Holocene: Climate Changes and Society

Burkhard Frenzel
Universität Hohenheim, Stuttgart, Germany

People are affected by climate, but in turn they also contribute to changes in climate. The key ideas of these two-directional interactions since the last Ice Age include:

1. *it is repeatedly stated that climate changes triggered migrations of huge numbers of people, such as the Migrating German Tribes in Europe and the raiding and migrating Mongols and Huns moving into Eastern and Central Asia and into Eastern, Central and Western Europe;*
2. *climate change may have triggered profound changes in, or a reorganization of, socio-economic systems, even when migration did not occur;*
3. *robust, stable human societies may have been able to buffer climate change, while other societies affected by internal political, demographic or economic dif culties may have been less able to adapt to climate change;*
4. *human economic activities may have strongly in uenced climate directly or indirectly, e.g., by forest clearances, excessively intensive land use, or commercial and industrial processes.*

Since the interactions between climate and society are highly complex and because these connections began in the dim and distant past, events early in history need attention as well as those of the recent industrial past.

The basis for considering the influence of changing climate on human societies is good knowledge of past climates, in time and space, and of the amplitude of past climatic oscillations. Originally it was held that during postglacial times (the Holocene, i.e., the last 11 550 years) several major changes of climate had taken place. They were thought to have produced important changes in the vegetation cover of the continents. It was held that these major shifts in climate had happened at the transition between periods characterized by more or less constant climatic conditions, the character of which was derived from plant-fossil assemblages in Norwegian peat bogs (Blytt, 1882). This was the basis for the well-known names of preboreal, boreal, atlantic, subboreal and subatlantic, the ages of which were estimated by assumptions about the velocity of sedimentation and by archaeological findings. Later on, many more indicators of past climates were used and better methods of dating palaeoecological samples were developed, especially the radiocarbon method (^{14}C (carbon); e.g.,

Godwin, 1975). It soon became evident that comparable steps in the vegetation history of various regions, such as Europe, had happened asynchronously. Thus, although names like preboreal, boreal and atlantic were still used in many countries, it became necessary to divide the Holocene chronostratigraphically, i.e., by the acceptance of certain well-defined ^{14}C-ages to differentiate between these biozones. This meant that during the Holocene, vegetation changes, even when they were highly marked, were much more governed by biological processes than by climate. On the other hand, analysis of a wealth of indicators of past climates, e.g., stable isotopes in the cellulose of tree-rings or in annually layered lake sediments, showed that the Holocene climate changed repeatedly and that the phases of change could be traced over vast regions of the globe, if not everywhere (e.g., Lamb, 1972; Frenzel *et al.*, 1992). The variability of climate appears to have increased considerably by about 6000 BP (before present; Frenzel *et al.*, 1997) with amplitudes of mean temperature in the month of August of about 2 4 °C. Using tree-rings, annually layered lake sediments or annual ice layers in inland-ice masses, it was demonstrated that the early ^{14}C dating method was not precise enough for reliable comparisons of radiocarbon data with historical data. In turn, this facilitated calibration of ^{14}C dates against tree-ring data (Stuiver *et al.*, 1998) so that physical age data of the past can be directly compared with historical data. This is important, if the relationship between climate change and events in early human societies and their economies are to be investigated.

Many claims are made that climate change triggered important changes in human society. No doubt, this triggering happened near the climatic boundary of permanent land use, e.g., at Lake Titicaca (Binford *et al.*, 1997) and during the Iron Age in Norway (Jankuhn, 1980). Yet the question remains whether this also holds for areas in more or less optimal climatic conditions. In this respect, the spread of Neolithic cultures from the Near East to Europe raises some questions. At that time, agriculture and livestock-raising spread from typically Mediterranean climates to typical warm- and cool-temperate continental to subatlantic and atlantic climates. Even though, at that time, minor changes of climate occurred, it is unlikely that these peoples could totally absorb the climatic contrasts within such a large area. Either migrating tribes or the diffusion of cultural traditions, or both, were at that time strong enough to spread into other climatic provinces. Here, climate cannot have been decisive, though a typical Mediterranean climate differs markedly from those of Central and Western Europe. Evidently new survival and adaptation techniques allowed this migration to occur.

As previously stated, the climate changed repeatedly during the Holocene, especially during the last 6000 years. At that time, particularly after about 3600 BP, several tribal migrations and movements of groups of people occurred. A comparison with the known history of climate change (Figure 1) reveals that sometimes periods of climatic change coincide with the start or the end of migrations, but often they do not. One interesting example is the raiding by the Mongols at the end of the 12th and beginning of the 13th centuries from the Altai Mountains and Mongolia into Eastern and Central Europe. This was the time of the so-called Medieval Climatic Optimum, which, in Central and Western Europe at least, in contrast to the concept of an uninterrupted climatic optimum, consisted of periods of cooler and moister and of warmer and drier climates (*see* Medieval Climatic Optimum, Volume 1). Yet these well-planned raids were carried out from 1190 AD onwards, with reconnaissance raids in various directions, mainly to the west and southwest. Only after these raids, and examination of the political and military situation in countries to the west, did the main attack occur from 1236 to 1241 AD. Of course, this example must not be generalized uncritically. However, it cannot be concluded that climate change in the past caused many tribes or groups of people to migrate and to occupy the territory of other peoples, had the migrating groups not been strong enough to do so. Thus, the interrelationships between changes of climate and the behavior of early human societies have to be analyzed as individual cases without premature generalization.

In this respect, yet another factor should be considered overpopulation, which cannot be sustained indefinitely if the climate becomes harsher or if groundwater resources decline. In these cases, society may collapse due to inappropriate decisions about resource management or unwise use of the environment. The other general problem in the relationship between climate and human societies is the impact of people upon climate, one of the causes of atmospheric changes. People began to influence global and regional climates several thousand years ago. Initially this was through changes in surface albedo, which was different in summer and winter in temperate and higher latitudes, and by forest clearance, which caused changes in surface heat and moisture fluxes.

Secondly, people caused considerable changes in tropospheric chemistry by burning wood, by agriculture, by overgrazing, and by ore smelting over several millennia. To estimate the influences and consequences of forest clearance on climate, computer simulations have been run, studying either global climate (Chase *et al.*, 2000) or regional climates (e.g., Dumenil and Lie , 1999). It turns out that, up to the present, global climate seems to have been influenced only weakly. However, strong regional differences exist, which, if they are to be believed, could affect human activities considerably.

Prediction of the consequences of man-made changes in tropospheric aerosols is even more difficult. Hong *et al.* (1998) reported on the deposition of copper aerosols

