1997). The CO_2 enhanced plant growth may result in an increased nitrogen sink strength which is detectable within a few days. As a result, nitrogenase activity is up-regulated to meet the increased nitrogen demand, a concept supported by some physiological evidence (Oti-Boateng *et al.*, 1994).

In annual legumes, up to one-third of photosynthates may be used for energy and carbon skeletons for nitrogen fixation and assimilation. Dark CO_2 fixation by nodule PEPC (phosphoenol–pyruvate carboxylase) may provide an additional source of carbon for nodule function and maintenance. With soybean, about half of the CO_2 efflux inside the nodule is recycled through the PEPC activity. Low rhizosphere (below 100 ppm) CO_2 concentrations result in a significant decline in nitrogenase (acetylene reduction) activity of some legume nodules (Bethenod *et al.*, 1984). However, increasing the partial pressure of CO_2 in the rhizosphere above ambient does not stimulate the nitrogenase activity of soybean (O Bethenod, personal communication). Therefore, direct effects of an increased rhizosphere CO_2 partial pressure on nitrogenase activity from nodulated legume roots are unlikely.

During biological N_2 fixation, H^+ and N_2 are simultaneously reduced by nitrogenase. The proportion of total electron flow through nitrogenase that is used in N_2 fixation to ammonia (NH_3) is usually not modified significantly under elevated CO_2 (Crush, 1993). Therefore, although the evidence available at present is rather limited, it seems that neither the nitrogenase activity per unit nodule dry weight, nor the efficiency or the carbon cost of the nitrogen-fixing

process within legumes, will be directly affected by an increase in the atmospheric CO_2 concentration.

Nitrogen-fixing activity is reduced in proportion to the amount of the available soil mineral nitrogen. In the presence of mineral nitrogen, the long-term inhibition of the symbiosis involves a decline in the number and in the total weight of nodules per plant, whereas the short-term (during a few days) decline in the nitrogenase activity is associated with a decreased nodule O_2 permeability and is thus reversible. With pea, the short-term increase in the atmospheric CO_2 concentration from 320 to 1200 ppm does not prevent the inhibition of nitrogenase activity by root medium nitrate, although it increases the supply of photosynthates to the nodule (Chen and Phillips, 1977). In the same way, with white clover (Zanetti *et al.*, 1998), in the presence of a high level of mineral nitrogen, elevated pCO_2 *per se* did not alter the percentage nitrogen derived from symbiosis. As long as the mineral nitrogen supply satisfies the CO_2 induced increase in the plant's nitrogen sink strength, the relative contribution of symbiotically fixed nitrogen as opposed to mineral nitrogen, would therefore be unaffected by the CO_2 enrichment.

CAN SYMBIOTIC N_2 FIXATION COMPENSATE FOR AN INCREASED ECOSYSTEM DEMAND FOR NITROGEN IN ELEVATED CO_2?

Symbiotically fixed nitrogen can be transferred to non-fixing species by an above-ground route via herbivore excreta and by below-ground transfer via either direct excretion of nitrogen compounds from legume roots or decomposition of legume nodule, root and senescing root material.

Whether elevated CO_2 can affect the above-ground transfer of fixed nitrogen is not known, due to a lack of grazing experiments in elevated CO_2. Concerning the below-ground transfers, data from model grassland ecosystems on fertile soils support the concept of an increased below-ground transfer of fixed nitrogen in elevated CO_2. In grass–clover mixtures, the proportion of legume increased significantly under elevated CO_2 (Hebeisen *et al.*, 1997), a conclusion also reached by a number of experimental studies with temperate and rather fertile managed grasslands. It appears that the entire additional amount of nitrogen assimilated in clover under elevated CO_2 came through symbiotic N_2 fixation (Soussana and Hartwig, 1996). The below-ground transfer of fixed nitrogen was estimated in these experiments with a ^{15}N isotope technique. This transfer of fixed nitrogen contributed up to 60% of the nitrogen nutrition of the mixed grass and was usually significantly greater in elevated than in ambient CO_2 during two growing seasons (Soussana and Hartwig, 1996).

An increased N_2 demand (Soussana *et al.*, 1996), both in the legume and in the grassland ecosystem as a whole, could account for these observations of an increase in nitrogen fixation and below-ground nitrogen transfer in elevated CO_2. The extent of competition for soil-available nitrogen by associated non-legumes is one factor that determines the proportion of nitrogen derived from symbiotic N_2 fixation in mixtures. This proportion will also increase if soil nitrogen availability is reduced by any other mechanism (leaching, denitrification, low mineralization, nitrogen immobilization).

These results suggest a direct physiological link between symbiotic N_2 fixation and the nitrogen demand of the whole ecosystem. Under elevated CO_2, N_2 fixation is likely to respond positively to the increased nitrogen demand of the ecosystem and this will, presumably, buffer the imbalance between the carbon and nitrogen cycles.

POSSIBLE LONG-TERM ELEVATED CO_2 EFFECTS ON THE POPULATION DYNAMICS OF LEGUMES

From the model by Schwinning and Parsons (1996), any CO_2 induced advantage of legumes in mixed communities, by increasing the soil nitrogen availability, will stimulate in the longer term the growth of non-fixing species. It would therefore be clearly over-simplistic to assume that the rise in atmospheric CO_2 concentration will lead to a steady increase in the legume content of the vegetation.

Moreover, for nitrogen fixation to track ecosystem carbon fixation in the long-term, more phosphorus must enter the biological cycle. Some experimental evidence shows that plants in elevated CO_2 may have the capacity to mobilize more phosphorus from so-called unavailable sources using mechanisms involving exudation of organic acids and phosphatases (Gifford, 1996). The interactive effects of elevated CO_2, supply of phosphorus and legume presence were studied in model communities of calcareous grassland by Stöcklin and Körner (1999). Legumes were significantly stimulated by P supply and their CO_2 response was much larger when P was added. Also, in another study with intact monoliths from calcareous grassland, the difference in biomass production between elevated and ambient CO_2 was higher when P was added, especially in legumes (Stöcklin *et al.*, 1998). Therefore, nitrogen-fixing legumes appear to be crucial for the community response, but legume responsiveness is largely controlled by P availability.

CAN A LARGER (FIXED) NITROGEN INPUT RESULT IN THE SEQUESTRATION OF ADDITIONAL CARBON UNDER ELEVATED CO_2?

The decline in leaf nitrogen concentration under elevated CO_2, which affects litter decomposition processes, is likely

to be restricted mostly to the non-nitrogen-fixing species (Hartwig *et al.*, 2000). Therefore, in elevated CO_2, the decomposition of the legume material could supply the soil and the ecosystem with a large nitrogen input. This result can be expected as long as the nitrogen-fixing symbiosis is not hampered by other factors, like low temperature, low phosphorus or water stress.

With monoliths of an established ryegrass/white clover mixture, net primary productivity below-ground and soil CO_2–C production were enhanced, resulting in a more rapid turnover of carbon at elevated CO_2. However, no detectable change in carbon pool sizes was observed in elevated CO_2 (Ross *et al.*, 1995). Therefore, with some soils, the positive effects of the nitrogen-rich legume material on the decomposition process might be dominant and lead to increased soil respiration rates, with no supplemental below-ground carbon storage. Nevertheless, in some other soils (acidic, calcic, or with large contents of clay) the high degree of protection of the soil organic matter (SOM) might favor an increased below-ground carbon sequestration under elevated CO_2.

A model of the interacting global carbon and nitrogen cycles (CQUESTN) was developed by Gifford *et al.* (1996). With increasing atmospheric CO_2 concentrations stimulating photosynthesis, and inputs of litter with increased carbon–nitrogen ratio, the model assumes that the increased chemical energy supply will enable the ecosystem to gradually acquire nitrogen either by biological nitrogen fixation or from the nitrogen that would otherwise flow to atmosphere or rivers. In CQUESTN, this is modeled as a tendency for ecosystems to shift the carbon–nitrogen ratio of humus back to an equilibrium value. This model also assumes that nitrogen acquisition from the atmosphere responds to demand, with its suppression by a high soil–nitrogen status and its stimulation by a low soil nitrogen status. With the nitrogen fixation response turned off, a large increase in the carbon–nitrogen ratios of the litter was predicted, as well as a slow increase in the carbon–nitrogen ratio of the total SOM. By contrast, when it was assumed that 5% of the nitrogen deficit in SOM below the pre-industrial value was recovered per year by fixation, the global carbon sequestration increased from 1.8–2.6 Gt C yr^{-1}. While this model is heuristic not predictive, it shows the major role that the nitrogen fixation process can play for the global carbon sequestration in terrestrial ecosystems.

Nitrogen Mineralization

Nitrogen mineralization is an aspect of soil mineralization (*see* **Soil Mineralization**, Volume 2) and is the conversion of organic nitrogen in the soil to the inorganic state. Nitrogen is probably the most important plant nutrient. It exists in soil in a number of mineralized forms (molecular nitrogen, ammonium, nitrite and nitrate) and each of these may be absorbed by either plants or microorganisms for use in the formation of amino acids, proteins and other organic nitrogenous compounds. In addition, many microorganisms are able to extract energy by oxidizing ammonium nitrogen to nitrite, and others by oxidizing nitrite to nitrate. This process is called *nitrification*. Still other microorganisms convert nitrate or nitrite to molecular nitrogen by the process of *denitrification*. Some denitrifying bacteria also convert nitrate to ammonia.

Higher plants are unable to absorb molecular nitrogen and most are not able to absorb organic nitrogen compounds to any significant degree. Therefore they must rely on added nitrogen fertilizer, or nitrogen fixation, or the mineralization of organic nitrogen that enters the soil as organic detritus. However, the presence of excess organic material in soils leads to very high rates of microbial growth and this may demineralize available nitrogen, even to the extent of using up a large proportion of agriculturally applied fertilizer. On the other hand, if excess mineralization occurs, there is a danger that the mineralized nitrogen will be permanently lost from the ecosystem by leaching (*see* **Nitrate Leaching**, Volume 3). It is thus very important, particularly in agricultural systems, that the soil nitrogen cycle of mineralization and demineralization be maintained in balance.

R G S BIDWELL *Canada*

Non-equilibrium Ecology

James F Reynolds
Duke University, Durham, NC, USA

One of the most controversial and well-known theories associated with global change is the Gaia hypothesis. Originated by biologist James Lovelock, this hypothesis states that over geologic time, biotic life on Earth has evolved to control the physical forces of nature, resulting in a bio-geosphere that is self-regulatory, or homeostatic. Thus, acting like the thermostat in your house, any deviation from this balanced condition or set-point will result in a corrective response in order to maintain the stable equilibrium. Do ecosystems behave this way? If so, predicting their response to global change would be relatively easy. However, notions of stable equilibria – as espoused by the Gaia hypothesis – are centered around the concept of the balance of nature, which has dictated western views of science since antiquity. It is ironic that the Gaia hypothesis is receiving such popular attention at a time when ecologists are eschewing the equilibrium-centered view per se in favor of a non-equilibrium one. During the past several decades, ecology has experienced a paradigm shift: from the balance-of-nature (equilibrium/stability) to non-equilibrium. This paradigm shift, which embraces spatiotemporal dynamics of ecosystems, is essential to our ability to develop a predictive understanding of the dynamics of ecosystems.

Many pioneer naturalists adhered to the belief that nature reflected a balance of destructive and constructive forces and would therefore maintain or achieve some degree of permanent condition or equilibrium if left undisturbed (Wu and Loucks, 1995). This *balance-of-nature paradigm* long dictated Western views of science and has greatly influenced our interpretation of natural phenomena. Frederic Clements (1874–1945) was particularly influential in shaping this attitude. Clements proposed that *natural succession*,

which is the directional change in community structure over time, always ends in a single type of self-perpetuating community within a given climatic region (a mono-climax). For example, if we were to observe an abandoned tobacco field in the Piedmont of North Carolina, USA over many years, we would initially see it colonized by various grasses and herbaceous vegetation, followed in time by woody plants, shrubs and small trees, and eventually by a forest of mixed hardwood species (the climax vegetation). The equilibrium view of Clementsian succession is that this balance of species over time is achieved via the mechanisms of tight biotic interactions and feedbacks (mainly competition and density dependent forces) within the constraints of a relatively constant environment. Once achieved, this predetermined climax community remains more or less stable through time unless disturbed by external forces. Even in the face of disturbance, the system persists, either remaining at its equilibrium (measured as resistance) or eventually returning to it (measured as resilience or return time). While Clements recognized that disturbance was omnipresent and that "... even the most stable association is never in complete equilibrium ...," he considered disturbance as simply a mechanism that reset the system on its inexorable march towards equilibrium (Pickett and White, 1985). This deterministic thinking dominated ecology for years and led to the development of numerous concepts related to the development and maintenance of stable equilibria in populations, communities, and ecosystems.

Today, however, the balance-of-nature paradigm has been supplanted with what might be more aptly termed the dynamics of nature. This viewpoint, commonly labeled *non-equilibrium ecology*, sees nature as being uncertain and constantly changing. Whereas equilibrium theory is only concerned with the behavior of a system at or near its equilibrium point, non-equilibrium ecology significantly broadens this view. Non-equilibrium ecology embraces transient dynamics, including behaviors like chaos, thresholds, multiple equilibria, and limit cycles. These dynamics are often in phase with naturally occurring disturbances, e.g., fires, floods, drought, windstorms, and insect outbreaks, which can have profound effects on ecosystems. They also result from the ever-changing local rules of species interactions, which vary over time and space during ecosystems development (Levin, 1998). Certain opportunistic species thrive while others disappear, often in ways that are hard to predict. The non-equilibrium view of succession sees historical effects, spatial heterogeneity, stochastic factors, and variability as key agents that affect the rates and directions of ecological dynamics.

Famous historical debates originated from the equilibrium and non-equilibrium points of view of nature, including the role of density-dependent versus density-independent population regulation, how competition structures ecological communities, and theories on ecosystem resistance, resilience, and stability (Wu and Loucks, 1995). In the context of current concerns about global change, a more germane question is, "Can we understand and predict the behavior of non-equilibrium ecosystems?" This question raises a plethora of issues that challenge our basic understanding of ecosystem structure and function. One key issue is the overwhelming importance of time and spatial scales in understanding and interpreting ecosystem dynamics. Given that the probability of observing an extinction in a population increases directly with temporal scale and inversely with spatial scale (Berryman, 1987; DeAngelis and Waterhouse, 1987), the following examples illustrate the importance of spatiotemporal scales in governing our perception of ecosystem equilibria and dynamical states.

At the temporal scale of the last 100 years, it has been a popular notion that aspen forests in Yellowstone National Park (Wyoming, USA) are in equilibrium. It's easy to see how these forests could be considered so since they appear to have always been there. It has also been noticed in recent years that aspen trees are failing to regenerate, something that has widely been attributed to the direct effects of fire suppression and/or excessive elk numbers. However, following the extensive Yellowstone fires in 1988, Romme *et al.* (1995) found that regeneration remained low. In sharp contrast to the equilibrium model, they concluded that aspen forests are actually temporary features of the Yellowstone landscape and are destined to disappear. In fact, the very existence of the present-day aspen stands is a result of circumstances that occurred during the period 1870–1890, where the numbers of elk, beaver and moose were low, climate was moist, extensive fires had recently occurred, and wolves were present – a unique and episodic set of conditions that favored aspen establishment. Similarly, the importance of spatial scale in interpreting ecosystem dynamics is illustrated in a study by DeAngelis and Waterhouse (1987), who describe the maintenance of rare species in areas where habitat is shrinking due to human encroachment. Using computer simulation, they partitioned a formerly contiguous forest into quasi-isolated patches resembling a checkerboard, where no forest patch could hold all of the species of plants, birds, mammals, arthropods, etc., that the original forest contained. The population dynamics of the small patches, unlike the original forest, were highly transient and often included species extinction (non-equilibrium properties). However, they showed that if the rates of plant migration and propagule transport between the forest patches were large enough, a suitably large and closely spaced cluster of forest patches would have characteristics of a stable equilibrium population. Hence, stable equilibrium is a attribute that can emerge asymptotically by extrapolating to sufficiently large spatial scales. These examples show that ecosystems may display elements of both equilibrium and non-equilibrium characteristics depending on the spatial and temporal scale in which

they are viewed. The non-equilibrium paradigm covers this spectrum of conditions, where at one end are stable equilibria dynamics structured primarily by biotic forces and few stochastic effects (i.e., self-regulating population growth, compensatory interactions, intense competition) and at the other are non-equilibria dynamics, characterized by weak biotic couplings, independence of species, abiotic controls, and large stochastic effects.

To illustrate the interplay between equilibrium and non-equilibrium factors in controlling how ecosystems may respond to forces of global change, I use an example of changing rainfall variability in semiarid rangelands. I select rangeland ecosystems because they are ecologically important, covering about 2/5 of the land surface of the globe and home to 20% of the human population, and because there has been much controversy regarding their behavior as either equilibrium or non-equilibrium systems. This debate has been influential in shaping scientific discourse, research approaches, and management priorities for dealing with land degradation, over-grazing by domestic herbivores, climate change, and famine (in pastoral regions of Africa) (Illius and O'Connor, 1999). Arid and semiarid rangelands are particularly vulnerable to climate variability, of which precipitation is the most important component. A slight shift in seasonal precipitation and/or frequency of extreme rainfall could potentially lead to major ecological and biogeochemical impacts, but the impacts may be influenced by local grazing history and management, current stocking rates, soil types, species composition, etc. In Figure 1, a hypothetical rangeland site is depicted in terms

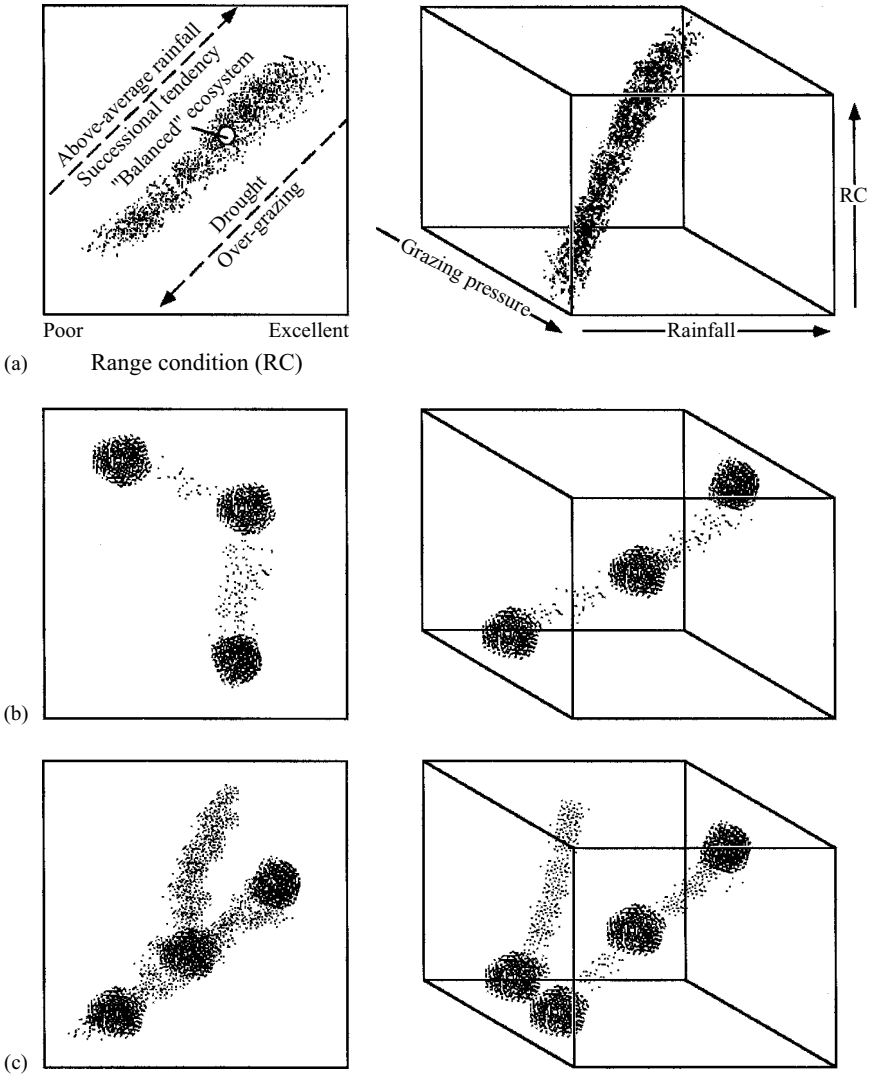

Figure 1 Probability distributions of a hypothetical rangeland site shown in two-(left) and three-(right) dimensional descriptive space. (a) Equilibrium Clementsian model. (b- c) Non-equilibrium model. (Based on Westoby *et al.*, 1989 and Stafford Smith and Pickup, 1993)

of how it might vary over thousands of years (based on Stafford Smith and Pickup, 1993). Over this long period of time, many site characteristics would change, including species composition, soil types, plant biomass, herbivore population densities, soil arthropods diversity, soil nutrient status, etc. If, for each year, we plotted the location of this site within the n-dimensional space defined by these site characteristics, a plot would emerge where the density of points at a particular location would be proportional to the probability that this site occupied that location. This is shown in Figure 1 but simplified for only two or three site characteristics. In Figure 1(a), we illustrate the range condition model, where different states of vegetation are portrayed along a linear gradient (following Westoby *et al.*, 1989). For over 50 years, this equilibrium model has been the dominant model for assessing and managing these systems. It assumes that rangelands ecosystems have a single persistent state: the Clementsian endpoint (equivalent to excellent range condition). Practices such as over-grazing drive the ecosystem in the opposite direction of its natural march towards equilibrium. As herbivory increases, perennial grasses decline and are replaced by unpalatable forbs and other weedy species (equivalent to poor range condition); a reduction or removal of the grazing pressure results in a recovery of the system towards its climax. Drought is considered to affect vegetation in a similar way to grazing whereas above-average years of rainfall accelerate the succession tendency. Consequently, typical development policies and intervention strategies in rangelands based on the range condition model consider over-stocking and over-grazing in pastoral rangelands in Africa as inevitable outcomes of practices by local pastoralists (Ellis and Swift, 1988) and, in principle, a land manager can employ a rather obvious strategy to achieve a sustainable yield of livestock products: select a stocking rate that establishes a long-term balanced ecosystem (Figure 1a) between the pressure of grazing and the natural succession tendency of the system (Westoby *et al.*, 1989). Presumably, shifts in rainfall variability would simply move the system along the linear continuum: upwards in wet years and downwards in drought years. In recent years the equilibrium model has been heavily criticized because, for most rangelands, it simply fails to explain actual dynamics. For example, removing a disturbance such as grazing does not result in an orderly resumption of succession towards some persistent endpoint nor is the cumulative effects of rainfall on the ecosystem linear. The equilibrium-based range condition model fails to capture the dynamic of nature.

As alternatives to the Clementsian model, various closely related non-equilibrium models have been proposed. Based on observations made in rangelands of Australia, Westoby *et al.* (1989) proposed state and transition models. Vegetation states at a particular rangeland site may change over time depending on both exogenous and endogenous causal factors, e.g., the consequences of initial conditions on subsequent patterns of development, how plants modify the soil environment, spatial heterogeneity in soil characteristics, temporal and spatial variability in weather, and opportunistic growth by different plant species. Transitions between those states are triggered by natural events (e.g., fires, drought, large rainfall events) or by management (burning, changes in stocking rates). The result is an assorted collection of vegetation states in which the adjustment or removal of a single factor, e.g., rainfall or grazing, does not necessarily result in a shift along a linear continuum, e.g., from a degraded to less degraded condition, as in the equilibrium model. For our hypothetical rangeland site, such dynamics are depicted in Figure 1(b), which shows the site oscillating between three different domains of attraction or states and where the transitions between these states are relatively rapid (i.e., the density of points between the clusters is relatively light). An even more complex possibility is shown in Figure 1(c). In this scheme, alternative succession pathways are shown for the site, each with different numbers of probable states. Note that based on just two descriptors they appear to intersect but when the third descriptor is added, separate paths are evident, which could represent a case where erosion processes result in a permanent modification of the site.

Does the non-equilibrium model suggest that it will be impossible to predict how ecosystems may respond to global change? Not necessarily. As Illius and O'Connor (1999) point out, previous attempts to draw a distinction between equilibrium and non-equilibrium behavior *per se* in terms of identifying the underlying mechanisms that control ecosystem function have not been very successful. Rather, the valuable lesson that emerges from this is that we must develop a robust framework for coupling pattern with process at different scales. We must develop an understanding of how ecosystems function both far from, and close to, equilibrium conditions, including the importance of initial conditions, what processes lead to steady-states (stable equilibria), and which ones lead to thresholds or breakpoints (unstable equilibria). Such understanding will only come from studies and models that explicitly focus on the spatiotemporal dynamics of ecosystems and embrace the dynamic of nature paradigm as a conspicuous and integral part of normal ecosystem function.

Non-linear Systems

David W Hilbert

Tropical Forest Research Center, Atherton, Australia

Not only in research, but also in the everyday world of politics and economics, we would be better off if more people realized that simple non-linear systems do not necessarily possess simple dynamical properties.

Sir Robert May (1976)

In a world of rapid global change, we would also be better off if more people realized that ecosystems are non-linear systems that can display surprising and unexpected changes in response to continuous and gradual changes in the environment. Will the storage of carbon by ecosystems change in direct proportion to changes in atmospheric carbon dioxide (CO_2), temperature and precipitation, or will there be discontinuous shifts where areas that now take up carbon suddenly release it to the atmosphere? Does gradual, continuous clearing of forests incrementally reduce biodiversity or are there thresholds beyond which extinction of species is much more rapid? Will the population dynamics of insect pests change qualitatively as global temperatures rise, with species that now have unpredictable outbreaks becoming common in all years and species that are now always rare entering into cycles of high and low abundance? The answers to these questions are largely unknown but it is known that non-linear systems display these kinds of thresholds and qualitative changes in behavior so an understanding of the dynamics of non-linear systems is an essential part of understanding how the biosphere will be modified by global change.

When the interactions among a system's components are not simply proportional, the system is said to be non-linear. This is the rule rather than the exception in biological systems and is a pervasive feature of most systems, whether physical or biological. Linear systems respond smoothly to gradual changes in their environment and have simple dynamics that lead to simple, constant states when the environment is unchanging. Non-linear systems, on the other hand, display many qualitatively different behaviors including the possibility of several different constant states, regular cycles, complex cycles, and seemingly random chaos. Non-linearity produces these complex behaviors in all but the simplest systems, but its greatest significance is that it can produce surprises in the form of sudden, discontinuous, and qualitative changes in a system's behavior in response to gradual changes in the external environment. So, while global changes in the environment may be incremental, the responses of ecosystems to these changes may not be gradual and continuous.

The word *system* refers to a collection of things that interact strongly with each other. For example, an ecosystem can be thought of as a set of components – soil, plants, animals, etc. – that affect one another and, in so doing, produce changes in the amounts of each component. For example, when grazing animals eat leaves, they decrease the amount of plants while increasing the amount of animal matter with perhaps some indirect affects on the soil. Of course, everything can interact and the entire Earth is a system. But many interactions are weak or indirect, so – to keep things manageable – one can define a system as just the set of components that interact strongly and are important for some specific interest. The study of the ways systems change through time often uses mathematical models where each component is represented by one or more variables (called *state variables*) that quantifies its essential properties. The values of the whole set of these variables describe the properties or "state" of the system at any particular moment. The real system is modeled by a set of equations that describe how each of

the system's components affects both itself and the other components. Of course, no system is isolated from the rest of the world so models of systems also need to include variables that represent the larger environment. These variables affect the system but are not strongly affected by the system itself. Rainfall, for instance, affects the growth of plants but individual plants don't have much direct effect on when or how much it rains. This concept of an interactive system imbedded in a larger environment is illustrated in Figure 1.

The behavior of any system depends on the responses of its components to the environment and to the interactions and feedbacks among the state variables. So, to understand and predict the impacts of global change on ecosystems, we need to know how their components respond to external environmental variables such as atmospheric CO_2 concentration, temperature and precipitation and the way these responses affect the interactions within the system. While we have less than complete knowledge of these factors, we do know that the interactions among variables in most real systems are non-linear. The defining feature of non-linear systems is that changes in a variable create non-linear changes in the rate of change of that variable and/or other variables in the system. This non-linearity has deep implications for the study of global change impacts on biological systems. Smooth, continuous changes in temperature, precipitation, atmospheric concentrations of CO_2, and other "external" variables, may have discontinuous impacts on the qualitative behavior of ecological systems. Since ecological systems are non-linear and their responses to the external environment are non-linear, we could even say that surprises in the sense of discontinuous changes from one dynamic equilibrium to another or from one form of behavior to another must be expected. Luckily, despite the bewildering variety of systems and models of systems, there is only a limited range of possible behaviors and these have been well described by dynamical systems theory. One focus of this theory is the study of how the dynamics of a system can change *qualitatively* as a parameter (including external variables like climate) changes smoothly. In other words, the field of non-linear systems dynamics is primarily about how surprises occur in the behavior of systems (see Ekeland, 1988).

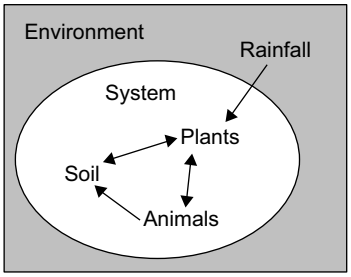

Figure 1 A schematic representation of a simple system and its environment. The system is de ned by three interacting variables (plants, animals, and soils) with their interactions indicated by arrows. These variables are separated conceptually from environmental variables, rainfall in this example, that affect the system in some way but are not themselves directly affected by the system. If any of the interaction among the system's variables is non-linear, then it is a non-linear system

The study of change in systems often uses the concept of *state space* developed by the French mathematician Henri Poincaré (1854–1912). A list of the values of all the variables that define the system at some moment in time describes the "state" of the system at that instant. For example, the population density of foxes and hares might describe the state of a predator–prey system. The state space for this system is the universe of all possible combinations of the system variables – in this case, a plane with the two axes representing the number of foxes and hares. So the state of the system at any particular time can be represented by its location in the state space; and the dynamics of the system is thought of as the trajectory of this point through the state space. For every point in the state space, there is a single vector defined by the direction and rates of change of each of the system variables. Often, there are especially important points in the state space where the rates of change of all the systems variables are zero. These are called *critical points*. If all the system's vectors near such a point converge toward it, the point is a stable critical point or equilibrium because, after any small perturbation, the system will automatically move back to that location. This is the state of the system we would expect to see most frequently. In this sense, a stable point is an *attractor* for the system since after starting the system at one of many places in the state space, it will be attracted to the stable critical point (*see also* **Chaos and Cycles**, Volume 2). Non-linear systems can also have more complex attractors such as closed curves (called *stable limit cycles*) where the system displays regular cycles that will be returned to after any perturbation. An analogous attractor in three dimensions is a torus (like the surface of a doughnut), which can produce very complex cycles called *quasi-periodic behavior*. The system follows a trajectory that continually spirals around the surface of the torus.

Box 1 Non-linearity

In non-linear systems, the rate of change of one or more of the state variables are non-linear functions of one or more of the state variables. For example, if a system has two state variables (x and y) and the rate of change of 'x' (dx/dt) is proportional to both x and y ($dx/dt = ax - by$) and the same is true for the rate of change of y ($dy/dt = cy - dx$), then the system is linear since the responses of the system are simply proportional to the values of the state variables. On the other hand, all more complex functions are non-linear, for example $dx/dt = ax - bxy$ or $dx/dt = ax^2 - b/y$.

Finally, non-linear systems may be chaotic – seemingly random but nonetheless having deterministic dynamics – in which case the attractor is called *strange* since it has a fractal, non-integer dimension (see Gleick, 1987 for an introduction to chaos). Logan and Allen (1992) provide an excellent overview of chaos in the context of population dynamics.

Lorenz's (1963) famous butterfly is the strange attractor of a model describing convection. Figure 2 shows part of the system's trajectory through state space for Lorenz's model. As the system continues to evolve through time, the trajectory will trace out more and more of the attractor, which looks somewhat like a butterfly's wings. Looking at the values of any one of the system's variables through time (see inset) the dynamics appears random. But, unlike truly random behavior, there is a very distinct, although strangely shaped, structure that attracts the system and produces a kind of order that keeps the system within clearly defined bounds. The dynamics are precisely determined by the interactions among the system's variables so, if we knew the exact state of the system at any moment, we could predict all of its future accurately. Unfortunately, chaotic systems are extremely sensitive to the starting point in the state space. Initial conditions that are unimaginably close to each other will eventually follow very different trajectories in the state space, although all will lie somewhere on the attractor. So, while chaotic, non-linear systems are deterministic, they are not predictable in practice since we can never measure their condition at any moment of time with perfect accuracy. A classic example of a chaotic system is the weather, which results from convection and turbulence in the atmosphere. Precise, long-term prediction of the weather will never be possible, because the atmosphere is a non-linear, chaotic system. Nonetheless, reasonably good, large-scale and general predictions can be made for weeks to months in advance since the weather/climate system is not truly random. Whether populations of organisms or ecosystems are sometimes chaotic is still being debated. One difficulty here is that ecological systems are strongly affected by weather, whose chaotic behavior may hide the true, underlying dynamics of the ecological system. But ecological systems are non-linear

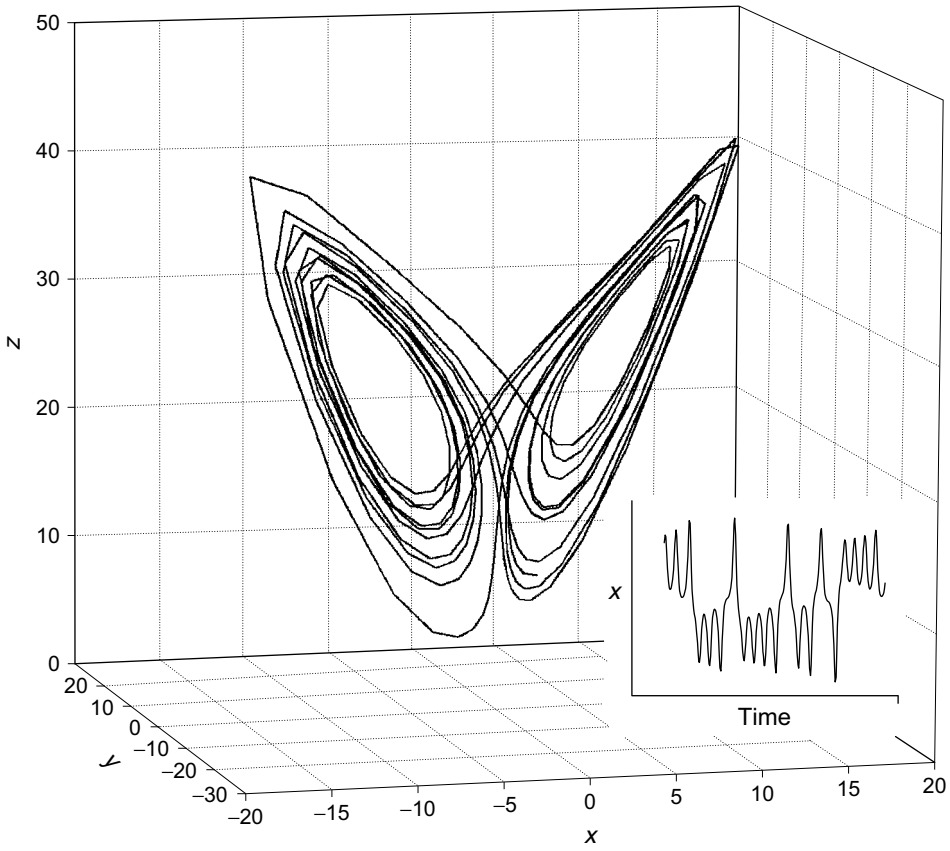

Figure 2 Lorenz's butter y attractor. The curve is part of a trajectory in the three-dimensional state space of a simpli ed model of convection described by the equations $dx/dt = 10(y - x)$, $dy/dt = -xz + 28x - y$, and $dz/dt = xy - (8/3)z$. The presence of the products xz and xy makes this a non-linear system. Starting from anywhere in the state space, the system's trajectory will be drawn to the attractor with the shape that is partially described in the gure by the butter y-shaped trajectory

and thus they could display chaos, at least under certain conditions. Most importantly, non-linear systems can display all these kinds of dynamics, from one or more simple point attractors, to cycles and chaos, depending on the parameters or levels of external variables like climate.

Non-linear systems can also have relatively simple dynamics (similar to linear systems) where the attractor is a stable point in the state space. In this case the system has one equilibrium to which it is always drawn. Even if the system is continually pushed away from this point – perhaps by droughts, floods or fires – it will move back to the original, stable condition. This is essentially the "balance of nature" concept that once dominated the study of ecology and natural history. The location of this equilibrium normally depends on environmental conditions like climate and the richness of the soil. So, e.g., an ecosystem's storage of carbon will depend on the mean annual temperature, annual rainfall, and nutrient content of the soil. If ecosystems were linear, then a change in climate or nitrogen added to the system would change the location of the attractor in some smooth and regular way. A somewhat warmer climate, for example, might slightly alter the equilibrium amount of plants the ecosystem can support. However, a typical feature of non-linear systems is the possibility of more than one possible equilibrium in at least some environments. An example is shown in Figure 3 for a hypothetical system made up of plants and the herbivores that eat them. In a cool climate there might be a single attractor with a relatively large amount of plant biomass and relatively few herbivores. The system will always move back to that equilibrium after any sudden change or perturbation like a fire that alters the state of the system. In a more moderate climate, however, the non-linear interactions between plants and herbivores might produce two simultaneously possible equilibria. Then, parts of the state space will lead to an attractor with lots of plants but few herbivores and other parts of the state space lead to an equilibrium with much less plant biomass but more herbivores. In this case, if the system was near the upper attractor and a fire reduced the plants to a very low-level, then the ecosystem would not return to its previous state. Instead, it would be attracted to the equilibrium with lower plant biomass. Situations like this may occur when fish populations are reduced to very low levels through over-fishing. The boundary between two equilibria may have been crossed so that even stopping the fishing will not allow the population to recover to previous levels. Returning to the illustration in Figure 3, one of the two co-existing attractors may cease to exist in a warmer climate where there is only one, low equilibrium for plant biomass. This property of non-linear systems – multiple attractors and the way they appear and disappear with small changes in the environment – is of obvious importance for how biological systems respond to global change. For some time, the affect of climate change may be smooth and regular until some threshold is passed when the number and qualities of equilibria suddenly change.

Hilbert *et al.* (2000), e.g., demonstrated this possibility for peatlands. Their simple model views peatlands, such as bogs and mires, as just two state variables; the depth of accumulated dead organic matter (peat) and where the water table is found beneath the surface of the peat. These system variables interact non-linearly, primarily because it can be either too wet or too dry for the growth of mosses. Under an intermediate range of precipitation, peatlands may have two possible equilibria with different amounts of accumulated peat and different depth to the water table. At lower or higher precipitation regimes, only one steady state exists. Thus, as climate changes there could be a discontinuous change in the behavior of a peatland as one equilibrium vanishes and another, possibly very different one appears. Similar cases of multiple equilibria have been described for grazing systems (Noy-Meir, 1975). Discontinuous changes in equilibria may also explain discontinuous changes in the characteristics of ecosystems along spatial gradients where environmental conditions vary gradually (Wilson and Nisbet, 1997).

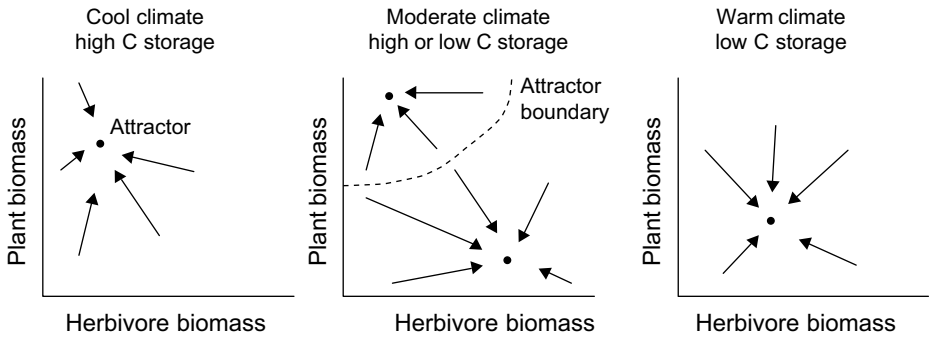

Figure 3 A hypothetical example illustrating how the number and location of equilibria (point attractors) can change as the external environment is altered. The arrows indicate the direction of the system's vectors when the system is at the tail of the arrow. When two simultaneous equilibria occur, there is a boundary between them that separates points that are attracted to one or the other equilibrium

The effect of a gradual change in the environment may be even more profound than in the example of multiple attractors because, as described previously, non-linear systems can have several qualitatively different types of behavior. A simple and generic example of this is the discrete logistic equation. This equation says that the population of an organism next year is a function of both the current population size and the square of its size. The presence of the square term in the equation makes the model non-linear and time is thought of as occurring in discrete steps (year 1, 2, 3, and so on). The effect of increasing the single parameter 'a' (see Box 2) on the population's behavior is illustrated in Figure 4. For each value of 'a' the figure shows the value of the population (x) that the model predicts for each of 300 years after the model ran for an initial 200 years. The inset figures, for 'a' = 2.8, 3.2, 3.5, and 3.9, plot the value of 'x' through time. When 'a' is below 3.0, the population comes to a single equilibrium that becomes higher as 'a' increases. When 'a' = 3.0, however, there is a qualitative change in the population's behavior. Suddenly, it cycles back and forth between two values as illustrated in an inset for 'a' = 3.2. As 'a' increases further, there is a quantitative change in that the difference between the high and low

Box 2 Discrete logistic

In this model of a seasonally breeding population with no overlap of generations, there is only one parameter (a), which determines how fast the population can grow. Discrete, non-linear equations like this one, show all the complex behavior of more complicated systems because they implicitly include a time lag in the feedback between the state of a system and its rate of change. May (1974, 1976) studied how this model's behavior changes as 'a' is varied. [If 'a' was a function of climate, he could just as well have been studying how population behavior could be affected by gradual, global climate change.] Surprisingly, this equation displays thresholds, a special kind of bifurcation, where the behavior changes from a single steady state, to simple cycles, to more complex cycles, and nally to chaos.

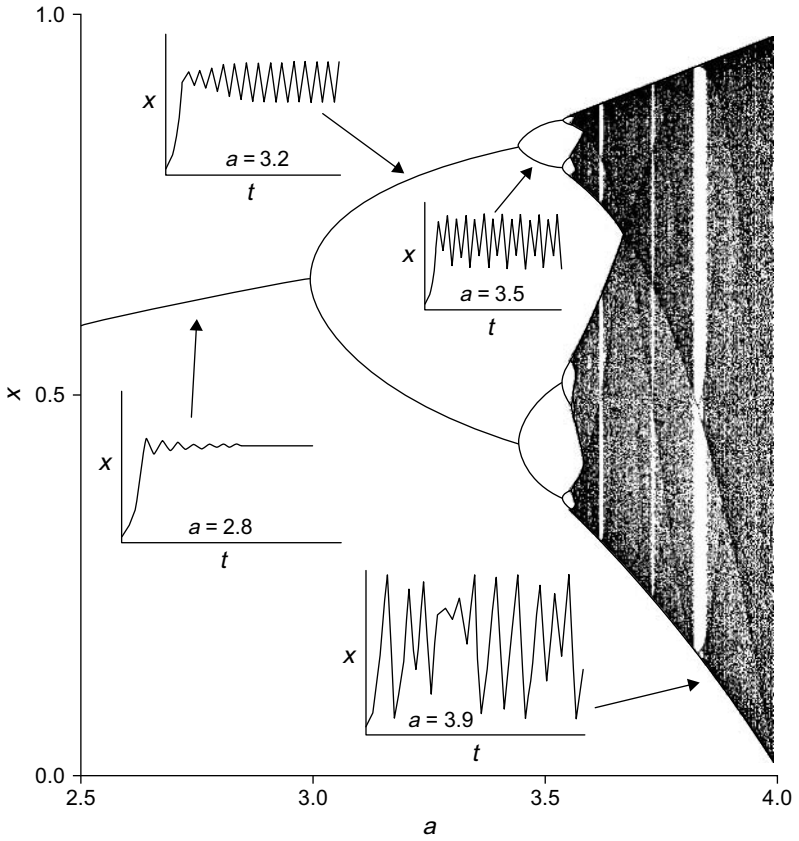

Figure 4 Behavior of the discrete logistic model of a population (x) changing in time (t), $x_{t+1} = ax_t(1 - x_t)$, as the intrinsic rate of increase (a) is varied. The graph shows the states of the population calculated from time 200 to 500 for values of 'a' from 2.5 to 4.0. When 'a' is below 3.0, the population reaches a single equilibrium (see inset for $a = 2.8$) so the graph of population states for time 200 to 500 is a single point. But as 'a' is increased, there are many thresholds, a type of bifurcation, where the behavior of the population changes qualitatively. Passing one such threshold, at $a = 3.57$, switches the system to chaotic dynamics. In this case the population changes erratically so it will be observed in many possible states, thus the dark bands lling in a range of 'x' values

values of the cycle become farther apart. At approximately 'a' = 3.4, there is another qualitative change where the population switches to a cycle with four different values (shown in the inset for 'a' = 3.5). Again there is a period of quantitative change until another qualitative switch occurs where the cycle has eight values. Eventually, at 'a' = 3.57, the dynamics become chaotic, illustrated by the inset for 'a' = 3.9. Surprisingly, there are islands of stable cycles within the potentially chaotic region. These appear as the largely white stripes in the figure for some values of 'a' above 3.57. This bifurcation diagram shows the great sensitivity of non-linear systems to changes in their parameters and many features of it are now known to be applicable to a wide range of more complex and realistic models. In the context of global change, the diagram illustrates that populations, and other kinds of systems, may suddenly change their qualitative behavior as parameters like temperature and precipitation change. Simple models of interacting predators and their prey have revealed that enriching the system, as might happen through increased nitrogen deposition or shorter winters, can cause a shift from a stable equilibrium to large cycles that are likely to cause extinction of both the predator and the prey (Rosenzweig, 1971). Even plant physiological processes may display sharp transitions from one type of behavior to another. The photosynthetic rate of a plant, e.g., has been observed to suddenly switch from stable oscillations to chaos as temperature is increased slightly (Luttge and Beck, 1992).

Traditionally, ecologists have assumed that ecosystems have relatively simple dynamics with a single equilibrium state. So, after a disturbance such as a fire, the ecosystem will go through a regular series of changes as the original ecosystem is gradually re-established. If climate were to change slightly, then the qualities of the ecosystem – species composition, total biomass, etc. – would change gradually and smoothly. However, this is only one way that non-linear systems can behave and we know that ecosystems are non-linear. So, the traditional wisdom is now less widely accepted and there is an increasing understanding that ecological systems can have much more complex dynamics including sudden quantitative or qualitative changes in response to gradual and smooth variation of the environment. The general conclusion is that non-linear systems can display abrupt changes from one equilibrium to another or from one mode of behavior to another (simple equilibrium to periodic, periodic to quasi-periodic, quasi-periodic to chaotic). Thus, system non-linearity implies that we cannot extrapolate one behavior, measured under a restricted range of external variables, to the full range. Instead we may be surprised that the behavior may change suddenly and qualitatively.

Odum, Eugene P

(1913-)

For more than 60 years, Eugene P Odum has taught both academicians and the general public the value of nature's goods and services, emphasizing that natural ecosystems provide the life support system for human societies.

Odum received his PhD with Charles Kendeigh at the University of Illinois, US, in 1939. After being turned down for about 30 college faculty positions, he took a job at the Huyck Preserve in upstate New York. A year later, he accepted a position at the University of Georgia, US, where he has remained and became an institution builder, setting up the Savannah River Ecology Laboratory in 1951, what is now called the Marine Institute at Sapelo Island in 1954, and the Institute of Ecology in 1961.

At a faculty curriculum committee meeting in 1945, when he proposed ecology as a required course for zoology majors and was asked What is ecology, anyway?, he decided to write a textbook. When a publisher balked, saying there were no general ecology courses and so no need for the book, his response was Let's create a market. In 1953, he published *Fundamentals of Ecology*. Soon, general ecology was taught at virtually every major college and university, and the book is now in its 5th edition. In addition to over 200 papers in scientific journals, he has written many popular articles and essays, and his latest publication, *Ecological Vignettes: Ecological Approaches to Dealing with Human Predicaments* (1998), is a book for the general reader.

In the field of biology, which has traditionally tried to learn about life by breaking it down into its parts, Odum has emphasized the importance of looking at how the parts work together to make a functioning whole. Many of Odum's earliest publications were fairly traditional studies of avian physiology and energetics, but by the early 1950s he began to study the physiology and energetics of whole ecosystems. Ever seeking ways of measuring ecosystem processes above the species level, he pioneered the measurement of the total rates of primary and secondary production, decomposition, and nutrient ow in aquatic and terrestrial ecosystems. He argued that ecosystems, like individuals, have homeostatic mechanisms that regulate energy ow and the recycling of nutrients. In *The Strategy of Ecosystem Development*, published in *Science* in 1969, he drew parallels between organismal development and ecological succession, pointing out the regularity of change in production and respiration over time. He also argued that, like individuals and species, ecosystems interact with one another, showing, for example, that the export of detritus from salt marshes is important to ocean productivity. Finally, drawing on examples of symbiosis in the plant and animal world, he argued that human ecology and economics are interrelated and that humans should recognize the value of nature's free goods and services and strive for a more mutualistic relationship with nature.

Formal recognition of Odum's contributions has been voluminous. He was elected to the National Academy of Sciences in 1970, he won the La Institute de la Vie Prize (jointly with his brother, H T Odum) in 1975 and the Tyler Award in 1977. In 1987 he received the Crafoord Prize from the Royal Swedish Academy of Science. This is often considered an equivalent to the Nobel Prize, which is not given in ecology. Other honors he has received are Georgia Scientist of the Year in 1967, Eminent Ecologist Award from the Ecological Society of America in 1974, and Educator of the Year from the National Wildlife Federation in 1983, plus over 45 teaching, service, and scientific awards and honorary degrees given by governments, clubs, conservation organizations, and universities.

I first met Eugene Odum in 1965. I was a sophomore in college, and he was already known as the Father of Modern Ecology. Although I was only a teenager, Professor Odum took me to lunch, shared his ideas with me, and listened to my ideas. Now at age 87, Gene looks more like a stately grandfather but he still has the youthful energy and keen intellect that have characterized his lifetime of contributions to science and society. About once a week I still go over to Gene's office in the Institute of Ecology to have lunch with this extraordinary man. He is a bit less sure-footed and much more bent over than he was in 1965, but his mind is as steady and straight as ever, and he is still excited about ecology.

OH–Radical: is the Cleansing Capacity of the Atmosphere Changing?

Guy Brasseur[1] and Ron Prinn[2]

[1]Max Plank Institute for Meteorology, Hamburg, Germany
[2]Massachusetts Institute of Technology, Cambridge, MA, USA

Many people consider the atmosphere's role in global change to be primarily associated with climate. However, human activities are also profoundly affecting the chemistry of the atmosphere in its own right, irrespective of the greenhouse properties of trace gases. One of the most important features of the atmosphere is its cleansing ability, its capability to transform a wide range of gases emitted from the Earth's surface. The primary chemical species responsible for this cleansing ability is the hydroxyl radical, OH.

The atmosphere is an oxidizing medium. Almost all hydrogen containing gases of natural and anthropogenic origin are oxidized by the hydroxyl (OH) free radical, a species often referred to as the detergent of the atmosphere. Other oxidation processes include reactions with ozone (O_3), hydrogen peroxide (H_2O_2), the nitrogen trioxide free radical (NO_3), and halogen species. Hydrogen peroxide, for example, converts sulfur dioxide to sulfuric acid in cloud and rain droplets at low pH, and hence contributes to the formation of acid precipitation. The nitrogen trioxide free radical plays a significant role at night, primarily in polluted areas.

The rate at which oxidation occurs varies widely from species to species. For example, the oxidation of methane typically takes nine years, while that of isoprene takes less than a day. Thus, even though the magnitude of the surface emissions of these two hydrocarbons is similar, their atmospheric burdens differ by several orders of magnitude.

The rate at which chemical compounds are eliminated from the atmosphere is very often not determined by the precipitation rate, but by the rate at which they are oxidized into a water-soluble compound. This oxidation rate therefore plays a central role in many global environmental problems. An important issue is to quantify any potential change in the oxidizing power of the atmosphere that may have resulted from human activities (Thompson, 1992).

Over the past decade and century, the oxidizing power of the atmosphere may have changed. For example, the increasing penetration of solar ultraviolet light in response to stratospheric ozone depletion and the increased emissions of NO_X and non-methane hydrocarbons from combustion tend to increase ozone and OH concentrations in the troposphere. Conversely, the increase in carbon monoxide emissions, which have also resulted from increased biomass and fossil fuel burning since the pre-industrial era, tend to reduce the ozone and OH abundances. Similarly, increases in the methane abundance due to increases in cattle, rice, and natural gas usage should have contributed to a decrease in the global OH concentration and therefore in the oxidizing power of the atmosphere.

Since there is presently no instrumentation for regional to global-scale observations of tropospheric OH, the change in the oxidation power of the atmosphere cannot be directly monitored. Estimates must therefore rely primarily either on model calculations or deductions using measurements of compounds destroyed by OH. Model calculations suggest that global tropospheric levels of OH have probably decreased significantly since the pre-industrial era. The quantitative value of this decrease varies from model to model, however, with figures ranging from 3% in the model of Lelieveld and Van Dorland (1995) to 22% in the model of Roelofs *et al.* (1997). Intermediate values of 9% are provided by Wang and Jacob (1998) and 10–15% by Crutzen and Zimmermann (1991). Earlier estimates based on one-dimensional models suggested a decrease, ranging from 10–30% (Thompson, 1992). The general consensus from modeling studies is that, despite the large increase in the emissions of carbon monoxide, hydrocarbons and nitrogen oxides, and the stratospheric ozone depletion during the 20th century, the partially offsetting effects of these factors implies that the globally averaged concentration of OH has remained relatively constant. Decreases probably do not exceed 20% (Wang and Jacob, 2000).

The analysis of the methylchloroform (CH_3CCl_3) observations performed since 1978 at several surface monitoring stations of the Atmospheric Lifetime Experiment/Global Atmospheric Gases Experiment/Advanced Global Atmospheric Gases Experiment (ALE/GAGE/AGAGE) (Prinn *et al.*, 2000 and references therein) provides an indirect method to derive trends in the global concentration of tropospheric OH. Methylchloroform's sources, which are purely anthropogenic, are believed to be very accurately accounted for. By combining the estimates of these sources with the methylchloroform measurements, little change in the OH density was deduced by Prinn *et al.* (1995) for the period 1978–1994 (specifically $0.0 \pm 0.2\%$ per year, 1s error range). A similar study by Krol *et al.* (1998) suggested a small increase in the OH density ($0.46 \pm 0.6\%$ per year, full error range) from 1978–1993.

In summary, recent analyses suggest that the oxidizing power of the atmosphere has remained relatively constant since the pre-industrial era, with a decrease in the OH concentration, and hence an increase in the lifetime of major primary pollutants (or greenhouse gases like methane) that have not exceeded 20%. On shorter time scales, the abundance of OH may have changed rather substantially, however; for example, in response to rapid ozone depletion in the stratosphere, uctuations in tropospheric water vapor, or in the emissions of nitrogen oxides or carbon monoxide (see, e.g., Madronich and Granier, 1992; Granier *et al.*, 1996). Future changes in the oxidizing power of the atmosphere will depend on future anthropogenic emissions and hence on future economic development and population growth.