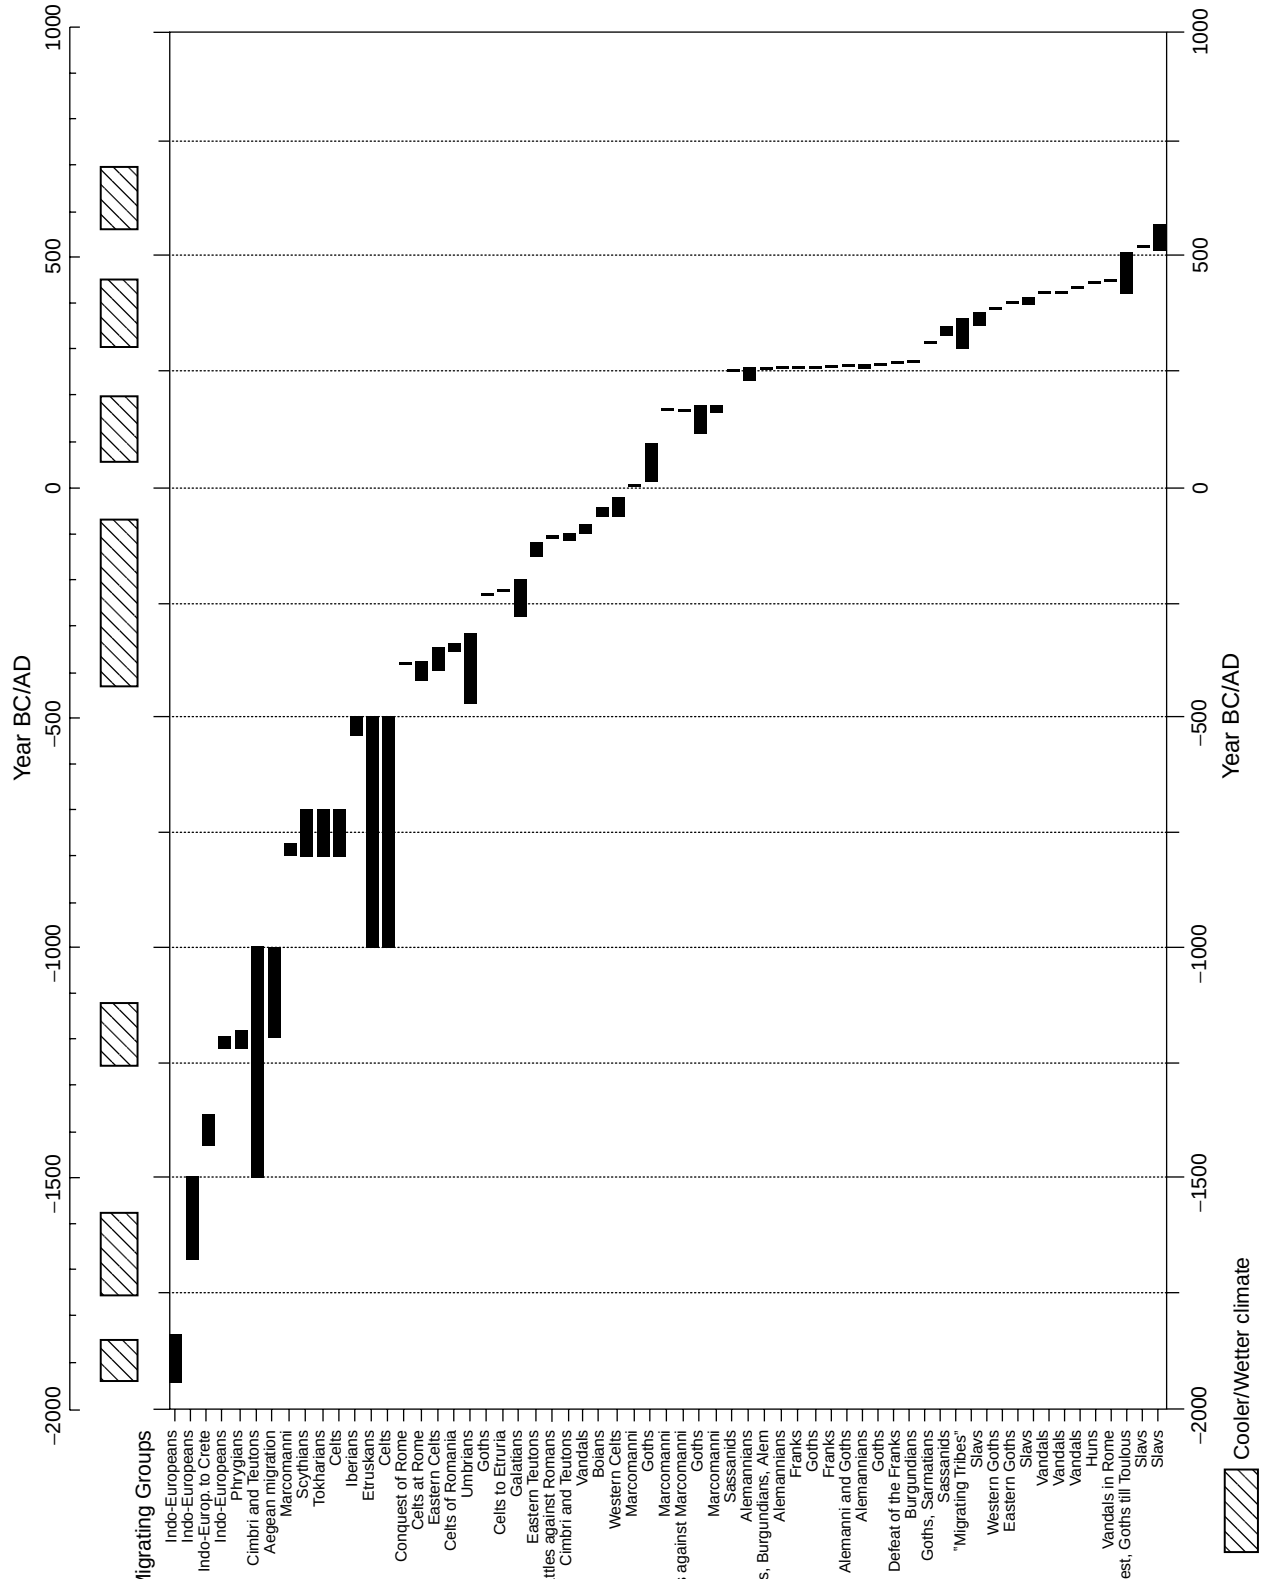

Figure 1 Times of migrations, of pressures of various tribes on other communities and periods of more pronounced climatic change in Europe. Diagonal hatching: relatively cold periods, generally moist summers. Black horizontal bands: phases of cold climate. No bands: periods of warm and generally dry summers. (Climate data from stable isotopes ($\delta^{13}C$ and $\delta^{2}H$) in the cellulose of accurately dated tree-rings)

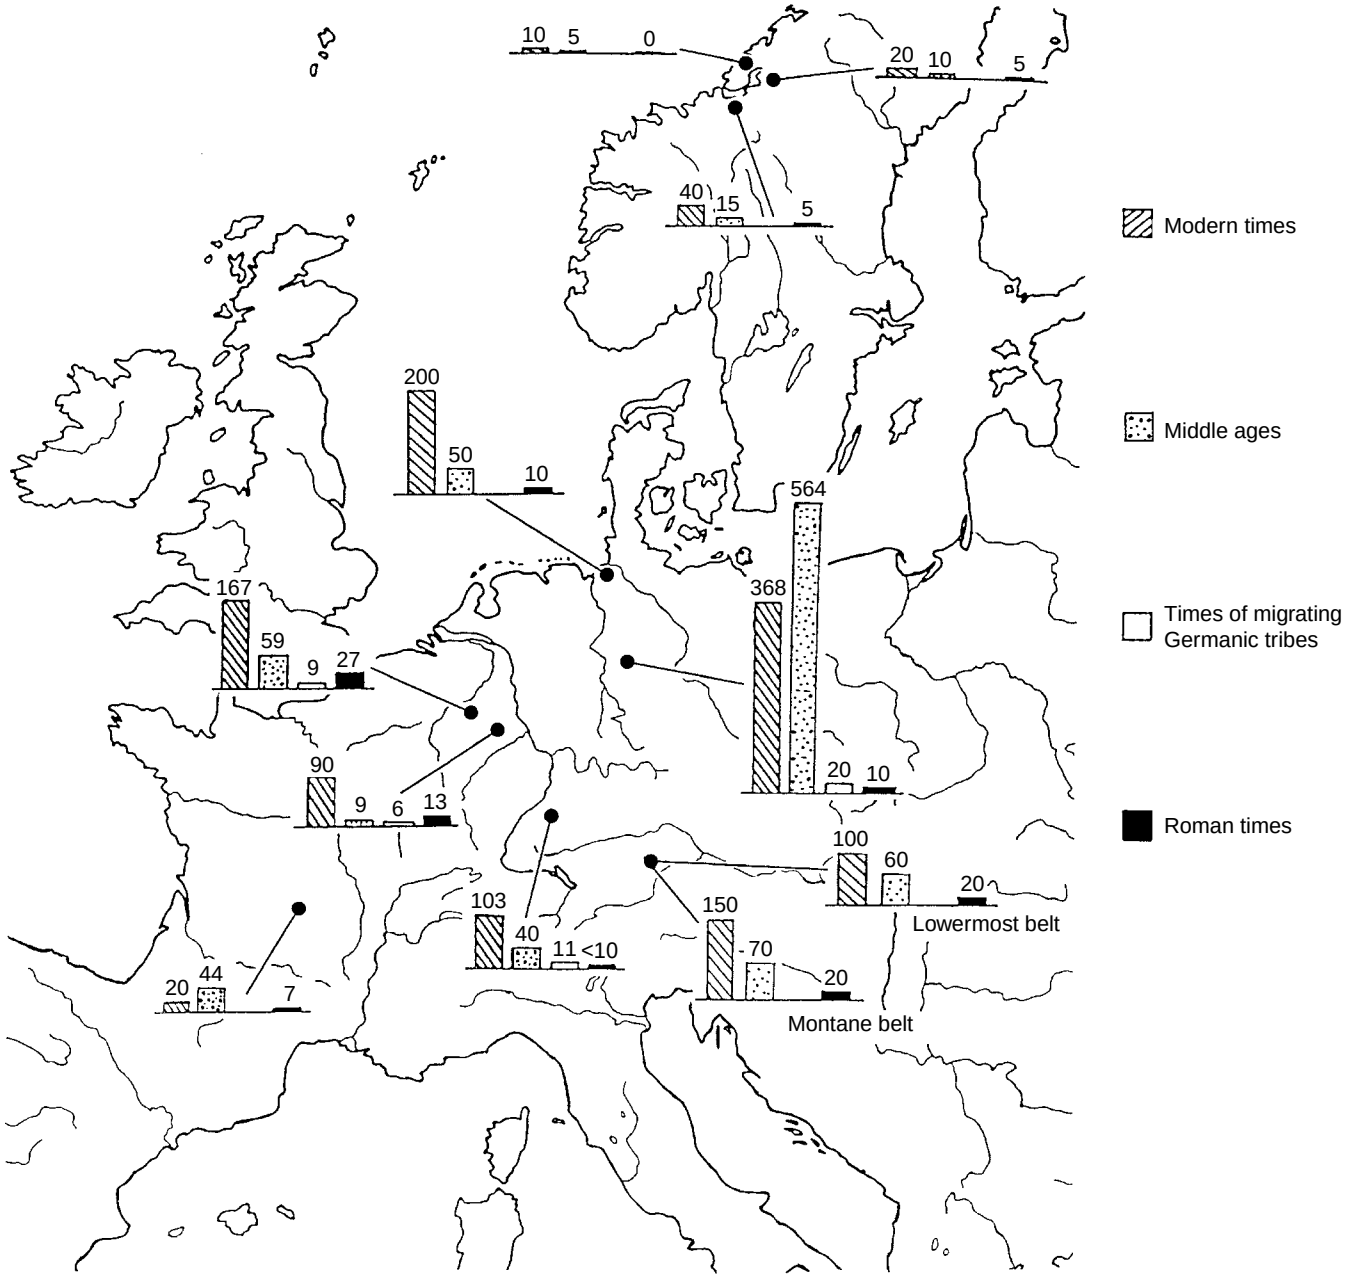

Figure 2 Lead (Pb) content as an indicator of commercial or industrial activities of man in ombrogenous peat-layers (in parts per million)

in Greenland during Roman times. Comparable investigations also took place in Southern Sweden and Central Europe (e.g., Shotyk *et al.*, 1998; Gorres, 1991). It became evident that the deposition of people-made aerosols has a long history. Yet calculation of source area emissions from the deposition rates has only just begun. Remarkable regional differences in the deposition rates of certain chemical elements in Europe (Figure 2) were the result of contrasts in agricultural practices, particularly plowing, during historical times, and of ore smelting and mineral processing. This is paralleled by observations of an increase in the deposition intensity of minerogenic dust in deep-sea cores off the West African coast. On the other hand, at the boundary of semiarid regions, as in Northwestern China, steppe soils and some forest soils are frequently covered by eolian dust. This may be interpreted as indicating the influence of the people-driven destruction of the natural vegetation cover, which loosened the soil and allowed

winds to blow away dust. (Some Chinese Scientists believe that the Silk Road contributed to desertification in the surrounding areas.) In turn, these tropospheric aerosols should have enhanced the formation of haze, fog and clouds, thereby influencing moisture and heat balances. Yet we are only at the start of pertinent but difficult investigations. These studies are difficult because many indirectly interrelated processes and factors have to be considered.

It must be concluded that much more research is needed on the interrelations between human societies and climate change, relying not only on modeling, but also on precise field investigations.

Indus Basin: a Case Study in Water Management

Ian Douglas
University of Manchester, Manchester, UK

The Indus rises in the Himalayas in the Tibet region of China at 4900 m above sea level in some of the steepest country on earth. Great glaciers and melting snows feed the stream that descends precipitously through steep gorges for the first 800 km or so of its 2900-km course. These snow and ice melt waters from the Karakoram in the Upper Indus Basin (UIB) supply much of Pakistan's hydroelectricity, irrigation water and domestic supplies. Their effective management requires a deep understanding of the physical processes that govern meltwater production in the UIB.

Through the mountains, the Indus flows northwest across Jammu and Kashmir, then bends to the southwest and descends to the hot, dry plain of the western Punjab. Punjab means land of the five rivers. They are the five rivers that empty into the Indus there: the Jhelum, Chenab, Ravi, Beas, and Sutlej. Next, the Indus crosses the Sind plain of southern Pakistan and reaches the Arabian Sea of the Indian Ocean through a delta some 210 km wide. Below the confluences of the Punjab rivers, the Indus widens and its gradient decreases. As its mean velocity falls with the gentler slope, much silt is deposited on its bed, raising its level above the sandy plain. Embankments are constructed to contain floodwaters, but occasionally they give way and floodwaters spread rich alluvial soils over vast areas of the plain.

In Pakistan and the Indian sector of the basin, cultivation of the rich alluvial soils has been the main economic activity for centuries. The Indus irrigation system is still the world's largest. In 1993, irrigation occupied 80% of Pakistan's 21.25 million hectare (ha) of cropland and employed about 55% of the labor force. The sustainability of the irrigation system is thus essential for the great majority of the people of Pakistan and for their neighbors in the Indian part of the Punjab.

Modern irrigation engineering work commenced around 1850, with the construction of large canal systems by the British administration. In many cases, old canals and inundation channels in Sindh and Punjab were revived, modernized and developed into the greatest canal irrigation system in the world. At partition in 1947, the international boundary between India and Pakistan split the integrated irrigation scheme of the Bari Doab and the Sutlej Valley Project between the two newly independent countries. Conflict arose because the headworks fell to India while the canals ran through Pakistan. This led to a disruption in the water supply in some parts of Pakistan. The dispute continued for some years until it was resolved through the mediation of the World Bank by a treaty between Pakistan and India (1960) known as the Indus Waters Treaty. According to this agreement, the flow of the three western rivers of the Indus basin: the Indus, Jhelum, and Chenab (save for a small quantity used in Kashmir) is assigned to Pakistan, whereas the entire flow of the three eastern rivers, the Ravi, Beas, and Sutlej, is reserved exclusively for India (see Figure 1).