Oligotrophic/Heterotrophic/Eutrophic

Oligotrophic/heterotrophic/eutrophic are terms that describe stages in the aging of aquatic ecosystems. They are usually applied to lakes and ponds but also to marine locations that are sufficiently sequestered to allow some degree of independence from the main body of the ocean. Freshwater aquatic ecosystems typically start as oligotrophic lakes, which have low nutrient levels and are consequently relatively unproductive. Oligotrophic lakes are characteristically pristine, have high oxygen levels and only small populations of plankton and fish. An input of organic materials (humus or pollution) may lead to a heterotrophic ecosystem, where a somewhat larger biotic component is supported by the external source of organic nutrition. Continuous enrichment of a lake with inorganic nutrients leads to the process of eutrophication. Eutrophic systems are highly productive, being characterized by heavy populations of plankton and of those fishes that thrive in polluted waters. Eutrophic lakes have much lower oxygen levels, and may be anoxic in their deeper waters; they have high levels of inorganic nutrients. Phosphate levels are especially helpful in characterizing their status: high or low phosphate contents respectively indicate the relatively stable oligotrophic or eutrophic condition; intermediate levels suggest an unstable system that is undergoing eutrophication.

The process of eutrophication is normal and natural, causing virtually all aquatic ecosystems slowly but inevitably to be converted into swamps and eventually to

dry land. But eutrophication is greatly speeded up by many human activities, so that pristine lakes are rapidly converted to ecosystems characterized by algal blooms, pollution and anoxia. Such an ecological succession involves major or almost complete replacement of the ora and fauna (including the species of both commercial and sport fishing) of the system, and results in very large increases in the rates of deposition of both organic and inorganic material.

PAR (Photosynthetically Active Radiation)

PAR is light of the specific wavelengths that are absorbed by the photosynthetic pigments of plants or bacteria and whose energy is trapped and used to drive photosynthesis. In most green plants the chlorophylls are the primary PAR absorbing pigments of photosynthesis. They absorb mainly in the red (620–720 nm) and blue (380–480 nm) regions of the spectrum. In red and brown algae and many photosynthetic bacteria, the phycobilin pigments (absorbing in the range 500–650 nm) are also photosynthetically active. Carotenes (420–540 nm) may transfer some of their absorbed energy to the photosynthetic pigments, but much of the light energy absorbed in the 500 nm region is not available for photosynthesis.

In most land plants, the important PAR is light at the blue and red end of the spectrum (absorbed by chlorophylls). Marine algae are faced with a problem in that red light is much more strongly absorbed by water than light of shorter wavelengths, and these plants have adapted in varying degree to overcome this difficulty. The green algae, which live mainly near the surface, rely primarily on chlorophyll for photosynthetic light absorption. Brown algae, whose range of PAR is substantially shifted toward the blue end of the spectrum, tend to live in deeper water. The red algae, whose pigments absorb more strongly in the blue region, live in the greatest depths of water, down to 200 m.

Not all light absorbed by plants is PAR. Higher plants, in particular, contain small concentrations of a range of pigments that are sensitive to daylength or that stimulate the hormone mechanisms that control morphology (e.g., phototropism). Other non-photosynthetic pigments whose precise physiological roles are often difficult to determine may be present in large amounts (e.g., carotenes, anthocyanins). They may create spectacular colors in plants or their parts, but they are not involved in photosynthesis.

R G S BIDWELL *Canada*

Passerine

Passerine refers to birds of the order Passeres or Passeriformes (perching birds). This large order includes about half of the known bird species, including most of the common land birds. The term is sometimes used to refer to sparrows, which are members of the Passeriformes, and is occasionally applied (descriptively rather than scientifically) to birds that resemble a sparrow or are approximately sparrow size (e.g., Passerine Owl, Passerine Parrot).

PET (Potential Evapotranspiration)

The term PET was introduced into the climatic literature in the mid-20th century by three scientists working independently: Thornthwaite in the United States, Penman in England and Budyko in the USSR. They recognized that two aspects of evapotranspiration must be identified. *Actual evapotranspiration* is the water that evaporates and transpires under existing soil moisture conditions, while *potential evapotranspiration* (PET) represents the amount of water that would be lost by evaporation and transpiration from a large vegetation-covered surface if an unlimited supply of water were to exist. All three realized that PET depends primarily on the evaporation equivalent of the available net radiation. Penman and Budyko derived formulae for estimating PET using data on net radiation, humidity and wind speed. However for most locations throughout the world, data on these parameters are not available.

Thornthwaite in the United States was aware of this problem and devised a method of estimating PET from data on temperature and length of day only. His formula was based on the use of water by irrigated crops in different parts of the United States, and monthly values of PET could be readily calculated from published tables and nomograms. PET was the central concept in his water budget model in which PET was compared with water supply (precipitation plus soil moisture) to derive estimates of actual evapotranspiration, water surplus and water deficiency. As computer programs of the water budget became available, it has been used worldwide by hydrologists, engineers, botanists and geographers to estimate actual evapotranspiration, water surplus and water deficiency.

PET can be measured directly by an evapotranspirometer, a Thornthwaite-designed instrument in which a block of soil with vegetation-covered surface is kept supplied with water by underground irrigation. Results from evapotranspirometers installed in various regions of the world indicate good agreement with computed PET in most areas.

Phenology

Martin J Lechowicz
McGill University, Montréal, Canada

Phenology is the study of the seasonal timing of events in nature: when flowers bloom, trees leaf out, birds migrate, animals hibernate, fish spawn, phytoplankton blooms, lakes freeze, and the like. Phenology is not concerned with events such as the solstices and equinoxes that are determined by astrophysical laws – these vary only slowly and predictably over millennia. Events that are influenced by climatic factors, on the other hand, are far more variable and less predictable from year to year. Organisms able to survive in a given climate must respond effectively to the vagaries of day to day weather during the seasonal cycle. The advance of spring warming is an expected and normal part of high-latitude climates, but no one expects the end of winter to begin on a particular date year after year or to follow a specific sequence of ever-warmer days until summer arrives. Phenological records thus can provide an integrative index of weather through the seasons, a capability that is becoming increasingly valuable in gauging trends indicative of changing climate.

Long before scientific interest in phenology arose in the 19th century, people had paid close attention to the seasonal timing of natural events. Some phenological events associated with cultural and religious festivals have been recorded for a very long time; annual records for the flowering of cherry trees in Kyoto, Japan date back to the 9th century. Before weather records and weather forecasting existed, the everyday lives of people depended on closely observing the timing of natural events. The return of migratory birds or the leafing of a particular species of forest tree could provide a reliable signal of when best to plant a frost-sensitive crop. Calendars of the seasons, collating this sort

of folk knowledge, began to appear in the 18th century and at about the same time, individuals and governments began to formally observe and record phenological events. The Marsham family recorded daily phenological observations at their estate in Norfolk, England from 1736 through 1925! Many, shorter series of phenological records are available, especially for sites in the north temperate zone.

The scientific study of phenology initially focused on the relationship between weather and the timing of events. Can we predict the timing of events from our knowledge of the response of an organism to a progression of weather conditions? Yes, to a considerable degree we can, usually with an accuracy of a few days. For example, it is possible to predict the timing of leafing out or flowering in most trees within 2–5 days from place to place and year to year. We also have some understanding of the reasons why different species in the same locality do not all have exactly the same phenology. Due to differences in functional organization conserved in evolution, each species at a locality responds to changing climatic conditions somewhat distinctly.

More recently, the scientific study of phenology has shifted to questions of how phenology will be affected by global change, and what consequences any changes may have for species distribution and ecosystem function. An important impetus to this shift was the recent discovery that modest changes in the length of the season when plants are actively photosynthesizing can significantly alter the storage of carbon. A forest at high latitudes can be a net sink or a net source of atmospheric carbon dioxide by virtue of a week more or less in the length of the growing season. In other words, there are feedbacks between phenology and factors affecting the global carbon balance that may act to accelerate or decelerate rates of climate change. The study of phenology therefore has taken on new urgency and scientific significance as we struggle to understand the nature and consequences of climate change.

BRIEF HISTORY OF PHENOLOGY

The modern roots of phenology as a science are in the careful observations of naturalists in the 18th and 19th centuries, Gilbert White and Henry David Thoreau being perhaps the best known among them. In these times, in fact, many people engaged in regular observation of phenological events. The daily records of the Marsham family, noting the seasonal activity of birds and plants in central England (Sparks and Carey, 1995), span the period between 1736 and 1925. Thomas Mikesell, a farmer in Ohio, made meticulous, twice-daily records of weather and phenology between 1883 and 1912 (Lechowicz, 1995). Long-term data sets of this sort exist in moderate amounts, usually for only single localities. Naturalists have continued a tradition of phenological observation into this century (Fitter *et al.*, 1995; Bradley *et al.*, 1999), and their efforts have been augmented by the collection of phenological data in various scientific and government networks with greater spatial coverage (Ahas, 1999; Bruns, 1996). For example, the Royal Meteorological Society (UK) published phenology data regularly for at least 75 years, terminating about 1945.

FACTORS AFFECTING PHENOLOGY

The precise timing of events in the natural cycle of the seasons often determines the success or failure of individual plants or animals. Many migratory birds must lay eggs in advance of the availability of ample food for their young, but neither so early that hatchlings want for caterpillars nor so late that the young are not ready to migrate in advance of winter. Deciduous trees burst bud only when the risk of late frosts is low, but not so long into summer that their annual period of photosynthetic activity is much diminished. In the seasonal tropics, many trees flower during the dry season with their fruits maturing in time for seedlings to establish themselves with the onset of the rains. In all these instances, the timing of phenological events must respond to environmental cues that presage future conditions, usually with allowance for the costs and benefits of alternative timing of an event. An exception is in events such as blooms of oceanic phytoplankton, which have very short life cycles and simply respond rapidly to periods of high irradiance in less cloudy weather when water temperatures are adequate (Townsend *et al.*, 1994).

Although the diversity and complexity of phenological responses are impressively great, the environmental cues on which phenological events depend are relatively few. Phenological cues fall into two basic classes: photoperiodic and climatic. Temperature influences predominate among the climatic cues, although precipitation and irradiance regimes sometimes also play a role. The photoperiodic and climatic signals differ in their nature and in their utility for gauging environmental conditions later in the annual cycle.

Photoperiod, the length of the day relative to the night, changes at different latitudes in a very predictable cycle through the year. The tilt of the Earth's axis of rotation and its orbital path around the sun determine the seasonal progression of photoperiod. As a consequence, photoperiodic cues in a locality are essentially invariant from year to year. Day length will begin to increase after the winter solstice, reaching 12 hours on the vernal equinox and getting steadily longer until the summer solstice; then the cycle reverses with shortening days until the winter solstice passing through 12 h of daylight on the autumnal equinox. The annual amplitude of variation in photoperiod does vary from place to place, being near zero in equatorial regions and increasingly greater toward the poles. Organisms in a given locality thus can use photoperiod to reliably gauge the time of year.

The problem with photoperiod alone as a phenological cue is that climate is nowhere entirely predictable within or among years. Just knowing the time of the year is insufficient to evaluate the likely environmental conditions in the weeks or months ahead. Lengthening days can cue the onset of spring, but not whether the spring will advance quickly or slowly, or be especially warm or cool. Organisms thus use temperature, and sometimes water, regimes to better estimate the progression of seasons in a given year and locality. These climatic signals are useful cues for phenological events, but are also not entirely reliable. Changes in atmospheric circulation may indeed bring an earlier than usual onset to spring warming, but not necessarily preclude a late freeze. Nonetheless, there is enough coherence in weather over weeks and months in a given year that recent events can help anticipate future conditions.

Many organisms outside the tropics seem to depend on short-term (2–12 week) temperature trends as the most reliable aspect of climate for assessing seasonal changes and triggering phenological responses. Phenological events in spring, for example, often can be predicted from heat sums, which are a measure of the accumulation of warmth above a base temperature. Phenological events occur when a certain heat sum is attained. Thermal summation may begin after some requisite degree of chilling obtains, or when a photoperiodic cue is satisfied. In some instances, the heat sum required to trigger the event is contingent on the degree of prior chilling or the length of the photoperiod. For example, longer chilling of trees can reduce the heat sum required for flowering. Similarly, some oak trees will leaf out at a lower heat sum as the days become longer. Photoperiod becomes a more dominant cue later in the season but some influence of warming or chilling trends persists. The formation of flower buds is often set by quite precise photoperiodic signals, but flowering itself depends on the temperature regime (Fitter *et al.*, 1995). Similarly, egg-laying by birds is set by a combination of photoperiodic and climatic cues, including indirect effects of temperature regime on the availability of insects to feed hatchlings (Visser *et al.*, 1998). The physiological means by which organisms actually monitor and respond to these sorts of direct and indirect influences of chilling, warming and photoperiod are poorly known. We can use photoperiod and weather data to predict phenological events, but without any sure understanding of underlying mechanisms (Hunter and Lechowicz, 1992; Chuine *et al.*, 1999).

In tropical regions, seasonal variations in photoperiod and temperature are less marked than at higher latitudes, but precipitation can be strongly seasonal in some regions (Corlett and LaFrankie, 1998). Although most tropical trees have consistent and fairly well defined flowering times during the year, the environmental cues that trigger flowering are not well known. Some trees flower and fruit when there is a recharge of tissue water either through the onset of rains or when the dropping of leaves in the dry season places less transpirational demand on the tree, but this is not a universal phenomenon (Wright and Calderon, 1995). Flowering and fruiting typically occur throughout the year on one species or another in tropical ecosystems, with the adaptive value of timing of flowering for each species obscure. The phenology of tropical species is too little studied to support broad generalizations (Corlett and LaFrankie, 1998).

PHENOLOGICAL VARIATION WITHIN COMMUNITIES

Species of generally similar organisms in a locality do not usually share exactly the same phenology. This is because phenology is only one element in each species suite of adaptations to the local environment. Take as an example, the warm- versus cool-season grasses that co-occur throughout the North American Great Plains (White *et al.*, 1997). The cool-season grasses are green and actively growing in the cool and moist weather of fall and spring, but brown and dormant in summer. The warm-season grasses conversely only begin greening up in late spring and are actively growing during the warm, dry summer months. The warm-season grasses have C_4 photosynthetic metabolism, well suited to warm, dry conditions but sensitive to chilling. The cool-season grasses have C_3 photosynthetic metabolism, well suited to cool, moist conditions but sensitive to drought. The contrasting phenology of the warm- and cool-season grasses is part of an integrated suite of traits that defines their functional ecology. There are, of course, also phenological differences among species within each functional group, but these are relatively minor variations within the basic dichotomy. The two groups of grasses together lengthen the effective period for photosynthetic production in the prairie ecosystem.

The phenological differences among co-occurring species sometimes can become more diverse and less easy to characterize by simple dichotomies. Consider, for example, the situation in a mixed wood at mid-latitudes where two functional groups of trees share dominance in the community. Deciduous species are leafless over winter, with individual leaves having longevity measured in months. Evergreen species keep leaves over the winter, with individual leaves having longevity measured in years. The two groups are apparently well defined by the sharp distinction in their overwintering leaf habit, but, in fact, they fall along a continuum of variation in leaf longevity that organizes their production ecology (Reich *et al.*, 1997). Evergreen and deciduous species overlap in their timing of production of new leaves in spring and early summer, both within and between the two apparent functional groups. Such differences in foliar phenology among co-occurring tree species are linked to evolutionary and paleoecological as well as

functional considerations unique to each individual species (Lechowicz, 1984). This individualistic nature of species phenology complicates the analysis of the impact of changing climate on community composition and ecosystem function. As climate shifts, we can expect that relationships among species differing in phenology may also shift, both in terms of competitive and trophic interactions (Harrington *et al.*, 1999).

PREDICTING THE EFFECTS OF CHANGING PHENOLOGY

We can imagine three basic responses of species to a reasonably gradual climate change. First, species may migrate to remain in climatic regimes to which they are phenologically well adapted. There is good evidence that such migrations have occurred during deglaciation. As glaciers retreat and climatic zonation shifts to higher latitudes, the formerly glaciated landscape has been colonized by species better suited to north temperate, boreal and arctic regions that have migrated from glacial refugia now subject to increasingly warm and less strongly seasonal climates. Second, species subject to a changing climate may not migrate to track their favored climatic regime, but rather stay in place and adjust to changing conditions. In terms of phenology, there is always a certain degree of variation among individuals within populations in their responses to environmental cues for seasonality. From an evolutionary point of view, we expect the maintenance of such variability among individuals as a form of bet hedging against normal patterns of year to year climatic variability. We, therefore, can expect the average timing of a phenological event in a particular species to track climate change provided the ongoing changes do not exceed the previous range of climatic variability. A simple shift in the balance of phenologically early or late individuals in a population can then accommodate the shift in climate; over sufficient time the shifting advantage of different phenological variants within the population may affect a genetically determined adaptive shift in the phenology of the species. Finally, species may simply fail to accommodate effectively to changing climate, perhaps becoming much less dominant in a locality or even going locally extinct. It is difficult to know with any certainty what effects these diverse changes at the species-level may have at the community and ecosystem levels.

RECENT SHIFTS IN PHENOLOGY ASSOCIATED WITH CHANGING CLIMATE

Since phenology is so closely linked to weather conditions, trends in phenology may serve as natural indicators of an ongoing climate change. Where we have suitable records over reasonably long periods of time, we can directly evaluate the degree to which recent climatic trends have influenced phenological events. Various phenological observations do suggest a climatic warming trend in recent decades in some parts of the world. This is the case for leafing of trees, timing of flowering, and egg laying by birds, and spring migration by both birds and butterflies. Modeling (White *et al.*, 1999), ground (Menzel and Fabian, 1999) and satellite observations (Myeni *et al.*, 1997) all support a recent increase of about 8–10 days in the period when mid-latitude forests of Europe and North America are in leaf. This lengthening of the growing season results primarily from earlier springs, but also a later onset of winter. The increasing earliness of spring has also been manifest in advances in the leafing and flowering of many individual plant species (Fitter *et al.*, 1995; Sparks and Carey, 1995; Bradley *et al.*, 1999). Egg laying in 36 species of birds in the United Kingdom has become earlier in recent decades (Crick and Sparks, 1999) as has the spring arrival of migrant species (Sparks and Carey, 1995; Sparks, 1999). These results suggest that recent climate warming may be having widespread impact on the phenology of many species, which can potentially alter biotic interactions at the community and ecosystem levels. While there are some observable changes in ecosystem function (Myeni *et al.*, 1997; Menzel and Fabian, 1999) and some butterfly species have shifted their ranges poleward (Parmesan *et al.*, 1999), there is no evidence at this time that global systems are being disrupted by widespread species migration or extinction associated with climate change. The real question is whether or not climate change has begun that in time will lead to such reorganization of biota and major shifts in global ecosystems.

PREDICTING LONG-TERM PHENOLOGICAL RESPONSES TO CLIMATE CHANGE

Climate may change in two respects, quantitatively in its regional expression, or qualitatively in its basic seasonal structure. Each has quite different potential consequences for species and ecosystems. A quantitative shift in local climate, provided it is neither too rapid nor too great, may have only negligible influence on species distribution and ecosystem function. Species may simply respond to their usual cues, perhaps prospering by a longer growing season or shifting their range to track their preferred climatic regime. It is unlikely that modest quantitative shifts in climate will dramatically alter community composition or ecosystem function. This sort of modest quantitative change seems to characterize our present situation. On the other hand, qualitative shifts in the nature of the seasonal cycle have greater potential to disrupt phenological responses in a community in ways that more rapidly disrupt ecosystem function. If the basic nature or stability of the seasonal cycle is altered by climate change, then cues evolved in

an earlier climatic regime may no longer lead to effective phenological responses. Even if the cues remain consistent with evolved phenological responses, any increase in the variance of climatic regimes poses a serious risk. Extreme events such as an early winter storm can extirpate populations adapted to a reliable progression of fall weather. There is evidence that global patterns of seasonality are reasonably stable from year to year, at least at the coarse temporal resolution afforded by satellite data (Potter and Brooks, 1998). We do not know whether more precise data would reveal trends in seasonality with adverse implication for the adaptive value of contemporary phenological responses. The greatest challenge of global change to contemporary biological systems may not be a gradual shift in average climate over time, but rather the possibility of qualitative shifts in the nature and stability of seasonality.

Phenotype/Genotype

The *phenotype* is the sum of the characteristics that are expressed by an organism; that is, its appearance. The *genotype* is the genetic constitution, the sum of all the genes present in an organism; that is, its heredity.

The phenotype of an organism is dependent to a large extent on its genes. Indeed, the phenotype of an organism changes with its development, and it may be affected by environmental factors. However, the development of the organism and the manner in which it reacts to environmental stimuli are programmed by the genotype. The phenotype is thus a product of the interaction of the genotype with the environmental factors it encounters during its lifetime. The

resulting variability in the appearance of organisms with the same genotype is referred to as *phenotype plasticity*.

The genotype of an organism is constant, or nearly so, during the organism's life, and is normally received at fertilization as a contribution from both its parents. Some organisms reproduce asexually (e.g., bacteria, primitive plants) or by apomyxis (in some higher plants, e.g., certain *Rosaceae* and *Compositae*, pollination takes place but fertilization does not, and the embryo develops from the egg cell only) or by natural cloning; these receive the unchanged genotype of only one parent. Changes in genome during the life of an individual normally occur only by genetic mechanisms involving actual changes in the genes (e.g., mutations) or their reassortment (e.g., by recombination).

It is possible for organisms to have the same genotype but different phenotypes because of developmental or environmental factors. It is also possible for organisms to have the same phenotype but different genotypes. This could occur, for example, if organisms were either homozygous or heterozygous for a dominant allele, which would be expressed equally in either case. But these possibilities do not alter the fact that the phenotype of an organism depends largely on its genotype.

Phosphorus Cycle

H Tiessen and John W B Stewart
University of Saskatchewan, Saskatoon, Canada

Phosphorus (P) is an essential component of all organisms, with both genetic information and energy metabolism depending on phosphorus. Nitrogen (N) and phosphorus are the principal nutrients limiting biological production, but the fixation of atmospheric nitrogen into biomass depends on an adequate phosphorus availability, so that phosphorus can be said to be the single limiting determinant of ecosystem productivity and function. Phosphorus is liberated from primary rocks, is relatively abundant in young landscapes and becomes scarce with the weathering of soils. Organisms contain phosphorus at concentrations much higher than those present in the environment and have therefore evolved mechanisms of acquiring, concentrating and recycling phosphorus. The need for efficient use of phosphorus has also prompted human populations to evolve elaborate management for maintaining phosphorus fertility in agriculture, recycle nutrients and limit phosphorus oversupply from wastes, particularly in aquatic ecosystems. Improvements in management are still needed if increasing populations are to manage their environments sustainably.

Phosphorus is the 11th most common element with an average abundance of 1200 mg kg^{-1} in the Earth's crust. Phosphorus is released from rocks to soils during weathering, and in natural ecosystems, phosphorus is cycled between inorganic and organic compounds (Figure 1) so that phosphorus concentration in the soil solutions (and therefore phosphorus availability to plants) is controlled both by physical chemical reactions such as sorption/desorption and precipitation/dissolution and by biological processes such as immobilization (uptake by plants and microorganisms) and by mineralization (decomposition of residues). Inorganic phosphorus forms are associated with calcareous compounds and amorphous and crystalline iron and aluminum oxides. Overall, soil pH is the main property controlling inorganic phosphorus forms with Ca compounds dominating phosphorus sorption in neutral and alkaline soils. In acid soils, amorphous and hydrous oxide forms of aluminium (Al), iron (Fe), and manganese (Mn) dominate phosphorus sorption processes. Organic forms include relatively labile biochemical compounds and more resistant humified materials. The forms generalized in Figure 1 are not discrete entities, as intergrades and dynamic transformations continuously occur among them.

Thus, if phosphorus were not removed from natural ecosystems, these cycling processes would ensure that phosphorus remained in the system for reuse. However, as the earth's crust weathers to form soils, over time both total phosphorus and solution phosphorus contents decrease. This change in total phosphorus is brought about mainly by a combination of plant phosphorus removal, phosphorus associated with erosion and run-off, and leaching so that extremely weathered and eroded soils may contain as little as 50 mg kg^{-1}. More commonly the range in soils is between 200 and 800 mg kg^{-1}. There is no direct correlation between total phosphorus and solution phosphorus as the latter property depends on several soil properties as illustrated in Figure 1.

At higher latitudes, soils have been regularly rejuvenated by the mixing-in of unweathered rocks during glacial periods with the most recent ice age being approximately 10–12 000 years ago. As a result, soils in these regions are more fertile than tropical soils, and continue to be highly productive despite the fact that they have supported agriculture for long periods.

On the stable land surfaces of the tropics, weathering has further advanced, and total phosphorus content has been continuously depleted by erosion and leaching, resulting in low phosphorus availability to plants. Since phosphorus limits nitrogen fixation and the uptake of other nutrients, such phosphorus-limited ecosystems are in general more fragile. Gardner (1990) estimates that release

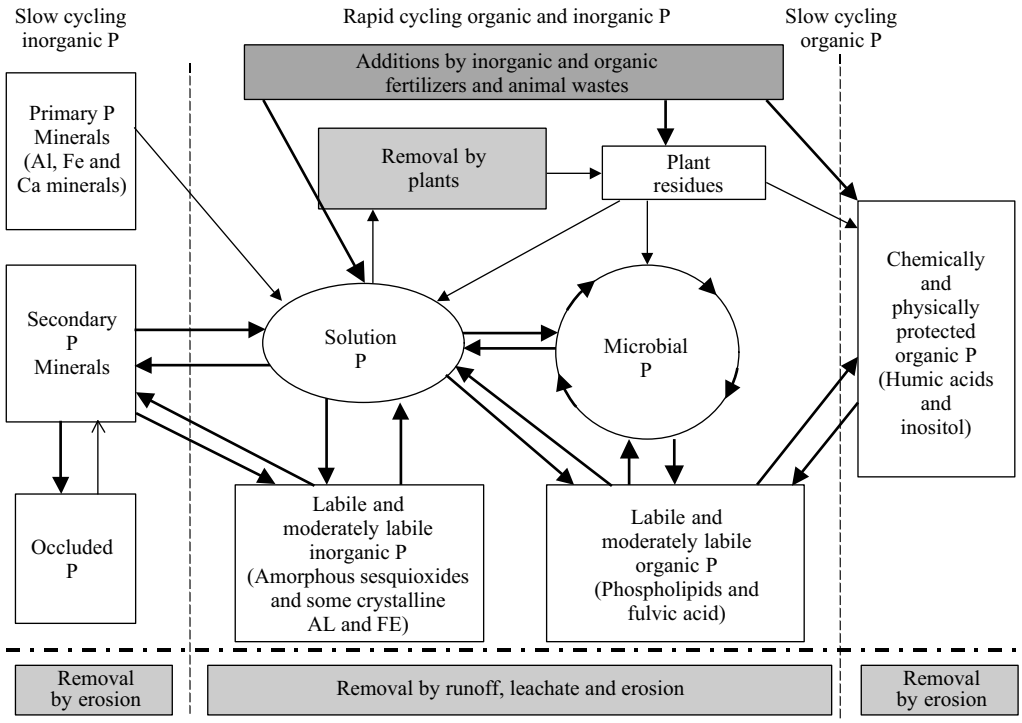

Figure 1 The soil phosphorus cycle: its components, forms and flows. (Adapted from Stewart and Tiessen 1987)

of phosphorus from rock weathering is in a range from 0–1600 moles km^2 $year^{-1}$ ranging from 163 for a temperate US site to 242 for the low-fertility Rio Negro basin and to 457 for the Amazon basin. Inputs into this ecosystem from aerial deposition is approximately 800 moles km^2 $year^{-1}$, and export from the three watersheds is 256, 820 and 4490 moles km^2 $year^{-1}$ respectively. This shows the large net export from the Amazon basin. Export is dominated by particles, with only a small portion of the phosphorus present in solution. Many of the enduring civilizations of warmer regions are associated with valleys, in which the soil resource is frequently renewed by sediments.

Farther downstream of such valleys, coastal seas receive large amounts of sediment-bound and dissolved phosphorus. Globally some 33 Tg P $year^{-1}$ are estimated to be discharged into oceans, of which some 15–20 Tg P $year^{-1}$ are carried by rivers and the remainder is coastal runoff (Howarth *et al.*, 1995). The bio-available portion of phosphorus in fluvial transport is estimated to be approximately 2 Tg $year^{-1}$. This quantity reaches estuaries and coastal seas, where it is responsible for the high productivity of near-shore waters. Water of the high oceans contains only 0.01 mg l^{-1} of phosphorus, and phosphorus is critically limiting productivity of these waters.

In addition to the chemical weathering and transport of phosphorus from land to eventually the seas, phosphorus enters into biological transformations. Biological materials concentrate phosphorus above average environmental levels, so that seeds or grains contain 400 mg kg^{-1} and mammals 25 000 mg kg^{-1} (on a dry weight basis). An example of the ability of organisms to accumulate phosphorus against a concentration gradient from their environment is the uptake of phosphorus by plants. Phosphorus concentrations in soil solution are near 0.1 mg l^{-1}, phosphorus concentrations in xylem sap, which transports nutrients from plant roots to tops, are near 100 mg l^{-1}, a concentration factor of 1000. High levels of phosphorus in the environment are therefore commonly indicators of present or past biological activity and the accumulation of biological residues. Some of the highest natural phosphorus concentrations are found in rock phosphate, which has an average phosphorus content of 144 000 mg kg^{-1}. Most deposits of rock phosphate are the product of the sedimentation and accumulation of marine organisms.

Plant and animal production therefore creates hot spots of phosphorus concentration and accumulation, and phosphorus loads in the environment are closely correlated with human occupation. A long-term record of diatom populations in the sediments of an English lake has shown the effects of 6000 years of agricultural and urban development (Anderson, 1997). The shift from slash/burn agriculture of the Neolithic period to more sedentary agricultural production in the early Bronze Age increased phosphorus loads in the lake water from 33–220 µg l^{-1} $year^{-1}$. A similar increase was observed in an Austrian lake caused by deforestation during the early Bronze Age, when phosphorus

concentrations increased from less than $10 -> 100\,\mu g\,l^{-1}$. The levels in the English lake increased further during the medieval period due to the development of towns with their effluent point sources of phosphorus. In the Canadian province of British Columbia, diatom records in lake sediments show a significant phosphorus enrichment since 1850, the time of European settlement. The advent of phosphorus fertilizers and concentrated livestock production in some areas has greatly increased phosphorus loads in surface waters.

Phosphorus inputs into fresh waters can accelerate eutrophication and impair water quality by restricting water use. Due to increased growth of algae and aquatic weeds and resulting oxygen shortages due to their decomposition, fresh water can be rendered non-drinkable and inland lakes made unusable for fisheries, recreation, and industry. Remedial action in such cases has focused on the role of phosphorus although nitrogen and carbon also are essential for the growth of aquatic biota. This is due to the difficulty in controlling the exchange of nitrogen and carbon between atmosphere and water and fixation of atmospheric nitrogen by blue–green algae (Sharpley and Rekolainen, 1997). An example of phosphorus flux in one Swedish lake watershed (Ryding *et al.*, 1990) illustrates the different components of an environmental phosphorus budget: inputs are up to 62% from fertilizer, 30% from manure, 5% from sewage, 2% atmospheric deposition and 0.3% from the natural weathering of rocks. Outputs are 93% crop exports, 6% due to arable erosion and 0.6% ground water export. Total inputs are three times greater than outputs, i.e., the watershed shows a net phosphorus retention. This is typical of many watersheds. Another example illustrates that since 1945, phosphorus has increased in rural Irish lakes by $1–2\,\mu g\,l^{-1}$ each year. This is related to increases in soil phosphorus levels by $10\,kg\,ha^{-1}$ each year from both inorganic fertilizer addition and an extensive use of animal manure. Since the mid-1970s when most point sources of sewage input to rivers were eliminated, dissolved reactive phosphorus, the most bio-available form, has increased in lakes by $1.5\,\mu g\,l^{-1}$ each year (Foy *et al.*, 1995; Withers *et al.*, 2000). This has been attributed to high livestock concentrations in neighboring farmland and extensive use of fertilizer and animal manure.

At the global level, some $10 \times 10^6\,Mg\,year^{-1}$ of phosphorus were traded and transported between world regions in the late 1980s (Beaton *et al.*, 1995), and a comparable amount was used as fertilizer. World trade movements of phosphorus were estimated to be 81% in fertilizer, rock or phosphoric acid, 15% in plant and 1% in livestock commodities. Since trade flows are uneven between world regions and since much of the traded phosphorus originated from mined deposits, these figures imply a significant enrichment of the earth's surface with phosphorus and also an important regional concentration of that phosphorus.

Soils commonly contain less phosphorus than they can hold, i.e., they contain active phosphorus sorption sites and are normally deficient in phosphorus relative to the requirements of crops. This phosphorus deficiency varies with soil type, ranging from $<1\,kg\,ha^{-1}$ in aridisols to $200\,kg\,ha^{-1}$ in oxisols and $300\,kg\,ha^{-1}$ in andosols. Oxisols cover large areas in the tropics and subtropics and account for 50% of the world phosphorus requirements for crop production. In many phosphorus-deficient tropical regions too little phosphorus is used for optimum crop production, because the high phosphorus-fixation and high phosphorus requirements together with low purchasing power of farmers in developing countries severely limit investment in fertilizers. On the other hand, too much phosphorus accumulates in regions with large and wealthy populations, which import both fertilizers and other phosphorus-containing commodities. Although most watersheds will show a net phosphorus retention even at substantial phosphorus inputs, they are leaky, and rates of phosphorus export are higher after phosphorus application than the natural levels. Exports of phosphorus from watersheds are thus related to population density: A regression performed on major rivers and their watersheds by Caraco (1995) showed loss rates of $0.3\,kg\,P\,km^{-2}$ at a population density of $0.1\,km^{-2}$, rising to $30\,kg\,P\,km^{-2}$ at $300\,km^{-2}$.

Some 10% of phosphorus export from land occurs by leaching and ground water transport, while 90% is transported by overland flow as sediment or dissolved phosphorus. Despite the small proportion of leached phosphorus, it has a greater effect on eutrophication of receiving waters because it is soluble and therefore easily available to biota. Phosphorus losses by over-land transport range from 0.1 to $10\,kg\,ha^{-1}\,year^{-1}$, or more on highly erosive sites. Not all site losses are exported from a watershed, because part of the sediment may be redeposited and part of the dissolved phosphorus may be resorbed within the watershed. On average, surface runoff waters carry $10\,\mu g\,l^{-1}$ of dissolved and $1000\,\mu g\,l^{-1}$ of sediment phosphorus (Melak, 1995). Often, sediment is phosphorus enriched relative to the source soil. While phosphorus is transported downstream, sedimentation and resuspension occur. The concomitant movement and recycling of phosphorus results in a spiraling of phosphorus as it moves down rivers. Spiraling varies along the stream and it is therefore difficult to quantify phosphorus fluxes, just as it is difficult to quantify phosphorus loads in a lake where phosphorus is released from the sediment when solution phosphorus is diminished. Best estimates (Howarth *et al.*, 1995) of river input of phosphorus to the ocean ranges from $21–30\,Tg\,year^{-1}$. The ultimate fate of most phosphorus entering the ocean is burial in sediments although a small amount of the total phosphorus is harvested in fish catch. Filippelli and Delaney (1994) used sediment core analysis to show a large decrease in the rate of phosphorus deposition in Pacific sediments over the past

five million years. The changes in sediment phosphorus were attributed to redistribution of phosphorus between high and low latitudes, to shifts between oceans and to changes in sea level. Phosphorus accumulation rates ranged from 5–60 μmoles P cm^{-2} 1000 $year^{-1}$. These figures could not be reconciled with continental weathering rates.

During these transformations and transfers, phosphorus activates biological production and biological cycles of other elements. The capacity of many ecosystems to sequester extra carbon dioxide (CO_2) depends on an adequate supply of phosphorus, and phosphorus is a key requirement for nitrogen fixation from the atmosphere by legumes. The key processes involved in the cycling of carbon, nitrogen, phosphorus and S have been the subject of many investigations (Bolin and Cook, 1983), continue to be a major part of ongoing International Geosphere–Biosphere Program (IGBP) investigations of ecosystem and atmospheric chemistry, and have been incorporated into predictive ecosystem models. Because of the interacting nature of these processes and controls, models of organic matter change and equilibrium under disturbance and management such as CENTURY (*see* **CENTURY Ecosystem Model**, Volume 2) are being applied worldwide to evaluate different management strategies.

ANTHROPOGENIC ENVIRONMENTAL CHANGE AFFECTS NATURAL PHOSPHORUS TRANSFORMATIONS AND TRANSFERS

The accelerating changes to the Earth's environment are being driven by growth in the human population, by the increasing level of resource consumption by human societies and by changes in technology and socio-political organizations (IGBP, 1997; Vitousek *et al.*, 1997). Four aspects were considered by IGBP under the term global change: (1) changes in land use and land cover; (2) the worldwide decline in biodiversity; (3) changes in atmospheric composition especially the rise in CO_2 concentration, and (4) changes in climate. From the perspective of the phosphorus cycle we know most about impact of changes in land use and cover. These can be summarized as follows:

1. Increased food demand from old, weathered, often tropical soils has reduced the fertility of these soils beyond the traditional capacity for regeneration (such as under shifting cultivation) and land degradation is evident. Phosphorus availability in these soils is very low and will not sustain a larger population without extra phosphorus inputs.
2. Fossil sedimentary phosphorus is mined and reintroduced into terrestrial production systems (principally high-input agriculture), where it activates biological systems and their element cycles.
3. Phosphorus-containing agricultural and industrial products are transported and concentrated in industrialized regions. The impact on water quality in these regions is greatest and already there are signs that several agro-ecosystems are unable to contain all the added phosphorus.
4. High-input agriculture increases phosphorus demands and speeds up phosphorus transformations and transfers.
5. Runoff and transported sedimentary phosphorus and nitrogen are reflecting increasing anthropogenic loads and are causing eutrophication of some near-shore waters.

One of the key issues for the future is the availability of phosphate ore reserves to meet the amounts of fertilizer needed to replace the phosphorus used by agricultural production. Tiessen (1995) combined available estimates and arrived at a range from <100 years to many hundreds of years of potential supply although economic and political constraints mean that at present, phosphorus remains in short supply over large parts of the globe. Soil phosphorus availability will remain a major constraint on food production. Management of fertilizer phosphorus inputs together with an understanding of organic matter cycling should allow for the development of more sustainable agriculture practices.

Coastal waters are increasingly suffering from high nutrient loads. Phosphorus is only part of the problem and management will be complex. The sensitivity of coastal regions means that prevention should be favored over damage management.

Inland lakes are affected by past fertilizer and animal waste management. More dialogue between freshwater and land use practitioners around the transfers of nutrients between systems is needed to develop regional plans to prevent phosphorus loss.

Photosynthesis

Photosynthesis is the use of energy from light to fix carbon dioxide (CO_2), reduce it, and convert it to organic carbon compounds. The process has three basic steps: the trapping of light energy and its conversion to chemical potential (the light reaction), the fixation of CO_2, and the biochemical reaction sequences that reduce the fixed carbon (the dark reactions).

In the light reaction, photons are absorbed by the photosynthetic pigments, the most important of which are the chlorophylls, although other pigments are involved. Energy from the absorbed photons is channeled by the pigments to oxidize water to oxygen and manufacture high-energy intermediate compounds. These products of the light reaction are used in the dark reactions to power a complex cyclic reaction sequence, called C_3 photosynthesis because the first product of fixation is a C_3 acid, which is ultimately converted to sugars, the normal end products of photosynthesis.

This reaction sequence has a serious problem: it evolved at a time when atmospheric oxygen levels were much lower than today and CO_2 was much higher. Ribulose bisphosphate carboxylase/oxygenase (Rubisco), the carboxylating enzyme of the C_3 cycle, is unable to distinguish adequately between oxygen and carbon dioxide. Oxygen acts competitively, and the oxygenase reaction leads to metabolically useless products that must be recycled and in part converted back to CO_2, a wasteful process, by the reactions of photorespiration. In today's conditions of high (20%) oxygen and low (0.04%) CO_2 the oxygenase function is sufficiently active to be strongly disadvantageous and greatly reduces photosynthetic capacity of the so-called C_3 plants.

An obvious experimental solution to this problem is to grow plants in a low oxygen, high CO_2 atmosphere. However, a natural solution is provided by an alternative reaction cycle called C_4 photosynthesis because the first product of carboxylation is a C_4 acid. In this cycle CO_2 (as bicarbonate) is fixed to a C_3 compound in the mesophyll cells (near the leaf surface) by the enzyme PEP carboxylase. The product of this reaction is converted to the C_4 acids aspartate (by transamination) or malate (by reduction), which are transported to an inner region of the leaf, the bundle sheath. There they are decarboxylated to produce CO_2, which is fixed by the normal C_3 cycle. The C_3 compound left after the decarboxylation is shunted back to the mesophyll, using energy from products of the light reaction. The C_4 cycle functions in effect to pump CO_2 to an inner compartment of the leaf. This raises the CO_2 concentration at the internal site of C_3 fixation where oxygen (which penetrates only slowly by diffusion) is well below atmospheric levels. The result is that the carboxylase function of Rubisco is greatly enhanced and the oxygenase function reduced, with a corresponding increase in the rate of photosynthetic production and decrease in losses due to photorespiration.

There are further consequences of C_4 photosynthesis. PEP carboxylase has a much higher affinity for CO_2 (as bicarbonate) than Rubisco, so C_4 plants can function well at much lower CO_2 concentrations. An important ecological result is that in the event of water shortage C_4 plants can continue photosynthesis with nearly closed stomata (through which water and CO_2 exchange of the leaf

occurs). This allows continued active growth with greatly reduced water loss, so C_4 plants survive well in hot, dry climates. The downside of C_4 photosynthesis is that substantial light energy is used to run the C_4 cycle, which in itself is unproductive. However, at high illumination, when C_3 plants are often embarrassed by excess light because not enough CO_2 can be fixed, C_4 plants can operate at full speed. The advantage of C_4 photosynthesis is not, therefore, that it is more efficient, but that it goes faster and continues under drought conditions when C_3 plants would be shut down to conserve water. C_4 plants that transport aspartate (aspartate transporters, e.g., *Atriplex* spp.) as the C_4 acid are slightly more energy efficient than malate transporters (e.g., sorghum, maize), but require a substantially increased metabolism and supply of nitrogen and therefore, under high light conditions, are at an ecological disadvantage.

Crassulacean acid metabolism (CAM) is an interesting variation of C_4 photosynthesis in which the C_3 and C_4 carboxylations are separated in time rather than in location. Many desert succulent plants and cacti use CAM to fix CO_2 into acids during the night (a process that does not require light energy). During the day the C_4 acids are decarboxylated and the released CO_2 is fixed by normal C_3 photosynthesis. Thus, CAM plants absorb CO_2 through their stomata at night (when the air is more humid and water loss not so serious) and carry on photosynthesis behind closed stomata during the day, when open stomata would result in deadly water loss. In this way they can survive and grow in extreme drought conditions.

C_4 plants tend to thrive best in dry tropical or subtropical grasslands. They include some major crops (e.g., sorghum, maize) as well as some pestilent weeds (crabgrass, goosefoot). They are not usually competitive where light intensities are lower and water plentiful as in temperate regions, although some successful alpine and tundra plants are C_4, perhaps because of the reduced availability of water due to freezing. The consequences of global warming – higher temperatures and greater areas of drought – suggest that efforts in selection, breeding or genetic modification to create new C_4 crops may be valuable, provided that cloud cover does not reduce light below levels where C_4 photosynthesis can increase production.

Phytophagy

Phytophagy means the eating of plants. Phytophagous animals (including many insects, seed-eating birds, and mammals such as most ungulates and rodents) are vegetarians. Their importance in communities has many facets, from controlling plant growth to seed dispersal and beyond. The ecological niches (*see* **Niche**, Volume 2) of phytophagous animals and insects are strongly controlled by the ecological relationships of their preferred food, and their niches vary in breadth in proportion to the niche breadth of their diet. Darwin's finches probably provide the best-known example of the relationship between phytophagous food preference and evolutionary adaptation in the development of ecological niches.

It is apparent that many phytophagous insects have coevolved with their specific hosts to the point where remarkably high degrees of specificity exist in some animal–host relationships. As with species diversity in general, the absolute frequency of such highly specific relationships is greatest in relatively stable tropical ecosystems and decreases toward the boreal regions.

Plant Competition in an Elevated CO_2 World

S Catovsky and F A Bazzaz
Harvard University, Cambridge, MA, USA

Elevated carbon dioxide (CO_2) influences the way plants interact with one another and these effects can have major consequences for natural ecosystems in the future. Plant competition, in particular, is a prevalent force structuring many processes within terrestrial ecosystems. In this paper, we consider how rising CO_2 levels may influence competitive interactions between plants and how these changes may scale up to affect the dynamics of populations, communities and ecosystems.

Elevated CO_2 can affect interactions between individuals of the same plant species (intraspecific). We address how elevated CO_2 influences the development of dense stands of plants and their future dynamics. Contrary to expectations from the addition of other resources to plant populations, elevated CO_2 seems to favor growth of smaller plants within a stand and thus reduce overall size differences between dominant and subordinate plants. These changes in the performance of different sized individuals within a population may also have implications for changes in the genetic composition of a population. Elevated CO_2 increases overall plant growth and hence tends to speed up competition between neighboring plants. As plants compete more strongly with one another, there is stronger selection on individual genotypes and the potential for evolutionary change is likely to increase. Based on current evidence, however, elevated CO_2 appears not to favor those plants whose individual growth is most strongly increased as CO_2 levels rise, but rather those that are better overall competitors in the stand. In addition, these CO_2 induced changes in stand development can have further consequences for population dynamics in subsequent generations. To date, however, our current knowledge about these future patterns of population development is rather limited.

Understanding competitive interactions between plants of different species (interspecific) can additionally refine our ability to predict future changes in community species composition. As we found for populations, information from individually grown plants may be inappropriate for accurately predicting dynamics at higher levels of organization. Many studies have now shown that plants grown individually often respond to elevated CO_2 differently than plants grown in mixed species stands. In addition, the direction of change is not consistent, with some studies finding that competition reduces species' responses to elevated CO_2 and others finding an enhancement of response. Our capability for predicting future community change will improve as we develop a mechanistic understanding of the nature of competition between different plant species. Plant competition can even influence CO_2 effects on ecosystem productivity. To date, all the evidence suggests that the expected amount of carbon taken up by terrestrial ecosystems is less if we use predictions from plant competition experiments than if we use CO_2 responses of individually grown plants.

The importance of plant competition at many levels of biological organization clearly warrants its incorporation into models of potential ecosystem responses to elevated CO_2. As we improve our understanding of the mechanisms underlying plant competitive interactions, we should be able to develop more complex and more accurate models of our future world.

IMPORTANCE OF PLANT COMPETITION

The central role of competition in structuring many ecological processes has long been recognized. There has been much debate about the precise meaning of plant competition but most agree on the basic tenants of the process. In this paper, we take plant competition to refer to an interaction in which individuals are drawing from a shared resource, the result of which limits their performance. Plant competition is an important component in our understanding of ecological interactions, because the sessile habit of plants means that they may spend much of their life next to other plants. Neighbors must continually compete with each other for limiting resources, and these competitive interactions influence processes at many levels of biological organization. Plants modify the distribution and abundance of local resources, which often affect the growth, survival, and reproduction of neighboring individuals. Alteration of individual plant function may then scale up to influence the dynamics of populations, communities, and ecosystems.

Given the importance of plant competitive interactions at many ecological levels, it is critical that we incorporate competition into our understanding of how global environmental change may influence terrestrial ecosystem structure and function. Rising levels of atmospheric CO_2 are likely to be the most direct environmental perturbation affecting terrestrial ecosystems in the future (*see* **Plants – from Cells to Ecosystems: Impacts of Global Environmental Change**, Volume 2). As a result, much ecological research has concentrated on determining potential influences of elevated atmospheric CO_2 on plant and ecosystem function. In this paper, we consider how elevated CO_2 influences plant competitive interactions, and what consequences these effects have for the dynamics of plant populations, communities, and ecosystems (Figure 1). We argue that incorporating competition into conceptual models of the effects of global change on ecological processes may change many predictions derived from information on individually grown plants. We focus our discussion on elevated CO_2 but consider other environmental perturbations (e.g., rising temperature, increased nitrogen deposition) when differences in response arise. Unfortunately, relatively little information currently exists on effects of other global changes on plant competition.

WHY MIGHT ELEVATED CO_2 INFLUENCE COMPETITIVE INTERACTIONS?

Increased atmospheric CO_2 may alter the way neighbors interact with one another by differentially affecting neighbor performance. CO_2-induced changes in individual growth rates will clearly alter competitive interactions, but so will changes in patterns of allocation and the timing of growth processes. It is now well established that elevated CO_2 often differentially influences the performances

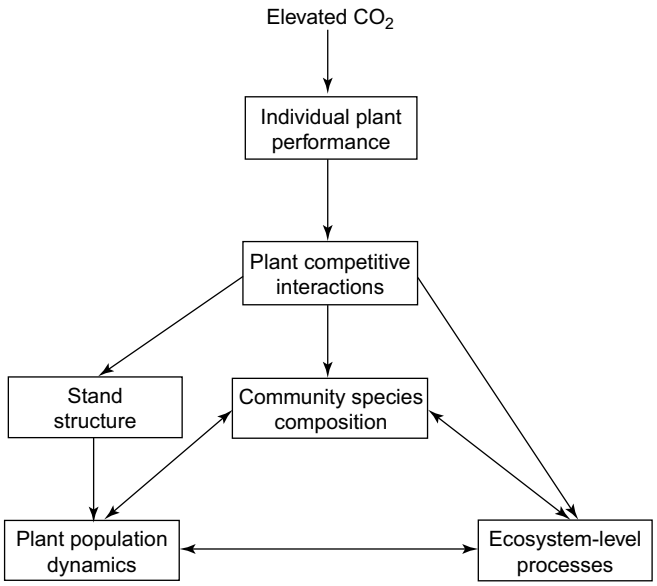

Figure 1 Schematic diagram for the effect of global environmental change on plant competitive interactions and their consequences for higher levels of organization

of genotypes within a population, and species within a community (Bazzaz, 1990). Alteration of patterns of growth and development may modify the way different genotypes or different species compete with one another, as different combinations of limiting resources (nutrients, water, and light) now affect plant performance. In addition, the presence of neighbors changes local conditions around an individual. These changes may directly influence plant responses to elevated CO_2, because the effects of elevated CO_2 on plants are commonly contingent on growth conditions (*see* **Plants – from Cells to Ecosystems: Impacts of Global Environmental Change**, Volume 2). When limiting resources are directional, and thus preemptable, competitive interactions are usually asymmetric. In these situations, small CO_2 induced changes in plant performance may be further magnified through time, potentially creating large differences in growth and development between genotypes or species.

ELEVATED CO_2 AND INTRASPECIFIC INTERACTIONS IN PLANT POPULATIONS

Competitive interactions between individuals within a population (intraspecific) often determine the nature of stand development, and ultimately, the future dynamics of the population. Many species that regenerate following a large disturbance (e.g., early successional species) often form dense, largely monospecific stands in the early stages of their life cycles. Consequently, early stand dynamics are frequently dominated by intense intraspecific competition. It is critical to understand how plant competitive interactions influence the development of these stands, as the outcome of competition determines which individuals reach reproductive maturity and thus contribute to subsequent generations. Ultimately, these early intraspecific interactions may influence the nature of selective forces shaping the population and the direction of evolutionary change. If rising atmospheric CO_2 concentrations influence intraspecific competitive interactions, then current patterns of population development will change in the future. We consider how elevated CO_2 may affect three distinct aspects of plant populations: stand size structure, population genetic structure, and intergenerational population dynamics.

Stand Size Structure

Many factors may contribute to the development of size hierarchies in plant populations, including patterns of seed dispersal, timing of germination, genetic variation in seed size and initial growth rates, fine-scale heterogeneity, and intraspecific competitive interactions. The importance of these different factors in stand development will vary depending on the species involved and the conditions in which the stand is growing. To date, the few studies that have addressed the impact of global changes on stand size structure have carried out the experiments in relatively controlled conditions. By their nature, such experiments emphasize more predictable processes (e.g., plant competition) over more random processes (e.g., small-scale heterogeneity and population variation). From basic ecological principles, we might predict that global environmental changes stimulating plant growth would increase the magnitude of size hierarchies in plant populations by intensifying intraspecific competitive interactions. The limited evidence we have so far, however, suggests that the influence of global changes on population size structure depends on how these changes affect plant responses to their local environment.

Wayne and Bazzaz (1997) grew competitive stands of yellow birch (*Betula alleghaniensis*) for two years and investigated the effects of atmospheric CO_2 concentration on stand size structure. They found that elevated CO_2 slightly, but consistently, reduced overall stand size inequality (Figure 2). As elevated CO_2 commonly stimulates plant growth, their results contrast with our original predictions. Wayne and Bazzaz provide evidence that size inequality was reduced in these stands because elevated CO_2 altered the way seedlings competed with one another for light. They suggest that these changes were, in part, brought about through greater CO_2 responsiveness in subordinate plants than in canopy dominants, perhaps because subordinates experienced less degree of photosynthetic acclimation in elevated CO_2 than did dominants. This acclimation is often observed in elevated CO_2 experiments, and is thought to occur because of starch accumulation in leaves and/or

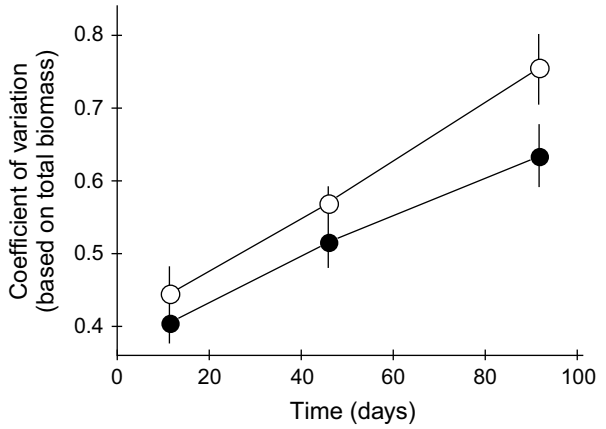

Figure 2 Stand size inequality (measured by coef cient of variation) for *Betula alleghaniensis* seedlings grown at ambient (○, 350 μl l^{-1}) and elevated (●, 700 μl l^{-1}) CO_2 at three times through the growing season (modi ed from Wayne and Bazzaz, 1997)

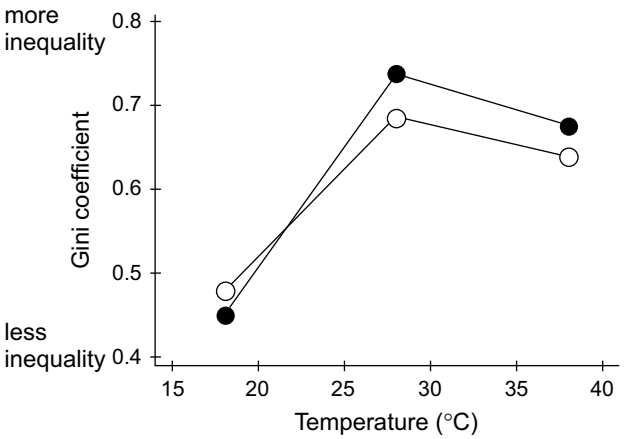

Figure 3 Stand size inequality measured by Gini coef cient, which measures the degree of size inequality in a population. It equals 0 when all individuals in a population are of equivalent biomass, and approaches 1 as the difference in biomass between individuals increases) for *Amaranthus retro exus* populations after 80 days of growth at ambient (○, 400 μl l^{-1}) and elevated (●, 700 μl l^{-1}) CO_2 and under three temperature regimes (data from Morse and Bazzaz, 1994)

direct inhibition of photosynthesis by low levels of inorganic phosphate (*see* **Plants – from Cells to Ecosystems: Impacts of Global Environmental Change**, Volume 2).

The only other study that has addressed the consequences of rising CO_2 levels for stand size structure found little effect of elevated CO_2 on population size hierarchies in two annual plant species (Figure 3; only *Amaranthus retroflexus* is shown) (Morse and Bazzaz, 1994). In contrast, they found very pronounced effects of temperature on size structure. For both species, stand size inequality increased significantly with increasing temperature, reaching a peak at 28 °C. By following stands through their development, Morse and Bazzaz ascertained that size hierarchies were magnified with increasing temperature, because greater initial recruitment into the population (higher germination rates) and faster growth rates intensified intraspecific competitive interactions. The increase in the strength of competition between individuals led to larger differentials in growth and survival between canopy dominants and subordinates. This experiment highlights how different global environmental changes might have contrasting effects on plant competition. These differences likely arise from the contrasting ways global change factors influence plant responses to other resources. For example, elevated CO_2 differentially improves plant growth at lower light levels, reducing the ability of dominants to outcompete subordinate plants for light, while elevated temperatures act to speed up competitive processes and resource preemption. Effects of nitrogen deposition on stand development are also relatively poorly understood, but from early agricultural experiments adding fertilizer to monospecific stands of crop species, it is clear that supplementing below-ground resources intensifies asymmetric competition for light above-ground and results in heightened stand size inequality.

Population Genetic Structure

The underlying genetic component in the formation of size hierarchies suggests that the dynamics of stand development may have evolutionary consequences. If we wish to ascertain whether elevated CO_2 will act as a future selective force for plant populations, we need to determine how rising CO_2 levels will influence the genetic structure of plant populations through time. As genetic variation for CO_2 responsiveness has been recorded in a number of experimental studies, the potential for evolutionary responses to elevated CO_2 certainly exists (Körner and Bazzaz, 1996). The extent to which variation for fitness-correlated traits under elevated CO_2 is heritable is, however, still unclear. In addition, this potential for evolutionary change might not be reached in natural plant populations, where biotic interactions and other abiotic factors may alter plants' responses to elevated CO_2. Thus, selection may not necessarily act to promote increased CO_2 responsiveness in the future. Competitive interactions, in particular, are likely to influence genotypic responses to the environment.

To date, only two studies (Bazzaz *et al.*, 1995; Wayne and Bazzaz, 1995) have compared the genetic changes that plant populations might undergo when exposed to elevated CO_2 as individuals and under crowded stand conditions. Despite using very different plant species, these two studies reached very similar conclusions, suggesting that the results might be more widely applicable. Wayne and Bazzaz (1995) tested their hypotheses on stands of *Betula alleghaniensis*, a mid-successional, deciduous

tree species, while Bazzaz *et al.* (1995) compared these *Betula* responses with those of *Abutilon theophrasti*, an old-field annual species. In both these studies, increasing the intensity of intraspecific competition by manipulating plant density led to greater variance among genotypes in CO_2 responsiveness (eight-fold increase for *Abutilon*, three-fold for *Betula*). This result suggests that intraspecific competition increases the potential for natural selection to act on responsiveness to elevated CO_2 in the future. This potential, however, is unlikely to be reached in stands of natural populations, as individuals favored in elevated CO_2 in high density stands were not those that showed inherently greater CO_2 responsiveness when grown at low density. In *Betula*, there was a complete reversal in ranking of genotype-specific growth enhancements in elevated CO_2 (Figure 4). Similarly, for *Abutilon* populations, there was a poor correlation between genotype-specific growth responses to elevated CO_2 at the two densities.

These results demonstrate that, although there may be strong potential for evolutionary responses to rising CO_2 levels, selection for increased CO_2 responsiveness in the future may be weak, especially in crowded populations. As competitive interactions intensify with elevated CO_2, selection may favor traits that enhance an individual's competitive ability in dense stands rather than its inherent CO_2 responsiveness, *per se*. These traits are likely to include those that improve an individual's capability to obtain other limiting resources in their environment, e.g., increased allocation to stem biomass when competing for light, and increased amount and activity of fine root biomass when competing for soil nutrients.

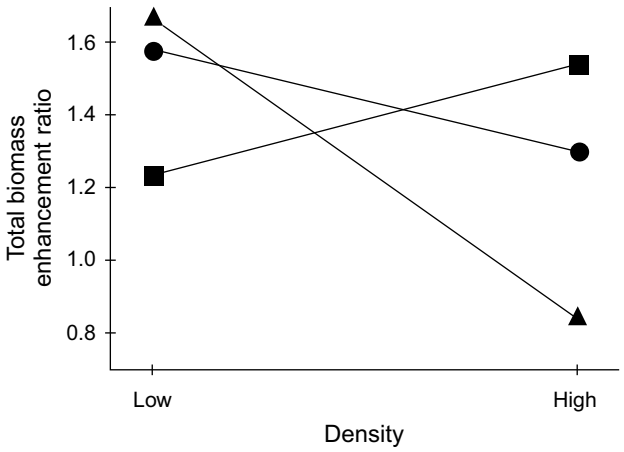

Figure 4 Total biomass enhancement ratio (biomass at 700 µl l^{-1}/biomass at 350 µl l^{-1}) for three maternal families (●, ▲, ■) of *Betula alleghaniensis* seedlings grown together in low and high density stands (data from Wayne and Bazzaz, 1995)

Inter-generational Population Dynamics

Patterns of stand development may also influence the future dynamics of plant populations. Despite the importance of this longer-term perspective, most studies use total biomass as their response variable, while few studies have directly considered the influence of elevated CO_2 on many population-level processes, such as recruitment, survival and reproduction. Although there is a reasonably good positive relationship between plant biomass and total reproduction, there is significant variation between individuals due to genotypic differences and phenotypic plasticity. This relationship may become further decoupled in the future as rising CO_2 concentrations alter patterns of allocation to flowers, fruits and seeds. In a survey of eight CO_2 studies, Ackerly and Bazzaz (1995) found that there was an overall positive relationship between enhancement of total and reproductive biomass, but that this relationship only explained 32% of the variation in response. In one-third of cases, even the direction of change in elevated CO_2 differed between total and reproductive biomass.

Of the few studies that do directly address the influence of elevated CO_2 on reproductive output, even fewer have considered interactions between CO_2 concentration and density. Given the ubiquity of competitive interactions in natural systems, understanding these effects is critical for predicting future patterns of population change. In another study on *Abutilon theophrasti*, Bazzaz *et al.* (1992) recorded significant effects of elevated CO_2 on several population level parameters, and they found that these CO_2 effects were highly dependent on population density. Elevated CO_2 increased population survivorship and the probability of flowering for surviving individuals, but only in the high-density treatments. Using a simple population dynamics model, Bazzaz *et al.* (1992) showed that these interactions between CO_2 and density effects would have significant impacts on the future dynamics of these populations. The higher fecundity of high-density populations grown at elevated CO_2 increased the magnitude of future population cycles. From this single study addressing effects of interactions between CO_2 and density on population parameters, it is challenging to make any generalizations. We can clearly see, however, that there is the potential for substantial effects of elevated CO_2 on population dynamics, especially under competitive conditions. These changes may be magnified over subsequent generations, as effects accumulate.

ELEVATED CO_2 AND INTERSPECIFIC INTERACTIONS IN PLANT COMMUNITIES

Scaling from Individual Responses to the Community

Understanding the influence of elevated CO_2 on ecosystem structure and function is a central goal of global

change biology. Community species composition is a key component of ecosystem structure and, as a result, has been the focus of much research. A large proportion of such research has focused on how species differ in their responses to rising CO_2 levels, and how differential responsiveness may lead to altered community composition. The vast numbers of species that exist on the Earth make it unfeasible to directly assess how each species may respond to elevated CO_2 in the future. Instead, ecologists are attempting to distinguish groups of species (and their related traits) that respond in similar ways to elevated CO_2, i.e., functional response groups. Only very few such groups that respond in predictable ways to rising CO_2 levels have been identified, e.g., species that differ from one another in photosynthetic pathway (e.g., C_3 vs. C_4 plants). In general, fully characterizing species' CO_2 responsiveness based on a limited set of traits has been difficult, and to date, we do not have good predictive abilities for determining species' responses in the future (*see* **Plants – from Cells to Ecosystems: Impacts of Global Environmental Change**, Volume 2).

As CO_2 research technology has developed, our ability to conduct larger scale, longer term, and more complex experiments has improved. Over the past decade, there has been a concerted effort to identify key global ecosystems and determine how they might be influenced by rising CO_2 levels. As a result, community level changes in response to elevated CO_2 have been documented in numerous studies (Körner and Bazzaz, 1996). These experiments have produced a wide range of results, from relatively little alteration of community species composition (e.g., Navas *et al.*, 1995), to extensive change in relative species abundance within the community (e.g., Potvin and Vasseur, 1997). Much of the research is still phenomenological, simply documenting the nature of change, rather than investigating potential underlying mechanisms. In a number of these experiments, community level change did not follow predictions based on functional groupings of species (see chapters in Körner and Bazzaz, 1996), but the overriding reasons leading to this divergence from predicted patterns have been unclear to date. Some progress in elucidating mechanisms of community change has been made by taking a resource-based approach. Studies that have come closest to explaining the underlying mechanisms for CO_2-induced changes in community structure have been those monitoring changes in resource availability under different CO_2 scenarios and documenting differential resource use patterns for different species, e.g., water availability in a Californian annual grassland (Chiariello and Field, 1996), and nitrogen uptake in disturbed seasonal grasslands from southwestern USA (Berntson *et al.*, 1998).

What information do we need to make predictions about future patterns of community change? Clearly, we need to understand the underlying physiological mechanisms behind individual species' responses to elevated CO_2. Even with this comprehensive information, we still face difficulties in scaling individual responses to community-level phenomena. Mechanisms for community change involve many interactions beyond individual species' responses that need to be incorporated into our conceptual models of global change. In this section, we focus on the importance of interspecific competitive interactions for determining future community patterns with rising CO_2 levels.

Importance of Interspecific Interactions

Competition between plant species (interspecific) is a ubiquitous process within most natural ecosystems and plays a central role in shaping the structure and dynamics of plant communities. The outcome of interspecific competition, however, is often difficult to predict *a priori*. The preemptive nature of plant competitive interactions means that quite small differences between individuals can influence which individual achieves dominance. Even when differential species' responsiveness to elevated CO_2 is clear, experiments with plants grown under competitive conditions may yield unexpected results. For example, Bazzaz *et al.* (1989) grew plants of *Abutilon theophrasti* (a C_3 annual) and *Amaranthus retroflexus* (a C_4 annual), both individually and in competition with one another. They found that, contrary to expectations, elevated CO_2 shifted the competitive balance toward the C_4 species in mixed stands. Growth analysis of the plants through the experiment suggested that *Amaranthus* responded earlier to elevated CO_2, and that this difference in the timing of response enabled the C_4 plant to compensate for the initial smaller size of its seedlings through increased allocation to leaves (higher leaf area ratio) in elevated CO_2.

The multitude of processes involved in interspecific interactions makes it challenging to predict community responses to elevated CO_2. Scaling from individual plant responses may only be possible with extensive information on behavior at many stages of a plant's lifecycle. Even then, plant responses to elevated CO_2 are rarely the same when grown individually and in competitive stands. As yet, we cannot determine the direction of change, as the range of responses are highly varied. In one of the first studies addressing this phenomenon, Williams *et al.* (1988) observed that, for herbaceous communities from California serpentine grassland, competition significantly damped the effects of elevated CO_2. They found that, as individuals, two species (*Agoseris heterophylla* and *Layia platyglossa*) showed significant CO_2 induced growth increases, while there were no such increases for any species in competitive stands. Similarly, when grown individually, sweetgum (*Liquidambar styraciflua*) seedlings responded

strongly to elevated CO_2 under dry soil conditions, while loblolly pine (*Pinus taeda*) seedlings showed no such increases. When grown together in mixed species, dry soil stands, however, seedlings of both species showed no substantial CO_2 induced growth enhancements (Groninger *et al.*, 1995). Competition treatments, however, do not always restrain CO_2 growth enhancements. For tropical tree saplings, Reekie and Bazzaz (1989) observed much larger differences in CO_2 responsiveness for plants grown in competitive stands than for individually grown plants

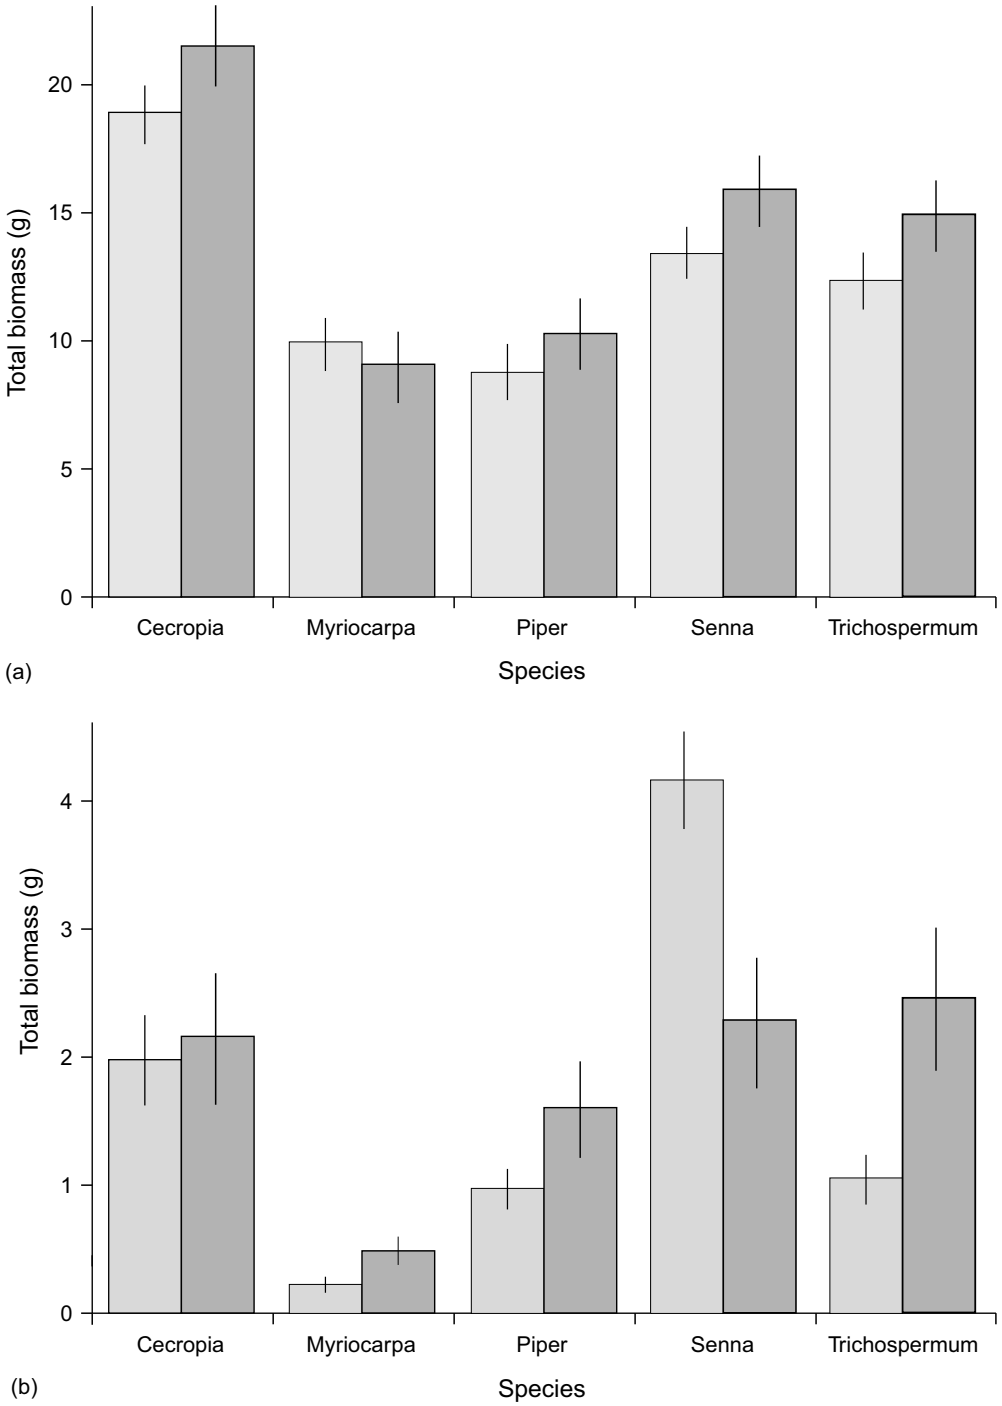

Figure 5 Total biomass for ve tropical tree saplings after one growing season at ambient (lighter box, 350 µl l^{-1}) and elevated (darker box, 700 µl l^{-1}) CO_2 and under two different competition regimes, i.e., (a) individually grown and (b) competitively grown (modi ed from Reekie and Bazzaz, 1989)

(Figure 5). In particular, in mixed species stands grown in elevated CO_2, they recorded substantial increases in *Trichospermum mexicanum*, *Piper auritum* and *Myriocarpa longipes*, mostly at the expense of *Senna multijuga*, while no significant CO_2 effects were found for individually grown plants. More recently, for two temperate forest birch species (*Betula alleghaniensis* and *Betula papyrifera*), Catovsky and Bazzaz (1999) found that competition magnified species' responses to CO_2 and water treatments, when compared with individually grown plants (Figure 6). *Betula papyrifera* showed substantially larger CO_2 growth enhancements in dry soil treatments, and these effects were more pronounced when the seedlings were grown in stands than when they were grown individually. Similarly, *Betula alleghaniensis* showed larger CO_2 growth enhancements on moister soils, but particularly when grown in competition.

Towards a Mechanistic Understanding of Interspeci c Competition

Why do we often find such disparate CO_2 responses between individually and competitively grown plants? Within populations, we have already seen that elevated CO_2 favors different phenotypic traits for plants grown individually and in competitive stands. In a similar way, for interspecific interactions, we suggest that species' traits correlated with improved performance in elevated CO_2 will differ for individually and competitively grown plants. In the competition experiment with tropical saplings described above, Reekie and Bazzaz (1989) found that competitive success in elevated CO_2 was highly correlated with increased canopy height (through increased allocation of biomass to stems). They hypothesized that rising CO_2 levels favored species that were better competitors for light in this system. Understanding which resources are most limiting within a stand may be the key to predicting competitive outcomes. Conceptual models from resource allocation theory may improve our predictive abilities for competitive mixtures (Reynolds, 1996). For example, when soil fertility is high, elevated CO_2 may intensify competition for light and favor plants with higher allocation to and activity of above-ground parts. Alternatively, at lower soil resource availability, root competition may be more intense, and plants dominating in elevated CO_2 may be those that are better competitors for below-ground resources. Naturally, many of these predictions will be highly density dependent.

As yet, few studies have addressed the interplay between root and shoot competition in elevated CO_2, and so we have few direct experimental tests of these resource-based models. Two recent studies have focused on elevated CO_2 effects on root competition and root growth in different resource combinations. Jifon *et al.* (1995) grew monocultures and mixed stands of loblolly pine (*Pinus taeda*) and sweetgum (*Liquidambar styraciflua*) under different CO_2–water–nitrogen combinations, and investigated variation in root length density (RLD) in these stands. In monocultures, they found that elevated CO_2 increased RLD most under low water, low nitrogen conditions, while in mixed species stands, the largest CO_2-induced increases in RLD were observed under the high nitrogen, high water treatment (Figure 7). This finding suggests that, contrary to our predictions, competition for

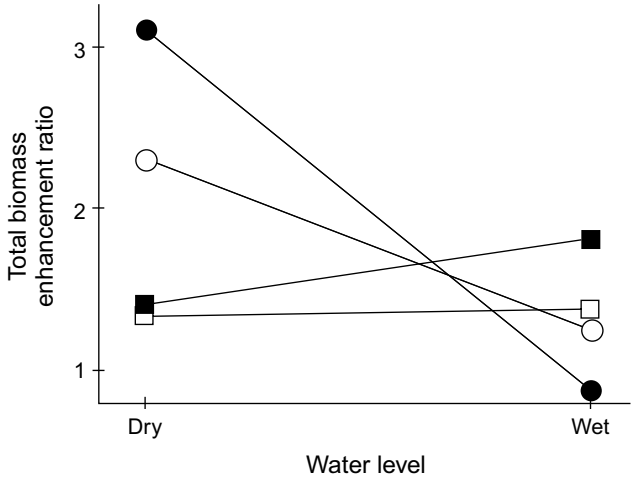

Figure 6 Total biomass enhancement ratio (biomass at 700 µl l^{-1}/biomass at 375 µl l^{-1}) for *Betula papyrifera* (○, ●) and *Betula alleghaniensis* (□, ■) seedlings grown individually (○, □) and in mixed competitive stands (●, ■) for one growing season (data from Catovsky and Bazzaz, 1999)

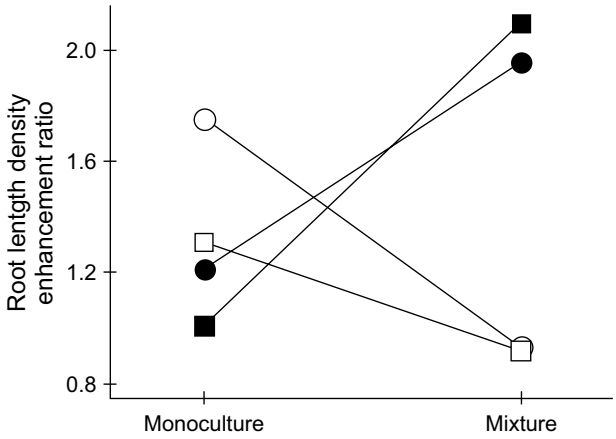

Figure 7 RLD enhancement ratio (RLD at 750 µl l^{-1}/RLD at 350 µl l^{-1}) for *Liquidambar styraci ua* (○, ●) and *Pinus taeda* (□, ■) seedlings grown with low (○, □) or high (●, ■) soil resources under two competition regimes (data from Jifon *et al.*, 1995)

light is not always favored in mixed stands growing in rich soil resource conditions. We should note, however, that Jifon *et al.* (1995) did not measure competitive interactions directly and had no individually grown plants in their experiment, which would provide a control for our hypotheses. In contrast, Arnone and Kestenholz (1997) did not vary resource levels, but did directly manipulate below-ground interspecific competitive interactions. They investigated competitive interactions between the annual ruderal species, *Linum usitatissimum*, and the annual weed, *Silene cretica*. Arnone and Kestenholz found that in competitive mixtures, *Silene* responded strongly to elevated CO_2, while *Linum* biomass was not significantly increased. When vertical soil partitions were placed between individuals in these mixtures, however, *Silene* no longer inhibited *Linum* responses to elevated CO_2 (Figure 8). This experiment demonstrates the potential importance of root competition in influencing species' responses to rising CO_2 levels, but we still do not know how the relative importance of root versus shoot competition would change under different resource scenarios. This information is critical for making accurate predictions about the outcome of competition in future elevated CO_2 concentrations.

Even if we were able to use species' traits to predict the outcome of competition under particular conditions, we might not be correct, as direct CO_2 effects on plant development may further complicate the result. In many of the experiments discussed so far, morphological responses to elevated CO_2 commonly determine the nature of competitive interactions among species. Our knowledge of changes (*see* **Allometric**, Volume 2) in the patterns of plant growth throughout their plant life may allow us to forecast the outcome of these interactions. If, however, elevated CO_2 differentially affects certain specific developmental pathways, as has been demonstrated in a small number of studies (*see* **Plants – from Cells to Ecosystems: Impacts of Global Environmental Change**, Volume 2), predicting the exact outcome of competition will be very difficult.

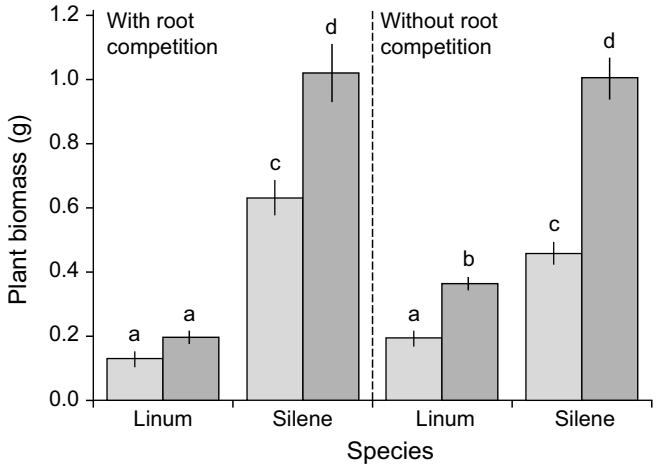

Figure 8 Total biomass of *Linum usitatissimum* and *Silene cretica* individuals growing at ambient (lighter box, 320 $\mu l\, l^{-1}$) and elevated (darker box, 600 $\mu l\, l^{-1}$) CO_2 and under two different competition regimes (with/without root competition) for 30 days (modified from Arnone and Kestenholz, 1997)

Competition in Natural Plant Communities

Elevated CO_2 will not only affect competition between plant species in natural ecological communities, but will also influence a suite of other interspecific interactions, including plant soil, plant herbivore, and plant pollinator. Experiments that have been carried out in more realistic field situations than those described above are often not able to uncouple the separate effects of elevated CO_2 on these individual processes. They are, however, able to place the results of controlled environment studies into context. For example, Leadley *et al.* (1999) found that, as with many glasshouse studies, individual plant responses to elevated CO_2 did not necessarily predict grassland community responses in the field. Interactions between plants and other organisms (e.g., herbivores, soil organisms) are likely to decouple plant–plant competitive interactions observed in controlled studies (Bezemer and Jones, 1998; Zaller and Arnone, 1999). More detailed examination of higher level interactions is necessary for a fuller understanding of elevated CO_2 effects on natural ecological communities.

ELEVATED CO_2 AND ECOSYSTEM FUNCTION

It is now well established that elevated CO_2 will have numerous, direct effects on a variety of ecosystem processes in the future. In particular, there is considerable focus on understanding factors that regulate carbon dynamics in terrestrial ecosystems, because of potential feedbacks to the global carbon cycle. Many studies have extrapolated from experiments on individually grown plants to make predictions about the impact of elevated CO_2 on future ecosystem productivity. This approach, however, may not provide an accurate representation of the future carbon gain capabilities of terrestrial ecosystems. Many of these studies may be misleading, as they rarely consider the impact of plant competitive interactions during stand development. The influence of plant competition on ecological processes may extend beyond plant population and community dynamics to whole ecosystem properties. A number of recent studies comparing plants grown

Table 1 Differences in enhancement ratio (biomass at 700 $\mu l\, l^{-1}$/biomass at 350 $\mu l\, l^{-1}$) for individually and competitively grown plants (low vs. high density)

	Enhancement ratio		
Species	Low density	High density	Reference
Abutilon theophrasti	1.16	1.04	Bazzaz *et al.* (1995)
Betula alleghaniensis	1.49	1.14	Wayne and Bazzaz (1995)
Brassica kaber (early)	2.41	1.59	Wayne *et al.* (1999)
Brassica kaber (late)	1.28	1.30	Wayne *et al.* (1999)
Sinapis alba	1.86	1.15	Retuerto *et al.* (1996)

individually and in monospecific stands have demonstrated that competition often reduces growth enhancement under elevated CO_2 (Bazzaz *et al.*, 1995; Wayne and Bazzaz, 1995; Retuerto *et al.*, 1996) (Table 1). In addition, enhancement effects appear to change though time during stand development (Wayne *et al.*, 1999). In a survey of studies investigating plant responses to CO_2 gradients, Ackerly and Bazzaz (1995) found that plants grown individually usually exhibited positive growth responses due to increasing CO_2 concentrations (61% of the time), while those in competition with neighbors only showed positive responses 19% of the time. The physiological and developmental mechanisms underlying this reduced enhancement with increasing density are currently unclear and certainly need to be investigated further to understand the consequences for terrestrial ecosystem carbon sequestration.

CONCLUSIONS

Plant competitive interactions may have substantial impacts on the responses of populations, communities, and ecosystems to rising CO_2 levels. Experiments comparing responses of plants grown individually and in competition demonstrate that using individuals to extrapolate to higher levels of organization may be misleading. Contrary to our expectations from individually grown plants, selection under future elevated CO_2 concentrations may favor traits that confer improved ability to compete for resources, rather than traits that promote individual CO_2 responsiveness. Similarly, species-specific growth responses to elevated CO_2 may not be useful for predicting future patterns of community change, as competitive interactions may either enhance or depress species' CO_2 responsiveness in mixed species stands. In addition, growing plants in competition consistently reduces estimates of future ecosystem productivity based on CO_2-induced growth enhancement of plants without neighbors.

Because of the ubiquity of plant competition in terrestrial ecosystems, predictions from individually grown plants cannot be extended to the majority of natural settings and are limited to a very small set of environmental conditions. It is clear that models of ecosystem responses to global environmental change should account for potential effects of plant competitive interactions – otherwise, they will be of limited use. As our mechanistic understanding of CO_2 and density interactions grows, we should be better able to develop models that account for the more complex underlying dynamics.

Plant Functional Types

Sandra Lavorel

Centre d'Ecologie Fonctionnelle et Evolutive CNRS, Montpellier, France

The search for schemes of species classification that move beyond analyses of particular patterns or phenomena has been a recurring theme in the study of ecological systems since Theophrastus' first recognition of the meaningfulness of plant life forms. This theme has been revived recently by the necessity to predict the effects of human-originated changes in climate, atmospheric composition and land use on ecosystem structure and functioning. Plant functional types (PFTs) can be broadly defined as groups of species with a similar response to one or several environmental factors, in conjunction or not with a shared physiognomy and biology. They are seen as tools that make it possible: (1) to describe the dynamics of plant communities and ecosystems in a generic way, (2) to use this general scheme to generate predictions of ecosystem change under changed environmental conditions, and (3) to develop management strategies that move beyond a focus on particular species. They can be used in a variety of situations, including cases where detailed information is limited. In order to be successful, such schemes need to be based on robust ecological patterns.

Recent research on the prediction of the effects of global change, in particular within the Global Change and Terrestrial Ecosystems (GCTE) program, has significantly advanced the conceptualization of plant functional groups (Woodward and Cramer, 1996; Smith et al.*, 1997; Lavorel and Cramer, 1999). PFTs were intended to be the building blocks of dynamic global vegetation models (DGVMs) that can predict shifts of vegetation types with changing climate and atmospheric composition. Though the initial aim of building a single, globally applicable key of PFTs was rejected, recent research has also demonstrated the usefulness of the PFT concept for approaches at a variety of scales, from the community to the landscape and the globe.*

A CLASSIFICATION OF PLANT FUNCTIONAL CLASSIFICATIONS

The idea of grouping functionally similar species has been used for a long time in biology and has been applied to plants, animals and microbes. Global change research has stimulated the development of plant functional classifications. Though these studies have focussed on plants, the conceptual and methodological advances presented in this article are now widely applied to other kingdoms, including

functional classifications for birds, fish and amphibians, ants or soil microbes.

Published approaches involving the analysis of sets of biological attributes fall into four main types of functional classifications of plant species (Lavorel *et al.*, 1997). In order of increasing specificity of objective, these are: (1) emergent groups – groups of species that reflect natural correlation of biological attributes; (2) strategies – groups of species sharing a set of biological attributes that are interpreted as adaptations to particular patterns of resource use; (3) functional types – species with similar roles in ecosystem processes by responding in similar ways to multiple environmental factors; and (4) specific response groups – species which respond in similar ways to specific environmental factors. The two latter categories represent substantial recent conceptual advances stimulated by research aimed at predicting the effects of global change on vegetation dynamics.

Emergent Groups

Emergent groups reflect the combination of adaptive responses and of evolutionary constraints appearing as sets of correlated traits. They are identified in an inductive manner, using multivariate analyses of usually large sets of traits – covering life history, morphology, physiology, phenology and regeneration biology – expected to determine species behavior in the ecosystem. Such classifications tend to not address any ecosystem function explicitly or, when they attempt to, lack relationship to particular mechanisms. They tend to produce sets of traits essentially corresponding to main life forms (trees, shrubs, grasses and forbs), although the degree of detailed subdivision depends on the breadth of the spectrum taken from global, to regional and to a particular vegetation type. Classifications into emergent groups have, however, been useful to identify broad correlation patterns, such as relationships between plant size or seed mass and important functional traits such as growth rate. Since these correlation patterns may sometimes only reflect the fact that taxa sharing common evolutionary ancestors (phylogenetically-related taxa) can inherit common groups of attributes regardless of function, it is essential to use analyses which compare pairs of phylogenetically independent taxa.

Trait correlation analyses have also pointed out that adult and regeneration traits can show incongruent patterns of correlation, as highlighted by the recognition of distinct regeneration strategies (Grime, 1979). This discrepancy is highly pertinent to the construction of functional classifications because it implies that in the analysis of traits relating to specific functions, adult and juvenile traits need to be considered independently.

Strategies - Adaptive Patterns Relating to Resource Use and Availability

The identification of adaptive strategies is a more directed exercise in linking species traits to variation in resource availability in habitats, and their consequences for plant growth and reproduction. Strategies are identified as "major recurring axes of adaptive specialization in life history and in the physiology of the adult (established) organism [which] appear to be associated with variation in the duration and quality of the opportunities which habitats provide for resource capture, growth and reproduction" (Grime, 1979).

The r-K strategy scheme is the oldest and perhaps best-known classification across subdisciplines. It distinguishes between colonizer species with a high intrinsic population growth rate, but poorly competitive, and species with a slower population growth rate and a strong ability to maintain themselves in competitive situations. These strategies are associated with biological attributes relating to life cycle, reproduction rates and allocation into individual offsprings.

The best known and most debated example in plant ecology is the plant strategy (or competition stress disturbance (CSR)) scheme (Grime, 1979) where species are classified according to their abilities to cope with competition (C), abiotic stress (S) and disturbance (R). These axes of environmental specialization are related to proposed sets of biological attributes, whose relevance has been fully demonstrated only recently in the case of the vegetation of Northwestern Europe (Grime *et al.*, 1997). These attributes can be grouped to define syndromes (i.e., groups of co-occurring attributes). However, the difficulty of using such predetermined syndromes is that they may be meaningful only in vegetation for which they were developed. Instead, the use of three simple plant traits, specific leaf area (SLA) (L), plant height (H), and seed mass (S) has been proposed to represent the C, S and R axes, respectively (leaf height seed (LHS) scheme, Westoby, 1998). These traits present the advantage of being easy to measure using a standardized methodology, while showing strong evidence for correlation with plant performance in competitive, stressful, or disturbed habitats, respectively.

The CSR scheme has been successfully applied in studies of the distribution and dynamics of many communities. However, these studies have tended to focus on the environmental classification as an interpretative tool rather than identifying attributes that are correlated to the same end of an environmental gradient. Although the scheme has been much criticized, it is important to recognize strategy classifications for what they are – general schemes. Their value is to provide a broad framework and to identify traits that may be used as a starting point in more explicitly targeted studies.

Functional Groups - Species with Similar Ecological Roles

Plant functional types (PFTs) are defined as groupings of species which perform similarly in an ecosystem based on a set of common biological attributes. These groupings are independent of whether species are taxonomically related or not. They can be defined in relation to either the contribution of species to ecosystem processes (such as carbon or water cycling) or the response of species to changes in environmental variables (such as climatic variables or disturbance). The search for functional groups usable in models of global vegetation dynamics needs to provide for species groupings that may differ according to the function or group of functions considered. For example, PFTs associated with climatic factors differ from those relevant to species migration. Classifications using *a priori* selected traits under present factor combinations, e.g., present climate, will also not necessarily hold under changing conditions, such as new combinations of temperature and precipitation regimes. These two concerns can be addressed by explicitly linking function to response mechanisms (Woodward and Cramer, 1996). This is possible for functions for which adaptive syndromes are established from direct structural manifestations, but ultimately functionality of any attribute should be assessed experimentally. For example, drought tolerance can be related to patterns of allocation to leaves versus roots, leaf characteristics and metabolic adjustments (e.g., C3, C4, CAM). In other cases, however, the relationship between form and function is known only from correlation patterns, as is the case for plant size and relative growth rate (RGR). Some essential functional attributes (e.g., photosynthetic pathway) do not translate to morphology. Finally, classifications cannot be expected to be universal, yet their development should aim at reaching greater generality by addressing mechanisms.

In practice, the construction of PFTs has involved a combination of subjective pre-selection of traits based on expert knowledge and correlation analyses applied to environmental gradients and experimental manipulations. Individual studies may combine emergent and function-oriented classifications, although not always explicitly. For example, classifications used to model global or regional vegetation shifts associated with climatic change are based on life form (Prentice *et al.*, 1992). That decision reflects both the outcome of emergent classifications at large scales and the relevance of life form to primary ecosystem functions such as carbon assimilation. Indeed subjective life form classifications have been repeatedly found to reflect broad ecosystem functions along regional environmental gradients. However, additional information on traits for which function has been explicitly demonstrated may be of primary importance to develop accurate, mechanistic predictions of vegetation response to global change drivers, as well as to understand plant distribution and dynamics along resource gradients within regions or landscapes.

Specific Response Groups

Refined analyses of vegetation structure and dynamics at landscape or community scales require different sets of traits, which explore the details of interactions between the plant and its abiotic and biotic environment. Searches for plant functional classifications at these finer scales have explicitly considered traits relating to response to competition (as described later in the section on PFTs along resource gradients) and other biotic interactions such as herbivory or litter decomposition, and to response to disturbance (as described later in the section on response groups to disturbance). These classifications are based on a detailed understanding of the effects of a limited set of traits on a specific plant function. For example, the identification of response groups and corresponding plant attributes has been a recurring theme in the grazing literature that predates the formalization of PFT approaches. Similarly, ecophysiological research has been focusing on physiological traits determining plant resource acquisition patterns. These traits are of interest for the detailed analysis of plant response groups for competition or different stress factors, but have only recently started to be included in plant functional classification studies.

METHODS FOR PLANT FUNCTIONAL CLASSIFICATIONS

General Approaches to Plant Functional Classification

Functional classifications can be achieved by following three types of broad approaches (Gitay and Noble, 1997). A *subjective* classification assumes the existence of functional types based on *a priori* knowledge of one or several ecosystems. It is not based on the knowledge of a particular process or of specific traits relevant to that process but solely on expert knowledge of the ecological dynamics. The classification of early-, mid- and late-successional species provides an example for such a classification. An *inductive* classification identifies functional types using a set of traits that are presumed important for a given function or set of functions. Species are then grouped according to common sets of attributes for these traits, and it is assumed that they will as a result perform similar functions. For example, models of vegetation dynamics following climatic and atmospheric changes have assumed that life form, phenology (*see* **Phenology**, Volume 2) and photosynthetic pathway determined species response and could hence be used to build a global vegetation

classification. Finally a *deductive* classification uses *a priori* knowledge of important ecological processes or functions and then deduces the set of potential functional types. A well-known application of this approach is presented by the Vital Attributes Scheme, which proposes a functional classification based on species survival and regeneration mode after disturbance and on their tolerance to competition for recruitment (Noble and Slatyer, 1980). Specific studies often use a mix of inductive and deductive approaches. Ideally, robust plant functional classifications should be based on the reconciliation of a trait-based classification (inductive) with a classification based on response for processes of interest (deductive). This approach involves four steps: (1) the selection of a list of traits to be analyzed; (2) the analysis of response of trait attributes for the process of interest; (3) the analysis of plant response for the process of interest and the identification of groups of species with a similar response; and (4) the reconciliation of steps (2) and (3) to build species functional types characterized by a list of determining attributes. In the following we present the main methods and issues for each of these four steps.

Trait Selection (Step 1)

Assuming that a specific function or set of functions have been identified, it is possible to use expert knowledge to build a list of potentially relevant traits. The selection of a final list of traits for analysis is an exercise in compromise between several constraints. Since traits should be closely linked to actual function, the choice should favor traits that are known to directly determine plant physiology or other aspects of plant behavior (e.g., germination requirements). Such traits, termed hard or functional traits, provide robust information but also present two main difficulties. First, for many functions the exact determining trait or set of traits is unknown. Second, if known, these traits can be difficult or costly to measure, a constraint which can often be incompatible with the need to carry out measurements on a large number of individuals and species, often in the field rather than in the laboratory. As a compromise, soft or structural traits may be chosen. These traits have morphological manifestations that can be measured directly on an individual plant, and are known or assumed to correlate with a harder trait which is the actual functional trait. For example, an accumulating body of evidence suggests that specific leaf area (SLA) provides a robust surrogate to assess the ability of plants to capture resources. The second advantage of soft traits is that they can be easily measured on large numbers of individuals, using relatively simple and inexpensive techniques. An additional constraint for trait selection is the requirement for traits to be robust to variation in other environmental or biotic factors than those considered for analysis. Finally, parsimony is an important quality of a trait list for the analysis of PFTs. The first reason for this constraint is practical but it is not the only one. Using partially redundant or irrelevant traits can also reduce the power of the analysis. In general, classifications are likely to include larger numbers of traits when scaling down from very general schemes applicable to the globe or broad regions, to more and more specific schemes at the regional, landscape and community scale.

Statistical Analysis of Trait Response (Step 2)

Vegetation sampling provides information on species distribution across samples taken under a set of environmental conditions of interest. This information can be represented by a matrix of sample $\times$ species records. For each species, attributes are measured for each of the traits in the selected list. This information can be summarized in a second matrix of species $\times$ attribute records. It is then possible to calculate the distribution of attributes across samples by a simple product between these two matrices. The resulting matrix of attributes contains the representation of each attribute across samples distributed across environmental conditions. Response of plant attributes to one or several environmental factors can then be carried out by analyzing the frequency distribution of particular attributes across factor levels. Traits significantly associated with a given set of environmental factors can then be termed functional traits, and the attributes represented under given environmental conditions are functional attributes. While providing direct tests of hypotheses regarding specific attributes, such individual testing does not provide insights into correlation patterns among traits, i.e., how specific attributes may be grouped into syndromes represented in actual species. The univariate method also lacks information about the relative importance of potential mechanisms. These shortcomings can be overcome through the use of multivariate analyses carried out on the attributes matrix. These can be either indirect methods (e.g., detrended correspondence analysis, DCA), where samples are ordinated and their position then interpreted to represent environmental factors, or direct methods (e.g., canonical correspondence analysis, CCA), where correlations with environmental factors are explicitly integrated into the analysis. Multivariate methods thus identify sets of correlated attributes represented for each environmental factor level. These then represent the functional syndromes. Multivariate methods also provide a ranking of importance of contribution of different traits, which can be used to generate hypotheses about the mechanisms of response.

Statistical Analysis of Plant Response (Step 3)

Groups of plants with a similar response to environmental factors of interest can be easily identified using multivariate analyses or classification techniques applied to the sample $\times$ species matrix. Species are grouped according to similarity in frequency distribution across samples. Direct ordination methods like CCA have the advantage

of making an explicit connection between species groups and environmental factor levels, and are recommended to achieve functional classifications. The groups of species identified through these classifications are species functional groups. At this stage they are not explicitly characterized in terms of biological attributes.

Construction of Functional Types (Step 4)

The construction of PFTs as formally defined implies that the species functional groups be linked with corresponding functional syndromes identified for the same environmental factor levels. This methodological stage has presented difficulties to date due to the lack of objective methods to reconcile what are effectively two classifications, each with a subjective component, in the delimitation of classes. Recent research has proposed direct ordination methods that can circumvent this difficulty (Pillar, 1999).

Robustness of Functional Classi cations

Functional classifications can be carried out at varying levels of specificity. Generality and applicability of PFT classifications outside of the specific ecosystem where they were developed, may hold under certain conditions. It is essential to distinguish different levels at which classifications may be repeatable (finding the same PFTs for several places or several dates using a common trait set) or congruent (finding the same PFTs based on different trait sets). Important factors that may influence the degree of robustness include general abiotic conditions, e.g., productivity, and evolutionary history of the flora.

PFTs ALONG RESOURCE GRADIENTS

Validation of the Plant Strategy Scheme

Several recent studies have carried out direct tests of the relevance of the plant strategy scheme to the distribution of plant species along productivity gradients. They evaluated the relevance of the proposed functional trait list to species distribution in specific regions. A comprehensive screening of traits in common plants of the British flora showed strong evidence for the organization of plant biology along a gradient from stressful (growth of all species limited by scarce resources) to competitive (growth limited by uneven access to abundant resources between species) conditions (Grime *et al.*, 1997). This gradient was associated with a suite of traits reflecting plant resource acquisition capacity. Similar patterns have been uncovered in analyses of functional types and syndromes in a range of habitats including wetlands, grasslands and heathlands.

Response to Resource Gradients

Beyond the competition-stress-disturbance (CSR) scheme and functional classifications *per se*, targeted studies have investigated changes in biological traits along the stress–competition gradient assumed to be associated with increasing resource availability. Results from this research bring important elements for the construction of PFTs in response to resource gradients.

Stress Tolerance

The relevance of a suite of traits to plant tolerance to nutrient stress has been examined. Results have first confirmed the relevance of several traits included as part of the stress–competition gradient, such as growth rate, plant height (or shoot mass), shoot : root ratio, loss of leaf tissue to herbivores, and mycorrhizal infection. In addition, seedling tolerance to stress has been shown to be correlated with seed mass as a reflection of embryo reserves. Further studies have concentrated on moving towards true functional traits reflecting physiological mechanisms. They confirmed the significance of traits relating to nutrient acquisition (e.g., SLA, tissue nitrogen concentration, specific root length) but also pointed out a trade-off between resource acquisition and resource conservation traits (Chapin *et al.*, 1993). Resource conservation traits include leaf life span and carbon-based defenses.

Competition: a Still Unresolved Debate

Several studies have attempted to predict plant response to competition. To date, this effort has not resulted in a clear-cut view of which functional traits are responsible for the outcome of competitive interactions. Competitive ability has been generally assumed to be strongly related to plant size, and more specifically plant height (e.g., Westoby, 1998). However, detailed studies have shown that the situation may not be quite so simple. While this trait seems to be a good predictor of plant competitive effect (i.e., the capacity for a plant to suppress its competitors), it may not be related to competitive response (i.e., the ability of a plant to cope with neighbor competition). In addition, in communities with a large number of short-lived species, seed size may be a better predictor of competitive effect than plant size. In perennial-dominated communities, competitive effect has been generally related to a number of root and shoot traits determining foraging for patchy resources. These include RGR, plant height, ability of lateral spread (e.g., phalanx vs. guerilla strategy in clonal perennials) and a trade-off between scale and precision in nutrient foraging.

RESPONSE GROUPS TO DISTURBANCE

At regional or landscape scales, natural and human disturbance regimes are primary determinants of vegetation

dynamics. Climate and land use affect both natural and human disturbance regimes. For example, fire regimes are directly affected by climate and human activities, at the levels of ignition and spread. Fire spread is affected by landscape heterogeneity. Landscape vegetation patterns are determined by the interaction between natural processes of colonization and growth, driven by climate and possibly atmospheric composition, and land use.

The identification of disturbance response groups has been developed, building on knowledge acquired from the development of the more general classifications.

Elements for the Identification of Disturbance Response Groups

In the CSR scheme, the axis describing disturbance has been subjected to much criticism because it potentially incorporates different types (e.g., soil disturbance, grazing, fire) and variation in intensity and frequency. The relevance of this so-called ruderal axis was, however, confirmed by the screening of traits for British plants (Grime *et al.*, 1997) as it has been for successional gradients in herbaceous and heathland communities.

Broad PFT analyses of species response to disturbance invariably converge on a growth-form based classification. For example, in herbaceous-dominated vegetation (e.g., old-fields, grasslands, herbaceous stratum of shrublands and woodlands) broad disturbance PFTs can be identified with four life forms: annuals and short-lived perennial forbs, perennial forbs, grasses (with possibly subdivisions between annuals and perennials), and shrubs if present. In further refinements, response-specific attributes have been used to split life form groups for particular disturbances, e.g., using palatability for response to grazing, or resprouting capacity for response to fire. Recent work to characterize response groups to specific disturbances in a given vegetation type, has shown the usefulness of classifications which explicitly operate in a hierarchical manner within life forms (Lavorel *et al.*, 1997). While the relevance of life form remains primary, and its effects are accounted for as a first step, further analyses within each life form are carried out to examine how other traits contribute. Different sets of traits can be examined for each life form. The degree of splitting within each life form and within life histories depends on the number of species within each group. Within each life form, traits are distributed into three categories designed and analyzed independently: life history, adult morphology, and regeneration. Studies in a given floristic and environmental context may involve removing and adding specific traits to a core list defined for a particular disturbance type.

Grazing and Small-scale Soil Disturbance in Herbaceous-dominated Vegetation

While the ruderal strategy is useful to describe broad disturbance functional types, e.g., at regional scales, it appears inappropriate for dealing with local disturbance effects, in particular by grazing. A redesigned scheme for the inclusion of grazing can account for disturbances of a different frequency and intensity. Specific attributes of grazing tolerance incorporate elements of either *S* or *R* strategies (e.g., low stature, tough and narrow leaves, low shoot : root ratio). The response of herbaceous-dominated vegetation to grazing and soil disturbance, the two most common disturbances in many grassland areas, has been related to a number of life history, adult structural traits and regeneration traits.

1. Life history – annuals or short-lived perennials are usually favored by disturbances that open gaps in the usually grassy and mainly perennial-dominated matrix.
2. Adult structural traits – tend to be well correlated with grassland response to disturbance. Plant size or height has often been found to decrease with increasing disturbance intensity. Presumably, this pattern results from the correlation between plant size and several physiological attributes that provide adaptation to open environments, and from the direct relationship between plant size and accessibility to grazers. Alternatively, synthetic descriptors like Raunkiaer's life form classification (based on the vertical distribution of perennating meristems during unfavorable periods, e.g., winter or dry season) can be used to analyze morphological changes along gradients of increasing disturbance intensity. The patterns obtained in analyses considering association of several morphological traits (e.g., height, lateral spread, leaf morphology) ultimately reflect life form. Finally, in the case of grazing, a number of traits relating to physical (e.g., spines) and chemical defense (e.g., secondary compounds) have been considered, though their relevance may strongly vary across regions and communities.
3. Regeneration traits – although generally inferred to be key factors determining plant population response to disturbance, they have received little detailed investigation. Synthetic classifications designed under the schemes of Grime's regeneration strategies and the Vital Attributes Scheme have attempted to capture species persistence mechanism (seed bank, dispersal or vegetative regeneration) and the spatio–temporal distribution of recruitment. When dealing with specific floras, the list of relevant regeneration traits depends on dominant life forms. In vegetation with a large annual component, seed persistence and germination phenology determine post-disturbance dynamics. When perennials dominate, seed size, resprouting ability and

clonal spread need to be considered. Finally, although its relationship to timing of disturbance is essential, species phenology has often been neglected.

Fire

Unlike the predominantly inductive approach described for grassland response to grazing and soil disturbance, response to fire has been analyzed through the examination of deductive functional types. A well-known example is that of the Vital Attributes Scheme (Noble and Slatyer, 1980). Functional types are based around a limited set of functional traits: species tolerance to fire as established individuals, species regeneration mode (seeding vs. resprouting), tolerance of competition and other abiotic constraints during regeneration, and species life schedules relative to fire return intervals.

GLOBAL CHANGE: TOWARDS A MORE COMPLEX VIEW OF PFTs?

At the scale of the globe or of very large regions, vegetation models have used for a long time functional classifications such as the Holdridge or the Köppen classifications, which are variations around the combination of life form and phenology (*see* **Holdridge Life Zone Classification**, Volume 2). These can reliably predict present distributions and capture important functional processes governing biome distribution. They can also be adequate to examine ecosystem functioning globally, e.g., geographical patterns of net primary productivity, and their changes under given climate change scenarios. However, the understanding of vegetation change in specific ecosystems or regions, and predictions of changes in ecosystem processes appear to require a greater level of detail in plant functional traits. At this level, the proposition of a global PFT key has been rejected (Woodward and Cramer, 1996; Smith *et al.*, 1997). In particular, a common classification for response to different components of global change (climate, atmospheric composition, land use and biological diversity) may not be feasible because non-overlapping classifications are expected when different components involve biologically independent traits. In particular, adult traits involved in the response to abiotic factors such as temperature, CO_2 concentration, or nitrogen availability are often decoupled from regeneration traits involved in response to land use disturbance. Previous sections have provided the elements for an examination of possible plant functional classifications in relation to changes in productivity (brought on by CO_2 enrichment, nitrogen deposition or climate change) and land use changes (through changes in disturbance regimes). Additional elements need to be included to account for response to changes in increasing atmospheric CO_2 concentration, specific climatic parameters and exotic species invasions. Table 1 presents a synthesis of different functional classifications that have been tested with respect to response to different global change factors, at a range of scales.

Response to Increasing Atmospheric CO_2

Studies of plant response to elevated CO_2 initially concentrated on the response of subjective groups, based on basic knowledge of plant physiology. These included: C3 vs. C4 grasses, nitrogen fixers (e.g., legumes) vs. non-nitrogen fixers, monocotyledons vs. dicotyledons and annuals vs. perennials. Overall, these *a priori* PFTs do not appear to be truly functional, as they are poor predictors of plant growth response to elevated CO_2. Tests of response among plant strategies (C, S, R) also showed a strong heterogeneity of response within strategies, invalidating the prediction that fast-growing, competitive species should show a strong stimulation. More focussed analyses were then concentrated on an inductive approach linking observed growth response to species traits. They have consistently shown the relevance of a few traits relating to carbon assimilation including SLA, RGR and stomata density. In addition, several reviews have pointed out the necessity to consider traits relating to degree and nature of plant interactions with soil organisms (in particular symbiosis and mycorrhizae), but few significant results are available at this stage. Finally, it is important to remember that traits affecting seed germination and seedling recruitment may be disconnected from those determining growth of established plants and that their effects on plant establishment under elevated CO_2 would also need to be considered.

Response to Changing Climate

Beyond the effects of increased numbers of growing days, taken into account at the level of life form and phenology, analyses of PFTs for response to climate change also need to consider changes in extreme temperatures. For example, frost resistance appears to be positively correlated with genome size (estimated by DNA content), while genotypes with small genomes are expected to show a greater growth response than those with larger genomes. As a result, expansion of small genome species may be limited by the distribution of frosts rather than by growing temperatures. This example points towards the difficulty of identifying PFTs that will reflect the possible complexities in response to temperature regimes rather than to mean temperatures. Similarly, analyses of PFTs relating to response to changed precipitation regimes have pointed out the importance of response to water stress. In semi-arid grasslands and shrublands, savannas, or rainforests, life form and species distributions

Table 1 Summary of functional classi cations whose relevance for different global change factors has been tested empirically or using models of vegetation distribution[a]

	Global change factor						
	Climate[b]		Atmosphere	Land use			Biodiversity

[a] Y, classi cation with consistent relevance; N, classi cation with no consistent effect; ?, hypothetical effect or incompletely proven.
[b] Effects on global or continental scale distributions over time scale assumed to allow for species migration are separated from effects within communities of particular regions that take place over a few years within the local species pool.
[c] Group of species affecting community resistance to invasion.
[d] Tree/shrub/herbaceous or sub-classi cations within each of these; the degree of re nement depends on the scale addressed.
[e] Annual, biennial, short-lived perennial, long-lived perennial.
[f] Monocotyledon vs. dicotyledon; particular families.
[g] Sempervirent vs. deciduous; summer vs. winter-growing.
[h] Height or height × lateral spread.
[i] RGR, rate of growth per unit of biomass; estimated based in soft surrogates such as SLA (SLA = leaf mass/leaf area) and leaf water content.
[j] C3, C4 or CAM.
[k] Measured as seed dimensions or preferably seed mass; correlates with seedling establishment capacity.
[l] Capacity resulting from the combination of fecundity and dispersal distance. This has been tested in only few speci c cases.

appear determined by differential capacities of plants to grow and survive during drought periods, either seasonally predictable, or unpredictable across years. These result from both water stress tolerance (related to root : shoot ratio, leaf characteristics, photosynthetic pathway for established plants and seed size for seedlings) and avoidance (through deep roots). Finally, in some biomes such as Mediterranean-type ecosystems, savannas, and arctic tundra, climate change is expected to have strong effects on fire regimes. In this case, a relevant functional classification would need to include features of fire response groups.

Interactive Effects of CO_2, Climate and Nitrogen Deposition

Global change components do not impact ecosystems in isolation but interactively. Potential growth response to CO_2 can be strongly modified by water or nitrogen availability. Similarly, the improvement of growth under higher temperatures and/or moister conditions is likely to be enhanced by increases in inorganic nitrogen availability resulting from atmospheric deposition. These types of interactions are those which pose the greatest challenges to PFT research because they involve responses to multiple factors, each involving different sets of traits.