INDUS BASIN PROJECT

To replace the water supplies lost to India through the diversion of waters of the eastern rivers, as provided under the 1960 treaty, the Indus Basin Project, involving the construction of two large dams, the Mangla and Tarbela, five barrages, one siphon and eight inter-river link canals, was undertaken by the Pakistan Water and Power Development Authority between 1960 and 1977. The Tarbela Dam was, at

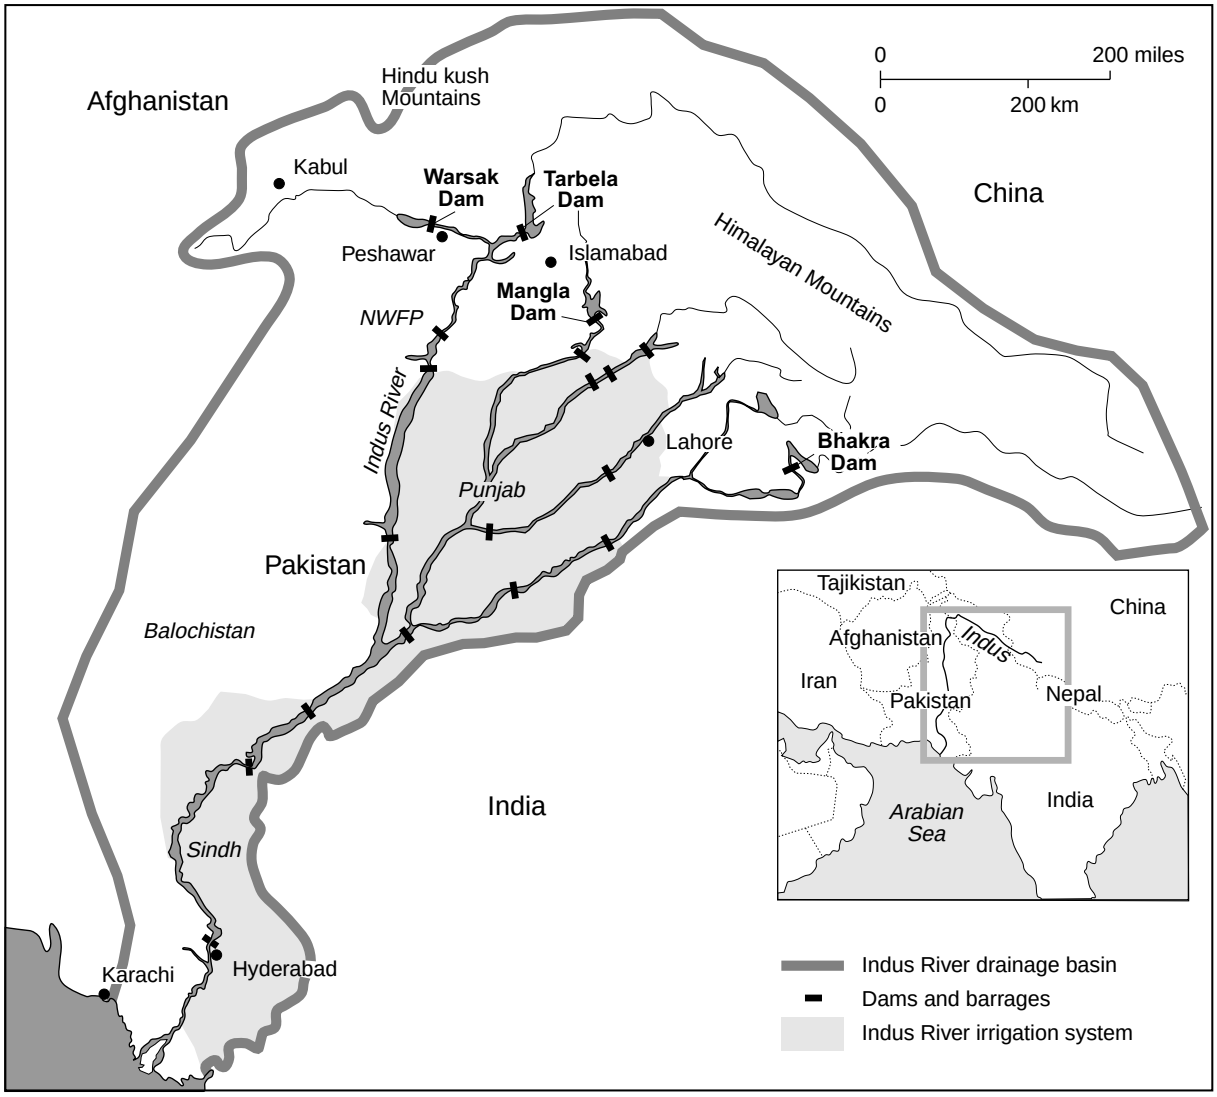

Figure 1 Map to show the major dams, barrages and irrigation areas of the Indus basin

the time, the world s largest earth/rock filled dam. The first large earthfill dam, the Mangla Dam on the River Jhelum was commissioned in 1967. The dam is 120 m high and has a live storage capacity of 5940 million m^3 with a power generating installed capacity of 1000 MW. The Tarbela Dam on the River Indus was completed in 1975 and put into operation in 1976. It is 160 m high and 3000 m long, with an original live storage capacity of 10 740 million m^3 and installed capacity of 3500 MW of hydropower generation (see Figure 2).

The eight inter-river link canals, some the size of large rivers, have a total length of over 622 km and over 400 principal structures with discharge capacities varying between 116 615 $m^3 s^{-1}$. At full capacity, a total of almost 3000 $m^3 s^{-1}$ could be diverted though these canals to transfer water of three western rivers, namely, Chenab, Jhelum and Indus, to canals formerly dependent on the three eastern rivers, the Sutlej, Beas and Ravi. The regularity of the water supply improved significantly after the commissioning of Mangla Dam and the improvement of the various barrages. The original design irrigation water supply rate was 0.21 $l s^{-1} ha^{-1}$, implying that about 80% of the available agricultural land could be used to grow crops in any year (40% in each season). The improved supplies, augmented by supplementary irrigation from shallow ground water sources, enabled the cropping intensity to be increased to over 130%, with about one-third of the land being double-cropped. However, this resulted in significant salinity and water logging problems.

After partition, a further three barrages were also constructed on the River Indus, the Guddu, Taunsa and Kotri Barrages. The downstream province of Sindh was greatly affected by all the changes upstream. Not only was the

Figure 2 The Indus in the foothills of the mountains before reaching the area of the major dams

Table 1 The annual distribution recommended in 1970 in million m^3

Punjab	64 715
Sindh	54 050

Baluchistan	3333
Total	128 665

quantity and quality of water reaching the irrigation channels of Sindh affected by all the diversions and uses upstream, but also water allocations within the Pakistan sector sometimes appeared to allow less than seemed equitable to be diverted to the Sindh. The Sindh Province complained about such inequity. Table 1 shows the annual distribution that was recommended in 1970.

This did not end arguments about distributions. When suddenly, in the Water Accord of 1991, the quantity of usable water was shown to be 144 415 million m^3 instead of the customarily accepted 128 000 to 130 000 million m^3, accusations were made that the new figure was false and fabricated just to keep the people of Sindh believing, on paper, that they were getting 60 000 million m^3 of water.

WATER SHORTAGES AND PRESSURES ON AGRICULTURAL LAND

Successions of wet and dry years have meant great irregularities in the annual water transfers, especially to Sindh. In some dry years, the total flow in the Pakistan Indus system is as low as 111 000 million m^3 with resulting water shortages. Between 1971 and 1990, only two years are said to have adequate flows to meet all irrigation demands. However, the period from 1991 1997 was wetter, with adequate flows in five of the years. In 1999, conditions were much drier. On November 14, 1999, all non-perennial canals of the Sakro Irrigation Division were closed until further notice due to non-availability of water in the Indus River. No water was available for any of the off-take canals originating from Kinjhar Lake. The water shortage would be met by re-adjustment of flow in the canal network to ensure that water supply schemes and standing crops obtained the quantities of water due to them.