Response to Changing Land Use

Plant functional classifications relevant to changing land use can be based on disturbance PFTs. However, because these are by essence specific to a single disturbance type (response groups), the challenge lies in combining different types of disturbances when new human disturbances (e.g., pollution, soil removal) are introduced.

Response to Exotic Invasions

Invasion by plant, animal or pathogen species that originated from exotic regions can have large impacts on plant community composition, ecosystem functioning, and disturbance regimes. At this point, very little is known about the susceptibility of different receiving communities as a function of their functional composition. Current knowledge suggests that functional classifications of invaded communities would have to be specific to the type of invader (i.e., response groups). In particular, in the case of plant invasions, it has been proposed that susceptibility of a resident community may depend on the relationship between the invader's functional traits and those of the invaded community.

CONCLUSION

PFTs, identified at broad scales, may conceal the more subtle mechanisms that underlie the response of species within life forms to a specified global change factor. While the feasibility of a global plant classification has been rejected, developing a global scheme of PFTs, based on major disturbances (e.g., fire, grazing) specific to different biomes and regions, is crucial for further developments of models of global vegetation dynamics. The aim should not be a universal classification but rather to identify a hierarchy of generality in functional attributes ranging from global to regional. Success will depend on setting a contextual framework, along with a standardized methodology, for comparing studies across regions with different climates, evolutionary histories and current land use (Lavorel and Cramer, 1999).

Plant Growth at Elevated CO_2

Hendrik Poorter[1] and Marta Pérez-Soba[2]

[1]*Utrecht University, Utrecht, The Netherlands*
[2]*Plant Research International, Wageningen, The Netherlands*

Elevated carbon dioxide (CO_2) concentrations stimulate the rate of photosynthesis of most plant species. Consequently, it is expected that prolonged growth of plants at increased atmospheric CO_2 concentrations will enhance their biomass. This prediction is in agreement with most experimental results performed at optimal growth conditions. However, plant growth is stimulated less than expected on the basis of the increased rate of photosynthesis per unit leaf area. This is due to the fact that plants at elevated CO_2 have reduced leaf area on display per unit biomass, thereby decreasing the relative amount of machinery. The reduction goes with increased accumulation of non-structural carbohydrates.

The magnitude of the growth response to elevated CO_2 depends on the plant species. Species like maize and millet, which have a special type of photosynthesis, show a marginal growth response to elevated CO_2 (on average 11%). However, most plant species respond more strongly, with an average stimulation in biomass of 47% for a

doubling of the present atmospheric CO_2 level. Inherently slow-growing species are generally less responsive than fast-growing species. The growth response also depends on the level of other environmental factors. In nutrient-poor and cold environments the proportional growth stimulation by elevated CO_2 will be less. There is a slight increase in response when levels of light and water are decreased. The strongest interaction is with ozone, with plants showing a much stronger CO_2 response when ozone concentrations are higher.

Elevated atmospheric carbon dioxide (CO_2) concentrations generally have two direct and momentary physiological effects on plants. First, they increase the rate of photosynthesis of the leaves, because of higher CO_2 concentrations at the sites where enzymes fix CO_2. Second, they cause stomata to partly close, thereby reducing the water loss due to transpiration. Thereafter, secondary effects may occur, when plants experience elevated CO_2 concentrations for a longer time. Respiration rates may decrease or increase, chemical composition of the plant may change, and so may leaf morphology and anatomy. For a review of the effect of CO_2 on these physiological processes (*see* **Plants – Carbon Balance and Growth**, Volume 2). In this contribution, we analyze how the myriad of direct and indirect changes affects the growth of individual plants in the vegetative stage. First, plant growth responses under relatively optimal conditions will be discussed. Thereafter, we will consider CO_2 effects under conditions limiting for plant growth. Responses are analyzed by compiling literature data for a large range of published experiments on individually growing whole plants, grown either in growth chambers, glasshouses or open-top chambers.

GROWTH STIMULATION DOES NOT ONLY DEPEND ON THE STIMULATION OF PHOTOSYNTHESIS

The growth of a plant over time can be adequately described by the relative growth rate (RGR; see Box 1 for more information). Mathematically, this variable is the product of three biologically meaningful growth parameters: ULR, SLA and LMF. The ULR is the biomass increase per unit leaf area and time, and is a composite parameter that includes the daily rate of photosynthesis per unit leaf area, the fraction of fixed carbon that is respired the same day and the carbon content of the plant material. SLA is the amount of leaf area formed per unit leaf biomass, a parameter linked to the light-intercepting capacity of a leaf. The LMF is the relative amount of total plant biomass invested in leaves, and thus in the process of carbon fixation.

How are RGR and its components affected by elevated CO_2? We analyzed 130 observations on the growth of species with the most common type of photosynthesis (C_3 species) from 50 published experiments (see Poorter and Nagel, 2000). For each growth parameter we calculated the ratio between the value at elevated CO_2 (approximately 70 Pa) and that at current levels (approximately 35 Pa). The distribution of these ratios is shown in Figure 1. On average, the RGR is stimulated to a small extent (9%). The increase can be attributed to an increase in ULR (23% on average). Although both respiration and carbon concentration may change to some extent (Bunce, 1994; Poorter *et al.*, 1997), it is mainly the stimulation in the rate of photosynthesis per unit leaf area that increases ULR. At the same time, the SLA decreases (13% on average), which implies that plants grown at elevated CO_2 have less leaf area on display per gram of leaf. This decrease in SLA counteracts the increased rate of photosynthesis per unit leaf area, the net result being that growth is stimulated substantially less than was expected on the basis of the stimulation in the rate of photosynthesis alone. The decrease is at least partly linked to the accumulation of starch and other non-structural carbohydrates (Körner *et al.*, 1995). The most likely reason for the accumulation is that plants have increased photosynthesis to the extent that they cannot usefully deploy the newly fixed carbohydrates into new growth. They are then accumulated as non-structural carbohydrates in the leaves, causing the SLA to decrease. The last parameter involved, the LMF, hardly changes (1% increase on average), indicating that biomass allocation is generally not affected by elevated CO_2 (Stulen and Den Hertog, 1993). In the end, it is the

Box 1 Terminology used. All biomass data presented in this article are on a dry weight basis

Abbreviation	Full term	De nition	Units
BER	Biomass enhancement ratio	Biomass at elevated CO_2/biomass at control levels	$g\,g^{-1}$
LMF	Leaf mass fraction	Fraction of biomass allocated to leaves	$g\,g^{-1}$
RGR	Relative growth rate	Increase in biomass per unit biomass already present and per unit time	$m\,g\,g^{-1}\,day^{-1}$
SLA	Speci c leaf area	Leaf area per unit leaf biomass	$m^2\,kg^{-1}$
ULR	Unit leaf rate	Increase in biomass per unit leaf area and time	$g\,m^{-2}\,day^{-1}$

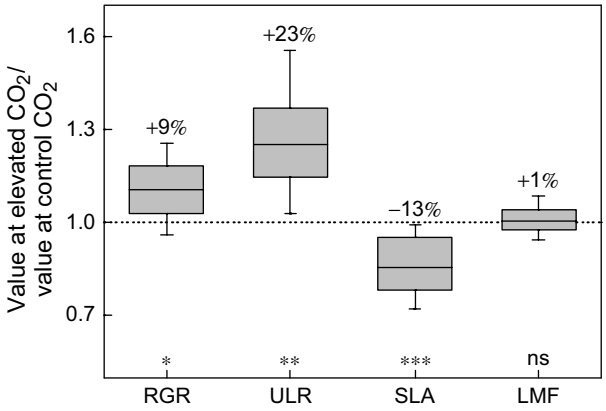

Figure 1 Effect of elevated CO_2 on RGR and its components ULR (g dry mass increase m^{-2} leaf area and day^{-1}), SLA (m^2 leaf area per kilogram leaf mass) and LMF (g leaf per gram total plant). The effect is calculated by dividing the value at elevated CO_2 by the value at ambient levels of CO_2. Results from 130 growth analyses (compiled in Poorter and Nagel, 2000) are shown as boxplots. The numbers above the boxplots are the average percentage increases due to elevated CO_2 (10%-trimmed means). Boxplots indicate the distribution of a range of observations. The lower part of the box shows the 25th percentile, the value below which 25% of the observations are found. The highest part of the box gives the 75th percentile, and the line in between the median (50th percentile). The error bars give the 10th (lower) and 90th (higher) percentile. Signi cance levels for the H_0-hypothesis that the ratio equals 1 are indicated above the *x*-axis: ns, non-signi cant; $^{*}P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$

net balance of all these physiological and morphological changes that determines the overall growth response of plants to elevated CO_2, and not only the response of leaf photosynthesis.

GROWTH STIMULATION IS TIME-DEPENDENT

Given the possible feedbacks discussed above (changes in physiological processes, biomass partitioning between plant parts and chemical composition), it is difficult to forecast the growth response of plants from short-term effects on the rate of photosynthesis and transpiration alone. This problem becomes even larger as the growth stimulation turns out to be time-dependent. In quite a number of studies, RGR is increased by elevated CO_2 only at the beginning of the experiment, the growth stimulation lasting *circa* 5–15 days. Thereafter, growth rate becomes more or less equal to that of plants at ambient CO_2. In the rest of this contribution, we will use the ratio of plant biomass at elevated and at ambient levels of CO_2 as a measure of the growth response of plants. We will call this the BER (*biomass enhancement ratio*). If RGR were only stimulated during the first 10 days of CO_2

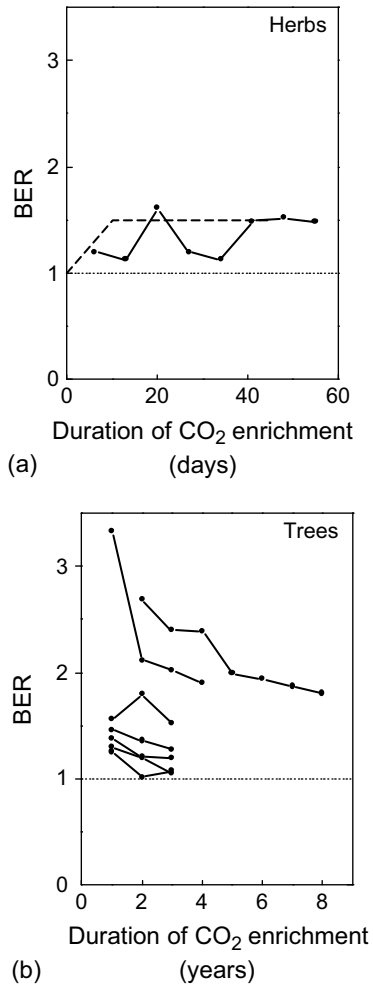

Figure 2 Time course of the BER due to elevated CO_2. (a) An example of an idealized response (bold line) and the response of a herbaceous species. (b) The observation for some tree species

enrichment, BER would start at a value of 1 at the beginning of the experiment, increase up to a certain level until day 10, and then remain constant (Figure 2a, broken line). Particularly in longer-term experiments with tree seedlings, it has been reported that BER even decreases after the first year of the experiment (Figure 2b). In this contribution we will not discuss possible differences in duration between experiments, the reader is referred to reviews like Poorter (1993) and Curtis and Wang (1998).

GROWTH STIMULATION DIFFERS BETWEEN GROUPS OF SPECIES

While keeping in mind that the growth stimulation may be time-dependent, it would be useful to condense the information from the numerous experiments on elevated CO_2 that have been carried out with a wide range of plant species. We

did so by screening the literature, restricting our analysis to experiments where plants were grown at elevated CO_2 levels between 60 and 80 Pa, and at control levels of CO_2 between 30 and 40 Pa. For each experiment and each species where whole plant dry mass was determined, we calculated the BER, arriving at a total of 600 observations (for more information see Poorter, 2001). These were first averaged per species, and subsequently species were classified into a limited number of groups that we thought to have important characteristics in common. Such a separation into functional types may increase insight into the differential response of groups of species and enables generalization of the results. The first distinction we made was on the basis of the type of photosynthesis. Most species fix CO_2 during the day, and experience relatively low levels of CO_2 at the actual site of fixation (so-called *C_3 plants*) (*see* **C_3 and C_4 Photosynthesis**, Volume 2). A number of species, like maize and millet, have a very efficient way to increase the CO_2 concentrations to high levels at the place in the leaf where carbon is fixed (so-called *C_4 plants*), even at low ambient concentrations of CO_2. Purely on that basis they can be expected to respond less to an increase of CO_2 in the atmosphere than C_3 species. Other species, like cacti, take up CO_2 from the air during the night but actually incorporate that carbon into carbohydrates during the day (crassulacean acid metabolism (*CAM*) species). The C_3 species respond most strongly to elevated CO_2, with an average increase in biomass of 47% (Figure 3). Data on CAM species are scarce; the mean response for the 6 species investigated being 21%. Rather unexpectedly, C_4 species also respond to increased CO_2 levels (11%). This might be due to increased rates of carbon fixation at elevated CO_2 in some C_4 species. Another explanation might be that in some experiments plants were thought to grow under optimal conditions, when in fact they were suffering from water stress to some extent. Then, the partial closure of the stomata caused by elevated CO_2 was advantageous for their water balance and would have enhanced growth by alleviating stress (see next section). Such an effect may play a role in experiments with C_3 species as well.

The second distinction we made was within the group of C_3 species. On average, crop species show the highest biomass enhancement (59%) and wild herbaceous plants the lowest (41%). Most of the experiments with woody species have been carried out with seedlings, thus covering only a small part of the life cycle of these plants. Their growth stimulation is on average 49%. Crop species are generally fast growing. The herbaceous wild plants consist of a wide mix of species, some growing as fast as crop species, others almost as slow as tree seedlings. It has been suggested that inherent variation in RGR may account for part of the interspecific variation between C_3 species (Poorter, 1993). Indeed, inherently slow-growing species respond generally less (27% on average) than the

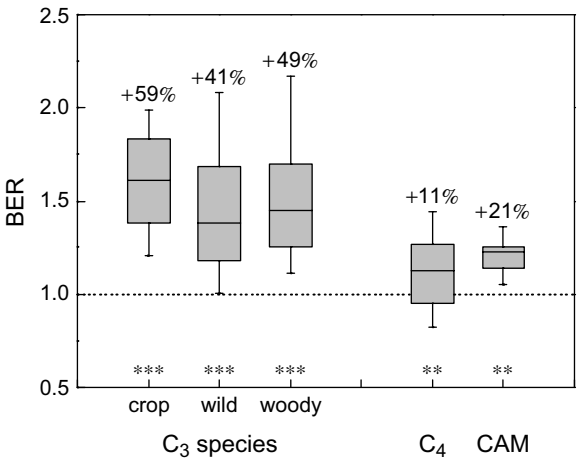

Figure 3 Distribution of BER for several functional types of species. Distributions are based on 540 observations from 280 C_3 species; 55 observations from 30 C_4 species; 13 observation from six CAM species. C_3 species were separated into three groups. There were 110 observations from 24 crop species; 190 from 115 wild herbaceous species; and 230 from 135 woody species. (Literature data compiled in Poorter, 2001)

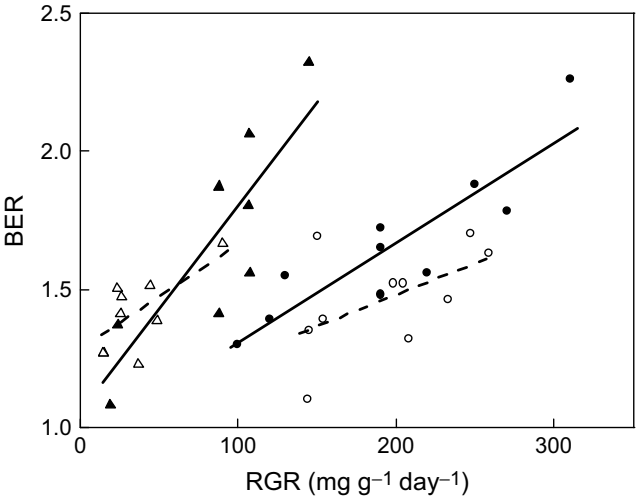

Figure 4 BERs of different species as a function of their RGR at ambient CO_2. All data pertain to C_3 species. Open triangles: temperate woody seedlings (Cornelissen *et al.*, 1999); closed triangles: tropical woody seedlings (Winter and Lovelock, 1999); closed circles: herbaceous crop and weed species (Bunce, 1997); open triangles: herbaceous wild species (Poorter, 1993). Continuous lines are regression lines that differ signi cantly from zero ($P < 0.05$), broken lines are non-signi cantly different

category of fast-growing species (60% on average). This generalization is confirmed in most experiments where fast- and slow-growing species are compared for their BER. Two examples for herbaceous species and two for woody species are shown in Figure 4. Although the correlation

is not always statistically significant, in all research on the response of a range of species, the slope of the line that fits the BER versus RGR data is found to be positive (Poorter, 2001). Most likely, it is the balance between the carbohydrates supplied by photosynthesis and those utilized in structural growth and/or specialized storage organs that determines the degree of response to elevated CO_2. This may explain why fast-growing species, or species with storage sinks as tubers are among the species showing the stronger responses (Reekie *et al.*, 1998).

GROWTH STIMULATION DEPENDS ON THE LEVEL OF PRIMARY RESOURCES

The former analysis was for plants that were grown under laboratory conditions at levels of nutrients, light and water that are generally optimal or close to optimal for growth. What will happen if one of the primary resources is in short supply and causes a growth limitation? Given that both control as well as CO_2 enriched plants would be hampered in growth, one may expect that the absolute growth stimulation by elevated CO_2 will decrease. This is indeed the case. But what will happen to the relative growth stimulation? We compiled experiments that have been carried out at ambient and elevated levels of CO_2, and with high and low levels of the three primary resources (nutrients, light and water) (Poorter and Pérez-Soba, 2001). The severity of the stress was expressed by calculating how much the biomass of sub-optimally grown plants at ambient levels of CO_2 was reduced relative to the biomass of the optimally grown plants at the same CO_2 level. We then calculated the BER at sub-optimal and optimal conditions, and subsequently the slope of the line that connects the two BER values. If the slope is positive, it implies that BER increases when a primary resource becomes growth limiting. An example is given in Box 2.

The distribution of the slopes for a range of experiments is represented by the boxplots of Figure 6. On average, the slope is negative in the case of nutrients. This implies that a decrease in nutrient availability decreases the relative response of plants to elevated CO_2. The pattern of responses was similar between experiments where nitrogen, phosphorus, or all nutrients together were varied. It seems that at ambient CO_2 conditions the growth of plants at low nutrient levels is not restricted by carbon availability, since high concentrations of starch and other non-structural carbohydrates are found in nutrient-stressed

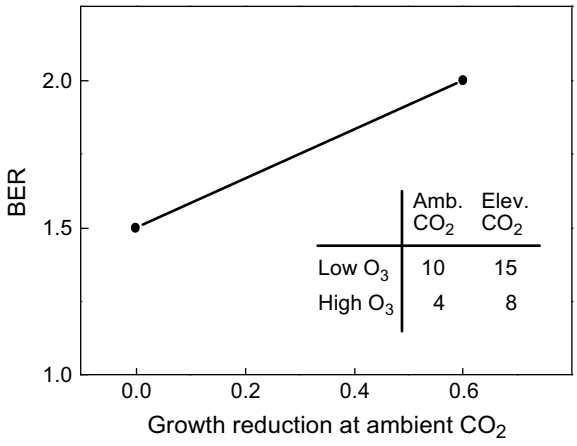

Figure 5 The CO_2 response of plants that grow under a low concentration of ozone (at $x = 0$) or at a high concentration. The insert gives the hypothetical biomass data on which the graph is based

Box 2 Calculating the effect of limiting factors on the BER

To analyze how elevated CO_2 interacts with another environmental factor at the level of plant growth, a minimum of four observations is required: the mass of plants at ambient and elevated CO_2 levels at both a low and high level of the other environmental factor. In Figure 5, an example is given for the interaction with ozone. Assuming that the mass of plants is as given in the insert, then the BERs are 1.5 and 2 at low and high ozone concentrations, respectively. It is dif cult to assess the severity of the ozone stress just from a description of the experimental design. Therefore, as a measure of the stress experienced by the plants, we use the growth reduction shown by the high-ozone plants at ambient CO_2, scaled relatively to the mass of the high-ozone plants at ambient CO_2. If that fraction is close to 0, the stress was minor; if the fraction is much higher, then the ozone stress was apparently more severe. The BER value of the low-ozone plants is plotted at $x = 0$. The BER value of the high ozone plants is plotted at $x = 0.6$, this value being the growth reduction due to the high ozone concentration. After plotting these ratios, the slope of the line connecting the points is calculated. A positive slope indicates that at high ozone concentrations, the relative increase of plant biomass by elevated CO_2 is larger. Note that in absolute terms, high-ozone plants at elevated CO_2 are still smaller than low-ozone plants at elevated CO_2.

The advantage of this approach is that the same procedure can be followed for other environmental variables, just replacing the low ozone treatment with, for example, low water supply or high SO_2. In the case of temperature there is an optimum rather than a linear response. Here we selected the treatment with the highest biomass as the optimal one. A disadvantage of the approach followed is that the analysis implicitly assumes that the BER changes linearly across the range of another environmental factor from sub-optimal to optimal. For the calculations, all BER values have to be transformed prior to any mathematical analysis, as ratios are log-normally distributed. The slope in this case is 0.48.

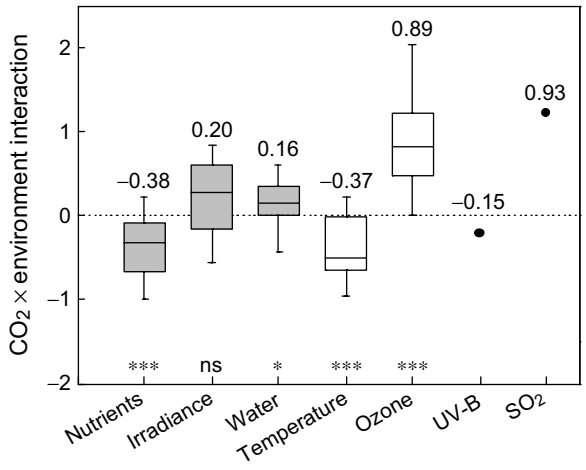

Figure 6 Interaction between elevated CO_2 and various environmental factors on plant growth. Boxplots give the distribution of the slopes, obtained as outlined in Box 2. Values below zero indicate that the relative stimulation of plant growth by elevated CO_2 is smaller at growth-limiting levels of the various factors under investigation. Values above zero indicate that the BER is larger. Data are based on a literature review (Poorter and Pérez-Soba, 2001) on factorial experiments with combinations of elevated CO_2 and nutrients ($n = 102$ observations), irradiance ($n = 19$), water ($n = 29$), temperature ($n = 56$), O_3 ($n = 24$), UV-B ($n = 7$) or SO_2 ($n = 3$). Due to the low number of observations for UV-B and SO_2 we only calculated the average values. Signi cance levels are given for the v-hypothesis that the slope equals zero

plants. Consequently, an increase in the carbohydrate pool due to an increase in photosynthesis by elevated CO_2 concentrations is not expected to stimulate growth to a large extent.

The slope is positive for the factor irradiance, but variability is high and the mean does not differ significantly from zero. A positive slope would imply that at low irradiance the response to elevated CO_2 is relatively stronger than at higher irradiance. It has been suggested that elevated CO_2 decreases the light compensation point of photosynthesis (*see* **Plants – Carbon Balance and Growth**, Volume 2). However, that would only hold at very low irradiance levels (Kimball, 1986a). Elevated CO_2 causes a partial closure of stomata, which in turn reduces plant water use. Therefore, plants growing at limited water availability might thrive longer on a given water supply. The relative growth response is expected to be higher, and this is indeed what has been observed (Figure 6). However, on average the interaction with water is small.

It should be noted that, in general, interactions can be expected between these primary resources: at low water supply, nutrients will be less mobile, and at high irradiance, plants will grow faster, with a higher chance of nutrient or water depletion around the roots.

CO_2 INTERACTS WITH OTHER GLOBAL CHANGE FACTORS

Global change is not restricted to an increase in the atmospheric CO_2 concentration. Increases in temperature due to the accumulation of greenhouse gases such as CO_2, methane and chlorofluorocarbons are anticipated as well. Moreover, because of anthropogenic activities, atmospheric ground-level concentrations of ozone (O_3), nitrogen oxide (NO_x) and sulfur dioxide (SO_2) are rising, and so is the UV-B radiation. How will these factors influence plant growth responses to rising atmospheric CO_2 concentrations? We followed the same approach as in the previous section, analyzing factorial experiments in which both CO_2 and one of these other environmental factors were investigated. Once more, we calculated the growth reduction under suboptimal conditions relative to the optimal one and determined the slope of the line connecting the two BER values.

The interaction of CO_2 with supraoptimal temperatures has hardly been investigated. On average there is a smaller growth response to elevated CO_2 at temperatures suboptimal for growth (Figure 6; cf. Idso and Idso, 1994). One explanation is that elevated CO_2 stimulates photosynthesis relatively less at lower temperatures. Another is that at suboptimal temperatures, growth is inhibited more than photosynthesis, causing non-structural carbohydrates to accumulate. As with low nutrient availability, this may preclude a strong response to increased CO_2. For those plant species that currently grow under sub-optimal temperatures, one may expect a greater CO_2 response if a global warming of the climate takes place.

Ozone shows the strongest positive interactions with CO_2 (Figure 6). For almost all observations, the slope is positive, implying that CO_2 strongly ameliorates the effect of ozone. There is good evidence that in plants in which stomatal conductance is reduced by CO_2 enrichment, O_3 flux into the leaf interior is reduced and this contributes to an amelioration of the detrimental effects of O_3 on plant growth and physiology (Turcsányi *et al.*, 2000). It is yet not clear to what extent other mechanisms induced by elevated CO_2 may play a role in amelioration, such as detoxification or repair processes. A second point of concern is the strength of the combined effect of elevated CO_2 and O_3 on the growth and productivity of species in which the stomata are less responsive to CO_2 enrichment, such as many conifers. Data indicate that for those species, there may be similar effects of O_3 at ambient and elevated CO_2, or at least much less amelioration of ozone damage than that observed in herbaceous species (Pérez-Soba *et al.*, 1995).

Experiments with $CO_2 \times$ UV-B interactions are scarce, the data hinting at the fact that elevated CO_2 could not compensate for the harmful effect of UV-B (Figure 6). However, these results obtained under artificial environmental conditions could result in responses different from

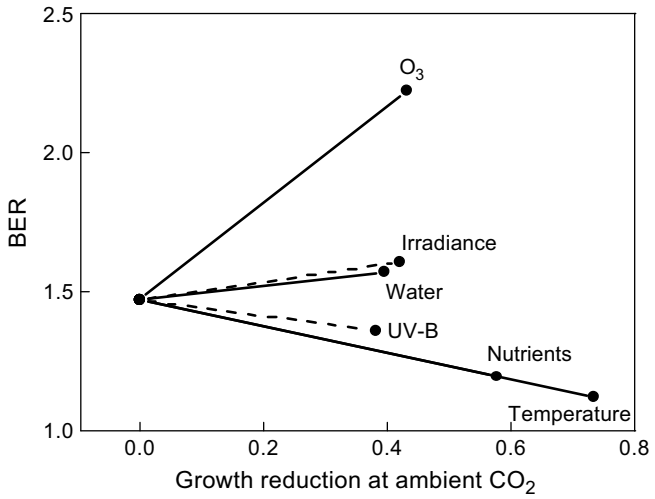

Figure 7 The average growth response of plants when elevated CO_2 is combined with sub-optimal levels of other environmental factors. Responses were calculated using a BER of 1.47 for plants grown under optimal conditions (Poorter, 1993). The average slope was calculated from the data of Figure 6 and the average reduction in growth at 35 Pa CO_2 as calculated in the compiled literature

the field situation. First, the UV-B levels used in the experiments are generally very high. Second, leaves developed under full sunlight have morphological and physiological adaptations that afford some protection from UV-B (Teramura and Murali, 1987). Consequently, plants in growth chambers, in which the visible light levels (*photosynthetically active radiation*) (*see* **PAR (Photosynthetically Active Radiation)**, Volume 2) are about two times lower than in field conditions may be more sensitive to UV-B than those in the field. The information on combined effects of elevated CO_2 and SO_2 or nitrogen (N) deposition is so limited that it precludes any generalized statement.

To summarize the effects of elevated CO_2 at sub-optimal growth conditions, we plotted the average BER values against the average growth reduction observed in the compiled literature (Figure 7). The growth enhancement by elevated CO_2 is severely reduced at low temperatures or poor nutrient supply. On the contrary, it is increased at low soil water availability, but the rise in BER is only small. The interaction between elevated CO_2 and O_3 shows the most dramatic response. The loss of biomass due to elevated ozone is, on average, more than compensated in the presence of elevated CO_2.

AN OUTLOOK

Up to now we have focused on experiments that have been carried out with individual plants in the vegetative stage. When extrapolating these results to the field situation, the following considerations should be taken into account. First, we have focused on average responses based on underlying data that are quite variable, partly due to the different growth conditions between experiments. Second, part of the increase in biomass is due to the accumulation of high levels of non-structural carbohydrates. This part of the extra-achieved biomass does not necessarily add to the performance of the plant and therefore may be regarded as non-functional in a number of cases. Third, generative biomass (seeds, fruits) is often stimulated to a lesser extent than vegetative biomass, at least in crop species (26% on average, Kimball, 1986b). In addition, it is not necessarily true that the species stimulated strongly in the vegetative phase will also be those that are stimulated relatively stronger in generative biomass (Ackerly and Bazzaz, 1995). Fourth, plants growing in monoculture have been shown to respond less than individually grown plants (Wayne and Bazzaz, 1995). Finally, most research was carried out with plants that have not been able to adapt genetically to high CO_2 levels.

How do growth responses of laboratory-grown individual plants, grown at optimal conditions, compare to those in the field? The above-ground biomass of monocultures of plants grown under agricultural field conditions increases by 20–40% due to elevated CO_2. This increase is somewhat smaller than that found in Figure 3. On the basis of the strong interaction with nutrients (Figure 7), it can be expected that natural types of vegetation, where plants are generally growing under far less fertile conditions, will show even smaller responses in biomass production. Current information shows that this is indeed the case, above-ground biomass in CO_2 enriched grasslands being increased by 14% on average (Mooney *et al.*, 1999). A discussion on the effects of elevated CO_2 on ecosystem functioning is given by Körner (*see* **CO_2 Enrichment: Effects on Ecosystems**, Volume 2).

Plant Migration

see Plant Dispersal and Migration (*Opening essay*, Volume 2)

Plant Ontogeny

Plant ontogeny describes the whole course of development of an individual plant. It represents the realization of the phenotype of the organism under the influence of its genotype (*see* **Phenotype/Genotype**, Volume 2). The ontogeny of a typical higher plant begins with fertilization and the determination by hormonal fields or external environmental factors of the polarity of the zygote. Differentiation and morphogenesis (the development of form and structure) proceeds in the shoot and root by terminal cell division and growth, and by enlargement through further cell division and maturation. At intervals (nodes), shoots, branches or leaves arise in specific patterns. At a time determined by the organism's genotype, and by environmental stimuli, the growth pattern of shoots undergoes massive changes with the induction of flowering. After flowering and seed production, the plant usually senesces, severs its leaves and dies – all actively controlled stages of the plant's ontogeny.

The control of all the events and stages of ontogeny – of plant development in space and time – is vastly complex. It stems from the plant's genotype, and operates largely through hormone interactions, metabolic gradients, and the influence of external stimuli such as photoperiodism, temperature and gravity. The patterns of ontogeny in lower plants are less complex, but are nevertheless governed by essentially similar controls, the complexity of

which depends only in small part on the morphogenetic complexity of the organism.

Ontogeny can be interrupted by accident and usually, if the damage is not too severe, reverts to an earlier stage and starts over. The ontogeny of plants, unlike that of animal early development, does not appear to reflect their phylogeny (evolutionary history). Plant ontogeny, in fact, is remarkable for the underlying or basic similarity of its patterns and control mechanisms in a very wide range of plant groups.

Plants - Carbon Balance and Growth

Robert W Pearcy
University of California, Davis, CA, USA

Photosynthetic carbon gain is the process by which plants sequester both the energy used for growth and the carbon necessary for actually constructing the plant. The balance of the gains in carbon and the losses of carbon due to the respiration involved in constructing and maintaining the plant body and in the acquisition of other resources such as water and nutrients is referred to as the carbon balance. Carbon balances can be measured for leaves, for branches or for whole plants. When determined for leaves over their life span, it expresses the net profit (measured in carbon units) derived from the leaf. The net profit is the carbon that, when allocated within the plant, can be used for growth, maintenance processes and reproduction. Carbon balances for whole plants are directly related to their growth rate.

*The carbon gain of a leaf is a function of its photosynthetic capacity and the effects of the environment that limit photosynthesis. Photosynthetic capacity is determined principally by the concentrations of photosynthetic enzymes in the leaf and the limitations imposed by the stomata to diffusion of carbon dioxide (CO_2) into the leaf. Environmental limitations such as temperatures that are too hot or too cold, light that is too low, or stresses such as drought can greatly reduce the realized photosynthetic rate. Plants also differ in their photosynthetic pathway for carbon fixation and this has important implications for global change. Photosynthesis of plants with the C_3 photosynthetic pathway increases much more strongly with increasing atmospheric CO_2 concentrations than does photosynthesis in plants with the C_4 pathway. This difference is projected to make C_4 species less competitive relative to C_3 species and lead to a future expansion of C_3 species (*see ***C_3 and C_4 Photosynthesis**, *Volume 2).*

The growth rate of a plant is a function of the carbon balance of its leaves and pattern by which this carbon is allocated to new structures. Investment in increasing the leaf area of the plant drives growth because it leads to more carbon gain. Increasing atmospheric CO_2 increases growth of C_3 plants via its stimulation of photosynthesis but this stimulation is partially offset by a lower allocation to leaf area production. Growth of C_4 plants exhibits only a small stimulation by high CO_2 because their photosynthetic carbon gain is only slightly stimulated. Carbon balance provides a conceptual framework for understanding the response of plant growth to climate change as well as a tool for assessing its quantitative impacts.

CARBON GAIN BY LEAVES

The photosynthetic capacity (A_{max}) of a leaf is defined as its net CO_2 assimilation rate under conditions where light is saturating, the temperature is optimum, the relative humidity is high and CO_2 and O_2 concentrations are within the normal range encountered during growth. It is the best photosynthetic performance a plant can achieve given its genetic potential and the conditions under which it has grown. Photosynthetic capacity can be expressed either per unit leaf mass or per unit leaf area. On a per unit mass basis it expresses the rate of return on investment in the leaf. However, the solar radiation that drives photosynthesis is measured on an area basis so that for many purposes such as scaling the values up to whole canopy photosynthesis, expression of photosynthetic rates on an area basis is advantageous. For either basis of expression, photosynthetic capacities among terrestrial higher plants vary over an approximately 100-fold range. Generally, species from resource-rich environments have higher photosynthetic capacities than those from resource-poor environments where water, nutrients or other environmental factors may be strongly limiting.

Leaf photosynthetic capacity is determined primarily by the concentrations and catalytic activities of enzymes involved in photosynthesis and to a lesser extent by the limitations on diffusion of CO_2 to the site of photosynthesis. These physical diffusion limitations are imposed by laminar boundary layer over the leaf, the stomata in the leaf surface and by the anatomical architecture of the leaf mesophyll. For leaves having the C_3 photosynthetic pathway the relationship between photosynthetic rate and the CO_2 concentration in the intercellular air spaces (c_i) typically exhibits a strong, almost linear increase up to about 200–250 ppm CO_2 followed by a gradually decreasing slope at higher CO_2 (Figure 1). This relationship is often referred to as an A/c_i curve. Elegant studies by von Caemmerer and Farquhar (1981) established that this

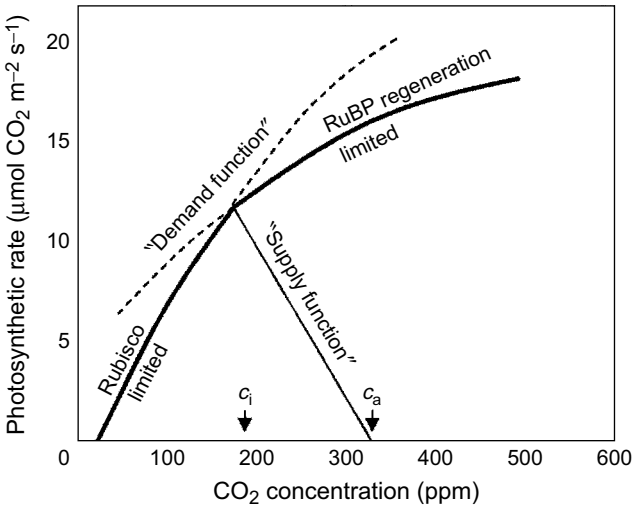

Figure 1 The dependence of photosynthetic rate on CO_2 concentration in the intercellular air spaces (bold line). This is the demand function for CO_2 while the supply function as determined by the stomatal conductance is shown by the thin diagonal line. Also shown are the Rubisco limited and RuBP-regeneration limited parts of the response

curve could be understood in terms of the kinetics of the primary CO_2 fixing enzyme ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) which catalyzes the condensation of ribulose bisphosphate (RuBP) with CO_2 to yield the first products of CO_2 assimilation. The carboxylation rate in a leaf depends on the amount of active enzyme present and any limitations by the substrates CO_2 and RuBP. In addition, oxygen in the atmosphere competitively inhibits carboxylation by Rubisco, leading to photorespiration.

At low c_i values, photosynthesis is limited by the CO_2 concentration itself while at high c_i it is limited primarily by the rate at which the acceptor molecule RuBP can be regenerated. RuBP regeneration is thought to be limited primarily by photosynthetic electron transport capacity that is responsible for generating the energy and reducing power required for carbon metabolism. The combined curve, reflecting limitations by Rubisco activity and RuBP regeneration activity, represents the demand function for CO_2 established by photosynthetic metabolism. The supply function is set mostly by the stomata and is represented by the diagonal line connecting the ambient CO_2 concentration (c_a) with c_i. The negative slope of this diagonal line is proportional to the stomatal conductance to CO_2. As the stomatal conductance decreases, the line rotates to the left and the new photosynthetic rate of a leaf is given by the intersection with the A/c_i curve. For unstressed plants, c_i is often close to the transition from strictly CO_2-limited to RuBP regeneration-limited photosynthesis. At this point, the investment in the photosynthetic apparatus is thought to be optimal because Rubisco and RuBP regeneration capacity are co-limiting rather than one or the other being present in excess of requirements. Increasing the Rubisco activity in the leaf increases the initial slope of the curve giving a higher photosynthetic rate at low c_i values. Achieving an increase at high c_i values additionally requires an increase in RuBP regeneration capacity. Although a small increment in photosynthetic rate will result even if the stomatal conductance does not change, realizing the full potential increase in photosynthetic rate also requires a concomitant increase in stomatal conductance. Indeed interspecific comparisons reveal a strong correlation between stomatal conductance and photosynthetic capacity (Körner *et al.*, 1979).

The variation in photosynthetic capacity between plants with different leaf characteristics has been shown to have a consistent global pattern related to investments in biomass for a given leaf area, leaf nitrogen contents and leaf longevity (Reich *et al.*, 1997). Long-lived leaves tend to be thick with substantial investments in cell wall material, giving a low specific leaf area (SLA, leaf area per unit of leaf mass) and also to have low nitrogen concentrations. At the other end of the spectrum, short-lived leaves tend to have high photosynthetic capacities, high leaf nitrogen contents per unit leaf mass and high SLA. Indeed, when photosynthetic capacity is plotted versus leaf nitrogen and SLA, a curved plane circumscribing the full range of variation results (Figure 2). The different leaf types then fall out on different parts of this plane. These patterns were essentially the same for all ecosystems or biome of origin suggesting that the same tradeoffs are involved despite large differences in climate. There were no species with thin short-lived leaves and low nitrogen, or with thick leaves with high nitrogen, in either a wide range of species measured by Reich and his colleagues or from published results from other researchers. Photosynthetic capacity and leaf nitrogen concentration are highly correlated because of the investments of nitrogen required in synthesizing photosynthetic enzymes. The correlation between photosynthetic capacity and SLA may be driven by several factors. Long-lived leaves may require substantial investment in cell walls and other structural components to withstand stresses and to resist herbivory. These thick dense leaves may cause internal shading within the leaf, limiting the light reaching some of the chloroplasts and they may also have greater internal diffusion limitations, limiting the supply of CO_2 to the chloroplasts. Selective pressures for increasing photosynthetic capacity by increasing photosynthetic enzyme concentrations would run up against these limitations. It could also be that thick leaves with high nitrogen would be subjected to a greater probability of herbivory over their long life, limiting their realized longevity and selecting against their evolution. On the other hand, short-lived leaves with a low photosynthetic capacity may be disadvantageous because of a relatively low payback over their life span.

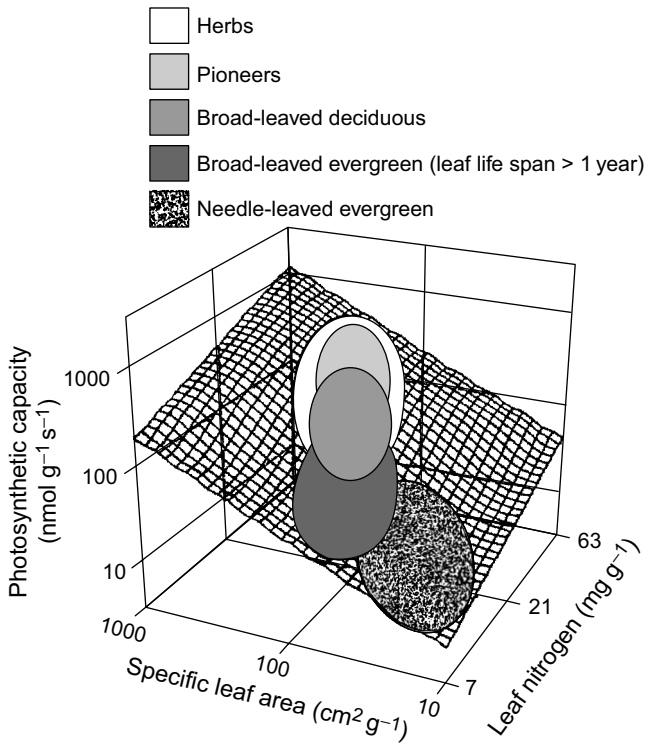

Figure 2 The dependence of photosynthetic capacity per unit leaf mass on the speci c leaf area and leaf nitrogen content. The shaded areas circumscribe the ranges of values for each leaf type independent of the biome or ecosystem of origin from the arctic tundra to tropical forests. Note that all axes are $\log_{10}$ scale [from Reich *et al.* (1997) reproduced by the permission of The National Academy of Sciences of the United States of America]

On a leaf area basis, photosynthetic capacity and leaf nitrogen per unit leaf area are positively correlated, and leaf life-span and leaf photosynthetic capacity are generally negatively correlated. But when expressed on this basis, there is a much greater divergence among leaf types and across biomes in the scaling of the relationships.

The photosynthetic capacity of a leaf can be altered by the growing conditions such as the prevailing temperatures or light. Leaves developing in the shade have a low photosynthetic capacity per unit leaf area as compared with sun-developing leaves. This acclimation of photosynthesis to the light environment appears to involve a tradeoff between maximizing light capture and maximizing photosynthetic capacity. Thinner leaves, but with greater chlorophyll contents per unit leaf mass allows for greater total leaf area on the plant, maximizing light capture in shaded environments. In high light, thicker leaves having a higher concentration of photosynthetic enzymes per unit area may maximize photosynthesis. In many cases the photosynthetic capacity per unit leaf mass is similar in sun and shade-acclimated leaves. This pattern is somewhat different than for the cross-species comparison presented above but the two- to four-fold variation in photosynthetic capacity between sun and shade leaves of a species is but a small fraction of the interspecific variation observed globally.

Acclimation can also occur in response to an increase in the atmospheric CO_2 concentration. In many species, growth in elevated as compared with normal ambient CO_2 concentrations results in a downward shift in the A/c_i curve (Drake *et al.*, 1997). This shift results in lower photosynthetic rates at the normal ambient CO_2 concentration and less of a stimulation in photosynthetic rates at the elevated CO_2 concentration than if no acclimation occurred. The decrease in the A/c_i curve is due to decreased investments in Rubisco and RuBP regeneration capacity. The resulting lower leaf nitrogen also has the additional effect of making the leaves less nutritious for herbivores. In addition, stomata often respond to elevated CO_2 concentrations, resulting in a reduced stomatal conductance, further limiting photosynthetic rates. Acclimation may function to balance the supply of carbohydrates from photosynthesis to the capacity to utilize them in growth. Not all species exhibit this acclimation response and some show a slight stimulation. Acclimation to CO_2 is usually greater when there are additional limitations to growth such as low nitrogen or water availability (Drake *et al.*, 1997). However the effect can be quite complicated since acclimation also in part relieves the demand for these resources.

Limitations in the environment often cause the realized photosynthetic rate of a leaf to be substantially lower than the photosynthetic capacity. These limitations occur because the light is too low, temperature is too high or too low for optimum photosynthesis, or the humidity is too low, causing stomatal closure. In addition, stresses such as drought, salinity, etc. can strongly limit the photosynthetic rate. The nature and extent of these limitations varies widely between ecosystems. In temperate deciduous forests low light due to cloudiness, short day lengths in the spring and fall and cool temperatures during this time can limit the annual leaf photosynthesis to 35–45% of its potential. In the desert, where water stress and high temperatures are the principal limitations, annual leaf photosynthesis may only be 20–30% of its potential.

ALTERNATE PHOTOSYNTHETIC PATHWAYS

Terrestrial plants can be grouped according to the three photosynthetic pathways known to occur in them. The C_3 pathway occurs in the greatest proportion of species while the C_4 pathway is found in grasses with an evolutionary origin in the tropics, many annual herbs native to warm environments and some arid habitat shrub species. The C_4 pathway is found in evolutionarily advanced genera and perhaps evolved multiple times as the angiosperms diversified. The third, crassulacean acid metabolism (CAM) is found in many succulent species including succulent

epiphytes in tropical forests and desert succulents. CAM plants are therefore only a minor component of the world's vegetation. C_3 plants account for about 85% of the world's photosynthesis. Crops such as wheat, barley and soybeans have C_3 photosynthesis as do virtually all tree species. C_4 grass species make especially important contributions in tropical grasslands and savannas whereas northern grasslands are dominated by C_3 grasses. The important crops, maize, sorghum and sugar cane as well as all tropical forage grasses are C_4 species (*see* **C_3 and C_4 Photosynthesis**, Volume 2).

In C_3 photosynthesis, all mesophyll cells have essentially the same complement of photosynthetic enzymes including Rubisco and the enzymes necessary for RuBP regeneration (Figure 3). In C_4 photosynthesis, two cell types are present with the mesophyll cells containing the enzyme PEP carboxylase that first fixes CO_2 into a C_4 acid. A cycle then operates between the mesophyll and bundle sheath that acts as a CO_2 pump, resulting in high CO_2 concentrations (>2000 ppm) in the bundle sheath cells where Rubisco is localized in C_4 plants. These high CO_2 concentrations cause Rubisco to operate efficiently and cause its oxygenase activity and therefore photorespiration to be suppressed.

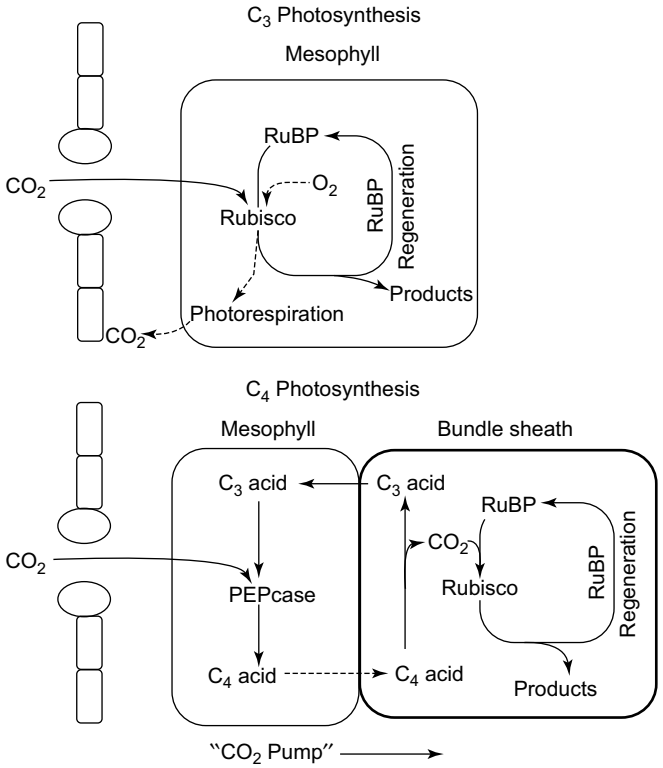

Figure 3 The pathways for CO_2 uptake and assimilation in C_3 and C_4 photosynthesis. Diffusion through the stomata is shown on the left side. In C_4 photosynthesis CO_2 is first fixed via the enzyme PEP carboxylase in the mesophyll. The C_4 cycle operating between the mesophyll and the bundle sheath acts as a CO_2 pump

C_4 plants can efficiently utilize low CO_2 concentrations but they tend to saturate at moderate CO_2 concentrations. Thus, in comparison to C_3 plants, C_4 plants exhibit a lower stimulation of photosynthetic rates with rising CO_2 concentrations in the atmosphere. The ability to efficiently utilize low CO_2 concentrations means that C_4 plants can maintain high photosynthetic rates with lower stomatal conductances than C_3 plants, giving them higher water use efficiency (ratio of photosynthesis to transpiration). Since increasing temperature stimulates photorespiration in C_3 plants, C_4 plants generally have an advantage in terms of photosynthetic performance in warmer climates. Indeed C_4 grasses reach their greatest importance in environments where most of the precipitation comes in the warm season. In these environments the high water use efficiency coupled with the photosynthetic advantage at high temperatures strongly favors C_4 over C_3 grasses.

The different responses to atmospheric CO_2 has important implications for the response of C_3 and C_4 plants to climate change scenarios. In C_3 plants, both temperature and CO_2 are important factors because they interact to determine the ratio of carbon flow through the wasteful process of photorespiration as compared with the assimilatory process of photosynthesis (Figure 4). As a result of these differences, C_4-dominated plant communities are hypothesized to have expanded during glacial periods in the Pleistocene when atmospheric CO_2 concentrations may have been only 190 ppm (Ehleringer *et al.*, 1991). The currently increasing atmospheric CO_2 should favor C_3 over

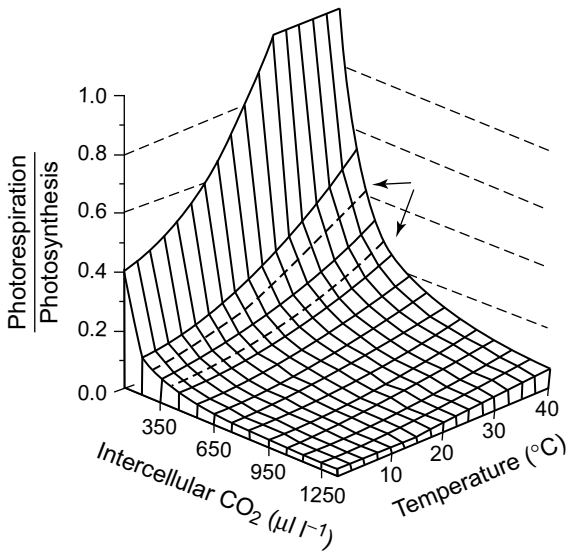

Figure 4 The dependence of the ratio of photorespiration to photosynthesis on temperature and intercellular CO_2 concentration. The arrows and dashed lines delineate the range of intercellular CO_2 concentrations typically occurring in leaves of C_3 species. (Reprinted from Ehleringer *et al.* (1991) © 1991 with permission from Elsevier Science)

C_4 species. This advantage for C_3 photosynthesis will also depend on any global warming. Moreover, local or regional changes in precipitation and especially its seasonality could be expected to further influence the shifts in distribution and abundance of C_4 versus C_3 species.

THE CARBON BALANCE OF LEAVES

Leaves must return more carbon from their photosynthetic activities than was required to construct them in order to provide any benefit to the plant. Initially during development, photosynthetic capacities are low and the leaf imports carbon for construction (Figure 5). Then photosynthetic capacity increases up to a plateau where it remains until senescence occurs. The realized daily leaf CO_2 exchange is in part a function of the photosynthetic capacity but it also depends on how favorable the environment is. Cloudiness, too warm or too cool temperatures, or periods of drought can significantly reduce it. Ultimately sufficient carbon is gained to meet the leaf construction costs and thereafter further carbon gain is net profit that can be used for growth. This can occur within a few days to a few weeks for herbaceous plants and deciduous trees, which have relatively high photosynthetic capacities and low construction cost leaves, but it can take considerably longer for evergreen species with thick, long-lived leaves. Evergreen leaves such as the needles of coniferous species gain little or no carbon over the winter months, but evergreen species do have the advantage of already having a canopy in the spring and of maintaining it in the fall. These are times when deciduous species may either be leafless or just developing or senescing leaves and therefore incapable of significant carbon gain. Also, long-lived evergreen leaves can continue to

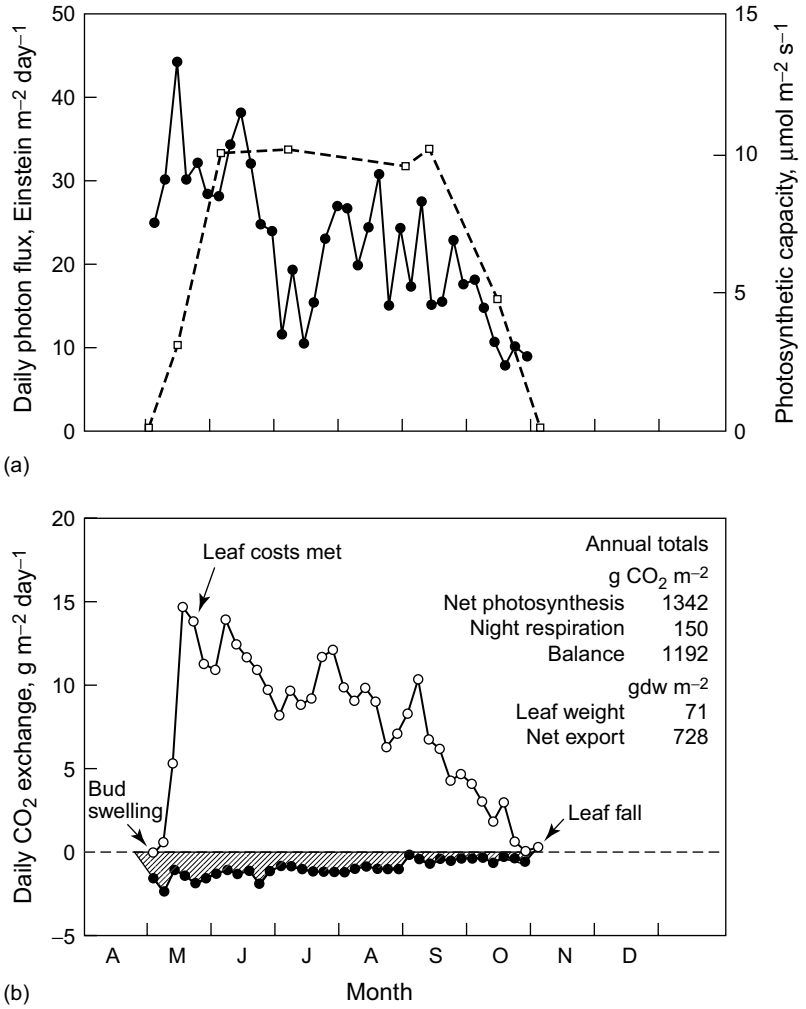

Figure 5 (a) Annual course of photosynthetically active radiation (●) and leaf photosynthetic capacity (□) for the deciduous tree, *Acer campestre* during 1980. (b) the daily CO_2 uptake (○) and nighttime respiration (●) for this species. Also shown are the annual total balances for net carbon gain and the resulting net export (pro t) from an *A. campestre* leaf [from Pearcy *et al.* (1987) as adapted from data of Kuppers (1984, 1985)]

return a profit over several years, albeit at a decreasing rate because of age-related decreases in photosynthetic capacity and because the leaves are typically increasingly shaded by new growth. At the other extreme are leaves of fast-growing weedy species and herbaceous crops with life spans as short as only 1–2 months. Leaves on these species are rapidly overtopped and shaded by newly produced leaves and thus the period when they return a high carbon gain is short. Indeed leaves held past the point where they become so shaded that net photosynthesis is negative begin to return a loss rather than a profit. In addition to minimizing losses, a rapid leaf turnover is also advantageous in these rapidly growing species because during senescence 40–60% of the nitrogen in the leaf is mobilized and exported. This nitrogen can then be utilized again in the upper newly expanding leaves where it will return the greatest benefit in terms of useful photosynthetic capacity.