The Sindh Province often suffers losses because of acute water shortages during the sowing months of April, May and June. Further problems arise in the lower reaches of the Indus when, sometimes for up to 10 months of the year, there is hardly any flow of water below the Kotri Barrage. Lack of freshwater outflow leads to a risk of intrusion of brackish water that threatens to damage crops in the Thatta District. Any further reduction in discharges below the Kotri Barrage would lead to ecological problems in the Thatta District, including damage to mangrove forests, shrimp cultivation and the palla fishery which earns much foreign exchange for the country.

Pakistan s population has continued to grow rapidly, rising from around 40 million in 1950 to 140 million in 1995, with a doubling to 280 million expected by 2025. The rate of increase has slowed from 3.7 2.8% per year, but nevertheless there are 4 million more mouths to feed every year. Despite movement of people into the cities, with Karachi and Lahore growing by over 4% every year, the pressures on irrigated agricultural land have grown. In the period 1820 1850 Sindh cultivated about 400 000 ha of land and Punjab about 300 000 ha. By 1995, Sindh was cultivating 3.6 million ha and Punjab almost 6.5 million ha. The cultivated land *per capita*, however, has decreased drastically from 0.3 ha per head in 1950 to 0.13 in 1995. There is thus enormous pressure to increase production by whatever means possible, including increased applications of water, fertilizers and pesticides.

Because the early canals were unlined and the drainage system was insufficient to flush salt off irrigated areas, about half the irrigated land has been increasingly affected by salinity; white sterile areas are visible throughout the plains. New solutions to the salinity problems are being sought and new canals are being dug.

SILTATION AND SALINITY

The glacier meltwaters carry huge quantities of fine sediment, some of which contributes to the gradual siltation of the great reservoirs as at Tarbela. Water released from the reservoirs has relatively low sediment concentrations but picks up sediments from the channel walls and beds, quickly becoming heavily laden with sediment. Silt gets deposited in the distributary canals, reducing their capacity. Sometimes contractors have been able to dredge the

canals, and maintain the original trapezoidal cross-section. But other times, they have just built up the canal banks, creating perched waterways above the land. Failures and floods overtop the banks. One of the major construction activities in maintaining the canal system is to rehabilitate these banks.

Waterlogging and salinity are the principal threats to the sustainability of irrigated agriculture in Pakistan. The environmental costs of the salinity problems in the Upper Indus alone are estimated at US$300 million. However, these salinity problems are more severe downstream along the lower Indus in Sindh Province. Drainage is necessary to combat them. The area requiring drainage, inclusive of areas where projects have been completed or are in progress, is about 7.75 million ha, of which 2.36 million ha are covered under on-going projects, 0.9 million ha are in areas with completed projects which require further rehabilitation, and 5.39 million ha are in areas with no drainage facilities.

The methods of disposal of saline effluent currently used in Pakistan are not environmentally acceptable on a large scale or on a permanent long-term basis. Twenty-four of the 33 million tons of salt brought into the Indus basin annually are retained and recycled within the basin: (i) 2.2 million tons are stored in leaky evaporation ponds in the Cholistan Desert which threaten the Pajnand Abbasia Canal on the lower edge of the Upper Indus; (ii) 2.6 million tons are stored in Pakistan s largest inland freshwater lakes (Manchar and Hammal) on the right bank of the Indus, which are now threatened with extinction; (iii) 0.7 million tons are trapped in the Peshawar Valley; (iv) 18.5 million tons are inadvertently stored in the aquifer through direct seepage from canals, watercourses, and drains; and (v) the rest is disposed into the Arabian Sea via the Lower Indus River itself. In the longer term, the only viable option is disposal of the effluent outside the system by developing a national surface drainage system by extending the left bank outfall drain northwards and constructing trans-Punjab link drains.

However, people in the Sindh fear that such a project might have severe impacts on their environment and livelihoods. Potential risks are seen as a rise in the groundwater table, effects on the ecology of the lower Indus, especially below the outfall of the right bank drain below Sehwan, impacts on the drinking water supplies of the cities of Hyderabad and Karachi and possible slow destruction of the Manchar and Keenjhar lakes by eutrophication.

POWER GENERATION AND COMPETITION FOR WATER

Further environmental concerns have arisen over the multi-purpose Kalabagh Dam Project designed to:

- generate 3600 MW of low cost hydro-electric power;
- replace the live storage capacities of Mangla and Tarbela reservoirs lost due to progressive siltation;
- provide additional storage on the Indus for better irrigation supplies to crops; and
- regulate and control flood peaks in the Indus.

Although this project is actively being considered for implementation with the consensus of all provinces, some argue that the Kalabagh dam will not only render large areas close to the dam infertile but will also accelerate soil degradation throughout the newly irrigated areas. If Kalabagh gets built, even more resources for drainage works than the huge amounts already envisaged under the 25-year national drainage plan will be required. The dam will deprive the lower Indus delta of the fertile silt and freshwater required to nourish its land and forests. Already, the silt volume has declined from 200 million t year^{-1} in 1947 to 36 million t year^{-1} in 1995.

IMPACTS OF CLIMATE CHANGE

Climatic change is most likely to affect the Indus irrigation system through increased variation of the monsoons. Doubling of carbon dioxide in the atmosphere, according to some models, could increase average summer monsoon rains by up to 60% (Second Asia Pacific Seminar, 1993). The resulting floods would hit the densely populated areas that produce most of the food, fiber and fodder in the country; they would destroy irrigation systems and crops, especially cotton, which is the main cash crop of Pakistan. Erosion and landslides from the aggravated rains in the mountains would accelerate reservoir sedimentation. However, another frequently used model (Watson *et al.*, 1997), by contrast, foresees summer monsoon rains decreasing, placing heavy stress on winter wheat, the main food staple. In either case, changes in agriculture and redesign of irrigation will be essential.

Although Pakistan is less vulnerable to sea level rise than some of its South Asia neighbors, the Indus delta, south of Karachi, already retreating because of a sharply reduced silt load, could lose up to 25% of its area if seas rise. Saline water would intrude and mangroves would be destroyed, harming fisheries, which account for 30% of exports. Coastal resources will need more protection.

Pakistan s forests now cover less than 5% of the nation s land. Small shifts in average temperature would lead to large shifts in latitude of optimal growing zones for many tree species. Forest resources will need to be preserved and enhanced for their intrinsic timber and biodiversity values, as well as their hydrologic importance. Integration of forest management with other activities, especially agriculture and irrigation, will be important for a sustainable future.

Climate change may shift the balance of cost effectiveness toward investment in the revival of riverine forests with consequential implications for irrigation.

The Indus River thus illustrates the complexities and conflicts in a basin where the great majority of people depend on irrigation. Competition for water, not only at the international level, but also between provinces and between uses (irrigation, power, and urban supplies) aggravates the management problems. Environmental responses to changes in water flows, such as waterlogging through over-irrigation, and soil degradation through salinity, require remedies that lead to new or additional environmental impacts. Saline drainage waters carrying agricultural chemical residues lead to the eutrophication of lakes. Raised embankments along partly silted irrigation channels produce greater seepage into groundwater aquifers, which produce higher water tables, and thus more waterlogging. The challenge in managing such a system is to try to reduce the problems at source and not to merely transfer the problems, silt or salt, farther down the basin and merely substitute environmental impact in one area for environmental impact in another. In the context of the rising Pakistani and Punjabi populations, the challenge is difficult, but the combination of good understanding of the dynamics of the hydraulic and ecological systems and engineering skill has the potential to create a much more sustainable irrigation system.

Insect Pests and Global Environmental Change

Richard Harrington
IACR, Rothamsted, UK

Insect pests are detrimental to mankind through direct competition for food resources and through transmission of diseases to crops, cattle and humans. As such, they cause huge losses of life, especially in poorer countries, and huge economic losses everywhere. Pest status is affected to some degree by virtually every aspect of the environment and thus the effects of environmental change on the impact of pests are of great relevance worldwide.

Whilst certain vertebrates, especially rodents, are important pests (e.g., in Indonesia the rice eld rat causes 17% pre-harvest yield losses, costing US$ one billion per year), invertebrates, and insects in particular, are predominant in terms of their impact worldwide and are the sole focus of this contribution. The label 'pest' cannot necessarily be applied to an insect throughout its range. Whether it is a pest will depend on whether it coincides in time and space with a host, which is of value to humans, and whether, in the absence of arti cial control, it is able to reach population levels that cause economic damage.

WHAT ASPECTS OF ENVIRONMENTAL CHANGE ARE LIKELY TO AFFECT PEST STATUS?

The potential rate of increase of all invertebrates is strongly dependent on temperature, and their survival is impaired at low and high temperatures. Changes in both mean temperature and the value and frequency of extremes can hence have a major impact on the status of pests. Rainfall is also especially critical to survival. Some pests are unable to tolerate extremes of drought, whilst others are disadvantaged by extremes of wetness. Other meteorological variables such as wind speed and direction may influence pest status, but effects are likely to be minor compared to temperature and rainfall. Increased concentrations of carbon dioxide (CO_2) increase carbon nitrogen ratios of plants. This leads to the need for crop pests to eat more in order to obtain adequate dietary nitrogen. This may be compensated by increases in plant biomass or levels of carbon-based defenses (Bezemer and Jones, 1998; Cannon, 1998). It is important to bear in mind the likelihood that responses to changes in any given variable will interact with responses to changes in other variables, not only meteorological (Figure 1). This may produce outcomes that are counterintuitive or synergistic to those expected when considering one variable in isolation. For example, economic

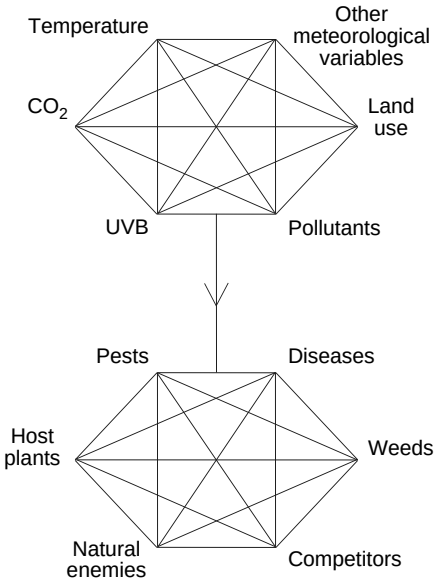

Figure 1 Interactions within and between abiotic and biotic components of climate change

and other considerations may lead to changes in land use and agronomic practice, which override any effect of climate on pest status. Unfortunately, little experimental work has been done to examine the interacting effects of multiple climatic or other environmental variables (Lawton, 1995). For this reason, it is useful to examine long-term datasets on pests, as any trends or relationships associated with environmental variables will occur despite all the interactions taking place in the system. There are few such long-term datasets, but a good example (The Rothamsted Insect Survey) is given later.

POTENTIAL EFFECTS OF CLIMATE WARMING

For insects currently limited by low temperature, some intuitive potential effects of a warmer climate are listed below. The realization, or otherwise, of this potential, will depend on the many complex interactions within and between the biotic and abiotic components of change alluded to above, and on adaptations in the species concerned. For species currently limited by high temperature, the intuitive effects of warmer conditions will often be the reverse of those outlined below.

Increase in Rates of Development and Reproduction

Rates of development and reproduction increase between the developmental threshold and an optimum temperature. In temperate regions, where insects generally experience conditions below that optimum for most of the year, increases in temperature generally increase developmental and reproductive potential. Generation times become shorter, and this often results in more generations in a year.

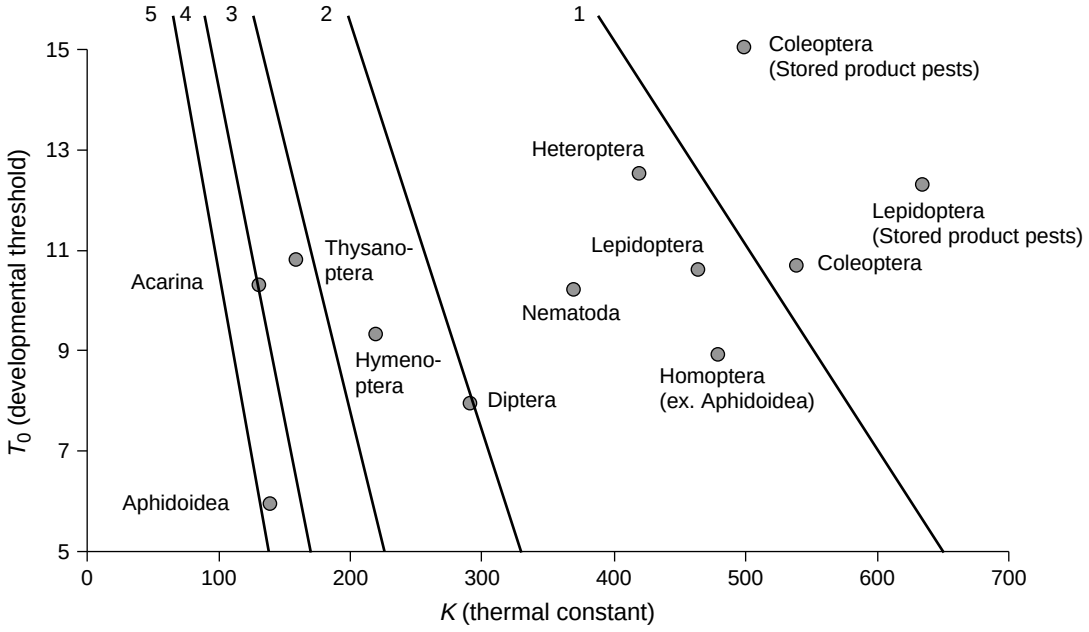

Figure 2 Number of extra generations likely for various insect taxa under a warming of 2 °C. The development threshold is the temperature (deg C) below which no development occurs. The thermal constant is the accumulated number of degree days above that threshold required for the insect to complete a generation (e.g., egg hatch to egg hatch). The lines 1 to 5 show the number of additional generations that each insect group shown is expected to get through in a year with 2 deg warming. (Reproduced with permission from Yamamura and Kiritani, 1998)

Figure 2 shows the expected increase in annual generation number for a range of insect taxa. However, some species are constrained, through responses to other stimuli, to a set number of generations each year, and changes in generation time must be compensated by increases in the duration of a dormancy period.

Extension of the Active Season

Warmer conditions may extend the period during which temperatures are above the threshold for development, reproduction and activity. This may advance the timing of phenological events such as the start of a migration or the progress to the next developmental stage, leading to an earlier completion of a particular activity or developmental cycle. Alternatively it may facilitate increased development or activity at both ends of their normal period of occurrence. The responses of pests will again depend on interactions with other stimuli such as day length. For example, insects often enter diapause in response to photoperiodic cues. Unless the duration of food availability is also extended, pests will be unable to benefit from the increased potential given by changes in temperature alone.

Overwintering Success

Winter mortality as a result of low temperature is a key factor in the dynamics of many temperate pests, especially those that do not enter diapause but continue activity throughout the winter as temperature permits. Warmer winters, or reduction in the frequency of extremely cold periods, may thus improve the prospects for survival of such species. However, species which are quiescent in winter may be disadvantaged by periods of unusual warmth, as activity increases, possibly in the absence of food, and depletes vital energy reserves required for survival until adequate food supplies are available.