Respiratory losses required for growth and maintenance of the leaf offset a portion of the carbon gain of leaves, reducing the carbon balance. In addition, there is an alternative pathway of respiration that appears wasteful in terms of energy but may be important for controlling levels of carbohydrates or balancing the needs for energy versus carbon compounds required to construct the plant. Early in their development, leaves exhibit elevated respiration rates because of the metabolic activities required for their growth. In addition, respiration is required throughout the leaf's life span to provide the metabolic energy needed to maintain the leaf cells, to synthesize sucrose and other sugars, and to load the phloem so that these sugars can be exported to other parts of the plant. The respiration rate of leaves is typically only 5–10% of its photosynthetic capacity, but under environmental conditions where the photosynthetic rate is strongly restricted, such as in the shade, it can be a much higher fraction. Under shaded conditions, mechanisms that reduce the respiration rate can be at least as important for the leaf carbon balance as those which enhance the photosynthetic rate in low light. In the short term, respiration rates increase with temperature, exhibiting an approximate doubling every 10 °C but in the longer term, physiological adjustment results in homeostasis of rates. Thus, global warming may have relatively little direct impact on respiration rates. Both increases and decreases in leaf respiration rates in response to increasing atmospheric CO_2 have been observed but these appear to be mostly indirect effects (Drake *et al.*, 1997). For example, when photosynthesis is stimulated by increased atmospheric CO_2, extra carbohydrate processing and phloem loading may be required, raising leaf respiratory rates.

PHOTOSYNTHESIS AND GROWTH

Understanding how the carbon balance of leaves scales up to whole plant carbon gain requires knowledge of the total leaf area and how light and hence photosynthesis is distributed on this leaf area in order to obtain a total for the whole plant. In addition, knowledge is required of the respiratory losses of the leaves and of the non-photosynthetic plant parts such as stems and roots. These processes are dynamic and continually change during development, with each process changing at a different rate. Leaf photosynthetic capacity changes with age and as new leaves develop, older leaves may become shaded, modifying their environment and reducing their photosynthetic rate. Ultimately these leaves will be shed, modifying the leaf area. Moreover, changes in allocation of carbon and nutrients can occur within the plant during its growth, increasing or reducing the rate at which new leaf area is produced. Reinvestment in leaves is especially important since this drives the tendency for plants to increase exponentially in size. Competing with this reinvestment is the need for sufficient investment in shoots and roots, which must supply adequate water, nutrients and support. Monsi (1960) demonstrated that because of the exponential tendency of the growth of plants, relatively small changes in either the photosynthetic rate of the leaves or in the allocation of carbon to leaf area production can result over time in large differences in plant size.

The complexity of determining whole-plant carbon balances has meant that only a few species have been studied in this way, especially over longer time frames. Instead most knowledge of how the growth of plants responds to the environment and differs between species has come from growth analysis. In growth analysis, plants from a uniform population are harvested at sequential times and the net whole-plant carbon gain is inferred from the increase in biomass. Expressed in dimensions of biomass produced per unit leaf area per unit time, it is referred to as the net assimilation rate (NAR). During growth analysis, the partitioning of biomass into leaves, stems and roots is also determined. Of most importance is the leaf area ratio (LAR) in dimensions of leaf area per unit biomass, which is a measure of how biomass is partitioned to produce the leaf area on the plant. It is essentially a measure of the leafiness of the plant. The product of LAR and NAR is the relative growth rate (RGR) of the plant, in dimensions of mass of plant produced per unit mass of plant per unit time. LAR and NAR are not completely independent variables, however. The major determinant of LAR is the SLA, which, as discussed above (Figure 2), also is correlated with photosynthetic capacity.

Most growth analysis studies have concentrated on the seedling stage because at this time all the leaves are more or less functionally equivalent with little self-shading within the canopy. Measured under conditions of adequate light, water, nutrients, and optimal temperatures the RGR of seedlings is taken as the maximum potential RGR for the species. Later, self-shading reduces the NAR; and a change in biomass partitioning towards greater investments

in stems and roots tends to reduce LAR. Thus, RGR declines.

Comparisons of fast and slow growing species of similar growth form (for example, herbaceous C_3 photosynthetic species) show that the fast growing species typically have a higher LAR and especially a higher SLA than the slow growing species (Lambers and Poorter, 1992). In contrast, there is in most cases little or no correlation between RGR and NAR for plants grown in the same optimal environment. Differences in NAR are, however, often more explanatory of the differences in RGR of plants of a single species grown in different environments. Thus, the growth stimulation in elevated CO_2 can generally be accounted for by an increase in NAR through the CO_2 effects on photosynthesis. However, the environment may also influence LAR and especially SLA so the effects are often complex. For example, shade-grown plants produce leaves with a high SLA, which partially compensates for the strong reductions in NAR in the shade as compared with the sun. As a result, the RGRs of shade and sun plants exhibit a smaller difference than would be predicted by the differences in NAR or photosynthetic rate per unit leaf area alone. Comparisons of herbaceous C_3 species grown under projected elevated atmospheric CO_2 concentrations reveal on average 1.47 larger dry mass at final harvest for those grown at elevated atmospheric CO_2 (Poorter *et al.*, 1996). This was accounted for by a modest (7%) increase in RGR, a 22% increase in NAR, which was in line with expectations for the stimulation of C_3 photosynthesis by elevated CO_2, and an 11% decline in LAR.

Ultimately, part of the carbon fixed in photosynthesis is partitioned into reproduction. This fraction varies widely, approaching 60% of the biomass in some annuals while being as little as 1–10% in some trees. Increased atmospheric CO_2 has been shown to increase reproductive yields in some C_3 pathway annual crops such as wheat, and cotton (Pinter *et al.*, 1996). On the other hand, increased temperatures have been shown to significantly decrease reproductive yields in rice, and therefore to partially offset or even eliminate the stimulation due to CO_2 (Baker *et al.*, 1996). Other factors such as nutrient and water supply are also important influences on the extent of CO_2 stimulation of reproductive yields in these crops. Thus, whether or not the potential for increased reproductive output is realized depends on complex interactions with other environmental variables. It is also likely to be highly species specific and depend on the phenological and developmental effects of increased CO_2 or temperature. Even less is known about the response of reproductive output in perennial plants such as trees and shrubs to increased CO_2 though it could be expected that additional carbohydrates would favor enhanced reproductive output. As with annuals, interactions with nutrient and water supply are undoubtedly important but little understood for these plants.

Population Sizes, Changes

Esa Ranta[1] and Veijo Kaitala[2]
[1] University of Helsinki, Helsinki, Finland
[2] University of Jyväskylä, Jyväskylä, Finland

Changes in population size are due to four separate processes, births, deaths, immigration and emigration, often expressed as per capita rates. The rates may (or may not) be independent from each other. Births and immigration increase population size, while deaths and emigration reduce it. Births and deaths are local processes whereas immigration and emigration are regional processes that connect population units to other similar units. Very few populations live in complete isolation. The relative importance of local and regional processes makes the local population either a source or sink population. Source populations send more individuals to nearby populations than they receive, and the fluctuation in source population size is governed by local population renewal. Sink populations behave in the opposite manner.

The net difference between birth and death rates is known as the per capita growth rate of the population. Often the growth rate of a local population is some function of the population size, know as density dependence. Density dependence may affect population growth rate directly or with delays. With delayed density dependence, the past population sizes affect the renewal process with lagged time. The upper limit for a population size is often given by local availability of resources. When this limit, the carrying capacity, is approached density dependency starts to reduce population growth rate due to increased competition on available resources.

The size of any given population is seldom constant but fluctuates due to various superimposed factors. Demographic stochasticity, most effective in small populations, is due to chance events in individual life histories. Environmental stochasticity, in turn, is seen as random (or temporally correlated) changes affecting either the carrying capacity of the population or the growth rate, or both. Stochasticity may cause local populations to become extinct even though the population would have survived in an undisturbed situation. Other causes of extinction include local catastrophes and population over exploitation, either by natural predators or by humans.

Populations are not homogeneously distributed over all areas suitable for independent renewal. Rather, they form networks where local units are connected with immigrating and emigrating individuals. Thus, dispersal of individuals may potentially rescue an extinct local population in an adjacent area. If dispersal is reduced, e.g., due to human-induced habitat fragmentation, the extinction rate of local populations is enhanced and this may lead to a loss of the entire population. Dispersal linkages also synchronize fluctuations of several local population units. The level of synchrony is often a function of proximity between the population sub-units. Nearby populations fluctuate in step, while more distantly located sub-units become increasingly out of phase. Another agent synchronizing fluctuations of populations is external disturbance. For example, adverse weather may cause all local populations to reduce in size at the same time. It is likely that synchronizing agents act in concert yielding a high level of region-wide synchronicity in dynamics of populations.

INTRODUCTION

Population ecology is interested in temporal changes in population size, known as *population dynamics* (Figure 1). Documented temporal changes are rich in their appearance ranging from cyclic and periodic dynamics to chaotic fluctuations, random walks and decreasing or increasing trends. Causes for such changes may be manifold. Even for such a limited data set as displayed in Figure 1, the list may include biotic interactions (e.g., predator and prey dynamics), local perturbations, large-scale environmental changes, human-induced modifications in habitat structure and over-harvesting. The challenge for ecology and population management is to understand what makes various populations fluctuate temporally the way they do.

The essence of population dynamics lies in two processes: births B and deaths D (Box 1). These processes may operate on current population density as well as on past population densities with time lags (Royama, 1992). Local populations change in size subject to demographic stochasticity (Figure 2b,c), hazards in life expectancy and breeding success of individual females (May, 1974; Hilborn and Mangel, 1997). In the classical definition, populations are understood as isolated units of interbreeding individuals (Emlen, 1977). However, populations rarely lie in entire isolation. The current view is (e.g., Tillman and Kareiva, 1997; Bascompte & Solé, 1998) that the landscape in which individuals live, is composed of a network of habitable areas. These local units are considered large enough to obey population renewal of their own, but they are also connected to other units via dispersing individuals. Dispersal can be decomposed into two opposing components, emigration, departure of individuals from their natal patch, and immigration, arrival of individuals from surrounding population sub-units to the focal unit.

Changes in population size from year to year can also be modulated with external noise (Figure 2e) and trends, which can be composed of regional and local elements (Box 1). Candidates for such modulators are many, but most often they are associated with local weather and regional, or global climate. The North Atlantic Oscillation

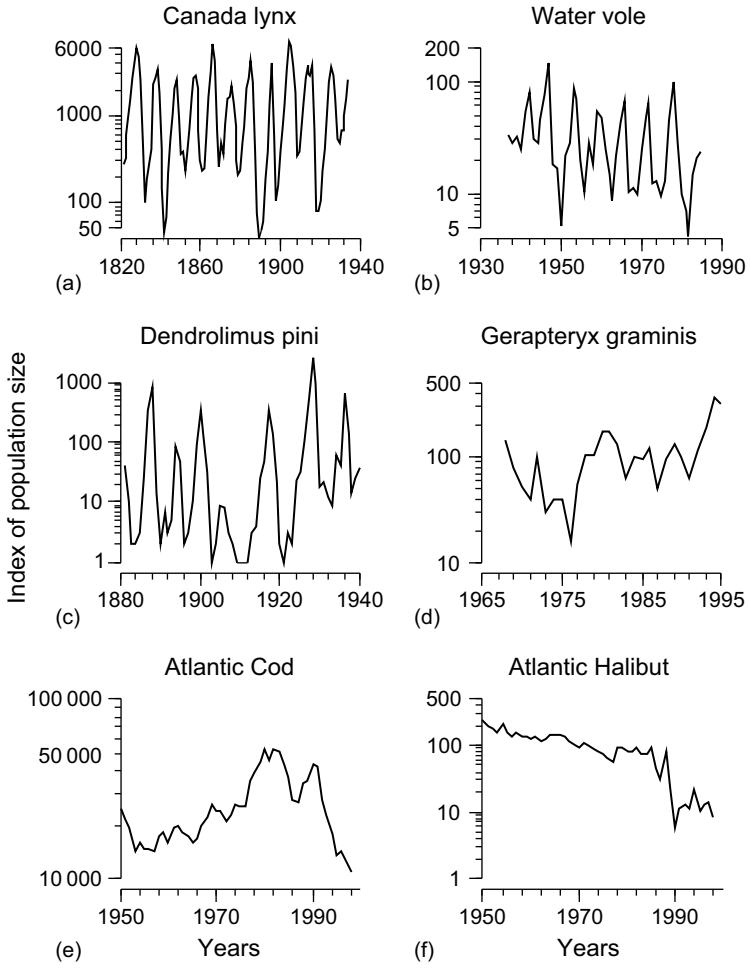

Figure 1 Examples of long-term population changes in mammals (a,b), insects (c,d) and sh (e,f). The Canadian lynx (trappers pelt returns) displays pronounced cyclic dynamics, periodicity is less clearly pronounced in the water vole dynamics (snap trap data). *Dendrolimus pini*, a forest pest, displays more or less irregular outbreaks while in *Gerapteryx graminis* there is no clear pattern of population uctuations (both trap data). The two Atlantic sh species are both targets of heavy sheries, and the past decade displays declining landing statistics (metric tonnes) in New England sh harbors. (Data in (a- d) from Ginzburg and Inchausti (1997), in (e) and (f) from http://www.st.nmfs.gov/st1/commercial/)

(NAO) is a good candidate for a large-scale modulator (*see* **North Atlantic Oscillation**, Volume 1). Furthermore, the anticipated global warming is a long-term change, which most certainly will affect all extant populations. This sets the stage for our endeavor to determine the significance of internal and external effects causing changes in population size.

Our view is that changes in population sizes are not due to population-specific intrinsic (density-dependent) processes only, but also to the changes in nearby populations (acting via density dependence in the focal unit), as well as to density-independent, or external processes of various scales. These factors modulate temporal changes in the size of local populations, even to the extent that their dynamics cannot be understood without referring to large-scale population dynamics. However, these facts are often rather hard to confirm with data on extant populations. Thus, computer simulations are used to demonstrate how population linkages, via dispersing individuals and external disturbances, or noise, may entirely change the intrinsic population dynamics.

SPACE, DISPERSAL LINKAGE AND DYNAMICS OF POPULATIONS

Two Examples

The argument of contemporary population ecology is that populations only rarely live in entire isolation (e.g., Bascompte and Solé, 1997). Rather, they are connected via dispersing individuals. Thus, individuals depart from and enter to local population sub units. This interplay keeps

Box 1 A few elementary models on population growth

For a change in population size, we write:

$$\Delta N = B + I - D - E, \tag{B1.1}$$

i.e., the change ΔN is the balance between births (B) and immigration (I) and deaths (D) and emigration (E). In discrete time t, the model can be expressed as:

$$\Delta N_t = N_{t+1} - N_t,$$

or

$$r_t = \frac{\Delta N_t}{N_t} = \frac{N_{t+1} - N_t}{N_t} = \frac{B + I - D - E}{N_t}. \tag{B1.2}$$

Here r_t is the *per capita* rate of increase (when $r > 0$ the population increases, with $r < 0$ the population decreases). Assuming that r is constant over all time intervals, a model for exponential growth of a population (Figure 2a) becomes:

$$N_{t+1} = N_t + rN_t \tag{B1.3}$$

One method to add demographic stochasticity into the equation is to take N'_{t+1} from random numbers obeying a Poisson distribution with the parameter N_{t+1}. An example of the effects of demographic stochasticity on exponential growth is shown in Figure 2(b,c).

No population can grow *ad in nitum* without any upper bounds. A way to add an upper limit for the population size is to assume a carrying capacity K for the population. One possible expression for bounded population dynamics is:

$$N_{t+1} = N_t + r\left(1 - \frac{N_t}{K}\right)N_t \tag{B1.4}$$

which is referred to as the logistic model for population growth. The behaviour of the logistic growth model is explored in Figure 2(d). The effect of environmental stochasticity, superimposed on K, on the emerging dynamics is illustrated in Figure 2(e).

A third model is the Ricker model (Ricker, 1954):

$$N_{t+1} = N_t \exp\left[r\left(1 - \frac{N_t}{K}\right)\right] \tag{B1.5}$$

The behaviour of the Ricker model is governed by a single parameter r and its dynamics are well-known (May, 1974). For this reason, the Ricker model has gained a bench-mark status in population ecology. The model has a stable equilibrium point when $r < 2$, from $2 < r < 2.526$ the model yields a two-point cycle, followed by more complex limit cycles (4-point, 8-point, etc.) and when $r > 2.692$ the dynamics assume chaotic behaviour.

The nal example is the Moran - Ricker model (Turchin, 1990), which - unlike the previous ones - acknowledges the in uence of a time-lag affecting the predicted population size:

$$N_{t+1} = N_t \exp(r + a_1 N_t + a_2 N_{t-1}) \tag{B1.6}$$

The parameters a_1 and a_2 take care of the direct and delayed density-dependency. Even this model can yield rich dynamics (Royama, 1992) ranging from stable dynamics to damped dynamics, to periodic and cyclic dynamics and to chaotic uctuations.

All population renewal models with one time lag can be written in a general form as:

$$N_{t+1} = f(N_t, \varepsilon_t) \tag{B1.7}$$

where f is a function mapping the population density at time t to time $t+1$, and ε represents environmental stochasticity, the Moran effect (e.g., a random deviate with zero mean). The spatial structure of a population can be written as:

$$N_{i,t+1} = (1 - m)f(N_{i,t}, \varepsilon_t) + \sum_{s,s\neq i} M_{si,t} \tag{B1.8}$$

where m is the fraction of individuals dispersing from the population sub-unit i. The summation term indicates how many immigrants the ith units have received from neighbouring units. Often the dispersal success is taken as $\exp(-cd_{si})$, d_{si} being the distance between the units s and i.

the semi-independent local units connected to the regional dynamics. This will be demonstrated here with two examples based on simulations. The argument is that dispersal linkage and spatial structure together may transform the local population dynamics such that they are qualitatively entirely different when compared to similar renewal of populations in total isolation.

First Example

Assume two habitable patches with matching carrying capacity are proximate enough to enable dispersing individuals freely to reach each of them. In every generation, a fraction m of the resident individuals leaves the natal population to disperse into the other population. Let the Ricker dynamics (Box 1; $K = 1$ for both populations) suffice as the renewal process (both populations have been initiated with independent random numbers from a uniform distribution from 0–1). The renewal dispersal process is allowed to run for 500 generations. Its effect on the dynamics of the two populations is evaluated by scoring the temporal match in the fluctuations between the two populations for the final 50 time steps. For this purpose, the cross correlation coefficient is used with zero time lag (Chatfield, 1984). Large positive values of the coefficient indicate a high level of temporal match, large negative values mean that the population pair fluctuates in the opposite phase, and values around zero indicate that the pair does

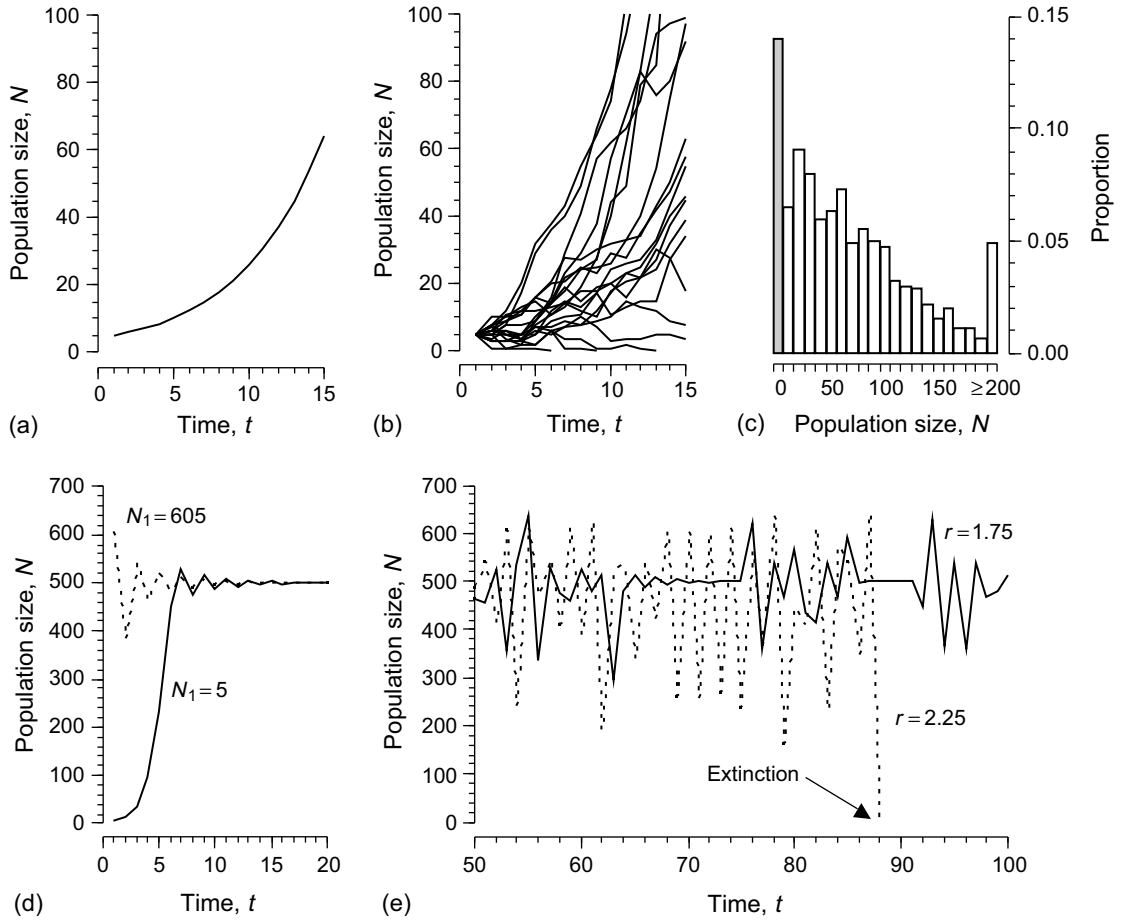

Figure 2 Behavior of selected models on population dynamics. (a) Deterministic exponential growth, Equation (B1.3), $r = 0.2$, (b) as in (a) but now with demographic stochasticity, (c) as (b) but the frequency distribution is the final population size at $t = 15$. Note that a modest fraction (13.8% hatched bar) of the iterations of exponential growth with demographic stochasticity leads to extinction. (d) Logistic growth (parameter values inserted) with two initial population sizes: when $N_1 = 5$ the model yields an exponential growth, which levels off at the carrying capacity (K) with some bouncing back and forth (due to the intrinsic density dependence with the selected r value). When $N_1 = 605$, density-dependent feedback in the logistic equation also brings the population size back to K. (e) Two (r values inserted) population size trajectories of the logistic growth with environmental stochasticity (Moran effect) affecting K with probability of $P = 0.33$. If an external disturbance takes place, K will be multiplied by uniform random numbers drawn from 0.8- 1.2. Note that this high perturbation rate quite often leads to population extinction when r is high enough

not have much in common in their phase of temporal fluctuations.

We examined the effect of dispersal as the synchronizing agent for the dynamics of the two populations over the periodic and chaotic range of the Ricker (1954) dynamics ($2 \leq r \leq 4$, Box 1). If the proportion m of individuals moving per generation is low, then the two populations do not share many individuals in common in affecting their dynamics via the density-dependent feedback (Box 1). However, even a small dispersal rate is capable of synchronizing dynamics of the two populations in the periodic range of r (Figure 3a). Further, even a small amount of dispersal will modulate the chaotic Ricker dynamics into a two-point cycle (Figure 3b). When the value of m is increased sufficiently, dispersal can perfectly synchronize the dynamics of the two populations (Figure 3a).

Second Example

To demonstrate further how space and dispersal may modulate local dynamics we shall replace the Ricker dynamics with the Moran–Ricker dynamics (Box 1), and will have 25 populations in randomized locations of a 25×25 grid (Ranta *et al.*, 1997a). In each generation 10% of the current population will take leave from the natal patch and re-distribute themselves among the remaining patches. Here the populations are in an explicit space, and distance will matter in the dispersal process. The dispersal is taken to be negatively distance dependent (Box 1): reaching

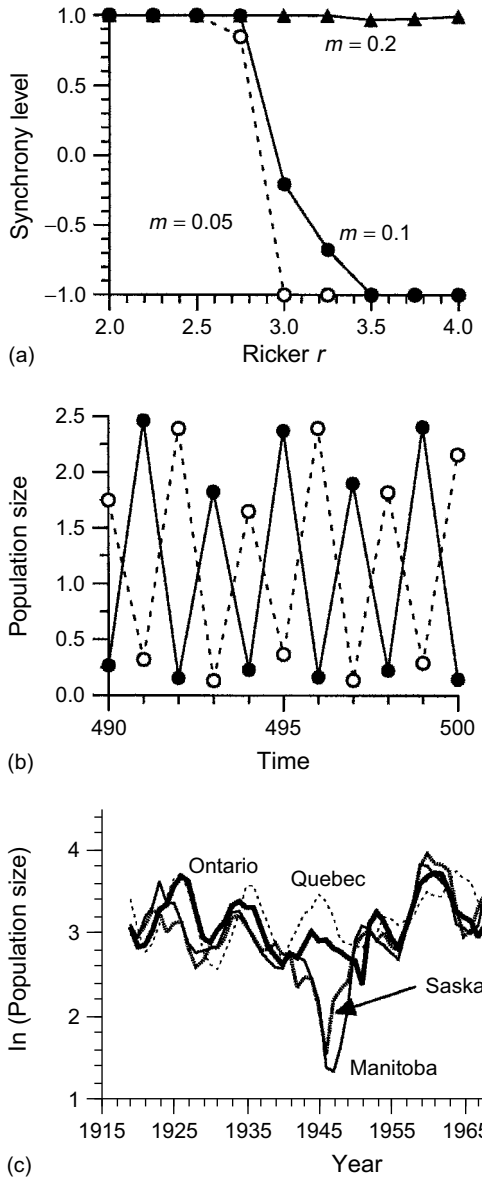

Figure 3 (a- b) Synchronicity of dynamics of two populations (a) obeying Ricker dynamics (only the range of r from periodic to chaotic dynamics is shown here) and sharing dispersing individuals (m gives the fraction of individuals dispersing in each generation), (b) with $m = 0.05$ and $r = 3$, the two populations do not become synchronized but uctuate out of phase. (c- e) Dynamics of the Canadian lynx in six Canadian provinces and two Territories (c,d). (e) Synchrony of the Canadian lynx uctuations are calculated in pairs between all provinces and Territories (28 comparisons) for the data in (c) and (d) using a 15-year sliding time window which is put through the 67 year lynx series with a time step of one year. Though the lynx population highs and lows roughly match, there are violent temporal uctuations in the level of synchronicity, e.g., between Yukon versus Ontario and Northwestern Territories (NWT) and Quebec. (Graph modi ed from Ranta *et al.*, 1997a.) See next page for Figures 3d and 3e

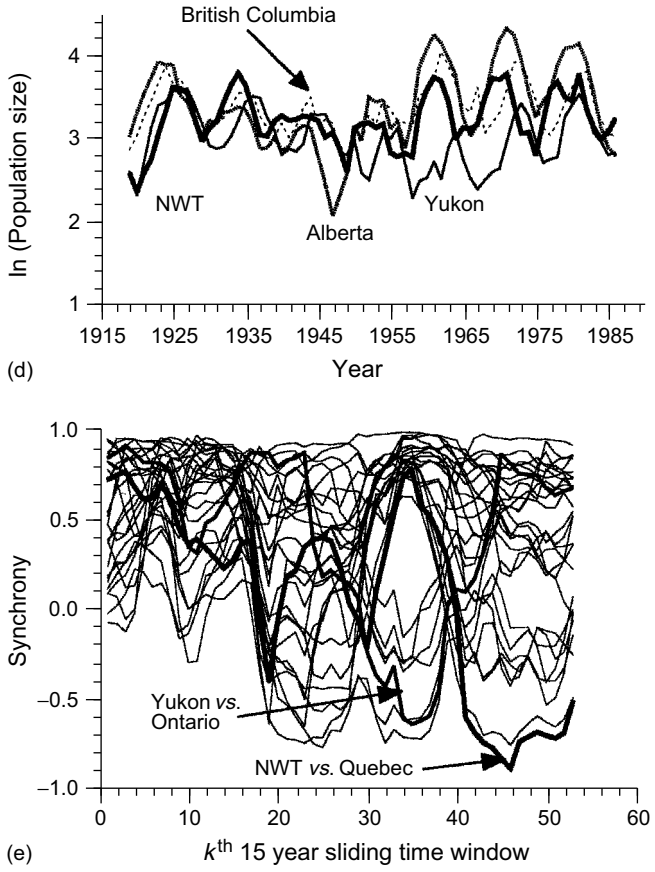

Figure 3 (*Continued*)

a nearby population is much easier than travelling over long distances. The populations were initiated in phase and left to renew after the Moran–Ricker dynamics with 9–10 year periodicity (Ranta *et al.*, 1997a) and the system was allowed to run for 1000 generations.

The outcome, exemplified by temporary fluctuations of a typical pair of populations, is illustrative. In such a system, there can be periods of high temporal match in dynamics for a substantially long time. This is not all, however. There can be times when synchronously fluctuating populations drift out of phase, drastic changes in amplitude may emerge, and even disappearance and re-appearance of the local cyclic dynamics can be witnessed (Ranta *et al.*, 1997a).

Canadian Lynx and Finnish Voles in Time and Space

An interesting question rises: do we find in nature such population dynamics as described above? The answer is yes! A particularly good and thoroughly studied example is the countrywide dynamics of the Canadian lynx (Elton and Nicholson, 1942; Royama, 1992; Ranta *et al.*, 1997a; Stenseth *et al.*, 1999). First, it is known that the dynamics

of the Canadian lynx obeys cyclic fluctuations with a 9–11 year period, as indicated with Canadian provincial and territorial data (Figure 3c,d). At times, two provinces may display high level of synchrony in fluctuations of lynx numbers. At other times, lynx records from the very same pair of provinces may be in opposite phase, to fluctuate later in step.

This feature of the Canadian lynx dynamics becomes more apparent when a sliding time window allowed to run through the entire data, and for each step, the level of synchrony is assessed for all pairs of time series. One finds that there are violent temporal fluctuations in the level of synchrony (Figure 3e). This has been interpreted in terms of travelling waves in population dynamics (Ranta *et al.*, 1997a).

Other, and perhaps more convincing examples come from voles in Finland (Ranta and Kaitala, 1997) and in Scotland (Lambin *et al.*, 1998). The travelling wave is actually not a flush of individuals passing by. Rather, one should understand travelling waves as spatially correlated fluctuations in population numbers. Thus, at any time one finds large regions with high population densities but with increasing distance these densities fade away to give large areas of low population densities. In particular, if the dynamics of the target species are periodic, like in the Fennoscandian voles (Hansson and Henttonen, 1985), the pattern in space repeats itself approximately with the cycle period length. Such a repetition of the spatial pattern gives an impression of travelling waves (Ranta *et al.*, 1997a; Ranta and Kaitala, 1997, 1998).

Habitat Loss and Dynamics of Populations

A particularly interesting question to be dealt with is how the loss of habitable area may affect the dynamics of dispersal-coupled local populations. For this purpose, we shall make use of cyclic dynamics. We choose to use Finnish grouse as an example (Lindén, 1981; Lindström *et al.*, 1995). Periodically oscillating populations have been one of the favorite subjects of research in population ecology since their first appearance in the literature three quarters of a century ago (Elton, 1924; Lindström *et al.*, 2001). Several hypotheses have been put forward to explain the remarkable pattern of self repeatability of cyclic dynamics as so well documented with the Canadian lynx (Elton and Nicholson, 1942; Royama, 1992) and especially with Fennoscandian voles (Stenseth, 1999). Despite the efforts by numerous research groups there is no consensus, not even with the Canadian lynx, as to what maintains the cycles (Stenseth *et al.*, 1999). A recent intriguing feature with the cyclic dynamics of the Fennoscandian voles is that in the 1980s the regular four year cycle waned to mere irregular variation (Hansen *et al.*, 1999). A similar waning has also been observed with the Finnish grouse, which have been showing a six-year periodicity in their cyclic dynamics at least from the beginning of this century (Lindström *et al.*, 1995; Figure 4a).

One starts to wonder: Where have all the cycles gone? An obvious explanation would be that something has changed, either these populations or in their environment. A harder answer is to find a candidate for the changed something. One option we can identify is landscape management, which has changed in Finland due to recent forestry practice. Forested landscape has become more fragmented due to cuttings and the fraction of old forest has declined both in Sweden and in Finland during the past 20 years.

To address the effect of habitat loss on population changes, we shall assume that our focal species obeys Moran–Ricker dynamics (Box 1) in its renewal process. By selecting the parameters properly, one can achieve cyclic dynamics with the period length of six years (Kaitala *et al.*, 1996). The landscape will consist of habitable areas coupled with dispersing individuals. We shall assume that migration among habitat patches close to each other is far easier than dispersing long distances. A further refinement is that, in the increasing phase of a cycle, a substantial proportion of the population consists of young individuals prone to disperse (Lindén, 1981). As the population declines the proportion of young individuals is lower, cutting down the dispersal rate.

For simplicity, we shall assume that the landscape is comprised of n habitable units ($n = 10$ in this example) arranged in one-dimensional space. In the homogeneous landscape the distances between the adjacent habitat subunits are equal (1 unit), and the distance dependency of dispersal is selected so that migrating individuals do not have any problems successfully crossing the short inter-patch distances. The landscape with habitat loss is composed of a gradient of habitable patches with increasing inter-patch distances from the dense end to the sparse end of the fragmentation gradient. In our example, the consequent inter-patch distances are 1, 1, 1, 1, 2, 4, 6, 8, 10, and 12 units from the dense end to the sparse end.

In the simulations, the populations in the local habitat units were initiated with independent random numbers drawn from a uniform distribution (between 1 and 20). The system was allowed to run for 2000 generations. We shall sample only the final 100 generations for calculating our descriptive statistic: the coefficient of variation in population size. Large values of this coefficient indicate that the periodicity of the cyclic dynamics is clearly pronounced, while small values suggest the dying out of the cyclic dynamics.

Our principal finding with the data on black grouse is that the cyclic dynamics has transformed into weak annual fluctuations around the long-term mean (Figure 4a). Our principal finding, with modeling of habitat loss and differential

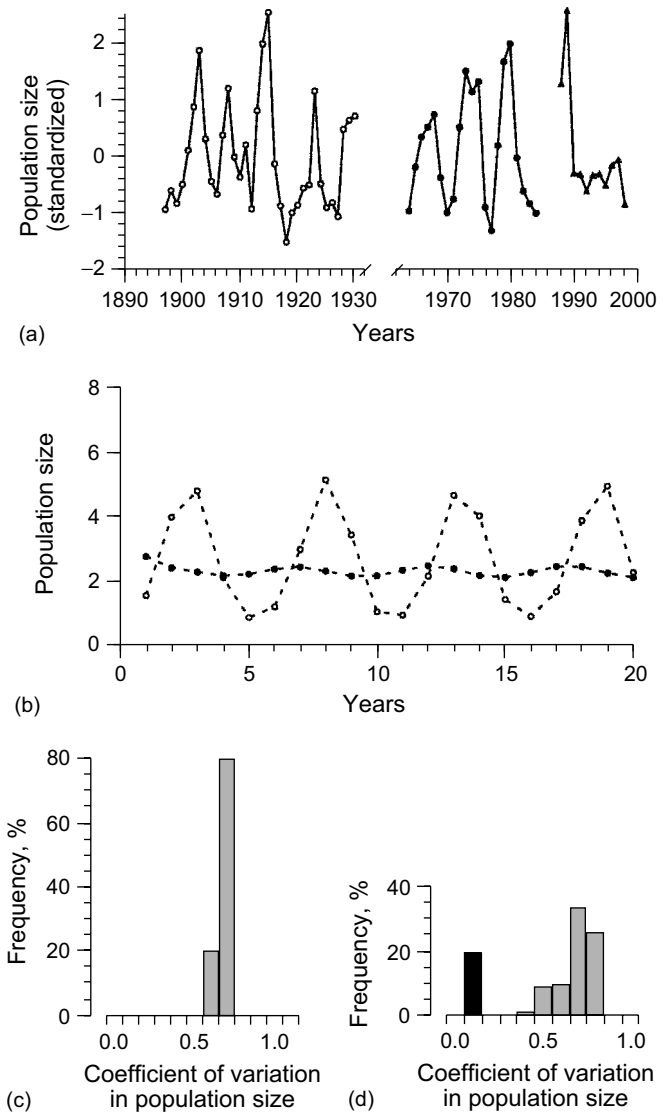

Figure 4 (a) Black Grouse dynamics (population size standardized to zero mean and unit variance for the three periods) in southwest Finland. Note the pronounced periodicity in the two older time series and the disappearance of the cyclic dynamics in the most recent data set. (b) Population trajectories of a Moran- Ricker model yielding 6- 7 year periodic dynamics ($r = 1.45$, $a_1 = -0.1$, $a_2 = -0.45$) in a fragmented landscape. The open symbol refers to populations in the dense end of the fragmentation gradient while the closed symbol is for the population in the sparsest end of the fragmentation gradient. (c) Coef cient of variation of populations in a system with no habitat loss (all values are relatively high, thus all populations uctuate from low to high values), and (d) with habitat loss. Some values are small indicating that there are populations with small temporal variability, some values are high, indicating high temporal uctuations in population size. (Modi ed from Ranta *et al.* in prep.)

dispersal in the increasing and decreasing phases of the cycle, is that the cycle disappears showing only minor variations around the mean population size (Figure 4b,d). It is worth noting that with uniformly structured habitat there are no signs that the cycle in the population dynamics will vanish (Figure 4c).

There are, of course, many other ways to demonstrate how the spatial linkage among habitable units affects population dynamics both at local and regional levels. However, the few examples mentioned here underline the fact that without acknowledging the significance of immigration and emigration (the links between local populations and regional dynamics) one can easily be misled when analyzing local population dynamics.

MORAN EFFECT: EXTERNAL PERTURBATION AND DYNAMICS OF POPULATIONS

Elton (1924) was arguably the first to draw attention to the large-scale synchrony in the dynamics of the Norwegian lemming and the snowshoe hare. He (Elton and Nicholson, 1942, 239–240) was very explicit about the synchronicity in the case of the Canadian lynx (Figure 3):

> The [lynx] cycle covers the whole northern forest zone of Canada, from Labrador to British Columbia to Yukon .... The most extraordinary feature of this cycle is that it operates sufficiently in line over several million square miles of country not to get seriously out of phase in any part of it .... (This evidence) makes it certain that some overriding process maintains the cycle in line over the whole extent of Canada.

Moran (1953a,b) proposed the idea of how two (or more) populations could become synchronized due to stochastic density-independent but correlated processes. His assumption was that population regulation may be density dependent, and that populations may be divided into smaller independent sub-populations.

Suppose (Moran 1953a,b) that the dynamics of two populations $N_{1,t}$ and $N_{2,t}$ in time t can be described as:

$$N_{1,t+1} = aN_{1,t} + bN_{1,t-1} + \varepsilon_t \quad (1)$$

$$N_{2,t+1} = aN_{2,t} + bN_{2,t-1} + \eta_t \quad (2)$$

so that the a and b are identical for N_1 and N_2. The random elements ε_t and η_t are different but correlated. The correlation arising between N_1 and N_2 will then equal the correlation between ε_t and η_t. If the density-independent series ε_t and η_t are caused by, or just correlated with regional disturbances, this provides an explanation for the synchronous dynamics of the two populations N_1 and N_2. The density-dependent coefficients a and b do not necessarily need to be perfectly matched between the two populations. Synchronous dynamics is still achievable via external disturbances but the correlation between N_1 and N_2 will not equal that between ε_t and η_t. This reasoning later became known as the *Moran theorem* (Royama, 1992)

or the *Moran effect* (Ranta *et al.*, 1997a). Contemporary population ecologists emphasize the importance of the interplay of density-dependent and density-independent factors (Kaitala *et al.*, 1996; Grenfell *et al.*, 1998; Hieno *et al.*, 1997), thus echoing Moran's (1953a,b) seminal ideas. A central finding of current research suggests that populations tend to fluctuate in step over large areas and that the degree of synchrony levels off with increasing distance among the population units compared (Ranta *et al.*, 1997a; Lambin *et al.*, 1998; Bjørnstad *et al.*, 1999). This finding is substantiated also by increasing evidence obtained from long-term spatial time series data sets from different animal taxa (as in Figure 5).

As an example, we take the data on 1964–1984 dynamics of Finnish Black Grouse in 11 provinces (Figure 6). Besides cyclic behavior (see also Figure 4a) there is also a high level of synchrony over large areas. Note, however, that the nation-wide synchronicity is far from perfect, and also that the level of synchrony tends to go down with increasing distance between the time series compared (Figure 5a). To propose possible causes for the observed patterns, we have made use of a variety of theoretical models (Ranta *et al.*, 1997a). The populations are assumed to consist of a number of habitable units, which are subjected to local environmental noise. To explore the effect of dispersal and the Moran effect, the units are either independent or linked by dispersal. Further, they are or are not subjected to global environmental disturbance.

The results show that the Moran effect is capable of synchronizing population dynamics, as indicated by the mean of the cross-correlation coefficients deviating significantly from zero (Figure 5). The Moran effect alone does not show (as expected) any trend with increasing

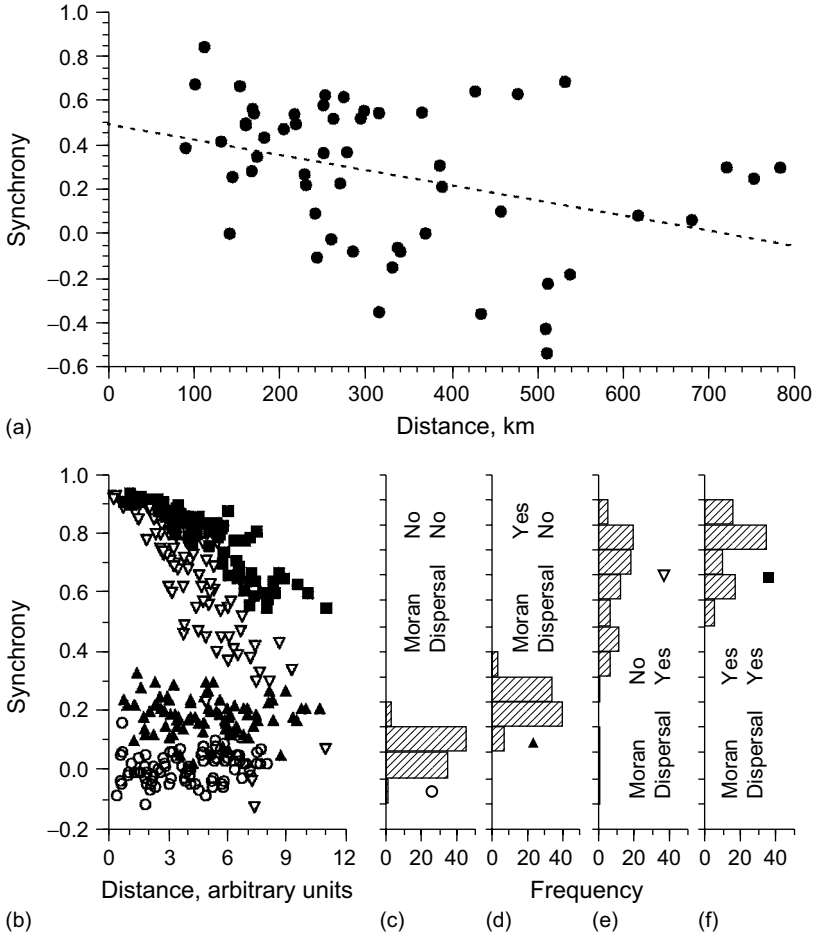

Figure 5 (a) The level of synchronous uctuations in Finnish Black Grouse dynamics (the 11 provinces in Figure 6 compared in pairs) is reasonable (mean of the cross-correlation = 0.265) but it levels off with increasing distance among the provinces compared. (b) Synchrony levels against distance in population dynamics of 10 populations in explicit 10×10 space obeying Black Grouse-like dynamics. The different symbols are for different combinations of dispersal and the Moran effect, indicated in panels (c- f) giving the corresponding marginal distributions of the synchrony measure. (Modi ed after Ranta *et al.*, 1997b)

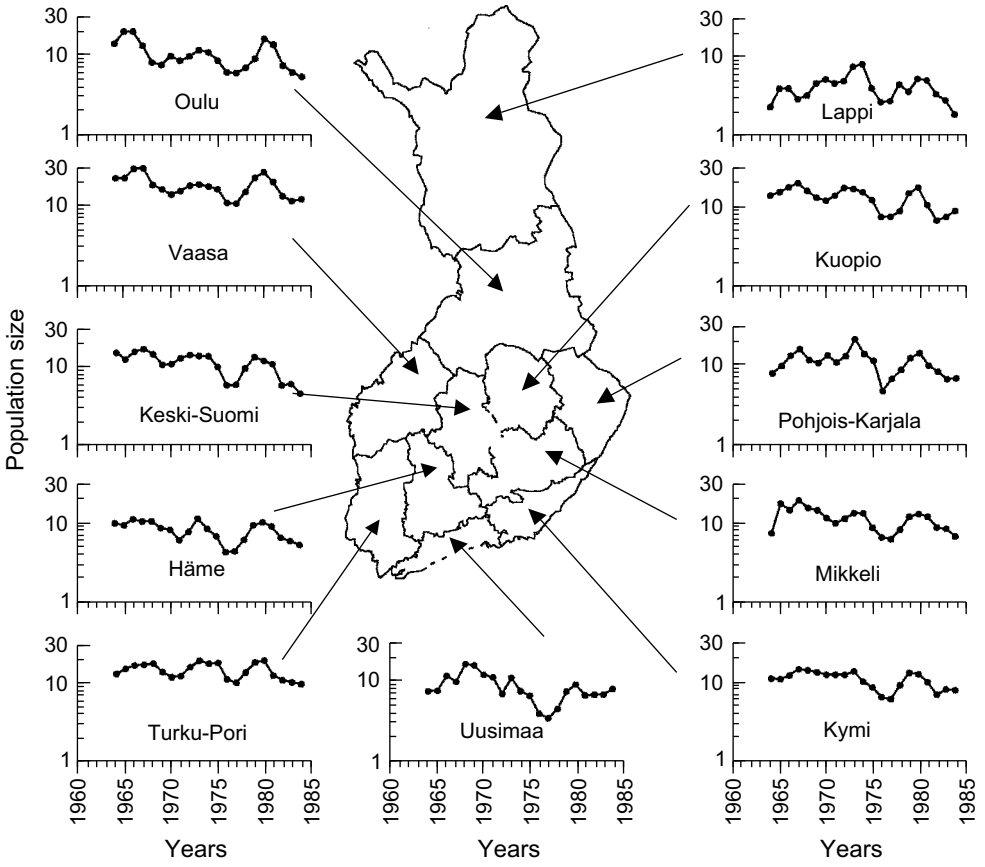

Figure 6 Black Grouse population (individuals km^{-2}) uctuations in different parts of Finland. (Data courtesy of Game Division of the Finnish Game and Fisheries Research Institute Lindén, 1981)

distance among the compared populations. On the other hand, dispersal among the populations alone is powerful enough to cause the populations to fluctuate in synchrony (see also Figure 3d), and the level of synchrony levels off with distance among the populations (Figure 5e). Superimposing Moran's effect on the dispersal does not improve much the level of synchrony, nor does it affect dramatically the negative correlation between synchrony and distance (Figure 5f). As a whole, we are facing the difficulty of deciding whether the negative correlation between the level of synchrony and distance among the compared natural populations is due to the effect of dispersal alone, or both dispersal and the global disturbance acting together.

According to one interpretation, the Moran effect (Moran, 1953a,b; Royama, 1992) can be understood as a global disturbance influencing the renewal processes similarly and simultaneously in different sub-populations or localities. From the above, we know that this effect is capable of synchronizing the dynamics of otherwise independent populations. However, in a process as described exactly by the Moran's theorem, the level of synchrony does not decrease with increasing distance. This prediction does not correspond to empirical observations. Consequently, two different alternatives have been proposed to develop Moran's idea further. First, the dispersal of individuals linking population sub-units has been put forward to explain this feature (Ranta *et al.*, 1997a,b; Kaitala and Ranta, 1998). Second, Ranta *et al.* (1999) applied an approach incorporating both spatially autocorrelated Moran effect and dispersal. With several different model classes of population renewal, they show that a spatially autocorrelated disturbance alone, especially in the presence of a population linkage by dispersal, is capable of producing synchronous dynamics with the synchrony leveling off with distance. There is one more complication, as emphasized by Kaitala *et al.* (1996), the actual agent causing the stochastic perturbation in nature is complex. It does not have to be the same every time, nor does it have to be the same for all species in a given year, supposing they are simultaneous enough.

CONCLUDING WORDS

Long-term population data collected simultaneously in more than two localities provide not only the means

to elaborate the relative significance of local and global processes but also permit evaluation of the significance of external perturbations, the Moran effect, on the dynamics of populations. There are few (if any) doubts that external disturbances affect populations on various geographical scales. Research on the dynamics of various animal species suggests that population fluctuations can be explained (at least partially) by weather and climate factors (e.g., Arditi, 1979; Slagswold and Grasaas, 1979; Steen *et al.*, 1988). This, in fact, dates back to the speculated causes of the regular dynamics of the snowshoe hare (Elton, 1924).

No population stays constant over many years, population sizes are prone to changes for several reasons. We have treated some of these cases above. In particular, our emphasis has been in the intrinsic population processes, that is, births and deaths. One has to acknowledge the fact that populations seldom live in perfect isolation. Emigrating individuals disperse elsewhere and immigrating individuals arrive from other localities. This process ties regional and local processes together. There is good theoretical and empirical evidence to indicate that proper understanding calls for research on both local and regional levels. A particularly good example is the recent study on the fluctuations of the Canadian lynx (Stenseth *et al.*, 1999) which shows that there are clear regional differences in the kind of dynamics the lynx displays in areas exposed to differing ecological conditions.

In this approach, the rationale is to hunt for weather and climate variables that best correlate with long-term data on population changes. This is because of a temptation to find biologically rational explanations for the effect of almost any weather-derived variable on population fluctuations via survival and reproduction, the key elements of population persistence. The origin of the idea is in the climatic control theory (Andrewartha and Birch, 1954).

Despite well articulated caveats (Royama, 1992) the climatic control paradigm continues to arise now and then. Recent concern about global warming has revived the search for correlations between observed ecological time series with climate indices such as the North Atlantic Oscillation (NAO) (*see* **North Atlantic Oscillation**, Volume 1), North Pacific Index, El Niño Southern Oscillation, or Palmer Drought Severity Index. These mostly deal with the NAO and aquatic taxa, e.g., North Atlantic phytoplankton density (Reid *et al.*, 1999), toxic plankton algae along the Swedish west coast (Belgrano *et al.*, 1999), dynamics of two calanoid copepod species in the Northeastern Atlantic (Fromentin and Planque, 1996), and annual landing statistics of European herring and sardines (Alheit and Hagen, 1997). There are also some examples from terrestrial ecosystems: flowering phenology and reproductive traits in some plant species (Galen and Stanton, 1991), population dynamics of moose, white-tailed deer (Post and Stenseth, 1998) and red deer (Forchhammer *et al.*, 1998a) and the breeding biology of migratory birds in the UK (Forchhammer *et al.*, 1998b).

When attributing long-term population changes to external factors, there is a caveat which is often forgotten. We shall illustrate the problem here with the annual salmon catch in one of the Norwegian rivers, the Namsen (Figure 7a). The data cover an exceptionally long period, 117 years (1876–1992) to serve as an excellent example of the central problem when trying to find an explanation for the long-term fluctuations in a population. For the same period of time we also have the standardized NAO index values (Figure 7b). Our rationale is to search for any covariance between these two time series. The cross-correlation coefficient with various time lags is a perfect tool for this purpose. However, prior to the analysis one has to remove any long-term trends. One now finds that with a lag of 10 years there is a positive correlation ($r_{10} = 0.385$, $P < 0.01$). An explanation for this long time lag is that the maturation of Atlantic salmon takes 4–6 years, and it may take two generations for the effect to cascade into the catchable adult biomass. *Ad hoc* explanations like this abound in the literature on climatic control theory.

With 117 years of data one can examine whether the aggregated correlation between the lagged time series remains if the covariance structure between the salmon catch data and the NAO index is studied in finer detail. A 20 year sliding time window was allowed to pass through the time series and we calculated the cross-correlation coefficient r_{10} for all subsequent windows. The results are not very encouraging (Figure 7c); cross-correlations obtained in this way fluctuate from statistically significant negative ones to statistically significant positive ones. Most of the time, however, there is no significant covariance. Based on this analysis, one must use caution in drawing conclusions about the covariance between population data and indices like the NAO based on short time series.

Without exception, populations change in size and spatial patterns through time. Both temporal and spatial patterns may be extremely rich and complicated. Two basic approaches are studied in population ecology to unravel the order behind population fluctuations. The first approach attempts to resolve the puzzle by postulating that the changes are due to an intrinsic factor in the populations, that is, density dependence. The second approach assumes that environmental fluctuations are diffused into the population dynamics. The current, commonly shared view emphasizes the synthesis of these two approaches: population fluctuations are a result of both factors. We should also add the spatial dimension of the population dynamics, which alone can act as a strong modifying factor in population dynamics. Unraveling such joint effects appears to

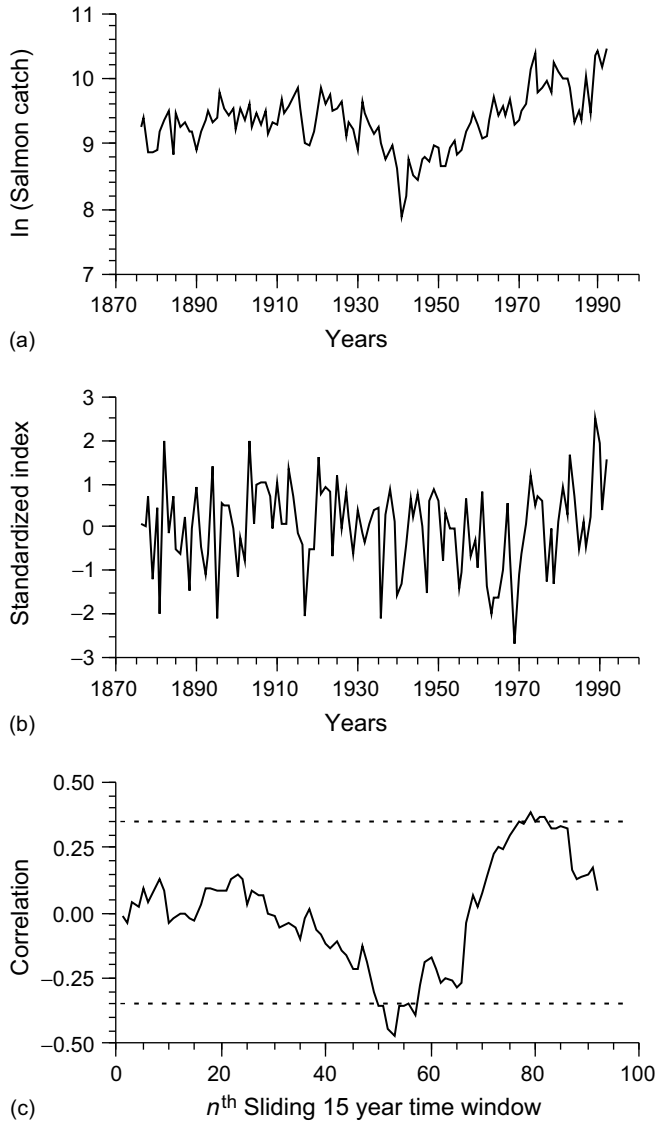

Figure 7 (a) Annual salmon catch in the Namsen river, Norway from 1876- 1992. (b) Standardized (zero mean, unit variance) NAO index for the corresponding period. (c) Temporal covariance structure between the salmon data and the NAO series (15-year sliding window is passed though the data with a time step of one year and the level of synchrony between the resulting time series is assessed). The broken lines indicate the 95% con dence limits of the correlation coef cient

be extremely demanding. The effects of combining all these factors, in population dynamics results commonly in complex and counterintuitive consequences where local consequences may differ from global ones. Thus, predicting the effects of a changing environment on the qualitative properties of population dynamics may remain a challenge for population ecologists for a long time to come.

Productivity

Most energy flow through an ecosystem begins with the fixation of sunlight and assimilation of carbon by green plants. Primary productivity, the rate of conversion of radiant energy and carbon by plants into organic substances which serve as food materials, refers to the first and basic form of organic matter production in an ecosystem. *Gross primary productivity* (GPP) is the total rate of this production including the organic matter used up in respiration. Like other organisms, plants consume stored organic matter through the process of respiration to fuel their reproduction and maintenance. *Net primary productivity* (NPP), the rate of total plant growth, is the total rate of storage of organic matter after subtracting the rate at which this stored organic matter is consumed through respiration (i.e., NPP = GPP − plant respiration). Net primary production can build up over time as plant biomass: while some is lost through decomposition, much of the rest may be retained as living material.

Plant productivity plays a crucial role in the carbon cycle, and hence in considerations of the greenhouse effect and global climatic change. For instance, in North American boreal forests, almost 50% of the carbon assimilated through photosynthesis (i.e., GPP) is consumed in plant respiration, leaving only about half for plant growth (i.e., NPP). About 90% of this plant growth is eventually returned to the soil as litter and is subsequently mineralized by soil organisms during their respiration. (The

resulting mineral nutrients can subsequently be taken up during future plant growth.) The remaining 10% of NPP is known as *net ecosystem productivity* (NEP) (i.e., NEP = NPP − decomposition respiration). Almost 90% of NEP is lost through disturbances such as timber harvest, fire, severe weather, or insect outbreaks. Because many of these disturbances have severe effects but occur very infrequently in a given area, realistic estimates of their average impacts must be made from data taken at very large (e.g., biome) scales.

Net biome productivity (NBP) is the 10% of NEP left in the ecosystem after subtracting losses to disturbance. Much of NBP exists as slowly decomposable organic material (stable humus) or long-lived carbon (charcoal). Carbon losses due to major disturbances (e.g., forest fire, insects) at landscape or larger scales, over long time periods (decades to centuries, or even conceivably millennia) should, in principle, balance net ecosystem uptake due to growth minus respiration and decomposition. Hence, in general NBP is much less than NEP which, in turn, is usually much less than NPP, and in at least some ecosystems, NBP should be negligible.

Productivity of Terrestrial Ecosystems

Stith T Gower
University of Wisconsin, Madison, WI, USA

Net primary productivity (NPP) of terrestrial ecosystems is a key determinant of the net exchange of carbon dioxide (CO_2) between terrestrial ecosystems and the atmosphere, and hence atmospheric carbon dioxide concentration. NPP varies by 12-fold among terrestrial ecosystems, with deserts having the lowest NPP and temperate broad-leaf evergreen and tropical forests having the highest. Water and nutrient availability strongly influence NPP; the basis for this relationship is that greater resource availability increases leaf area, which in turn increases the amount of photosynthetic active radiation (PAR) absorbed by the vegetation. Humans have altered the productivity of terrestrial ecosystems by changing the climate, atmospheric chemistry, land use, and disturbance regime of terrestrial ecosystems.

INTRODUCTION

Net primary production (NPP) is a useful measure of the metabolism of an ecosystem and the potential of the vegetation to produce food and fiber for human use. Detritus, which derives from the death and shedding of components of NPP, replenishes the soil with organic matter and nutrients that are essential to maintaining long-term soil fertility. Climate, soil fertility, and ecological variables influence the NPP of natural terrestrial ecosystems; thus it is not surprising that NPP varies greatly among major biomes. Few terrestrial ecosystems can be considered natural anymore because they have been directly or indirectly affected by global change. The three components of global change, land use and cover change, changes in atmospheric chemistry, and climate change, all influence NPP. Humans have changed land use and management practices, the chemical composition of the gases comprising the atmosphere, atmospheric nitrogen deposition, and climate. The potential of the biosphere to continue to meet the human demand for products of NPP is influenced by all the components of global change. Quantifying the effects of global change on the global carbon budget is limited by an incomplete understanding of how global change affects NPP. Food and fiber yield is directly proportional to NPP, and humans use almost half of total global NPP for food, fiber, and energy. Humans have noticeably changed or transformed 39–50% of the land surface to meet their needs for food and fiber (Vitousek *et al.*, 1997), and these changes directly and indirectly influence NPP. The rationale for converting natural ecosystems to managed forest plantations and agroecosystems is to increase yield, and economic profit. But shortened fallow periods and removal of a greater fraction of NPP from managed ecosystems may result in a long-term decrease in soil fertility because of the reduced input of detritus to the soil (Landsberg and Gower, 1997).

Humans have increased the atmospheric concentration of carbon dioxide (CO_2) (a greenhouse gas) by 30% since the pre-industrial era, and the increase will continue for the foreseeable future. The elevated atmospheric carbon dioxide concentration contributes to climate warming and may enhance the growth of plants in some regions (IPCC, 1996). Increased atmospheric nitrogen deposition may initially increase the productivity of nitrogen-limited terrestrial

ecosystems, but long-term chronic deposition may lead to permanent decreases in NPP of the terrestrial ecosystems and adjacent aquatic ecosystems (Aber, 1992).

There is general agreement that climate warming and greater interannual variation in climate are occurring, and that the magnitudes of changes differ among terrestrial ecosystems (IPCC, 1996). Predicting how these changes will affect NPP, and the availability of food and fiber, is problematic because of the complex interactive effects of changes in climate and chemistry of the atmosphere (e.g., ozone, nitrogen deposition, and carbon dioxide concentrations).

The objective of this article is to review the production budget, briefly summarize methods used to measure NPP, compare the NPP budgets of the major terrestrial biomes, and examine the major environmental and ecological factors, especially those affected by global change, that influence production budgets. The focus is on NPP because these data are more abundant than the other components of production.

For a summary of the influence of the physical environment on leaf-level carbon dioxide exchange, see **Carbon and Energy: Terrestrial Stores and Fluxes**, Volume 2. The focus here is on stand-level constraints on the productivity of terrestrial ecosystems.

DEFINITIONS AND COMPONENTS OF TERRESTRIAL CARBON BUDGETS (TABLE 1)

Photosynthesis is the assimilation of carbon dioxide by plants. GPP is the total amount of carbon dioxide assimilated by all vegetation life forms (i.e., overstory, shrub, herbs and bryophytes) (Figure 1, arrow 1). A fraction of the carbon dioxide assimilated by vegetation is used to construct new tissue (growth or construction respiration) and repair and maintain existing tissues (maintenance respiration). The sum of maintenance and growth respiration is referred to as *autotrophic respiration* (R_A) and results in a loss of carbon dioxide from the vegetation to the atmosphere (Figure 1, arrow 2).

NPP (Figure 1, arrow 3) is the balance between GPP and R_A (Equation 1)

$$NPP = GPP - R_A \quad (1)$$

NPP is expressed on a dry organic matter or carbon basis, per unit area per year. Values reported on a dry mass can be converted to a carbon basis by assuming carbon:organic matter ratios; the ratio for foliage, herbaceous vegetation and fine roots is approximately 0.45 and the ratio for woody tissue (e.g., stem wood and bark, branches and coarse roots) is 0.50 (Gower *et al.*, 1999). In practice, it is extremely difficult to measure NPP as the difference between GPP and R_A because GPP is difficult to measure; most estimates of GPP are derived from ecosystem process models. Consequently, NPP is calculated as the sum of the annual production (P) of all tissues (i) for all vegetation strata (v) (Equation 2)

$$NPP = (P_{vi}) + H \quad (2)$$

All tissues (e.g., stem, branch, foliage, coarse roots fine roots and mycorrhizae, reproduction) for all plant growth forms (overstory, understory, and ground cover) should be included. The loss of biomass to herbivory (H) should be

Table 1 Carbon budget symbols and de nition

Symbol	De nition
P_{vi}	Biomass production of the i^{th} tissue and v^{th} vegetation strata
C	Carbon
D	Detritus
GPP	Gross primary production
H	Herbivory
NEB	Net biome production
NEP	Net ecosystem production
NPP	Net primary production
NPP_A	Net primary production, aboveground
NPP_B	Net primary production, belowground
R_A	Respiration, autotrophic
R_H	Respiration, heterotrophic

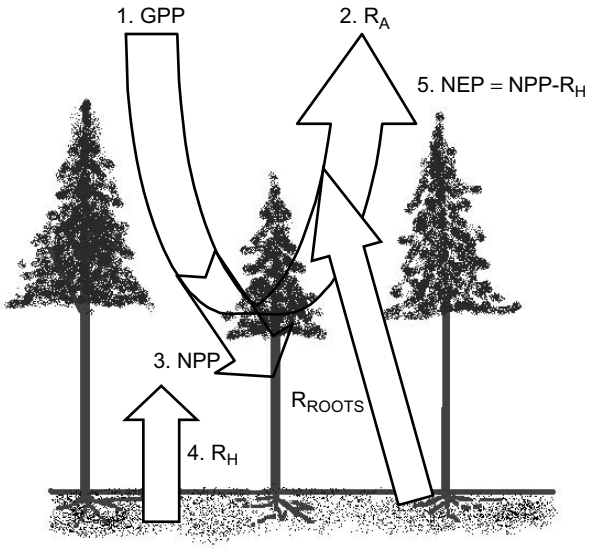

Figure 1 Conceptual diagram of the carbon budget of a forest ecosystem. The de nition of each ux is provided in the text. Processes such as R_A, NPP, soil surface carbon dioxide ux, detritus production, and heterotrophic respiration (R_H) can be measured separately, and the annual budgets are summed to estimate NEP. NEP can also be measured continuously using micrometeorological methods. GPP is dif cult to measure directly, and is usually estimated indirectly or modeled using an ecosystem process model

added to avoid underestimating NPP. During non-outbreak conditions, vertebrates and invertebrates consume <10% of NPP (Landsberg and Gower, 1997), suggesting that ignoring this small loss of tissue will result in only a small underestimation of NPP for forest ecosystems. This assumption is less valid for non-forested ecosystems and for forest ecosystems when herbivore populations are high.

The net exchange rate of carbon, in the form of carbon dioxide between the atmosphere and terrestrial ecosystems, including the vegetation and soil, is referred to as NEP (Figure 1, arrow 4). NEP is of great interest because it defines if the ecosystem is a carbon sink (accumulating carbon) or a source (losing carbon). NEP is the balance between two major processes: NPP and *heterotrophic* respiration, the efflux of carbon dioxide from the soil surface resulting from the oxidation of soil organic matter by heterotrophic organisms (Figure 1, arrow 5).

MEASURING NPP

Equation (2) can be used to calculate NPP for any ecosystem, although the measurement approach varies among ecosystems because of differing vegetation structure, spatial heterogeneity, etc. (Gower *et al.*, 1999). Two common approaches used to estimate NPP aboveground (NPP_A) are *area harvest* and *allometry*. Area harvest entails periodic destructive harvests of all aboveground live biomass in randomly located plots during the growing season. The harvested organic matter is dried (or sub-sampled and dried); then statistically significant increments, or production, of organic matter between each measurement period are summed to estimate NPP_A. This approach is best suited for short stature ecosystems such as grasslands, agricultural crops, tundra, etc. The area-harvest approach is inappropriate for most forests because the annual production of organic matter is small relative to the spatial variability of standing organic matter. The alternative is to establish permanent plots, record the diameter and species of each tree or shrub in the plot, and estimate the annual production of each biomass component from annual radial increment data and allometric equations. Allometric equations of the form $Y = a + \exp^{bX}$ where X is diameter at breast height are used (Gower *et al.*, 1999). The annual production of each tissue is calculated by measuring annual stem diameter increment for each tree in a fixed plot and applying the appropriate allometric equation to estimate the change in biomass for each tissue for one or more years. The theory and measurement protocol for estimating NPP is summarized by Gower *et al.* (1999).

There are far fewer data for belowground than aboveground NPP because estimating belowground NPP (NPP_B) remains controversial and all the methods used are laborious and costly (Gower *et al.*, 1999). NPP_B is comprised of two components: coarse- and fine-roots + mycorrhizae. There is no consistent definition for diameter size class to distinguish between coarse- and fine-roots, but fine-roots are generally considered to have diameters <2–3 mm. Coarse-root biomass far exceeds fine-root biomass, but fine-root NPP exceeds coarse-root NPP. Coarse-root biomass and NPP are estimated using allometric equations and Equation (2). Historically, fine-root NPP was assumed to comprise a constant fraction of NPP_A and much of the fine-root NPP data are based on this method. Approaches to directly estimating fine-root NPP include: max–min live fine-root biomass, sequential coring fine-root biomass, ingrowth cores, minirhizotron, nitrogen mass balance and soil carbon balance. More information about the different methods, and their limitation, to estimate fine-root NPP are given in Fahey *et al.* (1998).

NPP OF MAJOR TERRESTRIAL BIOMES

A *biome* is a group of ecosystems with similar climate, physical appearance, or physiognomy, and leaf habit (evergreen versus deciduous), and is the coarsest level of classification used for terrestrial vegetation. Figure 2 summarizes the average NPP for the major terrestrial biomes. Tropical broad-leaf evergreen and temperate broad-leaf evergreen forests have the highest NPP. Boreal forests have the lowest NPP of the forest biomes because of the extremely short growing season, and the cold soils restrict decomposition, and hence nutrient availability (Landsberg and Gower, 1997). The NPP of marshes can be extremely high because

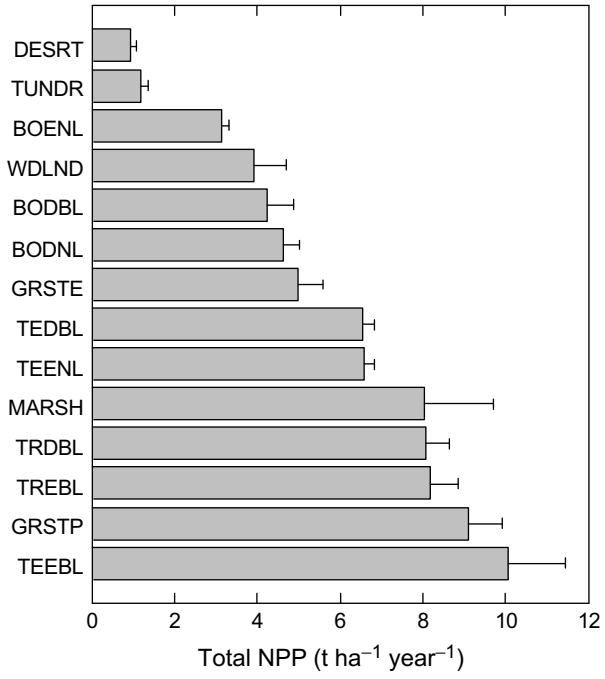

Figure 2 Average NPP for the major terrestrial biomes of the world. (Adapted from Gower *et al.*, 2001)

of the abundant moisture and high fertility resulting from the frequent deposition of nutrients and organic matter. The NPP of tropical grasslands is also very high because these biomes commonly occur on fertile soil, the climate is favorable for year-round growth, and water stress is moderate during the growing season. Deserts and tundra have the lowest NPP, but the environmental constraints on NPP differ between the two biomes. The low annual amounts of precipitation, the irregular distribution of precipitation, and large evaporative losses back to the atmosphere are the primary constraints to plant growth in deserts. On the other hand, the extremely short growing season (30–90 days), caused by extreme cold, and infertile soils are the primary constraints on NPP of tundra. Because the distribution, structure and NPP of terrestrial biomes are controlled by different environmental constraints, it is unlikely that the effect of climate change on NPP will be of similar magnitude or direction (IPCC, 1996).

ENVIRONMENTAL FACTORS INFLUENCING NPP

NPP of terrestrial ecosystems is influenced by a myriad of environmental factors, some of which are interrelated. For example, decomposition and nutrient mineralization, processes that influence nutrient availability to plants, are influenced by water availability.

Plants are photoautotrophs and require PAR for photosynthesis to occur (*see* **PAR (Photosynthetically Active Radiation)**, Volume 2). NPP is positively correlated to the annual fraction of intercepted, or more appropriately, absorbed photosynthetic active radiation (F_{APAR}); the relationship has a sound physiological basis (Landesberg and Gower, 1997). Photosynthesis by leaves is proportional to absorbed visible quanta or PAR. Although the light–photosynthesis relationship is non-linear for individual leaves, it is linear for most canopies, reducing the stand-level canopy photosynthesis to two primary factors: incident PAR and leaf area index (LAI). Incident PAR is strongly influenced by geographic location, aspect, and cloud cover. The fraction of incident PAR that is usable by plants is controlled by environmental factors that influence stomatal conductance (*see* **Carbon and Energy: Terrestrial Stores and Fluxes**, Volume 2; Landsberg and Gower, 1997). Extreme cold temperatures, high vapor pressure deficits, inadequate soil moisture, and nutrient deficiencies restrict canopy conductance, preventing the plant from using the absorbed PAR in the process of photosynthesis.

The large range in NPP among the terrestrial biomes is caused by environmental constraints on the amount of photosynthetic surface area, or LAI of vegetation and the diurnal-to-season patterns of carbon dioxide assimilation. If environmental constraints on canopy photosynthesis are accounted for, the ratio of $NPP : F_{APAR}$ is relatively conservative among biomes (Gower *et al.*, 1999). There is increasing evidence that plants optimize carbon allocation to equalize multiple resource limitations, thereby maximizing carbon gain. LAI and NPP_A are positively correlated to annual precipitation at the biome level (Figure 3a,b). The tropical broad leaf evergreen forests biome appear to occur below the general pattern, and may be explained by the fact that large fractions of the NPP data for this biome were for native *Metrosideros* spp. forests that occurred on extremely infertile soils in Hawaii. The basis for the strong positive relationship is optimization of carbon balance. The simultaneous processes of photosynthesis and transpiration, or carbon assimilation and water loss (*see* **Carbon and Energy: Terrestrial Stores and Fluxes**, Volume 2) couple the carbon and water budgets of plants. Plants can ill afford supporting large amounts of leaf area that will assimilate carbon dioxide for only a small portion of the year because respiration costs (Figure 1, arrow 2) continue, even though carbon dioxide uptake is limited by water

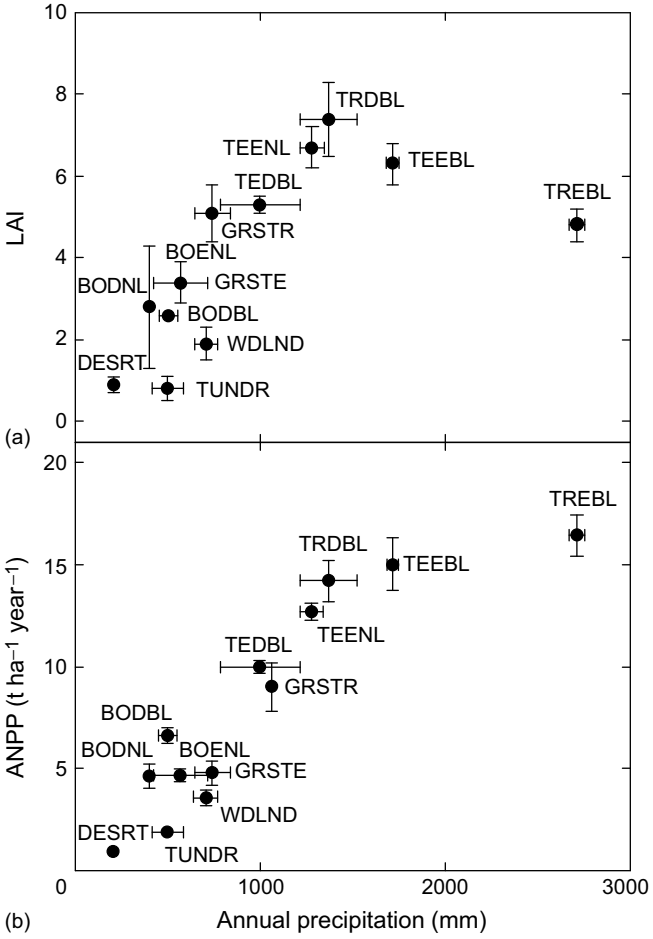

Figure 3 Relationship between annual precipitation and (a) LAI and (b) aboveground NPP for the major terrestrial biomes of the world. (Values are the biome average from Gower *et al.*, 2001)

and/or nutrient availability. An extremely short growing season limits the amount of leaf area, but evergreen forests have somewhat overcome this constraint by retaining needles longer. Thus, the structure and distribution of biomes appears to be in quasi-equilibrium with the environment in which they occur. Water and nutrient availability determine the maximum LAI of a terrestrial ecosystem. Grier and Running (1977) first demonstrated the strong positive relationship between site water balance, LAI, and NPP, and this relationship has been substantiated for temperate forests in the Midwestern US (Fassnacht and Gower, 1997). The physiologically-based interrelationships among water availability, LAI, and NPP suggest that changes in water balance, caused by either changes in precipitation or evaporative demand, will affect the structure and productivity of terrestrial ecosystems.

The availability of nutrients also influences the allocation of NPP to biomass components (Landsberg and Gower, 1997). Foliage has the highest nutrient concentrations of any major plant tissues (stem, branch, roots), thus large amounts of nutrients are required to construct a canopy. The allocation of carbon to the various plant components is determined by the availability of the most limiting resource (e.g., water, nutrients). Trees allocate less biomass to foliage production and more to fine roots and mycorrhizae production on infertile soils, and *vice versa* on fertile soils (Landsberg and Gower, 1997). Prescribed fire, which temporarily stimulates nutrient availability, promotes greater LAI of native grasslands (Aber and Melillo, 1991).

NPP is the balance between GPP and R_A (Equation 1). Views on the sensitivity of the fraction of GPP consumed by R_A to climate change have changed in recent years. The exponential relationship between respiration of individual tissues and temperature, and the asymptotic relationship between photosynthesis and temperature led early ecologists to assume that the fraction of GPP allocated to R_A would increase from cold to warm climates, and would increase with climate warming. However, the ratio of R_A : GPP for forests in contrasting climates is surprisingly stable, averaging around 0.50 (Landsberg and Gower, 1977). The stable proportion of GPP allocated to R_A can be explained by adjustments in carbon allocation to various biomass components and physiological acclimation of respiration to temperature (Ryan *et al.*, 1994).

Land-use change and disturbance history (i.e., frequency and intensity) are important components of global change and have a profound influence on NPP and NEP. Although NEP data do not exist for a disturbance sequence, a plausible scenario can be hypothesized based on a process-based understanding of the biophysical and ecological controls on NPP and heterotrophic respiration. Immediately following disturbance or land use change, NPP is small or close to zero. Heterotrophic respiration, however, is large.

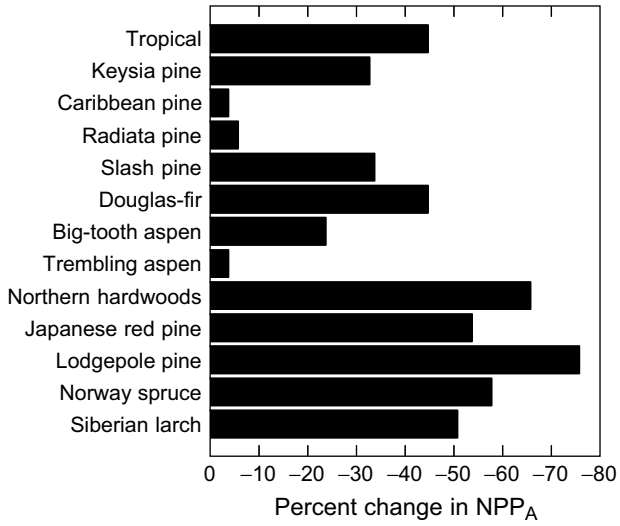

Figure 4 The relative change in NPP_A for forest age sequences in contrasting climates. A negative value denotes that NPP_A reached a maximum early during stand development and then decreased. (Data were adapted from Gower *et al.*, 1996)

The removal of the canopy increases soil temperature and moisture, which stimulate decomposition. NEP approaches zero and becomes positive as LAI and NPP increase and reach a maximum. Typically, aboveground NPP reaches a maximum during the early life of the stand, often corresponding to maximum LAI, and then declines by 20–60% as the stand ages (Figure 4). The physiological cause(s) for this age-related NPP decline are not well understood, but it has been observed in almost every forest biome of the world (Gower *et al.*, 1996). The two most plausible mechanisms responsible for the age-related NPP decline are nutrient constraints and hydraulic limitations (Gower *et al.*, 1996). The well documented age-related NPP decline and assumed relatively constant heterotrophic respiration in aging stands would imply that NEP would gradually decrease until it approaches zero.

In conclusion, NPP is an important component of the global carbon budget, and varies widely among terrestrial biomes, land use and management practices, disturbance regime.

Raven, Peter

(1936–)

Peter Hamilton Raven, US botanist and environmentalist, a native Californian with a lifelong interest in natural history, has built on his science to achieve international prominence in the fields of botany and conservation. After obtaining his undergraduate degree at the University of California, Berkeley (AB, 1957) and carrying on graduate studies at the University of California, Los Angeles (PhD, 1960), Raven pursued multidisciplinary and often collaborative studies of the plant family Onagraceae, the evening primrose family, throughout the world, making it one of the best-known plant groups. He made significant contributions to biogeography, many of them with D I Axelrod, and was among the first to link the distribution of organisms in the Southern Hemisphere securely with the developing concepts of plate tectonics. In the 1960s, while on the faculty at Stanford University, he developed (with P R Ehrlich) the concept of co-evolution, and acquired a lifelong interest in conservation and sustainability that has formed the theme of many of his activities subsequently. After assuming the directorship of the Missouri Botanical Garden in 1971, Raven has become a leading exponent of the central importance of biodiversity in the US, especially through his role in several key governmental and non-governmental advisory bodies, including the US National Academy of Sciences, the National Science Board, and the President's Committee of Advisors in Science and Technology. In addition, he has devoted a major effort to lecturing throughout the world and working with governmental and non-governmental agencies in many developing countries to promote the understanding of sustainable use of biological resources. He has been especially active in Russia and the former Soviet Union generally, raising funds for the repair of the Herbarium at the Komarov Botanical Institute in St. Petersburg and serving on major granting agencies concerned with building science in those countries. Building on his role as co-editor of the Flora of China project, he has interacted widely with scientists and scientific bodies in China and helped to develop international understanding there. His work is well expressed through the development of the Missouri Botanical Garden (since 1971) into one of the major institutions dealing with plant diversity throughout the world. Its activities are concentrated mainly in Latin America and Africa. He has authored numerous influential scientific papers and books, and is co-author of *The Biology of Plants*, now in its 6th edition, a world-leading botanical text. For these efforts, he has received numerous prizes and honorary degrees, and is a member or foreign member of more than 20 academies of science throughout the world. A tireless spokesman for biodiversity, sustainable development, and conservation, Raven has contributed much to our appreciation of the significance of the loss of biodiversity to global change, and its potentially severe impact on human futures.

Red eld Ratio

In 1934 Alfred C Redfield published a paper entitled *On the Proportions of Organic Derivatives in Sea Water and their Relation to the Composition of Plankton* (Redfield, 1934). In this paper he suggested that the ratio of

the nutrient elements, carbon, nitrogen and phosphorus, in sub-surface sea water is established by the decomposition of planktonic material and must reflect the ratio of these elements in the surface planktonic population. This ratio, which subsequently became known as the *Redfield ratio* has become of cardinal importance in the study of biogeochemical cycles. This is because the cycles of the nutrient elements are meshed by the processes of photosynthetic assimilation into biomass and by the catabolic regeneration of these elements. For marine plankton, an atomic ratio of P : N : C of 1 : 16 : 106 is generally accepted. This ratio does not possess the constancy characteristic of a defined chemical compound. The stoichiometry observed at any specific site will vary somewhat with the species composition of the planktonic population and with the nutritional status of the individual organisms. However, the metabolic and structural requirements of algal biochemistry will place stringent limits on the variability of the Redfield ratio. The situation becomes more complex when large multicellular organisms are involved. For instance, mature trees will contain a high proportion of carbon stored as wood. Nonetheless, Redfield's pioneering insight is crucial to our understanding of the dynamics of the biosphere. The relationship between rates of flow of nutrient elements in the biogeochemical cycles of all ecosystems is determined by the approximately constant chemistry of the metabolically active fraction of biomass.

Redox Potential

The chemical definition of an oxidation–reduction reaction (nicknamed *redox reaction*) is one that involves the complete or partial transfer of one or more electrons from one chemical species to another. In the biosphere, redox reactions control one of the fundamental requirements of life – the need to generate biochemical energy attained through the oxidation of organic carbon (CH_2O) to carbon dioxide (CO_2). The respiration reaction with molecular oxygen (O_2) yields considerable energy:

$$CH_2O + O_2 \longrightarrow CO_2 + H_2O + 502\,\text{kJ mol}^{-1}\ CH_2O$$

Plentiful microorganisms in the aquatic and terrestrial biospheres utilize O_2 in respiration. In soils, waters, and sediments, however, this reaction is limited because of relatively low concentrations of O_2. However, life does not stop in anaerobic environments. Aerobic organisms die off, but others arise that utilize oxidizing agents that substitute for O_2 in the respiration reaction shown above. For example, nitrate (NO_3^-) can serve the same purpose, albeit with less energy per molecule of organic carbon consumed:

$$CH_2O + \frac{4}{5}NO_3^- + \frac{4}{5}H^+ \longrightarrow CO_2 + \frac{2}{5}N_2 + \frac{7}{5}H_2O + 475\,\text{kJ mol}^{-1}\ CH_2O$$

There are in fact six molecules (including O_2) that control the oxidizing power of the biosphere. These are: (1) O_2; (2) NO_3^-; (3) manganese dioxide (MnO_2); (4) ferric hydroxide ($Fe(OH)_3$); (5) sulfate (SO_4^{2-}); and (6) CO_2. As illustrated in Figure 1, the choice of oxidizer proceeds via a preordained ordering, rather than by random utilization of all available oxidants. This ordering results from the relative oxidation potential of each molecule in its reaction with CH_2O, or, in chemical terms, its redox potential. The lower the redox potential, the lower the energy obtained from the reaction.

In an environment with a mix of oxidants, microbes preferentially select the one that yields the most energy. When that oxidant is used up, microbes use the oxidant with the

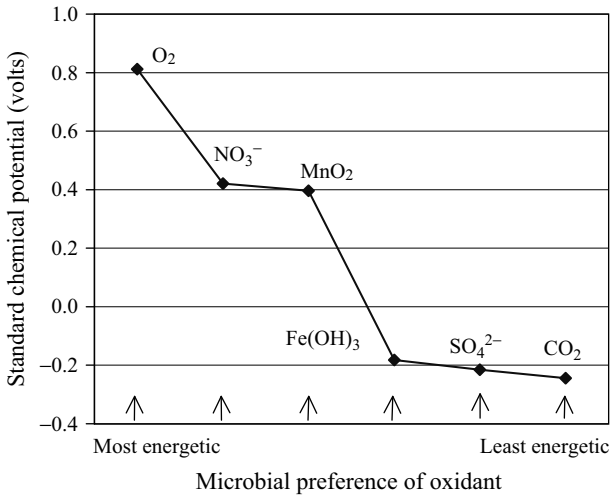

Figure 1 Six common oxidants in the biosphere and the sequence in which they are utilized by microbes

next highest yield of energy. Thus, one can think of redox potential as a kind of chemical switch that determines the observed sequence by which microorganisms utilize oxidants. In clean lakes with low amounts of CH_2O, microbes use O_2 as the preferred oxidant. When the amount of organic carbon exceeds about $3.4\,mg\,l^{-1}$ water, the O_2 will be depleted and nitrate becomes the preferred oxidant. When all of the nitrate is depleted, then MnO_2 becomes the preferred oxidant, and so on.

WILLIAM M STIGLIANI *USA*

Remote Sensing

Susan Ustin
University of California, Davis, CA, USA

Remote sensing imaging technologies provide a basis for monitoring, analyzing, and quantifying the information needed to characterize natural and human-induced environmental changes across a wide range of space and time scales. Imaging systems span spatial resolutions from submeters to kilometers and are available on a wide range of platforms, ranging from hand-held digital cameras to satellites. Many satellites and airborne imaging sensors are suitable for synoptic mapping and monitoring. These instruments provide, first, repeated measurements of the earth in a referenced spatial context, allowing explicit analysis of change detection, and second, in the case of satellite sensors, repeated measurements from as short a time as 30 minutes to years. There is, however, a general trade-off between frequent coverage by satellites and high spatial resolution.

Remote sensing instruments measure a physical property, electromagnetic (EM) radiation in specific spectral regions, thereby providing information about the Earth's surface that can be interpreted in terms of environmental conditions, and allow the user to spatially visualize this information. The past decade has seen extensive use of this technology for global change research and a transition from reliance on visual patterns and empirical relationships to ones based on physical processes and principles. These interpretative advances have depended on greatly improved detector technologies that became available during the 1990s, which are capable of measuring additional regions of the EM spectrum beyond the visible and near-infrared (NIR) wavelengths.

The development of spatial analysis tools using geographic information systems, and locational mapping using global positioning satellite systems occurred simultaneously with new remote sensing capabilities. More powerful computer capabilities and new quantitative analysis tools developed in the 1990s have contributed a suite of new tools to characterize site conditions in their spatially explicit contexts. While measurements at all scales are relevant to global change research, satellites are of particular interest due to the acquisition of images at regular repeated qintervals, making it more practical to quantify environmental changes.

SATELLITE AND AIRBORNE SENSORS USEFUL FOR ASSESSING GLOBAL ENVIRONMENTAL CHANGE

Global and Continental Scale Processes

An initial consideration of environmental assessments is to start by considering the scale(s) of the processes for which information is desired, the frequency with which repeat measurements need to be acquired to determine changes, and the type of environmental properties for which EM characteristics have potential to provide information. At the global scale, the weather satellites (metsats) provide the best source of environmental change information for processes manifested at regional to global scales. Many countries operate metsats, with programs going back to the 1960s. Data are of two types, the polar orbiting sun-synchronous satellites and the geostationary satellites. A range of meteorological data is acquired from multiple instruments but the most widely used for environmental change studies are from the imaging systems. These systems have relatively coarse ground resolution (kilometers) but may be acquired over much of the Earth at very frequent time intervals (0.5 hours to daily). The most widely used sensor for assessing global change has been the National Oceanic and Atmospheric Administration (NOAA) Advanced Very High Resolution Radiometer (AVHRR), available since 1983, which acquires data in visible ($0.4-0.7\,\mu m$), NIR ($0.7-1.0\,\mu m$), and thermal infrared (TIR) ($3-12\,\mu m$) spectral regions.

One of the first significant papers to examine feedbacks between the atmosphere and the terrestrial biosphere using satellite data was that by Tucker *et al.* (1986), who showed that AVHRR satellite measurements of planetary greenness, a property correlated with the amount of terrestrial vegetation and the absorption of photosynthetically active radiation (*see* **PAR (Photosynthetically Active Radiation)**, Volume 2), followed the cycle of atmospheric carbon dioxide (CO_2) concentrations measured by the global network of ground-based recording stations. A four-year data record showed that the monthly averaged greenness measurements followed the seasonal and interannual cycles and the latitudinal differences that had been reported by the CO_2 network. This study demonstrated that satellite data responded to terrestrial photosynthesis and respiration processes and provided unprecedented information about

temporal and spatial patterns in biospheric activity. Since then, numerous studies have used satellite data to establish carbon and water fluxes and surface energy budgets. For example, a 10-year satellite observation record was used to show that the arctic growing season is lengthening due to planetary warming and atmospheric carbon dynamics (Myneni *et al.*, 1997).

In other cases, increasing desertification due to unwise land uses and loss of vegetation following extensive regional droughts has been demonstrated using the AVHRR records. For example, the onset and extent of the devastating drought in the African Sahel in the early 1980s was demonstrated using AVHRR data (Tucker and Choudhury, 1987) and numerous other examples have been investigated since that time. Deforestation has also been examined using these data (e.g., Malingreau and Tucker, 1998), although due to the smaller scales of forestry practice, it has been less effective. Weather satellite data have contributed to improved global estimates of wildfires and the extent of biomass burning (French *et al.*, 1996), and have provided the most accurate maps of regional (Goward *et al.*, 1986) and global vegetation patterns (DeFries and Townshend, 1999). Satellite data have also been used to assess suitable habitat for disease vectors, such as Rift Valley Fever (Linthicum *et al.*, 1987).

REGIONAL ASSESSMENTS

The first non-military satellite to provide highly detailed images of the Earth was Landsat, launched in 1972, with four visible and NIR bands on the Multispectral Scanner (MSS). Landsat 4 was launched in 1982 and also carried a new seven-band sensor, the Thematic Mapper (TM). Beginning with the launch of Landsat-7 in 1999, an enhanced version of the TM (ETM+) became the only instrument on this satellite. The ETM+ has 30 m ground resolution pixels with six bands in the visible and reflected infrared regions, and one 60-m resolution TIR band. It also has a 15 m panchromatic sharpening band, which, when fused with the multispectral bands, produces a sharper visual image. The wavelength position of Landsat's spectral bands was chosen to provide information about plant pigments and water content, and structure of plant canopies, for accurate discrimination of environmental conditions. These data provide a bridge between local measurements at the scale of field experiments and the coarser resolution of the weather satellites. The multispectral data from Landsat contribute information that can be interpreted based on the general classes of materials composing the landscape (e.g., soils, vegetation, geologic outcrops, water, etc.). Landsat initiated a wide and growing range of environmental applications and provided the incentive to develop and launch many other land-observing satellites. Stoney (1997) identified 30 satellite sensors that are planned for launch by governments and private companies between 1999–2002. While some satellite programs have not been successful, it is clear we are at a new stage in the availability and quality of remotely sensed information. The Environmental Remote Sensing Center (ERSC) web site (http://rs320h.ersc.wisc.edu/ERSC/Resources/EOSF.html) provides a description of these satellites.

Among all classes of satellites there is a clear trend toward increasing the number of spectral bands and decreasing the minimum spatial resolution. For example, the National Aeronautics and Space Administration's (NASA's) Terra satellite launched in 1999 included two multi-band instruments, the Moderate Resolution Imaging Spectrometer (MODIS), with 36 spectral bands and spatial resolution up to 250 m pixels, and the Advance Spaceborne Thermal Emission and Reflection Radiometer (ASTER), with 14 bands and up to 15 m pixel resolution. It is now possible to obtain high spatial and temporal resolution data for virtually any type of spectral resolution sensor; therefore the problem now is to identify the most suitable data to address specific global change problems.

Radar Remote Sensing Systems

Radar satellites like the European Remote Sensing Satellite, the Japanese Earth Resources Satellite and the Canadian Radarsat are single-channel radar imagers with minimum spatial resolutions from about 100 m^2 to 10 km^2 and repeat cycles of a few days to about two months. At radar frequencies, clouds and water vapor are transparent, making these satellites almost the only option for viewing the ground for terrain with persistent cloud cover, e.g., in the tropics and the polar regions. Radar backscatter increases with the dielectric constant of natural material, and water is the only common material with a high dielectric constant. Therefore, image patterns generally reflect the water content of vegetation and soils, and produce images that resemble those detected by optical sensors that measure light absorption by photosynthetic pigments. Stereo radar data pairs produce interoferometric images that are used to generate high vertical relief digital elevation maps. NASA's Space Shuttle Topographic Mapping Mission in 2000 was designed to produce a detailed high-resolution digital elevation map for about 70% of the land surface of the Earth.

Multispectral Remote Sensing Systems

The Landsat MSS and TM are examples of multispectral satellites, while the French SPOT (Système pour l'Observation de la Terre) satellite and the Indian Resource Satellite are examples of commercialized multispectral satellites. Multispectral Satellites typically have between four to eight spectral bands and moderate spatial resolutions

(10–30 m), providing local to regional area coverage. There are plans for an additional 10 satellites in the early 2000s that will have Landsat-like multispectral capabilities. Most will have at least one short-wave infrared (SWIR) band (in the 1.5–2.5 μm range), a TIR band, and a higher resolution (1–15 m) panchromatic band. These sensors are designed to provide detailed spatial mapping and analysis of land cover and land use classes at the landscape scale. Band placements allow roads and developed infrastructure, water bodies, and general vegetation patterns to be mapped. Land use patterns, e.g., from agriculture and forestry, are routinely defined, as are boundaries between communities with different physiognomic forms, like grasslands and forests. The sensors provide information about vegetative cover and spatial patterns related to fragmentation and natural disturbances, e.g., wildfires, floods, droughts, defoliation, and severe storms. Coregistration of satellite images from different years provides detailed information on changing patterns of land use over time and makes it possible to assess rates of land conversion.

Regional environmental processes are better studied using the spatial detail that Landsat type data allow. Figure 1 depicts three years of MSS data over a 20-year period, centered over Lake Tahoe (largest lake, shown in black), on the border between California and Nevada. Each image (center panel) shows the midsummer greenness for the region (whitest pixels), covering an area approximately 34 225 km^2. Numerous small finger lakes are seen in the Sierra Nevada Mountains. The enlarged boxes shown above the regional images illustrate: (1) the temporary drying and loss of Washoe Lake (northeast of Lake Tahoe) due to a regional drought, which was in its seventh year in 1992 (above); and (2) the increasing number of clear cut logging areas and their extent in the Sierra Nevada Mountains (below). The logging activity changes forest connectivity in the region, creating habitat fragmentation and changes in species composition and age class structure. These changes lead to further impacts on the wildfire regime, erosion and runoff, and on the fluxes of gases and exchange of energy. These consequences are localized and the impacts depend on specific site conditions.

Hyperspectral Imaging Systems

These instruments represent the newest and most advanced remote sensing technology. Hyperspectral imaging spectrometers have large numbers (50–1000 s) of adjacent narrow wavelength spectral bands so that the band sequence produces a high resolution spectrum for each pixel. Due to the large number of coregistered spectral

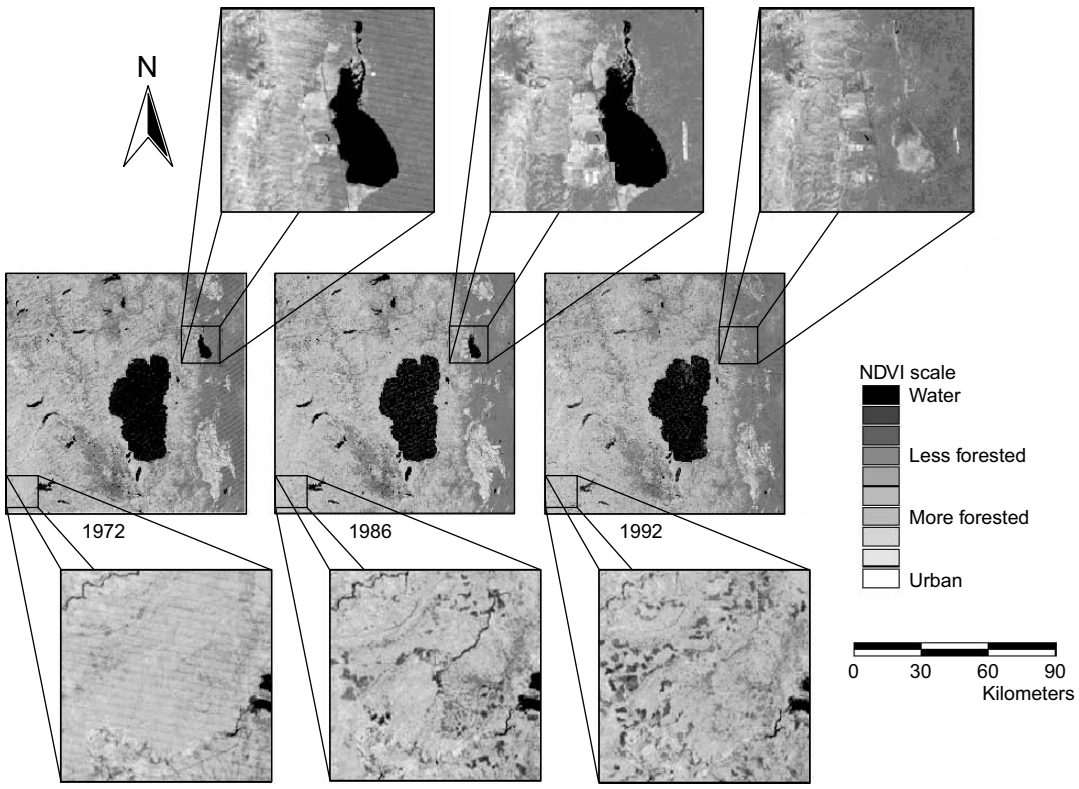

Figure 1 MSS normalized difference vegetation index (NDVI) images of Lake Tahoe region (California-Nevada, USA) in 1972, 1986, and 1992. NDVI is a normalized ratio of the NIR and red spectral bands, where brighter values indicate greater plant cover and darker values indicate lower plant cover. Diagonal striping in the 1972 image is an artifact

bands, a dataset is often described as an image cube. A way to visualize this is to imagine that all the images (created by displaying all the pixel values for each spectral band) are displayed as pages in a book. The first page in the book is the shortest wavelength band and the last page is the longest wavelength band. The data set that a multispectral satellite produces is analogous to a 4–8 page book compared to a 150–500 page book produced by a hyperspectral satellite.

The first hyperspectral satellite, Hyperion, was launched on NASA's EO-1 platform in November 2000, to be followed by three commercial hyperspectral sensors that are proposed for the 2000–2005 time frame. Each sensor has 150–220 spectral bands coverage covering the 0.40–2.50 μm spectral region and pixel resolutions of 30 m or better. More than 30 airborne hyperspectral sensors have been operated in different countries (see http://rst.gsfc.nasa.gov/sect13/is_list.html) and it is likely that more will be available in the future.

These spectrometers can be used to identify the surface expression of specific biogeochemical conditions in plants, soils, and geologic materials. Many minerals, clay minerals, carbonates, organic matter, and iron can be identified in soil (Clark, 1999; Ben-Dor *et al.*, 1999). In green foliage, photosynthetic pigments determine absorption of energy in the visible spectrum and water in the NIR and SWIR. These compounds determine the overall spectral absorption features of green foliage and plant canopies. For example, in dry leaves and woody tissues, structural carbon compounds like cellulose and lignin (Ustin *et al.*, 1999) and nitrogen compounds can be detected (Curran, 1989). From these spectral building blocks, it is possible to infer information regarding ecosystem health and possibly, the presence of stress agents, like contaminants. Most of the spectroscopy literature has been based on laboratory studies of environmental materials; however, some studies using airborne imaging spectrometer data demonstrate the potential to extract biogeochemical information from remotely sensed data. It is possible to map the distribution of canopy water content and pigments.

Hyperspatial Imaging Sensors

High spatial resolution image data (1–5 m pixels) are useful to identify localized environmental impacts and to evaluate the representativity of field data collected at specific locations, with respect to the larger region. There are potentially 12 commercial satellites that may acquire very high spatial resolution imagery from space (Stoney, 1997), focused largely on traditional markets of the photogrammetry industry. The Ikonos (Space Imaging Corporation), has a 1 m resolution panchromatic sensor and a 4 m resolution four-band (blue, green, red, and NIR) multispectral sensor on their satellite. Due to the narrow ground swath, global coverage will require periods from four months to two years to acquire a repeat measurement (Stoney, 1997). Off-nadir pointing capability will increase the frequency of repeating site measurements. Virtually any application where aerial photography is currently used is a candidate for using this type of sensor data. Clearly, these data provide a mechanism to scale measurements from field samples to landscapes. Many uses related to global issues are relevant for detailed site characterization at these scales, including mapping community composition in ecologically sensitive habitats, monitoring rare and endangered species, monitoring habitats threatened by invasion of noxious weeds, and characterization of habitat structure and successional states.

Remote Sensing, Terrestrial Systems

Anthony C Janetos
World Resources Institute, Washington, DC, USA

Field and forest, valley and mountain, wherever one goes, the land surface varies. The landscape is so varied that it has taken the work of many thousands of scientists to try to document its characteristics by going from place to place, compiling inventories of land characteristics and vegetation type. While much was accomplished and many detailed characteristics can be documented, an important problem was trying to ensure uniformity in the classification schemes, both because different scientists were making the observations and because observations were made at different times.

In contrast to the difficulties of surface measurements, satellite-based remote sensing can provide global coverage on a daily or near-daily basis. Such efforts were begun in the mid-1970s, and assembled data sets now provide rapid and relatively accurate sampling for some types of ecosystem status and characteristics. For a few variables, there is an approximately 25 year time series of reasonably well-calibrated data with nearly global coverage. In addition, because the costs of analyzing imagery are low, remote sensing offers essentially the only affordable means of sampling for measurements over very large spatial areas. Even though the capital costs of developing and launching satellite missions are extremely large, operational costs for satellite systems are not consistently higher than the personnel costs of large in situ monitoring efforts, and for whole Earth coverage, satellites become extremely cost effective.

LONG-TERM SATELLITE IMAGERY

Two types of satellite imagery are widely used by ecologists: (1) Landsat thematic mapper (TM), and (2) advanced very high resolution radiometer (AVHRR). Both cover the majority of the Earth's surface, with TM imagery providing 30 m resolution and AVHRR imagery providing 1 km resolution. Each system records the intensity of radiation reflected from the Earth's atmosphere-surface system in 5–7 spectral bands in the visible, near-infrared (IR), and thermal IR parts of the spectrum, and then uses this information to extract surface images.

The Landsat data record starts in 1972. Over this period, three primary instruments have been used. Video images, some of which are still archived, provided the initial record of surface conditions. The multi-spectral scanner, with approximately 80 m spatial resolution, was used along with the video system and very quickly became the preferred instrument for quantitative analysis. Since 1982, the primary instrument has been the TM, which measures six spectral bands in the visible and shortwave-near IR, all of which have 30 m spatial resolution, and one thermal band with 120 m spatial resolution. A Landsat scene is approximately 185 km on a side, and the combination of swath width and orbital characteristics of the satellite means that each location on Earth is revisited at about 16–18 day intervals. There have now been seven Landsat missions launched, although Landsat 6 failed to achieve orbit.

The US Geological Survey's Eros Data Center archives nearly global data from the Landsat system for the years 1972–1980, although the particular dates of cloud-free acquisitions vary from place to place on the globe. Starting in 1980, the US policy of commercializing the Landsat system resulted in a less comprehensive coverage being held in US archives (although the record for the US itself remains relatively complete). However, there have been 10–17 international ground stations operating during the period of the Landsat missions, many of which have maintained accessible data archives, so global data sets can be derived for the 1980s and early 1990s.

Landsat 7 was launched in early 1999, carrying an enhanced TM plus (ETM+), and this has improved the availability of data dramatically. The ETM+ observes the same spectral bands as previous Landsats, thus building on the already long time series, but also has a 15 m black and white band that is useful both in its own right and for sharpening the imagery from the 30 m bands. The ETM+ also has enhanced calibration capabilities compared to previous Landsats. Most importantly, however, the system used on Landsat 7 is designed to update the US-held global archive on approximately a seasonal basis, in addition to adding to the archives held by international ground stations (Goward and Williams, 1997). Data are also more affordable than was earlier the case.

The second primary data set on terrestrial ecosystems is derived from the AVHRR, which is a standard instrument on the National Oceanic and Atmospheric Administration polar-orbiting meteorological satellites. Although it was originally intended for use as a meteorological instrument, it has several spectral bands in the visible, near IR, and IR parts of the spectrum that are useful for monitoring terrestrial ecosystems. However, the AVHRR collects data with very different spatial characteristics than does Landsat, reflecting its origin as a meteorological instrument.

Global area coverage data, which are resampled on-board the satellite before being transmitted, have nominally 4 km spatial resolution. Local area coverage data, which are only directly transmitted to the ground, are nominally 1 km spatial resolution. The combination of the swath width (ca. 1000 km) of the sensor and the orbital characteristics of the satellite platform result in between daily and twice daily global coverage. However, unlike the Landsat TM or ETM+, whose radiometric properties are known and monitored with a high degree of accuracy, the AVHRR has no provision for on-orbit calibration; in addition, the various satellite orbits have drifted substantially over the years. Thus, the data include some noise because of the poorly known calibration of the instruments and poorly quantified intercalibration of instruments on different platforms. Therefore, although roughly decadal-length time series of truly global data exist, they have to be extensively preprocessed before they can be used for quantitative analyses of ecosystem properties and processes.

NEW SERIES OF SATELLITE IMAGERY

While efforts are being made to continue the long-term series, new, more detailed data sets are being generated. For example, the Earth observing system AM platform, known as *Terra*, was launched in late 1999. Terra carries five instruments, of which the moderate resolution imaging spectroradiometer (MODIS) is of particular interest from an ecological perspective. MODIS has 32 spectral channels, with stringently defined radiometric calibration. The majority of the spectral channels have 1 km spatial resolution, although a few have 250–500 m resolution. Global data sets are being acquired roughly every few days. Very importantly, the combination of spectral and spatial characteristics enables a more accurate calculation of a variety of vegetation indices, land-cover products, fire detection products, and land-cover change indices.

An even newer instrument will be the vegetation canopy lidar (VCL), an instrument capable of measuring the vertical foliage height profile everywhere on Earth. The technology has already been tested on the space shuttle, and the imager itself is currently being carried aboard a research aircraft. The satellite-mounted VCL will allow monitoring of harvesting and regrowth of vegetation, aboveground biomass, and structural habitats important to animal species.

The commercial sector is also increasingly active in providing remote sensing information. The IKONOS satellite, for example, provides very high spatial resolution data: 1 m resolution in black and white, and 4 m resolution multi-spectral information. Ecological and other scientific analyses of these data will almost certainly grow in number beyond this early stage. Analyses of recently declassified data with similar characteristics indicate that they will have great utility for vegetation classification and analysis of land-cover change. The recently declassified data themselves also provide the opportunity for analyzing time series of land-cover back into the 1960s in some locations.

INFORMATION HANDLING AND CALIBRATION

The use of remote sensing information for ecological analyses is still very much in its infancy, although tremendous strides have been made over the past five or six years. The ready availability of time series of satellite measurements with well-understood precision and accuracy has been an important issue in the use of remotely sensed data. In addition to the technical issues of sensor calibration and intercalibration of instruments on different satellite platforms, data access and affordability have also had to be considered because of the high capital costs of developing satellite systems and in part because of their commercial potential.

For many years, the technological challenges involved in simply handling and processing the data were so large that they inhibited the use of the systems by any but the most sophisticated laboratories. The rapid improvement, both in terms of cost and performance, of computer hardware and software is removing many of the technical impediments for the use of remote sensing. Two of the most important remaining issues, however, are the care, maintenance, and accessibility of data archives, and the intercalibration of the remote sensing instrumentation itself.

The latter is a serious challenge for the providers of remote sensing information, but is absolutely necessary for the information to be useful. Any instrumentation that is used to measure the long-term variation of ecosystems (or of any quantity) must be calibrated sufficiently that there can be confidence in ascribing changes in measurement to the ecosystem being measured and not to instrument drift. While this seems a simple requirement, achieving calibration precise enough for quantitative scientific measurements is tremendously difficult in practice. Very delicate hardware can be calibrated and tested on the ground, but it is subjected to tremendous vibrational stresses during launch, and then exposed to the thermal and radiation stresses of low-Earth orbit. Maintaining instrument calibration is thus a non-trivial task, although it can be achieved, as the Landsat data record shows. As important as calibrating each individual instrument, however, is ensuring that calibration is maintained for those data sets that are intrinsically long-term. This requires ensuring that data set calibration be achieved which lasts longer than the lifetime of any one instrument. This is best achieved by ensuring that successive instruments are flown for a period of overlap. This is especially important as both the hardware and software of

the instrumentation evolve so that trends due to degradation of instrument performance and offsets due to changing orbital geometry or new technology are identified and quantified before any analyses are attempted.