Extension of Range

Warmer conditions may be expected to promote the poleward extension of the range of species currently limited by low temperature, or the altitude at which they can survive. In temperate regions, a 1 °C increase in temperature is equivalent to a shift of approximately 200 km in latitude or 140 m in elevation (Parry *et al.*, 1989). At predicted rates of temperature increase, this could mean a potential range extension of 4 km per year in latitude or 3 m in elevation. Whether this occurs will depend partly on the availability of food sources in the new location. Generally, insects have the ability to extend their range far more quickly than do plants, and many pest insects easily have the potential to track climate change. Many plants are unlikely to be able to track climate change, although in the case of crops, if growing conditions are suitable they can, of course, be moved by humans. International trade also offers the opportunity for species to spread. It is not necessarily the case that if a species, which is a pest in one area, arrives in a new location, it will be a problem there as well. The reverse is also true. A species that is not a pest in one location may become one if it establishes, e.g., in an area relatively free of natural enemies or where hosts have not evolved adequate defensive strategies.

In the case of vector-borne diseases, the survival of the pathogen as well as the vector may be limited by temperature. For example, malaria can generally occur where the winter isotherm is around 16 °C as, although the vector can survive lower temperatures, the parasite does not develop below this temperature (Patz and Martens, 1996). Higher temperatures also increase mosquito biting rates and shorten the incubation period of the pathogen. The altitude at which this disease becomes endemic, and other diseases of humans (such as dengue and yellow fever) or of cattle (such as east coast fever) is likely to increase as temperatures increase. Malaria has been observed in unusually warm conditions at high elevations in Africa where it is not endemic, and dengue reached an altitude of 1700 m in Mexico during an unusually warm summer in 1998.

POTENTIAL EFFECTS OF CHANGES IN RAINFALL

In the case of the diseases mentioned above, the larvae of the vectors generally require warm, standing water, and particular problems develop when conditions are both abnormally warm and wet. In East Africa, such conditions may occur in strong El Nino years, and thus if these can be predicted, there is the possibility of taking appropriate steps to control the diseases.

Under conditions of drought stress or ozone episodes, there is a tendency for increased susceptibility of hosts, whether plant, animal or human, to pests and the diseases they transmit. However, this is not always the case and the impact will be determined by the balance of advantages and disadvantages conferred on the pest. In the case of plant hosts, phloem sap becomes more concentrated, leading to it acting as a richer source of amino acids for sap feeders. However, the concentration of a range of secondary plant compounds tends to increase under drought stress, leading to changes in the attraction of plants to a pest. The physical nature of the host plant may also change. Leaves may become thicker or waxier, or may change color, which could make them less palatable or attractive to pests.

Although drought stress often leads to increased susceptibility of hosts to pests, it may also alter relationships between the pests and their pathogens. For example, the spread of fungal pathogens of insects is often impaired by dry conditions, again favoring the pest. Heavy rain may also be detrimental to pests through direct effects on dislodging, but if the pest is able to recolonize its host, dislodging may result in increased disease spread.

CHANGE IN INTERACTIONS WITHIN OR BETWEEN TROPHIC LEVELS

Changes in climate may affect the rates of development of pests and their natural enemies differently, leading to variations in control potential. For example, it has been shown that ladybirds tend to control aphids better at higher temperatures as the consumption rate of aphids by ladybirds increases more rapidly with temperature than does the reproductive rate of aphids.

Changes in climate may affect interactions between species within or between trophic levels by disrupting synchrony. For example, many pests are dependent on synchrony between time of bud burst (or flowering) and the emergence of feeding stages. Surprisingly, there is little evidence of feeding stages being cued directly by bud burst. Instead, similar external cues often affect both bud burst and the appearance of feeding stages. However, the requirements are often complex combinations of day length and specific combinations of periods and extents of chilling and warming. Requirements are rarely identical for the plant and pest, and have developed over evolutionary time. It is quite conceivable that under the current rapid changes in climate being experienced, synchrony between trophic levels could become decoupled as a result of subtle differences in the impacts of changes on the timing of cues determining the phenology of constituent species (Harrington *et al.*, 1999).

Spatial synchrony may also be compromised by climate change. It is known from studying the fossil record that spatial associations between species are generally transient. This is likely to be due to the improbability of any two species sharing an identical set of environmental requirements and responses to given combinations of biotic and abiotic factors. Thus, as these factors become dissociated, so do species assemblages. The potential for such dissociation has been shown in laboratory studies on fruit flies. Flies were reared in a series of linked incubators in order to provide artificial temperature clines. The outcome of competition between three species of fruit fly depended on the temperature range and whether or not a parasitoid species was present. Temperature determined the outcome of the interaction between the fruit flies and their parasitoids, and different species of fruit fly dominated or became extinct accordingly (Davis *et al.*, 1998).

ADAPTATION

The extent to which pests are able to adapt to environmental change will depend on the genetic diversity of the population, the distribution of tolerant phenotypes, migratory tendency and competition. Genetically diverse populations are more likely than homogenous ones to include individuals better adapted to new conditions than the bulk of the population. In such cases, it may be expected that the better adapted genotypes will gradually displace those which are less tolerant of change. Adaptation will also be aided by mobility, as the more mobile a species, the greater the probability of suitably adapted founder individuals arriving from elsewhere.

OBSERVATIONS FROM A LONG-TERM DATASET

Because of the complex interactions that must be considered when assessing the potential impacts of environmental change, combined with interspecific, intraspecific and even intraclonal variability in responses, attempts at generalization will be largely unproductive. Process-based modeling can help to demonstrate the combined effects of some of these interactions, but it is unrealistic to expect to be able to parameterize all the relevant interactions in any system. Long-term datasets can be useful in demonstrating impacts of environmental change, and in validating predictions. However, predictions based on long-term datasets suffer from the inevitability that the range of values of relevant variables at the time for which a prediction is being made, will fall outside the multidimensional cluster of values experienced during the construction of the relationships used for that prediction. Such extrapolation may lead to erroneous predictions.

Some trends that may be due to environmental changes are apparent in a comprehensive set of data on aphids (Woiwod and Harrington, 1994). This group of insects may be expected to be amongst the most sensitive indicators of temperature change because of their low developmental thresholds and short generation times (Figure 2). They are predominantly pests of temperate crops and, as such, tend to be limited more by low than by high temperature. Expected increases in temperature are, therefore, intuitively likely to benefit these insects.

The Rothamsted Insect Survey has been operating a network of suction traps in the UK since 1964 in order to monitor flying aphids. The traps are emptied daily and all aphids identified. Similar traps operate throughout much of Europe

Figure 3 Location of suction traps for aphid monitoring in Europe. Seventy-five sites in 19 countries; shaded countries are EU members

(Figure 3), providing what is probably the most extensive, standardized dataset for any terrestrial invertebrate group. For many species at many sites, there is a remarkably strong relationship between the timing of the start of the spring migration and winter temperature (Figure 4). The milder the winter, the earlier the migration. This is probably due to a combination of more rapid development and reproduction and reduced mortality due to low temperatures. This conclusion is backed up by the fact that aphids which pass the winter as an egg tend to show very much weaker relationships between migration time and winter temperature than those that pass the winter in the active stages. Eggs are very much more hardy than the active stages and are hence less affected by low temperature. However, they are in diapause and, unlike the active stages, cannot take advantage of warm periods with a burst of development and reproduction. Thus, biological expectation shows through in these purely statistical relationships. The clear implication from this is that milder winters will result in earlier aphid migrations and hence in earlier threat to crops. The extent of change in economic damage will depend partly on the extent of change in the planting and emergence times of crops. As an approximation, the aphid species examined show an advance in the timing of the spring migration of about fourteen days for every degree centigrade rise in temperature. A rise in numbers trapped during the critical spring and early summer period is also found. At this time, crops tend to be particularly sensitive to damage caused by aphids through removal of plant sap and through transmission of plant viruses.