Resilience

Lance Gunderson[1], C S Holling[2], L Pritchard[1], and G D Peterson[3]

[1]*Emory University, Atlanta, GA, USA*
[2]*University of Florida, Gainesville, FL, USA*
[3]*University of Wisconsin, Madison, WI, USA*

Resilience has two meanings in the ecological literature, both related to system state and disturbance. Engineering resilience is the time of return to a global equilibrium following a disturbance. Ecological resilience is the amount of disturbance that a system can absorb before it changes state. Ecological resilience is based on the demonstrated property of alternative stable states in ecological systems, while engineering resilience implies only one stable state (and global equilibrium). The alternative meanings of resilience have significant implications for application of the concept to understanding and managing complex systems.

Resilience has been defined in two different ways in the ecological literature, each reflecting different aspects of stability. One definition focuses on efficiency, constancy and predictability – all attributes of engineers' desire for fail-safe design. The other focuses on persistence, change and unpredictability – all attributes embraced and celebrated by evolutionary biologists and by those who search for safe-fail designs. Holling (1973) first emphasized these different aspects of stability to draw attention to the tensions between efficiency and persistence, between constancy and change, and between predictability and unpredictability.

The more common definition, which we term *engineering resilience* (Holling, 1996), considers ecological systems to exist close to a stable steady-state. Resilience is the ability to return to the steady state following a perturbation (Pimm, 1984; O'Neill *et al.*, 1986; Tilman and Downing, 1994; Tilman, 1996). This idea of disturbance away from and return to a stable state is at the center of economic theory as well (Varian, 1992; Kamien and Schwartz, 1991).

The second definition, which we term *ecological resilience* (Walker *et al.*, 1969; Holling, 1996), emphasizes conditions far from any stable steady-state, where instabilities can flip a system into another regime of behavior, i.e., to another stability domain (Holling, 1973). In this case, resilience is measured by the magnitude of disturbance that can be absorbed before the system redefines its structure by changing the variables and processes that control behavior.

The differences between these two aspects of stability – essentially between a focus on maintaining efficiency of function (engineering resilience) versus a focus on maintaining existence of function (ecological resilience) – are so fundamental that they can become alternative paradigms whose devotees reflect traditions of a discipline or of an attitude more than a reality of nature. Those using the concept of engineering resilience tend to explore system behavior near a known stable state, while those examining ecological resilience tend to search for alternative stable states, and the properties of the boundaries between states.

Those who explore engineering resilience and the near equilibrium behavior of ecosystems operate in the primarily deductive tradition of mathematical theory (e.g., Pimm, 1984) that imagines simplified, untouched ecological systems, or they draw upon the traditions of engineering, that are motivated by the need to design systems with a single operating objective (Waide and Webster, 1976; De Angelis, 1980; O'Neill *et al.*, 1986). These approaches simplify the mathematics and accommodate the engineer's drive to develop optimal designs. However, there is an implicit assumption that ecosystems exhibit only one equilibrium steady state, or, if other operating states exist, that those states should be avoided.

On the other hand, those who emphasize ecological resilience come from traditions of applied mathematics and applied resource ecology at the scale of ecosystems, e.g., of the dynamics and management of fresh water systems (Fiering, 1982), of forests (Holling *et al.*, 1977), of fisheries (Walters, 1986), of semi-arid grasslands (Walker *et al.*, 1969) and of interacting populations in nature (Sinclair *et al.*, 1990; Dublin *et al.*, 1990). Since these studies are rooted in inductive rather than deductive theory formulation and in experience with the impacts of large scale management actions, it becomes clear that the variability of critical variables forms and maintains the stability landscape, and that when this variability is reduced, an ecosystem can flip from one state to another.

In economics, there has also been a focus on the single stable state. The history of economics has been to rapidly move from establishing the existence of a general equilibrium to issues of equilibrium uniqueness or stability. If multiple equilibria are shown to theoretically exist, then the

challenge that is usually taken up is to theoretically eliminate stable states by proposing individuals' strategic expectations and predetermined normative and social institutions. This approach does not examine or explain the conditions that can cause a system to move from one stability domain to another. However, the identification of multi-stable states due to path dependency (Arthur *et al.*, 1987), chreodic development (Clark and Juma, 1987) and production nonconvexities such as increasing returns to scale (David, 1985) has reintroduced multiple stable states to economics.

The existence, or at least importance, of multiple or a single stable state determines the appropriateness of an engineering or ecological approach to resilience. If it is assumed that only one stable state exists or can be designed to exist, then the only possible definition and measures for resilience are near equilibrium ones – such as characteristic return time. That is certainly consistent with the engineer's desire to make things work, not to intentionally make things that break down or suddenly shift their behavior. However, nature and human society are different.

Respiration

Respiration in plants is the oxidation of organic substrates by organisms to release useful energy, usually accompanied by the uptake of oxygen and the release of carbon dioxide (CO_2). All organisms rely on respiration to release, for metabolic purposes, the potential chemical energy stored in respiratory substrates (characteristically reduced organic compounds such as sugars and sugar polymers). Respiration is normally accomplished by a complex series of oxidative reactions, some of the energy so released being captured and temporarily stored in high-energy compounds such as adenosine triphosphate and reduced pyridine nucleotides. These high-energy compounds are then available to drive synthetic reactions, to power cellular or intercellular transport mechanisms, or to drive other energy-requiring activities such as the contraction of muscle-like proteins found in many plant cells.

The end product of respiration is CO_2, and normal plant respiration requires an approximately equal uptake of oxygen. Some respiratory activity can go on anaerobically by fermentation, in which the initial steps of respiratory metabolism permit the production of high-energy compounds at the expense of reactions that convert sugars to alcohol or other similar end products with the production of CO_2. However, fermentation releases only a fraction of the energy from the substrate compared with normal aerobic respiration.

Respiration of a plant is not a constant of that plant, but varies under the influence of many external and internal factors and controls. It is temperature sensitive and, without internal control, doubles on a 10 °C rise in temperature.

Internal controls include a series of biochemical and metabolic feedback mechanisms that prevent the organism from using up its resources merely because they are there, but increase or decrease the rate according to need. In the event that the normal substrates of respiration (sugars and starch in most higher plants) become seriously depleted, such mechanisms will allow the use of alternate (but metabolically or energetically less desirable) substrates such as proteins and amino acids or lipids.

Respiration and fermentation are characterized by the production of CO_2, and of organic end products such as alcohols in the case of fermentation. Also, because the respiratory process is only approximately 30% efficient in trapping the chemical potential of substrate molecules in high-energy intermediates, a substantial amount of heat is produced in respiration (ca 400 kcal $mole^{-1}$ glucose). This is not usually important in leaves, for example, but may raise the temperature of sequestered or insulated locations with a high biotic content (particularly of microorganisms) to the point of spontaneous combustion, as in damp hay bales.

The main ecological impact of respiration is CO_2 production, and respiration is one of the most important components of the biogeochemical cycling (*see* **Biogeochemical Cycle**, Volume 2) of carbon. Diurnal variation of plant respiration and photosynthesis as well as the annual variation in plant respiratory activity due to climatic temperature variations add very considerably to the complexity of the global carbon cycle. While plants do indeed remove large amounts of CO_2 from the atmosphere by photosynthesis, they return much of it in respiration. The difference (the amount of carbon that is actually sequestered) represents plant growth and litter production. Ultimately even that will be returned to the atmosphere (by microbial respiration) unless over even longer times it is sequestered as carbonate rock or coal, oil or gas.

R G S BIDWELL *Canada*

Restoration, Ecosystem

John P McCarty[1] and Joy B Zedler[2]

[1] *Environmental Protection Agency, Washington, DC, USA*
[2] *University of Wisconsin, Madison, WI, USA*

Ongoing changes to the earth's climate, disruptions of nutrient cycles, and changes in land use are expected to result in extensive disruptions to natural communities and ecosystems. These disruptions will likely result in the extinction of valued species of plants and animals and the loss of important ecological services. At the same time, the potential strategies for minimizing the effects of these changes on ecosystems at the regional scale are extremely limited.

Restoration of degraded ecosystems is one promising strategy for reducing the negative impacts of global change. Ecological restoration attempts to promote recovery of ecosystems damaged by human activities. Restoration is increasingly attempted in freshwater, wetland, grassland, and forest ecosystems. The results of these efforts have been mixed. Many restoration projects involve high inputs of time and money for each hectare restored and ongoing maintenance is frequently required. In many cases, the species that make up a community can be established but healthy ecosystem functioning is more difficult to restore.

In the future, restoration ecology will likely play an important role in speeding the recovery of ecosystems damaged by global change. While some of the difficulties facing ongoing restoration projects are likely to be overcome with time and effort, it is probable that future ecological restoration will be unable to restore degraded natural communities completely.

Restoration and related land-management projects offer potential tools for mitigating some of the effects of global change on ecosystems. According to the Society for Ecological Restoration, "Ecological restoration is the process of assisting the recovery and management of ecological integrity. Ecological integrity includes a critical range of variability in biodiversity, ecological processes and structures, regional and historical context, and sustainable cultural practices." This approach presents an attractive basis for addressing some of the effects anticipated from changes in climate, nutrient cycles, and land use patterns.

Around the globe, restoration efforts are underway to reverse the damages of historical land use to restore ecosystem services and natural diversity. Most projects are very small, but a few large regional programs are underway (e.g., restoring the hydrology of the Everglades (Florida, US) and restoring parts of the San Francisco Bay Delta, US). The ultimate goal of many restoration projects is to reestablish a community that existed prior to human disturbance. For the purposes of this article, we also include *rehabilitation* projects, where it is recognized that past conditions cannot be recreated. Instead, establishing some alternative ecosystem is the target. We also consider *reclamation* projects that attempt to create an ecosystem that will provide specific ecological services, such as constructing a wetland to treat runoff, without regard for the species composition or overall ecological integrity.

The typical goal of restoration ecology is to restore a past state. Yet the very nature of environmental changes at the

global scale, especially global climate change, means that conditions in a given area are changing in such a way that they will no longer be appropriate for the communities of recent history. Instead, restoration will provide tools and experience to smooth 'the recovery and management of ecological integrity'. For a given area, the target ecosystem will be one consistent with the new and changing climatic conditions. Restoration may also be valuable in helping to preserve currently existing, distinct communities by establishing them in new areas where climate has become favorable.

In this article, we first review how restoration ecology is being applied in different types of ecosystems. For each ecosystem, we consider how global change is expected to affect species and communities and how restoration ecology might address problems that emerge. We focus on climate change, rather than other aspects of global change, because changes in climate are expected to affect virtually all ecosystems (Intergovernmental Panel on Climate Change, 1996), and because prevention measures that might reduce impacts of changing climate have not been widely adopted. The lack of prevention strategies increases the importance of approaches such as restoration that focus on minimizing or reversing negative impacts on ecosystems. Restoration has proven to be a useful tool for addressing ecosystem degradation due to non-climate components of global change such as acid or nutrient deposition and changes in land use. Next, we discuss how ongoing restoration efforts might be modified to prepare for future climate change. Finally, we discuss the limitations and advantages of restoration ecology as a strategy for helping ecosystems adapt to climate change. While restoration has many advantages over other possible strategies for mitigating the effects of climate change on ecosystems, it is clear that none of the currently available tools will be sufficient to avoid the negative effects of climate change.

ECOLOGICAL RESTORATION AND POTENTIAL APPLICATIONS TO CLIMATE CHANGE

Traditionally, much of the focus of environmental science has been on removing sources of stress from the environment, such as removing toxic chemicals or reducing inputs of nutrients. Global climate change challenges this traditional approach in part because elimination of warming associated with global climate change presents formidable technological, social, and political obstacles. Because it is not likely that we will be able to reverse climate change in time to prevent widespread disruptions of ecosystems, it becomes necessary to find other means of reducing the negative impacts of climate change. One approach will be to speed the natural processes responsible for ecosystem recovery. We suggest that restoration, especially large regional projects, can help address these changes in the future. It is also possible for ongoing projects to incorporate actions that will help buffer ecosystems against the negative impacts of climate change.

Ecosystems will differ in how they respond to climate change, which would have far-reaching effects on natural ecosystems (Intergovernmental Panel on Climate Change, 1996). In general, the effects of climate change will act on populations and species. The tolerances of each species for changing climatic conditions will differ, but it is expected that many species will no longer be able to persist in part or all of their current geographic ranges (Intergovernmental Panel on Climate Change, 1996). Even species that can tolerate wide ranges of climatic conditions are likely to be impacted as their predators, competitors, and prey respond to climate change. In response, species might shift their geographic range to suitable areas, change their behavior so they are active at cooler times of year, or evolve to tolerate the new conditions. Species that fail to adjust to new conditions rapidly enough will become locally extinct.

Here we describe progress in ecological restoration in freshwater, wetland, grassland, and forest ecosystems. For each ecosystem type, we briefly outline special challenges they will likely face from changes in climate and outline how restoration might be applied to meet those challenges.

Freshwater Ecosystems

Under generally accepted climate change scenarios, aquatic ecosystems face possible changes in both temperature and the amount of water available (Intergovernmental Panel on Climate Change, 1996). Freshwater systems are already severely challenged and contain large numbers of threatened and endangered species (Dobson *et al.*, 1997). Many aquatic organisms are sensitive to water temperature and will face increasing stress from changes in thermal regimes.

Efforts to rehabilitate degraded lake ecosystems date back many decades. Most early efforts were responses to excessive nutrient inputs and resulting eutrophication. Noteworthy examples include Lake Washington in Seattle, US and Lake Erie in the US and Canada, where reductions in nitrogen and phosphorus inputs produced dramatic improvements in water quality. Similar approaches will be most relevant where climate change exacerbates existing problems, such as increased nutrient loading due to increased precipitation or decreases in dissolved oxygen concentration due to higher water temperature.

Acid deposition is one component of global environmental change, and the scale of the efforts devoted to treating impacted areas suggests that substantial resources can be dedicated to regional restoration efforts. One approach to restoring lake ecosystems affected by acid deposition involves application of lime to neutralize acid (Schindler, 1997). In Sweden alone, 7500 lakes have been repeatedly

limed as part of efforts to restore acidified lakes (Appleberg, 1998). Regular application of lime can moderate acidity but additional restoration, such as restocking of fish, is usually needed to restore communities fully (Schindler, 1997; Appleberg, 1998).

Changes in thermal characteristics of habitats will likely exacerbate the already high rates of endangerment of aquatic species (Dobson *et al.*, 1997). Many endangered and threatened aquatic species have geographic ranges that encompass a narrow range of thermal conditions and have limited abilities to disperse to new habitats. Rising water temperatures will tend to exclude fish species from areas where they now exist, while appropriate thermal habitats will occur to the north of current ranges. Restoration ecology could play a role in providing new habitats for those species in thermally appropriate areas. The slow rate of dispersal to new habitats, especially for species in isolated lakes, will severely limit the ability of fish to shift their geographic range in response to climate change. Translocations could speed the adjustment of dispersal-limited species. However, many of the existing problems in aquatic systems result from introductions of species by humans to new habitats. Introducing species to cooler waters would need to follow thorough research on the potential impacts to species already in place and acknowledgment of the ecological risks involved. Creation of new habitats in enclosed basins (reservoirs) may be one approach to minimize the risks from such assisted range extensions.

Of particular importance to future efforts will be improving techniques for dealing with invasions by nuisance species. Changes in water temperature will probably allow further expansion of the ranges of aggressive exotic species, exacerbating existing problems. Experience with aggressive invaders such as rusty crayfish *Orconectes rusticus* and zebra mussel *Dreissena polymorpha* as well as numerous aquatic plant and fish species shows the difficulties managers face in attempting to limit ecosystem damage caused by invaders. Introductions of predatory game fish have disrupted many unique communities, but significant restoration can be initiated if the fish can be eliminated (McNaught *et al.*, 1999). Unfortunately, attempts to control the species composition of aquatic communities, especially smaller, non-game fish, algae, and higher plants, have had limited success (Welch and Cooke, 1987) (*see* **Lakes and Rivers**, Volume 2).

Wetland Ecosystems

Climate change threatens to stress wetland species through direct effects of temperature and carbon dioxide (CO_2) concentration and through changes in hydrology due to precipitation, evaporation and sea level changes (Michener *et al.*, 1997). Temperature increases are likely to damage wetlands that store carbon in the form of organic matter. Canadian peatlands and the Arctic tundra could release major quantities of carbon to the atmosphere through increased decomposition rates as a result of warming or drying (Intergovernmental Panel on Climate Change, 1996). Experiments with multiple factors and many types of wetlands are needed to make long-term predictions of community change, however. The hydrologic restoration of drained peatlands in advance of climate change would help buffer the globe against these impacts.

Small ponded wetlands and dry-end wetlands will be very sensitive to altered hydrology (Sorenson *et al.*, 1998). Because half of North America's waterfowl are reared in prairie potholes, and because duck production is directly correlated with the number of small ponds, there would be measurable impacts to waterfowl following changes in precipitation and evaporation (Sorenson *et al.*, 1998). The acceleration of current efforts to restore drained potholes throughout the Midwest could mitigate some of the negative impacts in advance, but biodiversity would still likely decline, as not all species return with renewed ponding (Galatowitsch and van der Valk, 1996).

Many wetlands have lost their natural water regimes, especially flood pulsing and the accompanying mechanical disturbances and nutrient influxes that invigorate floodplain wetlands (Middleton, 1999). In some cases, restoration may be accomplished simply by removing impediments to water flow (Gilbert and Anderson, 1998). Where dams permanently reduce flooding of wetlands, significant improvements can be achieved by periodic water releases that mimic seasonal floods (Vaselaar, 1997; Middleton, 1999).

Hydrological changes may be greatest for coastal wetlands, where sea levels in many areas may rise more than 0.5 m by 2100 (Intergovernmental Panel on Climate Change, 1996). Salt marshes will be lost where sea walls obstruct their migration inland and/or where sedimentation cannot keep pace with inundation. Restoration efforts would help mitigate future losses due to sea level rise. Methods include reestablishing tidal flow through removal of dikes, reintroducing species, and excavating new wetlands (Simenstad and Thom, 1996; Zedler, 1996a; Williams and Watford, 1997). Inundation problems can be combated by encouraging sedimentation and marsh building (Smit *et al.*, 1997) or accommodated by 'managed retreat'. In the latter process, levees can be breached to allow salt marsh to reestablish in low lying areas (Packham and Willis, 1997; Gilbert and Anderson, 1998) or broad inland buffers can be set aside to allow salt marsh migration up slopes.

One of the most damaging effects of climate change on coastal wetlands may be from increased storm frequencies and magnitudes. Extreme high tides can carry salts inland on to intolerant vegetation and soils. Salty soils will favor the inland migration of halophytes, which will be necessary to maintain salt marshes where sediment accretion cannot keep up with inundation (Michener *et al.*, 1997).

Species will likely migrate into newly inundated areas at different rates and be affected by different substrates and competitors inland, so some species may need to be translocated. The high-intertidal marsh of Southern California, US, is a good example of an assemblage that may need to be translocated in anticipation of sea-level rise. Three high-marsh perennials are already rare and they rarely reproduce from seed. *Frankenia palmeri* has only one natural occurrence in the US, but in Mexico it occurs in both salt marsh and upland areas. *Salicornia subterminalis* (= *Arthrocnemum subterminale*) and *Monanthochloe littoralis* are more widespread in Southern California but their populations have been greatly reduced by trails, roads, and other disturbances. These species show promise for experimental planting in upland buffers. Plants should be grown from seed to provide genetic diversity, so that selection could operate after tides begin to inundate the populations. The benefits (enhanced genetic diversity) and risks (contamination of local gene pools) of bringing in seed from Mexico would first need to be weighed.

Much of the motivation for restoring wetlands is to provide ecological services, such as nutrient removal and retention. Restoring specific functions is usually more difficult than simply reestablishing plant cover (Mitsch and Wilson, 1996; Simenstad and Thom, 1996; Zedler, 1996b), and even state of the art techniques cannot yet restore a heavily disturbed ecosystem to a specific, self sustaining state.

The most restorable sites are those with some remnant of natural topography, hydrology, or species composition. The return of the channeled Kissimmee River to its historical riverbed rapidly restored native wetland plant cover and attracted populations of desirable invertebrates, fishes, and birds in the pilot demonstration project (Toth, 1996). More challenging is the plan to restore water flows to the Everglades, as water supplies are finite and Southern Florida, US, metropolitan areas permanently divert much of the water that used to form the 'river of grass'. On the positive side, the US National Park System sustains a large area of native vegetation, and providing more water should help it persist. Least restorable is the San Francisco Bay Delta, a huge complex system of river channels (mostly leveed for flood control), water diversion canals (designed to move water to Southern California), and islands (leveed, because farming has caused substantial subsidence). Although the main ecosystem restoration goal is to enhance native species and reduce exotics (especially fishes), there is little natural habitat left and water demands preclude full hydrologic restoration. Restoration to historical conditions is not possible, but this is just the type of project that could include large experiments to create climate-buffered ecosystems. Some portion of the project could be designated as an experimental climate change reserve (*see* **Marshes, Anthropogenic Changes**, Volume 3).

Grassland Ecosystems

Grasslands and prairies occur where conditions are wet enough for grasses but too dry for shrubs and trees (or too disturbed by fire or grazing). Because moisture and fire are key factors, grassland will be especially sensitive to changes in precipitation and in climate variability.

Grasslands and prairies have undergone extensive restoration over the last 65 years to recreate the aesthetic structure of prairies, to reintroduce fire to rehabilitate prairie remnants, and to create functioning ecosystems on abandoned farmland (Kline and Howell, 1987; Muller *et al.*, 1998). Restoring biodiversity requires continual planting and continual management of exotic invasions. Some species are notoriously difficult to maintain, while many invasive exotics are notoriously difficult to eradicate (Cottam, 1987; Kline and Howell, 1987). A good understanding of the ecology of the organisms involved and ongoing management, are needed to maintain restored habitats (Cottam, 1987). Difficulties are compounded when the original soil is badly degraded and a diverse seed bank absent. Success of restoration attempts of species-rich grasslands in France has been slowest and least predictable in areas where intensive agriculture or engineering processes have caused degradation of soil quality and loss of seed banks (Muller *et al.*, 1998).

In North America, prairie restoration tools include the use of herbicides, cultivation, and planting (Cottam, 1987; Kline and Howell, 1987). Labor intensive seed gathering and planting has been successful on small-scale plots (Cottam, 1987; Packard and Mutel, 1997). Larger scale efforts have adapted agricultural practices to the harvest and planting of native species.

Perhaps the most important lesson from work on grassland restoration is the usefulness of controlling fire and other disturbances as a means of altering or maintaining community composition. Many grassland communities depend on the periodic disturbance caused by fire to prevent woody species from invading (Packard and Mutel, 1997; Davison and Kindscher, 1999). The manipulation of disturbance in the form of fire or grazing can be used to restore native communities. Compared to many restoration activities, controlled burning or grazing can impact large areas of habitat, as will be needed to mitigate effects of global change.

Prairie restoration has focused almost exclusively on the establishment of plant communities, assuming that animals will find their way to suitable habitats (Kline and Howell, 1987). While many prairie specialist birds and small mammals do become established on restored prairies, many others will not do so without active intervention. For example, mound building ants play an important role in natural prairie ecosystems by cultivating the soil and providing open space where forbs can become established. Experience with the restored prairies at the University

of Wisconsin Arboretum, US, found that even 50 years after plant communities were in place, ants were absent from much of the available habitat (Kline and Howell, 1987).

Because most restored prairies require continual maintenance (time and money), opportunities for mitigating the effects of climate change exist primarily at small spatial scales. These efforts could provide important source populations for the eventual natural spread of prairie species. Even relatively small patches of habitat may prove valuable in this role. For example, the 24 ha Curtis Prairie at the University of Wisconsin Arboretum, US, has maintained populations of about 170 native prairie plant species, even though it is surrounded by non-prairie habitats (Cottam, 1987). Manipulation of disturbance will be possible at larger scales, provided grassland species are already present (*see* **Temperate Grasslands**, Volume 2; **Tropical Savannas**, Volume 2).

Forest Ecosystems

Forest ecosystems experience ongoing degradation and destruction through harvesting and clearing activities. Remaining fragments are subject to multiple stresses such as air pollution, invasive species, and new pests and pathogens. Changes in temperature and moisture will be a source of added stress, which will likely alter forest productivity and ecosystem functioning, while the distributions of most temperate zone trees will shift poleward, changing species composition (Intergovernmental Panel on Climate Change, 1996).

From the long history of tree planting, we know that many species can thrive when planted far outside their natural ranges (Ashby, 1987). Hence, some tree species should be able to survive despite climatic changes, while others should be able to grow when planted in favorable sites. While this is encouraging, forests also provide some of the clearest examples of the need to plant locally adapted populations or ecotypes (Ashby, 1987). The ease with which trees are established in artificial settings does not mean that planted populations will be self-sustaining or that other forest species of plants and animals will establish a functioning ecosystem (Ashby, 1987). One of the more difficult factors to account for in future restoration of forests will be the tight symbiosis between many plants and mycorrhizal fungi. Most plants depend on mycorrhizae for efficient uptake of water and nutrients, but the abilities of soil organisms to adapt to climate change are unknown. The ability of restoration to promote the rapid reestablishment of forest functioning will depend in large part on our ability to establish healthy populations of soil organisms (Haselwandter, 1997).

Longleaf pine (*Pinus palustris*) forest ecosystems provide a good case history for restoration of forest landscapes. Longleaf pine forests once covered 60% of the Southeastern US coastal plain, stretching from North Carolina to Texas. Longleaf pine forests host a surprising diversity of plant and animal species, including a large number of threatened and endangered species. Critical to the maintenance of these systems are periodic fires carried by understory plants that prevent invasion by deciduous oaks. Today, less than 10% of the original forests remain intact (Johnson and Gjerstad, 1998). This loss of a valuable ecosystem has led to an increasing interest in restoring longleaf pine communities by reintroducing fire and establishing populations of indigenous plants and animals. Some of the largest restoration projects ever undertaken are now in progress. The US Department of Defense military bases alone manage approximately 400 000 ha of longleaf-type vegetation (Johnson and Gjerstad, 1998).

Wiregrass (*Aristida* spp.) forms the dominant groundcover in most natural longleaf communities and provides fuel to carry fires (Means, 1997). Attempts to create a wiregrass understory in longleaf pine restorations provide an informative example of the limitations of restoration efforts. While wiregrass populations are present in many stands undergoing restoration, and plantings can be established with relative ease, these populations have typically failed to spread (Means, 1997; Seamon, 1998). Thus, while the species is present in the community, it fails to expand to serve a necessary function in the ecosystem (e.g., promoting the spread of beneficial fires).

Large-scale restoration of tropical forests has been initiated in both Latin America, Asia, and Australia. In Costa Rica, restoration efforts have focused on facilitating the natural recovery of ecosystems by promoting regeneration of forest trees and by attempting to control disturbance due to fire (Janzen, 1988; Holl, 1998). An alternative approach is to increase the ecological integrity of the large areas of tropical forest that have been converted to timber plantations. These areas may be improved, though not restored to a pristine state, by promoting the use of native species, planting mixtures of species, and altering landscape patterns of forests to provide buffers (Lamb, 1998). The experience gained through landscape-scale forest restorations is highly valuable for evaluating impacts and adaptation to global change, as well as our ability to compensate through restoration (*see* **Boreal Forest**, Volume 2; **Nitrogen Deposition on Forests**, Volume 2; **Temperate Coniferous Forests**, Volume 2; **Temperate Deciduous Forests**, Volume 2; **Rainforest**, Volume 2).

BUILDING A CLIMATE CHANGE BUFFER INTO RESTORATION PROJECTS

Significant uncertainties about future climatic conditions exist. This is especially true at the relatively small scale

of ecological processes and for precipitation and climatic variability. In order for current restoration efforts to prepare for the negative impacts of climate change, we need to understand the nature of climatic changes anticipated for a given site, and how land-management projects can best be planned to accommodate them. Significant advances in both climatic modeling and in understanding how ecosystems respond to changing climate will be needed before this is possible.

All sizes of restoration projects can build in some buffer against the negative aspects of climate change, but the greatest potential lies with the larger projects, such as the longleaf pine forest, Kissimmee River, Everglades, and San Francisco Bay Delta projects in the US. Large size restoration projects, like large preserves, can sustain more species and more genotypes. They can also support more effective exotic-species control programs, as they are more likely to have smaller perimeter/interior ratios, thus reducing chances for reinvasion. Finally, they would have the space needed to include well-planned translocation experiments.

Until more specific information is available, recommendations for buffering restoration sites are general, and they focus on increasing the resilience of communities in the face of environmental variability. These actions include:

1. Reintroduction of the full range of biodiversity (plants, animals, microbes) that was thought to occur prior to site degradation.
2. Maintenance of topographic heterogeneity; too many restoration sites have artificial landforms that are unnaturally smooth, due to modification by bulldozers.
3. Reintroduction of diverse gene pools. Growing plants from seed in preference to vegetative propagation. If the latter is necessary, ramets should be from multiple clones.
4. Eradication of exotic species and monitoring range expansion by new invasive species.
5. Allowing native species to remain on site. Some exceptions might be highly aggressive natives that might lower overall biodiversity.
6. Carefully monitored, experimental translocations of declining native species at restoration sites outside these species' natural range. This recommendation is consistent with biodiversity conservation efforts involving gardens, zoos, and seed banks but must be carefully planned to avoid adverse effects from introducing non-native species.

These suggestions are not specific to any climate scenario but are meant to increase the resilience of natural communities faced with a variety of anthropogenic stresses. Thus, they could be applied before reliable site-specific information on climate change becomes available.

THE STATUS OF THE SCIENCE OF RESTORATION ECOLOGY

Several scientific challenges will need to be met before climate-buffered ecosystems can be designed.

1. Foremost, we will need reliable predictions of when, where, and how environmental conditions will change.
2. Next, we need to predict how species will respond to these changes, especially which species are most likely to go extinct as a result of climate change and which ecosystem functions will be impaired.
3. We need to be able to select appropriate tools to sustain biodiversity.
4. We need to understand the relationship between ecosystem structure and functioning. More attention will need to be directed towards the interactions among species that govern processes such as nutrient and water cycles, community stability, and the regulation of primary productivity.
5. We need to document the current status of reference sites. A major constraint on restoring historical habitats is our lack of knowledge of their structure and functioning. But looking ahead 50 to 150 years, we will have no excuse for not making detailed records of conditions such as species composition, productivity, and nutrient dynamics. With new technology, such as remote sensing, we can plot the precise locations of rare species populations and the geographical boundaries of species with various traits, for which we hypothesize likely expansions, compressions, range shifts, or no change. This will provide future biodiversity managers a basis for assessing change and considering restoration actions.

Climate change may affect critical components of the ecosystem that are yet unknown. The processes that go on below ground, for example, are at the frontier of ecology. The tight symbiosis between plants and mycorrhizal fungi has not received the attention it deserves. Owing to their poor dispersal and habitat specificity, mycorrhizae need to be added to highly degraded restoration sites (Haselwandter, 1997). While this is a common tool, we do not know the abilities of mycorrhizae and other soil organisms to adapt to climate change. Further complications may involve other microbes.

Research will need to be done before we can rely on restoration tools to ameliorate the effects of climate change at the large scale. Some encouragement comes from fire and water management, however, as both have been used to restore large expanses of habitats. The release of flood waters from Glen Canyon provides a positive model (Vaselaar, 1997), although the magnitude of planned flooding can never match historical extremes. We

encourage replication of flooding experiments over time and large-scale experimentation in general.

CONCLUSIONS

It is unlikely that restoration tools can be used to prevent negative impacts on ecosystems caused by climate change. However, global change can and should be considered when designing restoration projects. Detailed adaptation of ongoing ecological restorations is hampered by the uncertainties about the exact nature of future changes in climate and about ecosystem responses at specific sites. Until we have reliable, site-specific predictions, it is premature to suggest translocations into natural habitats, as we know too little about how the receiving site might be affected. A possible exception would be restoration sites designed to sustain rare plants and animals beyond their natural range (climate change reserves).

In general, restoration tools will be more useful after natural systems are noticeably degraded by climate change. If ecosystem degradation due to changing climate cannot be prevented, then ecological restoration may be one of the few strategies available to ameliorate the damage. Once again, restoration is unlikely to compensate fully for the loss of species and the reduction in ecosystem functioning that will likely result from significant climate change.

We expect that most efforts to ameliorate climate change will be of small spatial scale. Nevertheless, they will be important. Small patches of habitat provide refugia for sedentary species and sources of propagules and colonists for future natural expansion. Preservation of genetic diversity will offer greater potential for natural selection in the face of changing climate. The result, especially if the restoration site is large, should tend toward a climate-buffered ecosystem.

Progress in developing restoration tools provides both a reason for hope and sometimes a sobering lesson in the complex task that awaits us. Additional research advances will be needed to understand how ecosystems function and how humans can intervene in disturbed communities to promote diverse and healthy ecosystems.

ACKNOWLEDGMENTS

Rhizosphere

Rhizosphere is the volume of soil in which the microbial populations and the physical properties of the soil are influenced by the proximity of a plant root. It constitutes, in effect, the environment of the root. The major components of the rhizosphere are the soil and its nutrient minerals, soil water, and the microorganisms that live in the soil. The root and the rhizosphere, including all its components, exist in a dynamic reciprocal relationship. The size of the rhizosphere depends to some extent on its water content and the ease of diffusion of nutrients through the soil. It also depends on the availability of water for a specifically biological reason: plants react to drought stress by growing much larger and more extensive roots, which thereby increases the volume of the rhizosphere in drier areas.

The most important component of the rhizosphere is the microbiological population. The presence of roots leads to a substantial increase in the variety and a very great increase (as high as 100–2000 fold) in the numbers of bacteria. Plant roots are the major source of substrates and energy for the soil microflora, through sloughed off root cells (from root caps and root hairs), by the exudation of organic compounds (sugars, organic acids, amino acids) and by the production of mucilaginous gels that allow the root to pass easily through the soil. In addition, many bacteria or fungi may be closely associated with or attached to the root (i.e. on the *rhizoplane*, the root surface), and others may penetrate into the root where they live symbiotically (*see* **Symbiosis**, Volume 2). Pathogenic microorganisms are also found in far greater numbers in the rhizosphere.

Interactions may be even more complex. The rhizosphere microbial population may influence nutritional uptake by roots in various ways: reducing it by competition or by damaging roots, or stimulating it by stimulating uptake mechanisms or by acting to dissolve minerals that would otherwise be unavailable to the plant. Some rhizosphere organisms produce substances (e.g., gibberellins) that are powerful plant growth hormones, and so stimulate root growth. Others may cause a buildup of inhibitory substances: many fungi metabolize lignins in the rhizosphere litter, releasing phenolic acids which inhibit ion uptake by roots.

It is well known that certain rhizosphere and rhizoplane (and also symbiotic) microorganisms, both bacteria and fungi, fix nitrogen which greatly enhances the growth of plants. These microorganisms obtain the energy for their metabolism and nitrogen fixation from the plants, even in cases where there is no physical association of roots and microbes. Other beneficial consequences of rhizosphere bacteria and fungi are less well defined, but evidence has been presented that adding appropriate microbes much improves the survival of planted tree seedlings and results in stronger growth and increased production in some agricultural crops, particularly potatoes. The mycorrhizal fungi (symbiotically associated with tree roots) may transport nutrients to the roots and in turn be nourished by organic nutrients from the tree roots.

The rhizosphere is one of the most important aspects of the environment of plants. Its health and stability are essential to the successful growth and survival of plants.

r- K Strategies

In theory, the life history strategy of a species is the result of eons of natural selection acting to optimize the allocation of energy within each individual among growth, maintenance, and reproduction. According to evolutionary theory, individuals of a species are expected to use energy for maintenance and growth in order to maximize their reproductive contribution to future generations (growth is important because fecundity and survival often increase with size).

The r- and K-strategies represent the extremes in a continuum of realized life history strategies. (The letters, r and K, correspond to the parameters of an equation used to describe population growth in very simple ecosystems). The *r-strategists* produce large numbers of seeds, eggs, or offspring, which have poor survival rates; they include many weeds and insects. In the life histories of r-strategists, natural selection has sacrificed longevity and survival in order to maximize reproduction. These species are opportunists, dispersing widely to invade ephemeral habitats quickly and exploit the relatively uncompetitive situations there while they last. The mate-finding tactics of r-strategists tend to be very efficient during the periods of very low population densities, which they often experience. Although many local populations may go extinct as their habitats change, species of r-strategists as a whole tend to be very resilient. They are typically the colonizing species of ecological succession and make dangerous biological invaders.

Compared to r-strategists, *K-strategists* tend to grow into bigger, longer lived, more competitive individuals, which produce fewer offspring but provide more care for them. K-strategists are the climax species of ecological succession and they tend to have more stable population sizes than those of r-strategists. Generally, populations of K-strategists are less resilient than those of r-strategists when reduced to low densities, and if substantially depressed throughout the entire range of the species, extinction becomes a real threat. Consequently, K-strategists rather than r-strategists generally merit the greatest concern of conservationists. According to the fossil record, individuals in many lines of animals have increased steadily in size as their populations have gone extinct. Natural selection fine-tuned these lines to become ever more extreme K-strategists, closely adapted to a specialized habitat, which eventually shrank and disappeared as its environment changed.

Rodin, Leonid E

(1907–1990)

Leonid E Rodin was a famous Russian ecologist, botanist, geographer and traveler. He graduated from the Leningrad State University, Department of Biology. Since 1933, until the end of his life, he worked at the Department of Geobotany of the Komarov Botanical Institute. From 1970 until 1980 he was head of this department. Earlier he was head of the Laboratory of Arid Zone Vegetation. Most of his life was devoted to study of the vegetative cover of Middle (Central) Asia, especially the deserts of Turkmenistan. He has written many papers on this problem (Rodin, 1955, 1956, 1958, 1961, 1963), and has prepared many maps of vegetation and pasture zones. From the early 1950s in collaboration with soil scientists, Rodin studied the process of biological turnover in desert biogeocoenosis and he made his first generalizations on this subject (Rodin and Bazilevich, 1968; Rodin *et al.*, 1968).

From the very beginning of the creation of the International Biological Program (IBP), L E Rodin was one of

the heads of the Soviet National Committee and a head of the Committee on Productivity of Terrestrial Communities. For many years he coordinated the IBP program in some interdisciplinary stations in Middle Asia and Kazakhstan and he was editor of numerous publications on the results of these investigations (Rodin, 1972, 1975, 1977, 1978). At that time Rodin worked at the interdisciplinary station Repetek in southeastern Kara-Kumes, where under his leadership the most complete complex of biological units and communities was studied. Moreover, Rodin took part in a geobotanical study of Algerian pastures. As a result, recommendations on the rational use of arid areas were given, geobotanical articles were written and vegetation maps were prepared (Rodin, 1970). The last large project of Rodin for the Program of Man and the Biosphere (MAB) of the United Nations Educational, Scientific and Cultural Organization (UNESCO), was the project on Phytocoenosis of the Main Ecosystems in the Badkhyz: Structure and Functioning (1976–1986) (Rodin, 1978). In the last years of his life Rodin became very interested in the problem of the influence of fire on desert vegetation. Unfortunately, a book that he was writing on the subject was not completed.

L E Rodin was an author of many popular-science books and botanical journeys around Brazil, India, and the Near East. He expounded ideas and works of the Russian geneticist and botanist–geographer N Vavilov. For many years L E Rodin was a main scientific secretary of the Russian Geographical Society.

Rosswall, Per Thomas

(1941–)

Per Thomas Rosswall was born and educated in Sweden at the University of Stockholm and Uppsala. His research has focused on biogeochemical cycling, and has ranged from microbial ecology to global interactions. He is the author of over 100 papers and editor of more than 10 scientific books, as well as numerous articles in the popular press. Rosswall has had many national and international appointments and has held such major positions as secretary-general of the Scientific Committee on Problems of the Environment (SCOPE) (1986–1988), director of the International Global System for Analysis, Research and Training Secretariat (START) (1992–1993), and executive director of the International Geosphere–Biosphere Program (IGBP) (1987–1994). His leadership is characterized by a consultative and consensus style that is credited with fostering interdisciplinary collaboration among scientists from different countries, and forging effective international networks in both hemispheres.

Rosswall's first major research project was connected with the International Biological Program (1964–1974), in which he investigated carbon and nitrogen flows through tundra communities, and served for part of the time as

secretary to the International Steering Committee. Charged by the Swedish Natural Science Research Council with stimulating the field of microbial ecology in Sweden, he organized the first international symposium on microbial ecology in 1972, established a series of Nordic Summer Schools on the topic, and played a key role in the Swedish Coniferous Forest Research Project, in which his work on carbon and nitrogen cycling achieved international recognition. From 1978 to 1980 he was director of the SCOPE/United Nations (UN) Environment Programme International Nitrogen Unit, served on the executive committee of SCOPE for many years, and was its secretary-general from 1986 to 1988. From 1980 to 1983 he was secretary and chairman of the International Commission on Microbial Ecology. At the same time, he was instrumental in promoting microbiology in developing countries as member and secretary (1979–1983) of the UN European Office/UN Educational, Scientific and Cultural Organization/International Cell Research Office Panel on Microbiology.

Rosswall became well known for his participation in the Swedish University of Agricultural Sciences project *Ecology of Arable Land*. He contributed to the understanding of nitrogen cycling with his quantification of denitrification losses and the regulatory role of water and cropping systems on gaseous soil losses.

In 1984, Rosswall was appointed professor at the University of Linköping where his research focused on land and water use management in the tropics, and the effect of microbial processes on metal mobility in terrestrial ecosystems. In 1987 he became the first executive director of the IGBP. Under his leadership the program was defined and successfully initiated. Taking a temporary leave of absence from IGBP from 1992 to 1993, he accepted an appointment as the first director of the International START Secretariat in Washington, DC, where he began to organize regional networks to strengthen the abilities of developing countries to take part in international research collaboration dealing with global issues. Rosswall continues to play a crucial role in developing links among different scientific disciplines, between the natural and social sciences, and between scientists and policy makers. Since 1994 he has served as the rector of the Swedish University of Agricultural Sciences in Uppsala.

S

Salinization

Terrestrial salinity refers to the presence of soluble salts, such as sodium, magnesium and potassium, in water and soil. It is measured in various ways, including parts per million (ppm) and electrical conductivity (EC) units (microSiemens cm^{-1}). Salinization is the accumulation of salts to levels that result in the degradation of the water and soil, either naturally or as a result of human activities. The salts come from precipitation, rocks and aeolian deposits. They are dissolved and mobilized by water, and brought to or near the surface by rising groundwater levels and capillary action. Salts then become concentrated as a result of the water movement, both over the ground surface and within the soil profile. Where water movement is impeded, evaporation leads to increasing concentrations, resulting in the salinization of the land. Over large areas, water containing salts, applied to the land naturally by precipitation or artificially by irrigation in excess of that needed by growing plants, infiltrates down to the watertable. In time, the watertable rises to or near the ground surface, producing the same salinization impacts. Salinization is particularly associated with irrigation in arid and semi-arid areas where there are high rates of evapotranspiration and inadequate or non-existent drainage. In particular, it can result from the excessive and wrongly timed application of water. In coastal districts, salinization can occur where seawater moves into aquifers as a result of over use of the groundwater. Dryland salinization occurs where deep-rooted native vegetation has been cleared and replaced by shallow-rooted crops and pastures that allow too much rainfall to pass into the groundwaters. Throughout agricultural history, salinization has resulted in reduced agricultural productivity and, ultimately, the sterilization of the land (for all but the most salt-tolerant plants). Its costs are enormous, from the collapse of early societies to the decline of many modern irrigation developments and the emerging problems of dryland salinization in parts of Australia, Canada and the United States.

Soil Mineralization

Soil mineralization is the process of the breakdown of organic material in soil and the conversion of organic complexes of nutrient chemical elements in the soil to inorganic

states. Organically bound sulfur, nitrogen, phosphorus, manganese, copper, iron and various trace elements may be mineralized, e.g., converted respectively to sulfides or sulfates, to ammonium, nitrite, nitrate or molecular nitrogen, to phosphates, and to various metallic ions and salts. In addition, organic carbon is mineralized to carbon dioxide.

Mineralization of soil often occurs following *humi cation*, in which organic detritus is converted into humus by microbial digestion or by earthworms. Mineralization takes place mostly by the action of soil bacteria (e.g., *Bacillus* and *Pseudomonas*) or fungi (e.g., *Aspergillus* and *Penecillium*). Mineralization goes on naturally in all soils, and is a normal aspect of the soil cycling of nutrients. Some nutrients must be mineralized before they can be absorbed by plants (e.g., nitrogen), while other nutrients are no longer available following mineralization because they cannot be absorbed (e.g., some phosphates), or become insoluble (e.g., iron). In addition, many mineralized nutrients, being soluble, are readily leached from the soil. Nutrients are also *demineralized* in the soil cycle by being incorporated into microorganisms during growth, and these are then unavailable for plant uptake. If the soil cycling process becomes unbalanced as a result of reduced input of organic material (e.g., by routine removal of crops) then the soil is in danger of becoming strongly or fully demineralized and its fertility, as well as its physical structure, may be seriously compromised.

While mineralization is a natural process, it can be harnessed for ecologically and agriculturally useful purposes in the practice of *composting*. In this process, waste organic materials are allowed to decompose under somewhat anaerobic conditions, which reduces nitrogen loss and oxidation of minerals to salts that may be unavailable to plants. The composting site is usually protected from rain to prevent leaching, and at least somewhat insulated so that the heat generated by biological activity will speed the process. The initial step is humification, and the product may be used as humus for gardens and fields. If composting is allowed to continue, mineralization occurs and a lower volume of richer fertilizer results.

Stable Isotopes

James R Ehleringer and Thure E Cerling
University of Utah, Salt Lake City, UT, USA

Stable isotopes *indicate those isotopes of an element which are stable and that do not decay through radioactive processes over time. Most elements consist of more than one stable isotope. For instance, the element carbon (C) exists as two stable isotopes,* ^{12}C *and* ^{13}C*, while the element oxygen (O) exists as three stable isotopes,* ^{16}O*,* ^{17}O*, and* ^{18}O*. As is the case with both carbon and oxygen, the more common stable isotope species typically contains the fewest number of neutrons for that element. Stable isotopes should not be confused with* radioactive isotopes *of an element. Radioactive isotopes have limited life times and undergo a decay to form a different element, although the time required for this decay may vary widely ranging from nanoseconds to thousands of years. For instance, carbon has six radioactive isotopes (*^{9}C*,* ^{10}C*,* ^{11}C*,* ^{14}C*,* ^{15}C*, and* ^{16}C*) of which* ^{14}C *is perhaps best known because of its utility in dating biological materials and as a tracer in metabolic studies.*

HOW COMMON ARE STABLE ISOTOPES?

A brief listing of the stable isotopes and their abundances for the elements most commonly used in global change research can be seen in Table 1.

HOW ARE STABLE ISOTOPE ABUNDANCES TYPICALLY MEASURED?

Of particular interest for global change studies are variations in the isotopic abundances of hydrogen, carbon, nitrogen, and oxygen isotopes. These relatively light elements are typically measured using a gas isotope rationing mass spectrometer. The mass spectrometer consists of a source to ionize the gas, a ight tube with a magnet to de ect the path of the ionized gas, and a detector system at the end of the ight tube to measure the different isotopic species. First, the element of interest must be converted to a gaseous form for introduction into the mass spectrometer. The most commonly used approaches involve introducing hydrogen as H_2, carbon as CO_2, nitrogen as N_2, and oxygen as CO_2. As the gas is introduced into the mass spectrometer, it is ionized by removal of an electron as the gas is bombarded by a source. Then as the ionized gas travels down the ight tube (under vacuum), the paths of light and heavy isotopic species are de ected differently by the magnet. Detectors are positioned at the end of the ight tube to

Table 1 A brief listing of the stable isotopes and their abundances for the elements most commonly used in global change research

Element	Isotope	Abundance (%)
Hydrogen	^{1}H	99.985
	^{2}H	0.015
Carbon	^{12}C	98.89
	^{13}C	1.11
Nitrogen	^{14}N	99.63
	^{15}N	0.37
Oxygen	^{16}O	99.759
	^{17}O	0.037
	^{18}O	0.204
Sulfur	^{32}S	95.00
	^{33}S	0.76

	^{36}S	0.014
Strontium	^{84}Sr	0.56
	^{86}Sr	9.86
	^{87}Sr	7.02
	^{88}Sr	82.56

measure the abundance ratios of the heavy and light isotopic species.

EXPRESSION OF STABLE ISOTOPE ABUNDANCES

The abundance of stable isotopes is typically presented in delta notation (δ), in which the stable isotope abundance is expressed relative to a standard (Equation 1):

$$\delta = \left(\frac{R_{\text{sample}}}{R_{\text{standard}}} - 1 \right) \times 1000 \qquad (1)$$

where R is the molar ratio of the heavy to light isotopes, e.g., Equation (2):

$$R = \frac{^{13}C}{^{12}C} \text{ or } \frac{D}{H} \text{ or } \frac{^{18}C}{^{16}O} \qquad (2)$$

For the most commonly used light isotopes, the internationally recognized standards are shown in Table 2.

Table 2 Internationally recognized standards for the most commonly used light isotopes

H	SMOW[a]	$R = 0.0001558$

HOW DOES NATURAL VARIATION IN STABLE ISOTOPES COME ABOUT?

Variations in the abundances of stable isotopes among different compounds arise because the chemical bonding is stronger in molecules containing heavier isotopic forms, making it more difficult to break up the molecule in a chemical reaction (often termed *kinetic fractionation*), or because of differences in the physical properties of molecules containing heavier isotopic forms (often termed *diffusive and equilibrium fractionation*). With kinetic fractionation, the rate of an enzymatic reaction is faster with substrates that contain the lighter isotopic form than in reactions involving the heavier isotopic form. As a consequence, there will be differences in the abundances of the stable isotopes between substrate and product. Such differences will occur unless, of course, all of the substrate were consumed, in which case there would be no difference in the isotopic composition of substrate and product. Expression of a significant kinetic fractionation in most biological reactions involves substrates at branch points in metabolism, such as the initial fixation of carbon dioxide in photosynthesis. Equilibrium fractionation events re ect the observation that during equilibrium reactions, such as the equilibration of liquid and gaseous water, molecules with the heavier isotopic species are typically more abundant in the lower energy state phase. Diffusive fractionation events re ect the observation that heavier isotopic forms diffuse more slowly than lighter isotopic forms.

WHAT IS THE NATURAL RANGE OF ISOTOPIC VARIATION IN NATURE?

The natural variations in isotopic abundance can be large. Figure 1 illustrates the natural variations found for materials frequently of interest in global change studies: waters, greenhouse gases, and biological materials. As a starting point, note that some atmospheric gases, such as CO_2, N_2, and O_2, exhibit limited variation, while N_2O and CH_4 exhibit wide isotopic variation. The larger isotopic ranges in the latter two gases re ect both significant isotopic fractionation by microbes as well as different biological substrates which are used to produce these gases.

Oceans, the largest volume of water on Earth, exhibit only small variation in isotopic abundance and most of this is associated with changes in salinity. However, once water evaporates from the oceans and later recondenses as precipitation, there are large isotopic variations that are dependent on both cloud temperature and the amount of residual moisture remaining within the cloud mass. Lakes and rivers re ect precipitation input values, but are often further enriched by evaporative processes, which favor the movement of lighter isotopic forms of water into the vapor phase.

There can be significant biological fractionation against carbon dioxide during photosynthesis, which results in

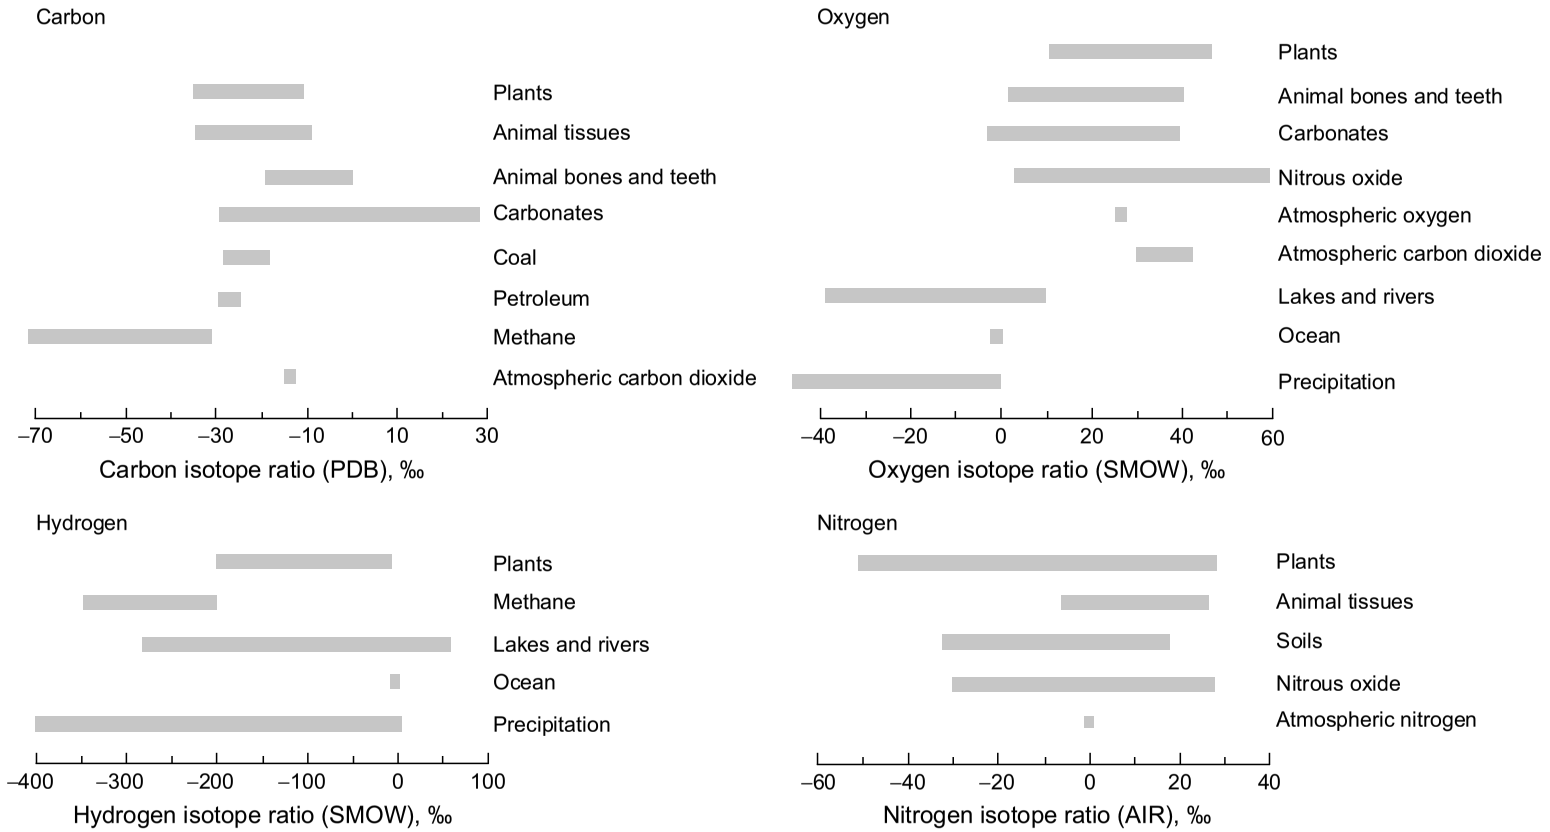

Figure 1 Variations in the carbon, oxygen, hydrogen, and nitrogen isotope ratios of materials of interest in global environmental change studies. (Data were collected from a very wide ranging series of studies)

plants being isotopically depleted relative to the carbon dioxide substrate. Animals largely re ect the carbon isotopic composition of their food resources, a useful tool for food web studies. However, the carbon in animal bones and teeth consists of carbonates, which are isotopically enriched relatively to the original carbon dioxide substrate (in this case respired food resources or animal tissues). In general, carbonates are both ^{13}C and ^{18}O enriched, relative to their substrates, carbon dioxide and water.

There is very limited isotopic variation in diatomic nitrogen. The microbial process of nitrogen fixation ($N_2 \rightarrow NH_4^+$) exhibits little isotopic fractionation and thus these products have a similar nitrogen isotope ratio as the atmosphere. Yet subsequent nitrogen transformation reactions exhibit strong isotopic fractionations. In general, the isotopic composition of animals within a trophic level are enriched by ~ 3 relative to their food substrate. The wide variations in nitrogen dioxide re ect the large differences associated with aerobic versus anaerobic processes and industrial versus stratospheric processes.

HOW ARE STABLE ISOTOPES USED IN GLOBAL CHANGE RESEARCH?

Stable isotopes are useful for several important aspects of global change research. One major area is to use stable isotope ratios to reconstruct past environmental conditions, which is possible when a compound is laid down and preserved over time. Some common examples would include ice profiles, the shells of mollusks, and tree rings. Another major application of stable isotopes is to reconstruct diets of animals and ecosystem structure. The isotopic composition of an animal re ects its food source; while soft tissues and hair are lost after animals die, the bones and teeth can be used to reconstruct past diets. Similarly for ecosystems, the isotopic composition of soil organic matter re ects the plant material that occupied the surface in the past. Another very common application of stable isotopes is as a tracer to identify where materials had originated. This is a particularly powerful approach in atmospheric studies where the interest is in identifying which terrestrial surface (e.g., ocean versus land) or which terrestrial ecosystem (e.g., grassland versus forest) is contributing or removing a gas species from the atmosphere.

Below we provide several examples to illustrate how stable isotopes are used in global change research. However, because of space limitations, we will only consider examples involving hydrogen, carbon, and oxygen isotopes.

Reconstruction of Past Air Temperatures using Hydrogen Isotopes of Water in Ice Cores

The hydrogen and oxygen isotope ratios of water have been used to reconstruct temperature patterns. The basis for this observation is that the isotopic fractionation associated with cloud vapor to precipitation formation is temperature dependent. Scientists have capitalized on this observation by analyzing deep ice profiles, such as the ice in Antarctica. Figure 2 shows the initial depth profile of hydrogen isotope ratios of ice water found in the Vostok ice core. The data shown reveal the isotopic oscillations observed during a glacial–interglacial cycle. When these isotopic values are converted to equivalent temperature differences, we see that the temperature at this location varied by $10\,^{\circ}C$ between glacial and interglacial periods. Of particular importance also are the smaller temperature cycles, which re ect oscillations in climate. Note also how rapid the change is from one temperature regime to another. The bottom of the Vostok ice core extends back to 420 000 years before present. By analyzing the ice records from different locations, scientists are able to reconstruct the spatial patterns of temperature changes and the extent to which climate oscillations were of regional versus global extent.

Carbon Isotopes in Fossils and Fossil Soils are used to Reconstruct Past Terrestrial Ecosystems

The carbon isotope difference between C_3 and C_4 vegetation can be exploited to determine ecological change in the past. C_3 and C_4 plants (*see* C_3 and C_4 Photosynthesis, Volume 2) have $\delta^{13}C$ values averaging approximately -27 and -12 , respectively. The ratio of C_3 to C_4 plants in the ecosystem or in the diet of herbivores is recorded in fossil soils as organic carbon or as soil carbonate, and in mammalian tooth enamel. Organic matter preserved in soils has about the same $\delta^{13}C$ value as in the original soil, whereas soil carbonate and mammalian tooth enamel are both enriched by about 14 compared to the vegetation.

The study of fossil soils and fossil tooth enamel from the Siwalik sediments in Pakistan illustrates how isotopes can be used to reconstruct past ecosystems. In Figure 3,

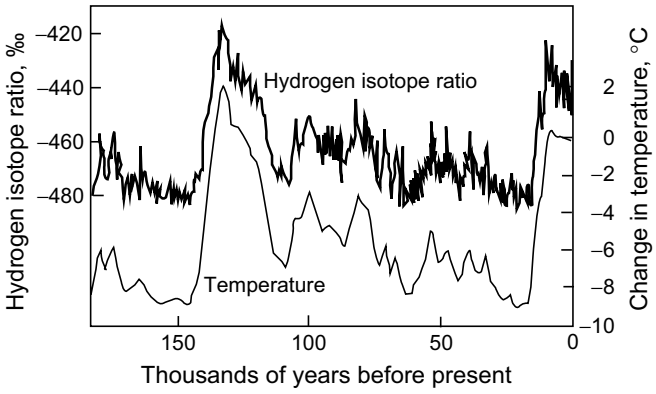

Figure 2 The hydrogen isotope ratios of waters from segments of ice from the Vostok ice core in Antarctica and the calculated temperatures associated with those time periods for the past 200 000 years. (Adapted from Jouzel *et al.*, 1990)

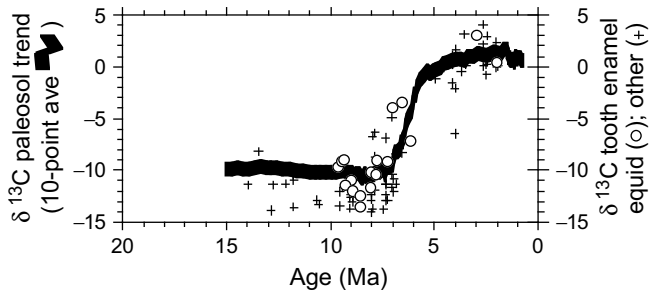

Figure 3 $\delta^{13}C$ values for soil carbonates from the Siwaliks in Pakistan shown as a 10 point running mean. $\delta^{13}C$ values for equids show that they had a C_3-dominated diet before 8 million years ago, but changed to a C_4 diet as the ecosystem underwent a change from C_3 dominated to C_4 dominated. (Adapted from Cerling *et al.*, 1998)

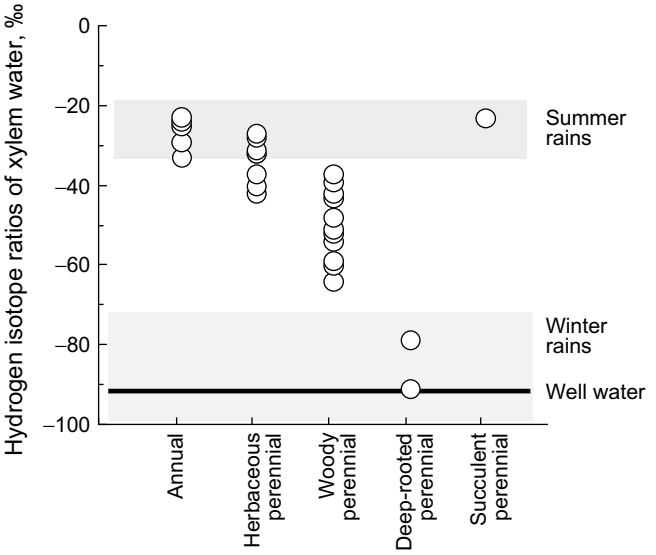

Figure 4 Hydrogen isotope ratios of water found in plants growing in the same arid land location in southern Utah following an intense summer rain event. Shown also are the observed variations in the isotopic composition of summer rains (upper depth soil moisture source) and winter rains (lower depth soil moisture sources). (Adapted from Ehleringer *et al.*, 1991)

the fossil soil record shows that before eight million years ago, the local ecosystem was dominated by C_3 plants, and that they were gradually replaced by C_4 plants so that by five million years ago the ecosystem was dominated by C_4 plants. Fossil tooth enamel from the same region shows that equids and other mammals had a C_3-dominated diet before eight million years ago, but changed to a C_4-dominated diet as the ecosystem changed to become C_4-dominated. This change in vegetation is accompanied by a significant change in the $\delta^{18}O$ of local water of atmospheric origin indicating that the monsoon system may have undergone a significant change at this time. Recent studies have also shown that this was a time of major faunal turnover in the region (Cerling *et al.*, 1998).

Hydrogen and oxygen isotope ratios of water are used to determine current sources of plant water from within the soil, while those isotopes in cellulose of tree rings provide historical patterns. For plants, the primary sources of hydrogen and oxygen are from waters of atmospheric origins. Since the isotopic composition of precipitation will vary both seasonally and geographically, largely re ecting cloud condensation temperature, we have a tool for addressing ecological and global change questions. In plants, the isotopic composition of tree rings will in part re ect the isotopic composition of plant water sources, providing a tool for now understanding how precipitation patterns

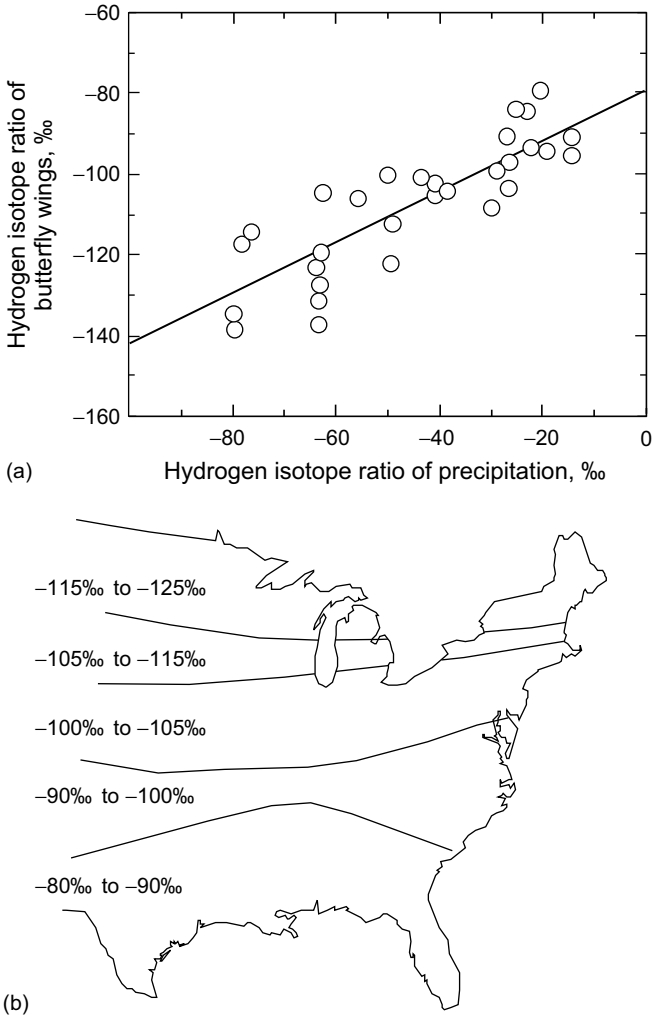

Figure 5 (a) The relationship between hydrogen isotope ratios of wings of field-raised monarch butterflies and of weighted mean growing-season precipitation. (b) Geographic patterns of hydrogen isotope ratios of precipitation across the eastern US. (Adapted from Hobson *et al.*, 1999)

as re ected in tree rings may have changed during a plant's lifetime. For long-lived organisms, such as redwood trees, this provides a valuable tool for reconstructing climatic variations over periods of hundreds to thousands of years.

A second area in which isotopes of water are used in plant global change studies is for understanding the dynamics of water use by different species within a community, particularly for evaluating which species may or may not be competing for water. Figure 4 illustrates the hydrogen isotope ratios of different species at an arid site in western North America following intensive summer rains, which saturate the upper soil layers while the remaining winter moisture exists only in deeper soil layers. Shown also are isotopic ratios expected for rains falling in summer versus winter months. Note that species utilize different moisture sources, suggesting a strong sensitivity of each species to whether rain falls in winter or summer. Strong interannual variations in precipitation are associated with El Nino events and this will in uence the growth and competitive dynamics of plants in those regions of the globe impacted by El Nino Southern Oscillation (ENSO). While analyses of water within stems of modern plants can be used to immediately assess the impact of ENSO on plant performance, tree ring analyses can be used to reconstruct the periodicity and extent of the impact over historical periods.

Reconstruction of Animal Migration Routes using Hydrogen and Oxygen Isotope Ratios of Feathers

In global change studies, it is often useful to know if animals have changed their migration routes, re ecting some change in the quality of an environment. Or for animals that congregate in a common winter location, such as the monarch butter ies that winter in central Mexico, where did these individuals originate? The isotopic composition of butter y wings and of bird feathers have been shown to re ect the isotopic composition of water at the location where that tissue was initially formed. Thus, isotopes provide a powerful tool for identifying where an individual might have originated from. In the case of the monarch butter y, Figure 5(a) illustrates the strong correlation between the hydrogen isotope ratios of precipitation at a location and the subsequent hydrogen isotope ratios observed for organic matter in the butter y wings. Since virtually all of the hydrogen in organisms (both plants and animals) originates from precipitation, the strong correlation is expected. The offset from a 1 : 1 relationship re ects biological fractionation processes during synthesis of the wing. The basis for geographical variations in isotopic composition of precipitation re ects temperature differences in the clouds at the time of precipitation. Colder storms are found at higher latitudes. As shown on Figure 5(b), there is a variation of ~45% in hydrogen isotopes across the eastern portions of the US allowing sufficient variation for scientists to identify regions from which a monarch butter y might have come.

Dissecting the Global Carbon Cycle Today with Carbon and Oxygen Isotopes in Carbon Dioxide

The carbon isotope ratios of fossil fuels are depleted in ^{13}C relative to the atmosphere (Figure 1). Since the increases in atmospheric CO_2 are largely associated with fossil fuel emissions, there has been a long-term trend of progressive decreases in the average carbon isotope ratio of atmospheric carbon dioxide from −6.5 to −8 today.

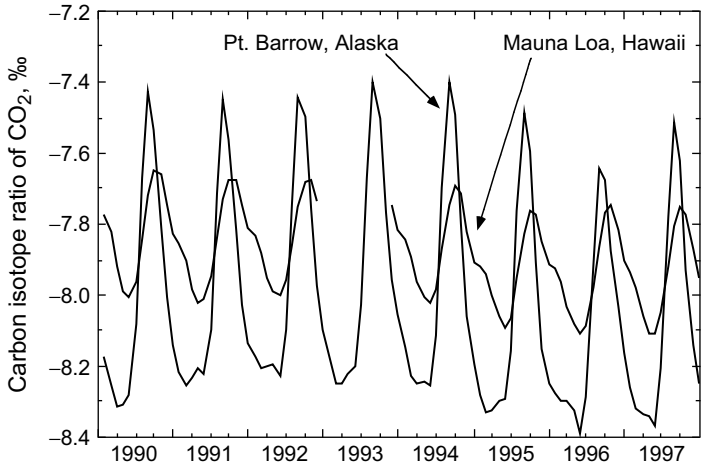

Figure 6 Seasonal changes in the carbon isotope ratios of atmospheric CO_2 at Point Barrow (Alaska) and Mauna Loa (Hawaii) between 1990 and 1997. The seasonal changes are driven by differences in the relative rates of photosynthesis and respiration by ecosystems at these latitudes. The enhanced amplitude at northerly latitudes reflects the shorter growing season. (Adapted from the National Oceanic and Atmospheric Administration – Climate Monitoring and Diagnostics Laboratory Monitoring Program; data courtesy of Jim White and Pieter Tans)

On an annual basis, variations in the carbon isotope ratio analyses of atmospheric carbon dioxide are used to understand seasonal dynamics on the land surfaces. In Figure 6, the monthly average carbon isotope ratio, for atmospheric carbon dioxide at Point Barrow, Alaska (latitude 71 °N) and Mauna Loa, Hawaii (latitude 19 °N) are shown for the period 1990–1997. The strong seasonal cycles re ect the addition of carbon dioxide during periods when ecosystem respiration exceeds photosynthesis, resulting in a net loss of carbon dioxide from the ecosystem. In contrast, during periods when photosynthetic activity is high, the carbon isotope ratio of the atmosphere increases as photosynthetic processes discriminate against the heavier $^{13}CO_2$. By analyzing these time trends, it is possible to detect changes in the length of the growing season over time and to address carbon cycle questions, such as the extent to which terrestrial versus oceanic surfaces are responsible for absorbing anthropogenically produced carbon dioxide.

Succession, Definition of

The assemblage of species in a given location changes continuously. One cause of this change is disturbance, which ranges from local events such as the creation of a gap in the forest canopy by a fallen tree, to events with broader and more severe impacts such as large forest fires. By removing biomass and opening space, each disturbance provides an opportunity for new species to colonize that location. Often the most successful colonizing species quickly dominate the disturbed location, but after a while they are succeeded by other species. This succession occurs because the most abundant of the early colonizers are too short lived to maintain their dominance or because they alter the local environment so that it begins to favor even newer species. In the altered environment, these newer (latter successional) species eventually exclude the colonizers by out-competing them for resources. These newer species may themselves be succeeded by even newer species for the same reasons. Thus, succession can produce consistent patterns of changing species composition and species replacement after disturbance.

Two types of succession are widely recognized. *Primary succession* occurs in areas where the soils initially support no life (e.g., new lava ows). *Secondary succession* is much more common; it occurs where the soils initially contain remnants of previous species assemblages (e.g., fire resistant seeds).

At least three stages of succession are commonly distinguished. In the *colonizing stage*, ecosystems typically have few species and short food chains. In this stage, ecosystems are very productive (accumulating organic matter much faster than they break it down) but they are unstable. In the *mature stage*, ecosystems tend to be more complex, more diversified, and more stable. Many ecosystems in the final (*climax*) stage of succession are quite stable and exhibit

large species diversity and complex food webs. Climax ecosystems tend to be unproductive because almost all captured solar energy is needed to maintain the large amounts of organic matter already accumulated, leaving little for the production of more organic matter.

Succession

Virginia Dale
Oak Ridge National Laboratory, Oak Ridge, TN, USA

The process of succession refers to the gradual replacement of one species population by another that occurs over time after a site has been disturbed. The concept can be extended to the replacement of one kind of community by another kind, the progressive changes in vegetation and in animal life, which may culminate in dominance by a community that is stable until the next disturbance. Succession refers to changes that occur over 1- 500 years and not to seasonal changes in populations.

*A typical successional sequence, or sere, is initiated by a disturbance that removes much or all of the vegetation. The process is called primary succession if it begins on an entirely denuded site such as in the aftermath of a lava ow or glacier retreat. Studies of succession in Glacier Bay, Alaska US, show that a newly exposed area is rst occupied by mosses and lichens, and then by dwarf willows (*Salix *spp). After about 50 years a dense thicket of alders (*Alnus crispa*) occupies the area, and this community is gradually replaced by Sitka spruce (*Picea sitchensis*) and hemlock (*Tsuga heterophylla *and* T mertensiana*) to form a taiga community after about 200 years. This pattern of changes in species over time has been documented in new volcanic soils in such diverse locations as New Zealand, Iceland, Indonesia, and Mexico.*

Secondary succession occurs when remnants of the prior community remain. For example, old- eld succession in the piedmont region of North Carolina, US, occurs after agricultural activities are abandoned. The site is rst occupied by annual and then perennial herbaceous species. Pine seedlings that mature and eventually die out as they succeed to oaks and hickories gradually replace this herbaceous community. Wildlife composition and number of species also change with each successional stage. The most apparent changes in bird species occur as new life forms become established (e.g., the herbaceous community is replaced by pines and later by hardwoods), for birds relate more closely to the structure of the vegetation than to the species. No one plant or bird species is dominant over the entire sere; instead each species thrives best at some point in the successional period.

The original paradigm that successional communities eventually mature to a persistent climax state has been replaced by the realization that disturbances are characteristic of almost all ecosystems, and thus a nal persistent endpoint is rarely achieved. Furthermore, the distinction between primary and secondary succession is now recognized as being too simplistic to capture the true complexity of the variability in successional patterns and processes. Instead, primary and secondary succession are treated as extremes along a continuum of abundance of biotic and abiotic residuals left by a disturbance and a continuum of soil development.

A HISTORY OF THE CONCEPT OF SUCCESSION

McIntosh (1999) provides a thorough overview of the developing concepts about succession. Thoreau coined the term succession in 1860. However it was not used again until Cowles (1899) revived the concept and emphasized its dynamic nature, sought to describe patterns of succession, and produced a physiographic theory based on his classic studies of the Lake Michigan sand dunes. He emphasized the variability in the process and noted that it was not a step-by-step linear process to one particular endpoint.

Clements (1916), in contrast, described succession as an orderly, predictable, progressive and convergent phenomenon and even assigned superorganism properties to it. Although the concept of the superorganism was rejected fairly quickly, the orderly and predictable nature of succession was accepted by a host of ecologists. Gleason's (1917) recognition of the individualistic concept of succession as a mobile and unfixed process ew in the face of these ideas but were largely ignored or denied.

Nevertheless, Cowles' ideas were revived by Whittaker's (1953) acknowledgment of succession as involving highly variable and irregular changes in populations over time. Olson (1958) revisited the Michigan dune sites using new techniques and observations to quantify Cowles' focus on the variable nature of succession. Subsequently, Odum (1969) presented a list of trends to be expected under

Table 1 Trends expected during succession (based on Odum, 1983 and Bazzaz, 1979)

Species and community structure
Species composition changes
The number of species increases
The distribution of species becomes more even
r-strategists replaced by K-strategists
Life cycles increase in length and complexity
Size of organisms and propagules increases
Mutualistic symbiosis increases
Physiological characteristics of dominant species
Seed dispersal distance declines
Seed germination less enhanced by high light levels, fluctuating temperatures, and high NO_3
Seed germination less inhibited by far-red light
Light saturation intensity declines
Light compensation lower
More efficient at low light
Lower photosynthetic rates
Lower respiration rates
Lower transpiration rates
Higher stomatal and mesophyll resistances
Higher resistance to water transport
Slower recovery from resource limitation
Energetics
Biomass and organic detritus increase
Gross primary production increases; secondary production changes little
Net production decreases
Respiration increases
The ratio between gross production and respiration moves toward one
The ratio between biomass and gross production increases
Nutrient cycling
Element cycles increasingly closed
Turnover time and storage of essential elements increase
Cycling ratio increases
Nutrient retention and conservation increase
Stability
Resistance increases
Resilience decreases
Overall strategy
Efficiency of energy and nutrient use increases

succession which are still debated by some but endorsed by others (a subset of Table 1).

The use of mathematic analysis and computers has led to a new era of successional studies. Many computer models are now available that build upon the transition model approach of Horn (1975) and the JABOWA model developed by Botkin *et al.* (1972) that uses life history characteristics of individual tree species to simulate establishment, growth and survival in tree gaps. Yet models do not exist for succession in areas with complex spatial heterogeneity. The advantage of the modeling format is that it quantifies theories of succession and makes testable hypotheses more apparent.

Today, analysis of succession often combines field and modeling components. Together these approaches provide documentation of changes and a way to formalize the concepts and extrapolate them over the long time over which succession typically occurs. Succession remains as a key concept in ecology, yet its complexity still defeats scientists' desire for order and simplicity.

CHARACTERISTICS OF SUCCESSION

The causes of succession are more realistically viewed as a continuum ranging from changing external geophysical forces (*allogenic* succession) to biological processes modifying conditions and resources (*autogenic* succession). Under allogenic succession, physical forces override biological causes. For example, a regional drying trend over the past 100 years in the Southwestern US may be partially responsible for the replacement of desert grassland with desert scrub. Accelerated cycles of erosion and deposition during the Dust Bowl in the central US changed vegetation patterns. Alterations in the meandering of rivers over time change riparian vegetation and create new sites for succession. Autogenic succession occurs as a result of the organisms' effect on their environment. Plants can create shade, add to the litter, moderate temperature oscillations, increase humidity, and alter soil structure and chemistry. Autogenic succession is the focus of this article.

Succession occurs within a physically changing environment as changes in biological composition, structure and function over time affect ecological processes and *vice versa*. As global environmental changes occur, they create a new backdrop for ecological succession. Odum (1969) hypothesized that the major traits changing over a sere include biomass, net primary production, plant-species diversity, species life-history traits, propagule-dispersal modes, propagule longevity, and nutrient storage (Table 1). Many later studies have documented that these traits do change over successional time; however, less clear are when these traits change and how changes in the spatial heterogeneity of the physical and biological conditions in uence the successional process.

The species dominating early and late successional communities typically have a common set of characteristics. Early successional communities are characterized by species with light, wind-dispersed seeds that germinate and grow rapidly under high light conditions, whereas late successional communities are dominated by species with heavy seeds that germinate and grow more readily under low light conditions. These groups of species are referred to as *r-strategists* and *K-strategists*, respectively, depending on which part of the logistic growth curve (Equation 1) is

most responsible for the increase in population size:

$$\frac{dN(t)}{dt} = \frac{rN(t)[K - N(t)]}{K}$$

or

$$N(t) = \frac{K}{1 + e^{-rt}} \quad (1)$$

where r is the rate of growth of the population, K is the asymptote of the S-shaped curve, and $N(t)$ is the population size at time t. Thus, dN/dt is the rate of population growth. In uncrowded environments, selection favors species with high rates of reproductive potential, and thus r-strategists are more common. In contrast, crowded environments favor species with lower growth potential but better abilities to compete (K-strategists) (*see* r–K Strategies, Volume 2).

Life history traits of surviving species relate to resistance to or tolerance of disturbance and influence the species composition of the biotic residuals. For example, aquatic plants tend to survive floods by growing upward into the light zone as waters rise. After the 1993 midwestern floods in the US, a rare species of false aster (*Boltonia decurrens*) became abundant, for it requires fresh mud flats for seed germination (Smith *et al.*, 1998). Furthermore, surviving seeds can greatly influence reestablishment as evidenced by the dramatic recruitment that occurs from buried seed after a fire. Similarly, seed survival in serotinous cones or fruits permits rapid establishment after a fire. The nitrogen-fixing capability of lupines that survived the 1980 eruption of Mount St Helens, US, ameliorated soil nitrogen conditions, and thus facilitated establishment by other plants. Where deposition of volcanic ash from Mount St Helens is only a few decimeters, surviving pocket gophers (*Thomomys talpoides*) mix the original soil into the ash, and thus both expose buried seeds ripe for germination and improve nutrient conditions of the new ash (Anderson and MacMahon, 1985).

Early stages of succession are influenced largely by substrate characteristics (soil texture, moisture, and nutrient condition), distance to a seed source, and seed morphology, whereas later plant establishment is largely determined by environmental changes caused by earlier immigrants. *Facilitation* is the process of early successional species altering conditions or the availability of resources in a habitat in a way that favors later successional species. For example, the first species to become established create shade, alter the soil moisture properties, and ameliorate soil texture and nutrient conditions via decomposition of their parts. Often nitrogen is a limiting factor in the early stages, and the presence of plants with the ability to fix nitrogen through association with nitrogen-fixing bacteria enhances soil development. In the Pacific Northwest of the US, the early successional tree, alder (*Alnus* spp) is a key facilitating species because it (1) fixes nitrogen; (2) has light, wind-dispersed seeds that germinate readily; (3) grows rapidly; and (4) reproduces at an age as young as three years.

In contrast to facilitation, the process of *inhibition* may actually arrest successional development. This process occurs when a resource is so intensely used by a species that it is not available to other species. Space is the resource that is typically constrained. For example, following a mudslide off a steep slope of Mount Rainier in Washington State, US, the Kautz Creek area was quickly inundated by an almost continuous mat of mosses and lichens. Germinating tree seedlings could not penetrate the mat to reach the mineral soil, thus tree establishment was inhibited for decades.

Both facilitation and inhibition can be important in any one successional sequence. For example, early successional species typically alter the physical environment to make it more suitable for other species. But as these plants grow, they may inhibit other species by shading them and competing with them for moisture.

Life history characteristics can thus influence the time over which succession occurs. The early establishment of a particular species can inhibit some species and thus shorten the time to dominance by a late-successional species. In the Northeastern US, abundant establishment of cherry (*Prunus pensylvanica*) inhibits the growth of other mid-successional species. On the other hand, the peak of forb and graminoid seedling recruitment three years after the 1988 fires in Yellowstone National Park and the scarcity of conifer seedlings may have lengthened the time required for forest development or may have precluded it entirely. Thus, ecosystem structure, composition, and processes may reflect for centuries the presence or absence of residuals following a disturbance.

SUCCESSION AS A CYCLE

Succession can be viewed as a cycle that moves the ecological system between the functions of exploitation and conservation (Figure 1) (Gunderson and Holling, 2000). In early stages of succession, *exploitative* processes dominate and lead to an organization of the resources by means of binding of nutrients, accumulation of biomass and modification of the environment. Later, *conservative* forces, such as competition, dominate and increase organization via trophic and competitive connections. Forces of changes also affect the ecological system: organisms die and are replaced, thus releasing previously bound resources. Holling (1986) refers to this stage as *creative destruction*, for it contains both destructive features and creative ones. The final stage is one of *renewal*. In this stage, the system has carbon, nutrients and energy available for use by component organisms.

The cycle is presented as a pattern in time, but it also reflects patterns in space (Holling, 1986). The more rapidly a system moves through the cycle, the more likely it is to create a patchy system. Whereas those systems that move slowly through the cycle tend to be uniform in space as a

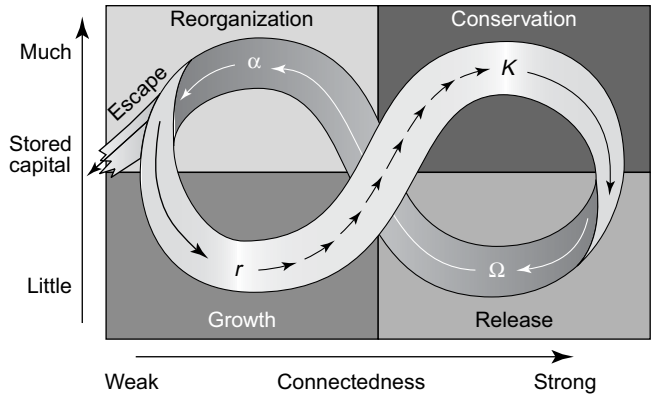

Figure 1 The dynamics of a system as it is dominated by each of the four processes: rapid growth (r), conservation (K), release (Ω), and reorganization (α). The arrows indicate the speed of the cycle. The short, closely spaced arrows indicate a slow change, while the long arrows indicate rapid change. The cycle reflects systemic change in the amount of accumulated capital (nutrients, resources) stored by the dominant structuring process in each phase, and the degree of connectedness within the system. The exit from the cycle at the left of the figure indicates the time at which a systemic reorganization into a less or more productive and organized system is most likely to occur. (Adapted from Gunderson and Holling, 2000)

result of discontinuous changes that move as a wave across space (like an insect outbreak in a forest).

SUCCESSION IN OTHER ENVIRONMENTS

Succession is just as common in aquatic habitats as terrestrial ones. However, succession in ponds, lakes, and streams are particularly in uenced by anthropogenic inputs of materials and energy that speed up, slow, or even stop community development.

Studies in intertidal communities have been particularly useful in developing successional theory, for in these environments the entire sere occurs over a decade where it may take centuries to a millennium in forest ecosystems. Wave action is the most common disrupting force in the intertidal. Newly exposed substrates are colonized by a series of algae that eventually cover 60–90% of the rock surface. However, the presence of the early succession green algae, *Ulva*, can inhibit further succession. In fact, the succession is characterized by a series of species, each of which inhibits its successor. The early pioneers are more resistant to the rigors of the physical environment but also more susceptible to grazers in the system (e.g., crabs). As grazing pressure increases, the early successional species are removed, making way for later successional species.

Degradation is one type of succession in which dead organic material is decomposed. Over time, a series of species of microorganisms and detritivorous animals will exploit and decompose the organic matter until it is completely metabolized and mineralized (*see* Intertidal Zones, Volume 2).

PERSPECTIVES ON SUCCESSIONAL ENDPOINTS

As mentioned previously, the idea that all seres end in stable climax states is no longer accepted. Instead, late successional communities are thought to be in a state of dynamic equilibrium. The equilibrium perspective is based upon the importance of interspecific interactions in shaping the community. There may be some species turnover in a system in a state of dynamic equilibrium, but the addition of new colonists is balanced by extinctions. Predation, competition, and symbiosis become more common in the late successional stages, and this biotic saturation thwarts the introduction of new species.

Alternatively, some communities reach cyclic successional stages on a local scale. In this situation, the juveniles of the late successional species may not be able to establish themselves in the presence of the adults. Shrub-dominated communities often undergo cyclic succession. For example, open areas within the Texan desert scrub in the US are typically invaded by the widely-dispersed creosote bush (*Larrea tridentata*); these areas subsequently succeed to a cactus, the Christmas tree cholla (*Opuntia leptocaulis*), and eventually revert back to bare ground, only to renew the cycle (Yeaton, 1978). The cactus establishes itself in the shade of the creosote bush and over time outcompetes it for the limited supply of moisture. Yet when the protection of the creosote bush is gone, the cactus is subject to erosion and burrowing rodents, which weaken its root system. The cycle begins anew on the barren soil.

A perspective contrary to the dynamic equilibrium views communities as continually being in a state of ux. At all stages in the *sere* (the successional sequence), the identities and numbers of species change. This non-equilibrium model assumes that unpredictable factors such as dispersal and disturbance dominate development of community structure and composition. In this situation, the course of succession may vary with the particular species that become established first. Severe and frequent disturbances may prevent equilibrium from ever being achieved.

Multiple stable states are alternative successional outcomes that exist in one environment, yet do not converge over time to a single state. Multiple stable states are rarely observed but may be more common under intense human activities or natural disturbances. For example, livestock grazing and clear-cutting can lead to new stable conditions. Where grazing pressure in intense and a major source of deforestation, such as in the Brazilian Amazon, grazing can result in a downward spiral toward unsustainability of the land (Serrao and Toledo, 1990). Alternatively, extreme

natural floods in 1991 may have produced multiple stable states now present in riparian vegetation in Southwestern Colorado, US (Baker and Walford, 1995).

Most communities occur in a complex mosaic reflecting the diversity of past disturbances or the topography. For example, fires occur with a variety of intensities across a landscape, which leaves a distinct pattern of vegetation in different states of succession. The progressive retreat of a glacier leaves bands of vegetation in different stages of succession. The matrix of different stages of succession is called a *chronosequence*. When the mosaic reflects topographic differences such as might occur along an elevational gradient, it forms a *toposequence*.

SUCCESSION FROM LARGE, INFREQUENT NATURAL DISTURBANCES

The spatial variability in disturbance intensity can lead to a heterogenous pattern of surviving organisms (Turner *et al.*, 1998). The abundance and distribution of these biological legacies or residuals influence successional dynamics. These surviving organisms dictate the patterns of survival and highly influence the initial stages of reestablishment. They provide some of the earliest seeds as well as the competitive environment to which the new seedlings are exposed. Residual plants often grow larger vegetatively, compared to the newly established seedlings. For example, after a tornado created a 400-ha windthrow in Northwestern Pennsylvania, US, thickets of surviving beech (*Fagus grandifolia*) and maple (*Acer pensylvanicum*) had a clear size advantage over new plants, and that dominance has been maintained (Peterson and Pickett, 1995).

Physical and abiotic legacies are also important to reestablishment after a disturbance. The presence of large rocks or downed trees can provide a safe site where soil moisture and temperature may be more suitable for seedling establishment and growth. The physical presence of plants or even spider webs can trap seeds and retain enough moisture to enhance germination.

Disturbance intensity and size influence those processes that affect succession (Turner *et al.*, 1998). For high intensity disturbances, reestablishment is almost entirely dependent upon propagules being transported from outside the disturbed area. Long-distance colonization by propagules is important especially in the middle of disturbed sites. Typically, the density of propagules dispersed into a disturbed area declines with distance from the edge. However, this pattern of declining density of propagules does not hold as one moves toward the interior of very large disturbances. Disturbance size also interacts with the life history characteristics of potentially colonizing species. For example, *ruderal* (growing on wasteland) species are often common in large disturbed areas. Fireweed (*Epilobium angustifolium*) reestablishes via its light plumed seeds even in large burned areas in the Western US. Yet late-successional species that typically have large seeds are rare. The rate of species migration is also influenced by the size of the disturbance. Furthermore, disturbance size can influence biotic interactions such as herbivory, which can accelerate, impede, or redirect succession. Herbivores are noticeably rare subsequent to large disturbances.

For illustrative purposes, consider one of the largest natural disturbances of the 20th century: the eruption of Mount St Helens in Washington State, US. Plant succession in the aftermath of the 1980 eruption has similarities to recovery after other volcanic eruptions around the world, but, in contrast to other natural disturbances, is much slower and more heterogeneous, probably because of its large size and diversity of impacts (Turner *et al.*, 1997). The 1980 eruption created a variety of disturbances: a 15-km^2 pyroclastic flow, 550 km^2 of trees that had been blown down bordered by 96 km^2 of scorched trees, a 60-km^2 debris avalanche, and massive mud flows. Each of these disturbances resulted in a unique pattern of surviving plants, depending on the life form of species present before the eruption and the characteristics of the disturbance. For example, the Mount St Helens avalanche is the largest landslide in recorded history, and few species or plants survived. There has been a gradual increase in diversity and cover, but only 61% of the species present before the eruption were reestablished in the first 15 years. At that time, plant cover averaged 36% but was extremely patchy. Because part of the avalanche was deliberately seeded by nonnative plant species to reduce erosion, the site offers the opportunity to compare successional processes occurring with and without nonnative species.

Fifteen years after the eruption and 10 years since the seeding by introduced species, sites with dominance by nonnative species have greater vegetation cover and more native plant diversity than plots that were not seeded. Significantly greater mortality of conifers occurred in the plots dominated by nonnative species shortly after seeding, but no difference in conifer mortality has occurred since then. Even so, the plots dominated by nonnative species still have fewer conifer trees. Thus, the short-term pulse of conifer mortality after the seeding of introduced species may have long-term effects on the recovery of the dominant vegetation. Long-term recovery trends and effects of nonnative species on succession are important to understand since typical management practices rely on nonnative species for enhancing vegetation recovery of denuded sites along roadsides, strip mines or other human-generated clearing.

QUESTIONS STILL REMAINING

It is difficult to sort out the relative role of pattern versus processes in the early stages of succession because spatial heterogeneity, nonnative species, long-distance dispersal,

herbivory, and many other factors in uence the path and rate of the seral process. Unfortunately, there is no single instance in which all of these factors have been examined. Current theory of early succession does not adequately consider the broad range of biotic and abiotic variables controlling the early stages of plant establishment and succession. Yet, it is in understanding the early stages of succession that ecological theory may provide the greatest insight into the recovery of disturbed landscapes.

Ecologists are still challenged to predict the role of spatial heterogeneity on vegetation recovery even though the gradual replacement of species through succession is well described. It is not known how the early successional process is shaped by the spatial distribution of resources; the location and diversity of reestablishing species; and the frequency, severity, and extent of stochastic environmental events. There is a need for better understanding of the links between landscape patterns and ecosystem processes to enable better understanding of in uences on plant establishment and biodiversity. These in uences include nonnative species, herbivores, subsequent disturbances, dispersal, and spatial heterogeneity. Appropriate modeling of species invasion is a critical need for forest succession models.

The introduction of nonnative species into established vegetation areas can have far-reaching and long-term impacts. The significant short-term effects of competition with introduced species during early stages of succession are already known. However, how long the introduction of nonnative species during early seral stages will have an effect is not predictable. Alternative stable states of succession may be achieved, or later species in the sere may not be affected by competition between native and nonnative species during the early successional stages. Better understanding of such long-term effects would provide information necessary to develop appropriate management strategies for dealing with nonnative and invasive species.

Seed dispersal typically declines with increasing distance from the parent plant. The pattern of short-range dispersal is well predicted by current theoretical methods. Over larger distances, fewer seeds are dispersed, but their presence has a disproportionate effect on invasion. Seed dispersal over long distances may best be explained by seed morphology and the physical conditions of the surrounding landscape (e.g., microtopography, deposition zones, or wind patterns) (*see* Plant Dispersal and Migration, Volume 2).

Herbivory selectively impacts certain species. Yet the effects of herbivory on early succession are difficult to predict in variable environments. For example, on the debris avalanche at Mount St Helens in Northwestern US, plant diversity and cover are higher within elk (*Cervus elaphus*) exclosures than outside. However, a possible plant response to herbivory is to increase reproduction. The effects of these responses on succession are not clear.

Although succession is a much-studied phenomenon central to ecology, many questions remain about how succession occurs in heterogeneous environments. As global environmental changes alter the Earth, understanding how succession occurs under changing conditions will become even more important. For example, with the growth in human population and subsequent land use changes, there is an expansion in the number and size of areas experiencing early successional conditions. Also, it is not clear how the rate of succession may alter with changing regimes of temperature and precipitation. Furthermore, changes in disturbance regimes can affect patterns of succession.

Suess Effect

The *Suess Effect* is the dilution of radioactive carbon in the atmosphere by the combustion of fossil fuels. Atmospheric carbon dioxide contains a relatively constant content of the radioactive isotope of carbon, ^{14}C. When carbon dioxide is used by photosynthetic organisms, ^{14}C is incorporated into cellular material, for example the cellulose and lignin of growing plants. ^{14}C has a half-life of 5700 years and therefore the ^{14}C content of preserved biological material decreases with time. Thus measurement of ^{14}C in biologically derived objects provides an important method of dating such remains. Fossil fuels are many times older than 5700 years and the radioactive carbon of the original plant material from which they are derived has decayed to unmeasurable levels. Consequently, when such fuels are burned, the extra carbon dioxide liberated into the atmosphere contains no ^{14}C and the radioactive carbon of the atmosphere will be diluted. It is to be expected that the ^{14}C content of the biological products of photosynthesis from this atmosphere containing anthropogenically derived carbon dioxide will be correspondingly low in ^{14}C. This dilution effect is clearly shown in tree rings dated between 1820 and 1950, an observation that was first reported by Suess (1955), after whom the effect is named.

The dilution of atmospheric ^{14}C by fossil carbon provides a key piece of evidence for the impingement of human activity on the global carbon cycle. Unfortunately, this important record was totally obscured by the major release of ^{14}C into the atmosphere as a byproduct of nuclear weapons testing.

Symbiosis

Symbiosis describes the situation where two distinct species are closely associated so that they live together. In the broadest definition, symbiosis describes all possible types of consortium between dissimilar organisms, whatever the outcome. In practice, the term is more often applied to relationships where the outcome is beneficial or neutral. When the result is negative or lethal to one member the term *parasitism* is applied. The outcome of parasitism is normally disease (e.g., the growth of mistletoe on poplar trees, or any disease-causing bacterial infection).

Symbiotic association can be *facultative*, where the partners may live either alone or in association, or *obligate*, where one or both of the partners is unable to survive independently. The best-known examples of obligate symbiosis are the lichens, where algal cells within the thallus of a fungus supply organic nutrition by photosynthesis to their host, and are in turn provided with inorganic nutrition and an adequate environment. In the mycorrhizal symbiosis (*see* Rhizosphere, Volume 2) fungi infect roots, usually of trees, and absorb nutrients from the soil, which are transported to the host trees. In return, the trees exude or transport organic nutrients to the fungi. This provides a specific advantage to trees because the fungi may be better able to absorb inorganic nutrients than tree roots. Also, it costs much less, in terms of mass production, to penetrate and mine a given volume of soil by growing fungal hyphae than by growing roots. Both these associations are examples of mutualism, in which both partners benefit from the association.

There are many examples of plant–plant and innumerable examples of animal–animal, bacteria–plant or bacteria–animal associations, but only a few of plant–animal symbiosis. Algal cells living within the cells or protoplasts of animals such as clams, sea anemones or hydra result in the apparent anomaly of photosynthetic animals. Such associations may be long term, with the algal and animal cells dividing in synchrony so that the number of algal cells in

a host cell remains constant. While such associations may not be mutualistic, the animals clearly benefit, and mobile forms will move to seek illumination.

One of the most important symbioses, in terms of agriculture, is the association of nitrogen-fixing bacteria (mostly *Rhizobium* spp.) with the roots of legumes. The process of nitrogen fixation, powered ultimately by the host's photosynthetic metabolism, is estimated to fix upwards of 10^8 tons of nitrogen year^{-1} worldwide. It greatly outweighs the amount of nitrogen applied as fertilizer even in developed countries, and its production is pollution-free.

There are many other nitrogen-fixing symbioses, including the Actinomycete–alder association that can effectively return run-down pastures to productivity. A very interesting example is the association of a cycad (a primitive tree) and a blue-green alga, in which the alga causes a reversal of the normal positive *geotropism* (i.e., downward growth) of the host roots so that they grow up through the soil surface and the algae are able to intercept light for photosynthesis. But this, and the many forms of insect–plant association in which the insect induces the plant to grow an elaborate structure or gall in which it can live, are really examples of non-lethal parasitism.

Tamm, Carl Olof

(1919–)

Tamm, Carl Olof, Swedish forest ecologist, is Professor of Forest Ecology at the Forestry Faculty of the Swedish University of Agricultural Sciences, and one of its forerunners, the Royal College of Forestry (1957–1984). Carl Olof Tamm is one of several prominent members of the family Tamm; his father Olof Tamm was professor of Forest Soils at the Royal College of Forestry in Stockholm. Young Tamm received much inspiration from his father's work and also from the senior colleagues of his father at the Forest Research Institute like ecologist/soil biologist Lars-Gunnar Romell and the plant ecologist Carl Malmström. After studies in Lund and Stockholm, Tamm obtained a PhD in botany in Stockholm. During his time in Lund, he demonstrated that a typical so-called "nitrate-plant", fireweed (*Chamaenerion (Epilobium) angustifolium*), could exist on ammonium as the sole nitrogen source, which suggested that the nitrogen ecology of this plant was a question of competition for nitrogen rather than a physiological demand for nitrate. His knowledge and talent were rapidly recognized, and he obtained his Professorship shortly after his PhD. Tamm energetically organized a number of thorough large-scale and long-term experiments with nutrient additions to forests. The larger of these are still unique in an international perspective in terms of the number of treatments, the number of replicate plots and the size of the experimental plots. His work clearly confirmed that the growth of boreal forests was limited by the supply of nitrogen; the experiments also demonstrated that phosphorus, boron, potassium and magnesium might impose secondary limitations on plant growth. When acid rain became a matter of concern in the late 1960s, he was quick to add soil acidification (additions of sulfuric acid or elemental sulfur) and liming treatments to his trials. These treatments, as well as the long-term nitrogen additions, have provided most important insights into the effects of nitrogen and sulfur deposition on forests, and on the effects of remedial actions like liming. Because these trials are located in relatively unpolluted environments, they are ideally suited to assess the effects of soil acidity alone (without any impact of gases like sulfur dioxide), and the effects of nitrogen alone or in combination with other elements, on tree growth. Tamm's interests have been and are wider than this. He stimulated the seminal work on plant nutrition by Torsten Ingestad, played a leading role in the Swedish International Biological Program (IBP) Coniferous Forest Project, explored the ecological role of ground mosses, studied the long-term dynamics of a forest herb, and re-analyzed the soil pH of his father's plots to study acidification, etc. He has set a lasting example with his careful analytical and strongly experimental approach. The scientific legacy of Carl Olof Tamm is found in his 1991 book on terrestrial nitrogen cycling, published seven years after his retirement (his successor as Professor of Forest Ecology was Sune Linder).

Taxon

Taxonomy arranges organisms into groups with certain degrees of similarity called *taxa* (singular *taxon*). The term *taxon* applies to any taxonomic group regardless of its size or rank. A taxon may thus be very large (e.g., a *kingdom*, which is subdivided into many smaller taxa) or small (e.g., a *genus*, which contains *species*). The taxonomic hierarchy of plant classification may be summarized as follows: the *kingdom Planta*, which contains all plants, is subdivided into divisions (e.g., Magnoliophyta, the flowering plants), which are further divided into classes (e.g., Magnoliopsida, the dicotyledonous plants). The next subdivision is *orders* (e.g., Rosales, the roses and their relatives), further divided into families (e.g., Rosaceae, the rose family), the *divisions* of which are *genera* (e.g., the genus *Prunus*, the plums and cherries), which contains species (e.g., *Prunus domestica*, the plum). Each of these levels of the taxonomic hierarchy is a taxon. It should be noted that various systems of classification, containing more or fewer taxa and levels in the hierarchy of taxa, have been proposed and are currently in use. The one described above for plants, shown in Box 1, is widely but by no means universally accepted.

Box 1 Hierarchy of a plant taxonomic system, with examples

Kingdom	Planta	The plants
Division	Magnoliophyta	Flowering plants
Class	Magnoliopsida	Dicotyledons
Order	Rosales	Roses and related families
Family	Rosaceae	Rose family
Genus	*Prunus*	Plums and cherries
Species	*Prunus domestica*	Cultivated plum

The exact size of taxa and the degree in which they should be grouped or subdivided are still matters of opinion and debate (*see* **Taxonomy/Systematics**, Volume 2).

R G S BIDWELL *Canada*

Taxonomy/Systematics

Taxonomy is the study of the classification of organisms. Classification means fitting organisms into groups or taxa (singular taxon; *see* **Taxon**, Volume 2) based on specific shared characteristics. Various methods of grouping organisms have been developed. The earlier ones were largely artificial and static, i.e., they relied on obvious, usually visual characteristics (e.g., flower color) and regarded all organisms as fixed (the products of creation). The Swedish botanist Linnaeus understood the value of *natural* categories, i.e., categories based on biological characteristics of the organisms, but he was aware that the basic biological understanding of organisms at his time was inadequate. Darwin's theory of evolution provided a much more biologically sound basis for the classification of organisms based on the relationships of their evolutionary ancestry, and this became known as *systematics*. Today the terms *systematics* and *taxonomy* are used virtually interchangeably. Modern taxonomy relies more and more heavily on evolutionary relationships, but many less natural conventions still prevail where adequate genetic evidence of relationships has not yet been developed.

The fundamental unit of taxonomy is the *species*. Species are usually defined as groups of individuals that are similar or identical in appearance and other characteristics and that can interbreed, geographic conditions permitting. However, it is now clear that the species is not a static unit, as organisms continue to evolve. The result is that the definition of any given species is frequently blurred and often quite arbitrary, i.e., to suit the conventions of the taxonomist. Furthermore, species are frequently subdivided into *subspecies* and *races* in order to place organisms that appear to belong to a single species into smaller groups on the basis of consistent, but minor, differences in certain characteristics.

Taxonomy, once considered a purely descriptive science, is now developing on a wide experimental base. The systematic approach includes classification on the basis of genetics, cytology, biochemistry and chemistry. In addition, the structure of the taxonomic system depends more and more on genetic and evolutionary analyses. Nevertheless, the earlier requirements for observation, description, nomenclature and documentation (i.e., collection) of species and specimens are still essential in the science of taxonomy.

Temperate Coniferous Forests

Richard H Waring
Oregon State University, Eugene, OR, USA

Temperate coniferous forests include representatives of the most massive forms of terrestrial life on Earth. In the

coastal redwood (Sequoia sempervirens) forests of northern California, trees may reach heights >100 m and accumulate biomass in excess of 3000 t ha^{-1}. In the more extensive Douglas fir (Pseudotsuga menziesii) forests of the Pacific Northwest, USA and Canada, biomass in older stands frequently reaches 1000 t ha^{-1}, with an additional 500 t ha^{-1} of standing dead and fallen trees. Above-ground biomass ranges widely, however, as does above-ground growth. Temperate coniferous forests produce an average of about 5 t ha^{-1} year^{-1} of above-ground biomass but in climatically diverse areas production may range from <1 to >20 t ha^{-1} year^{-1} (Runyon et al.*, 1994).*

Because of their high growth capabilities, favorable wood structural properties and columnar form, temperate coniferous forests play a disproportionate role in meeting global demands for lumber and fiber. As a consequence, the geographic range of temperate conifers has been extended beyond the native ranges of many species.

In this contribution we focus on the attributes of temperate evergreen coniferous forests that distinguish them from their major competitors, deciduous hardwoods. This differentiation should help us anticipate the future role and importance of temperate coniferous evergreen in relation to rising levels of air pollution, atmospheric carbon dioxide (CO_2), and changing climate.

EVOLUTION

Conifers bear naked seeds, unlike angiosperms, and differ from other gymnosperms by having the seeds arranged inside cones. During the Carboniferous period (300 million years ago), conifers represented a minor group of gymnosperms, but they evolved rapidly as conditions became drier and colder during the Permian (286–240 million years ago). Temperate coniferous forests were most widely distributed during the Tertiary period (90–15 million years ago), with coastal redwood (*Sequoia sempervirens*) and dawn redwood (*Metasequoia*) distributed throughout both Eurasia and North America. Today, conifers are the dominant representatives of gymnosperms with about 50 genera and 550 species, predominantly in the Northern Hemisphere (Raven *et al.*, 1986).

Conifers are well adapted to arid and cold conditions. The surfaces of needle-shaped leaves are protected by waxes and sunken stomata and a large proportion of their stems consists of sapwood that serves as a storage reservoir, as well as a conduit for transport of water from roots to leaves.

GEOGRAPHIC DISTRIBUTION

Today, temperate evergreen coniferous forests cover approximately 2.4×10^6 km^2 (Melillo *et al.*, 1993; Landsberg and Gower, 1997). Conifers dominate the montane forests in North America, Europe, and China. Smaller areas of temperate conifers are located in montane regions of Korea, Japan, Mexico, Nicaragua, and Guatemala. In Europe, the distribution of native and introduced conifers has been expanded into areas more climatically favorable to hardwoods. Pines (*Pinus*), represented by more than 90 species, are the most widely distributed conifer and their range has increased by widespread planting in the Southern Hemisphere. Other important genera include the firs (*Abies*), spruces (*Picea*), hemlocks (*Tsuga*), false-hemlocks (*Pseudotsuga*), larches (*Larix*), cypresses (*Cupressus*), cedars (*Chamaecyparis*, *Thuja*, *Libocedrus*) and juniper (*Juniperus*). In the yews (*Taxus*), the seeds are not borne in cones but are enclosed within a fleshy structure. Additional conifer genera (*Araucaria*, *Fitzroya*, *Austrocedrus*) are present in the Southern Hemisphere, where they were once more widely distributed (Axelrod *et al.*, 1991).

ECOLOGICAL DISTRIBUTION

The potential ecological niche of temperate conifers falls within regions of >250 mm in annual precipitation that experience subfreezing conditions, down to, but not below −45 °C, which is the limit for supercooling of water. Only boreal tree species, which include some pines and spruces, are adapted to temperatures below this limit (Waring and Running, 1998). In regions where precipitation is well distributed throughout the growing season, deciduous hardwoods usually dominate over temperate conifers. Following major disturbances, however, conifers can become established and achieve temporary dominance (Landsberg and Gower, 1997).

In the Pacific Northwest region, where summer drought is common, the situation is reversed and many long-lived conifers replace earlier established hardwoods (Waring and Franklin, 1979). To explain these shifts in dominance requires an appreciation of how resources are captured by temperate evergreen conifers throughout the year.

PHYSIOLOGICAL AND MORPHOLOGICAL ADAPTATIONS OF CONIFERS

Conifer leaves are more clumped and narrower in cross-section than the foliage of most angiosperms, and the branch structure is much less extensive. These properties allow light to penetrate more deeply through conifer canopies than through hardwood forests with comparable leaf area. As a result, the maximum surface area of conifer foliage, often expressed as m^2 of (projected) leaf area per m^2 of ground surface, may reach 10–12, while hardwood forests rarely exceed half these values. In addition, conifer canopies reflect only about 5–10% of intercepted solar radiation, whereas hardwoods reflect 15–25%. In combination,

these differences in canopy properties permit coniferous forests to absorb a greater proportion of incoming solar radiation than forests composed of hardwoods (Jones 1992).

Although conifers absorb a larger fraction of intercepted radiation than hardwoods, they are less prone to suffer damage from elevated temperatures because the needle-shaped foliage dissipates heat efficiently, even under unventilated conditions. Consequently, conifers conserve water under conditions where broad-leaf species must transpire at higher rates, wilt, or shed foliage to prevent temperatures from rising above 45 °C, when enzymes begin to become unstable.