Plant viruses add another layer of complexity to the potential impact of climate change on problems caused by aphids. The extent of the complication can be understood by considering the example of barley yellow dwarf virus

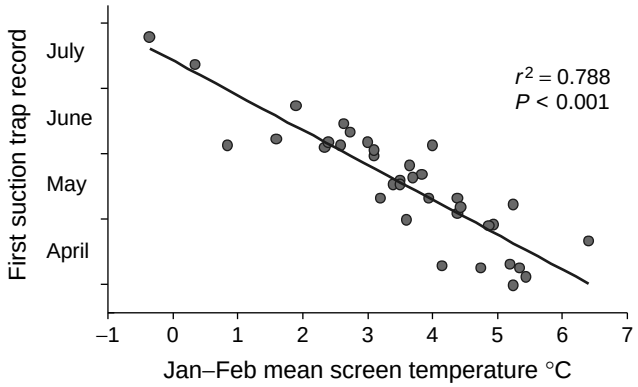

Figure 4 Relationship between winter temperature and the time of the start of the migration of the peach-potato aphid at Rothamsted, UK

(BYDV) in the UK. The virus is important worldwide and has a range of grass and cereal hosts and a range of strains, which are transmitted with different efficiencies by different vector aphid species. One strain is particularly common in maize and is transmitted efficiently by the corn leaf aphid. Maize is a minor crop in the UK but with climate warming, may become more viable and hence more widespread. The corn leaf aphid is also rare in most parts of the UK in most years, but the expansion of maize growing will encourage spread of the aphid. The aphid has no hardy egg stage and an increased frequency of warm winters will further aid its survival. At higher temperatures, other aphids become capable of transmitting the maize strain of BYDV to cereals such as wheat and barley. Therefore, warmer conditions, through their effect on interactions between host plants, aphids and viruses may render the maize strain of BYDV important in wheat and barley for the first time in the UK.

The long-term nature of the aphid dataset makes it possible to look for trends with time that may be attributable to climate change, as well as trends with meteorological variables themselves. In an analysis involving five species in the UK, there is evidence for an advance in phenology of 3 6 days over a 25-year period during which the temperature rose by 0.4 °C (Fleming and Tatchell, 1995).

RESPONSE OPTIONS

Whilst there is good reason to expect pest problems to increase, there is a danger that over-emphasizing the risks will lead to a false perception of current problems and an increased prophylactic use of pesticides. Control programs which include monitoring and take account of ecological and economic factors in determining the need for using chemicals are crucial to prevention of a vicious circle of increased reliance on pesticides and increasing resistance to those pesticides. Pest management decisions also need to be integrated into the broader context of total resource management. For instance, pesticides may reduce food sources for birds and other animals of conservation interest.

It is also important to realize that the efficacy of control methods may change as environmental conditions change. It is well known that the persistence of many conventional pesticides is very reliant on temperature, rainfall and soil moisture content. Newer technologies are not immune from such considerations. For example, cotton that has been genetically modified to include a bacterial gene that produces an insect toxin is more efficacious when grown at higher temperatures. No doubt examples could be found where the reverse is true, and it cannot be assumed that any given control method will be equally effective under the environmental conditions of the future.

Inter-basin Transfer (IBT) for Water Supplies

Geoff Petts
The University of Birmingham, Edgbaston, UK

Historically, water availability constrained the location and size of settlements. Across the globe, population growth and urban development in drylands is placing considerable strains on water resources requiring water transfers from relatively humid areas, often supported by water-storage reservoirs. Even within relatively humid regions there are demands for water transfers to meet the demands of urban populations. Today, desert cities in the USA such as Phoenix, AZ, and Las Vegas, NV, and Adelaide in Australia depend upon the importation of water from distant regions, while in many areas of the world, modern industrialized agriculture is heavily reliant upon IBT schemes. IBTs have become a feature of regional water supply infrastructure and are a key component of river regulation schemes discussed elsewhere in this volume.

IBTs have been de ned as (Davies et al.*, 1992): the transfer of water from one geographically distinct river catchment or basin to another or from one river reach to another. Impacts include arti cial ow levels in the donor (reduced ows) and recipient (augmented ows) streams, a change of water quality in the recipient stream, and the breakdown of biogeographical barriers to the dispersal of animals, plants and their associated diseases. The manipulation of river ecosystems through IBTs is occurring on a global scale and the conservation of riverine biodiversity is being severely compromised (Davies* et al.*, 2000).*

A HISTORY OF IBT

Major river diversions have been attempted from at least the 17th century. Many were built for navigation, requiring reservoirs to maintain water levels in summit sections, or for flood protection. One of the most ambitious attempts was the 36 km-long navigation canal to link Lake Neuenberg and Lake Geneva in Europe (Vischer, 1989). This was notable in that it would have crossed the great European water divide between the catchments of the Rhine and Rhone; 46 locks were required from the summit to Lake Geneva, 80 m below. Begun in 1638, the project ran out of funds and was never completed.

TRANSFERS IN THE UK

Early transfers of water utilized the simple observation that water could be transferred easily under gravity along relatively low gradient channels cut across the contours of hillslopes, over a watershed to a town in an adjacent river basin. In the UK, the first water-supply reservoir was constructed at Whinall in Scotland to supply the rapidly urbanizing center, Greenock. Over the next 40 years, earth dams over 15 m high were built in England as part of the increasingly sophisticated water systems to power the industrial revolution and to provide water supplies to such industrialized areas within the southern Pennines (Figure 1). Transfers from the catchwater basins left their streams dry during periods of low flow. In most cases, the transferred waters were used within an urban area before being discharged as untreated wastewaters into the receiving streams. Thus, between 1848 1884 a chain of five separate reservoirs were constructed to exploit the resources of the river Etherow. This Longdendale Scheme supplied water by gravity to Manchester. The dams command a catchment area of 78 km^2 and have a combined capacity of about 15.5 million m^3. However, even at this early time, storage in two of the reservoirs was allocated exclusively to maintain a compensation flow in the Etherow to meet the needs of mill owners downstream.

Larger schemes of water transfer were advanced towards the end of the 19th century. Parliamentary Bills enabled the construction of large reservoirs in the Vyrnwy and upper Wye valleys of Wales to supply Liverpool (1880) and Birmingham (1892), respectively. Both schemes involved dams over 40 m high and water transfers of more than 100 km. Vyrnwy, with a capacity of nearly 60 million m^3, was the largest reservoir in Europe at the time. Later, in 1919, proposals were advanced to transfer water from Haweswater in the English Lake District to Manchester. Today, of the 1310 streamflow gauging stations in the UK, 40% are significantly affected by IBTs for water supply, either by abstraction from a reservoir or river intake (26%) or by effluent return via sewage works or industrial works (27%).

At the regional scale, supply and demand are inversely correlated. West east contrasts in the UK are dramatic: rainfall is above 750 mm in the west, rising to over 1500 mm in the headwater catchments, and below 750 mm in the east, falling to about 500 mm in some areas; population densities are about 250 persons km^{-1} in the west rising to nearly 500 in the east; and forecasts of the public water supply deficit for 2021 range from a continuing surplus in the west to a deficit of over 250 megaliters per day (Mld) in the east under a high-use scenario. West-to-east water transfers offer a solution to any water deficit in eastern England (Figure 1). The River Severn is a typical donor river being heavily regulated, by reservoirs in mid-Wales and by the Shropshire Groundwater Scheme. The river supports abstractions of 2300 Mld approximately 500 Mld for the city of Birmingham. The River Trent receives over

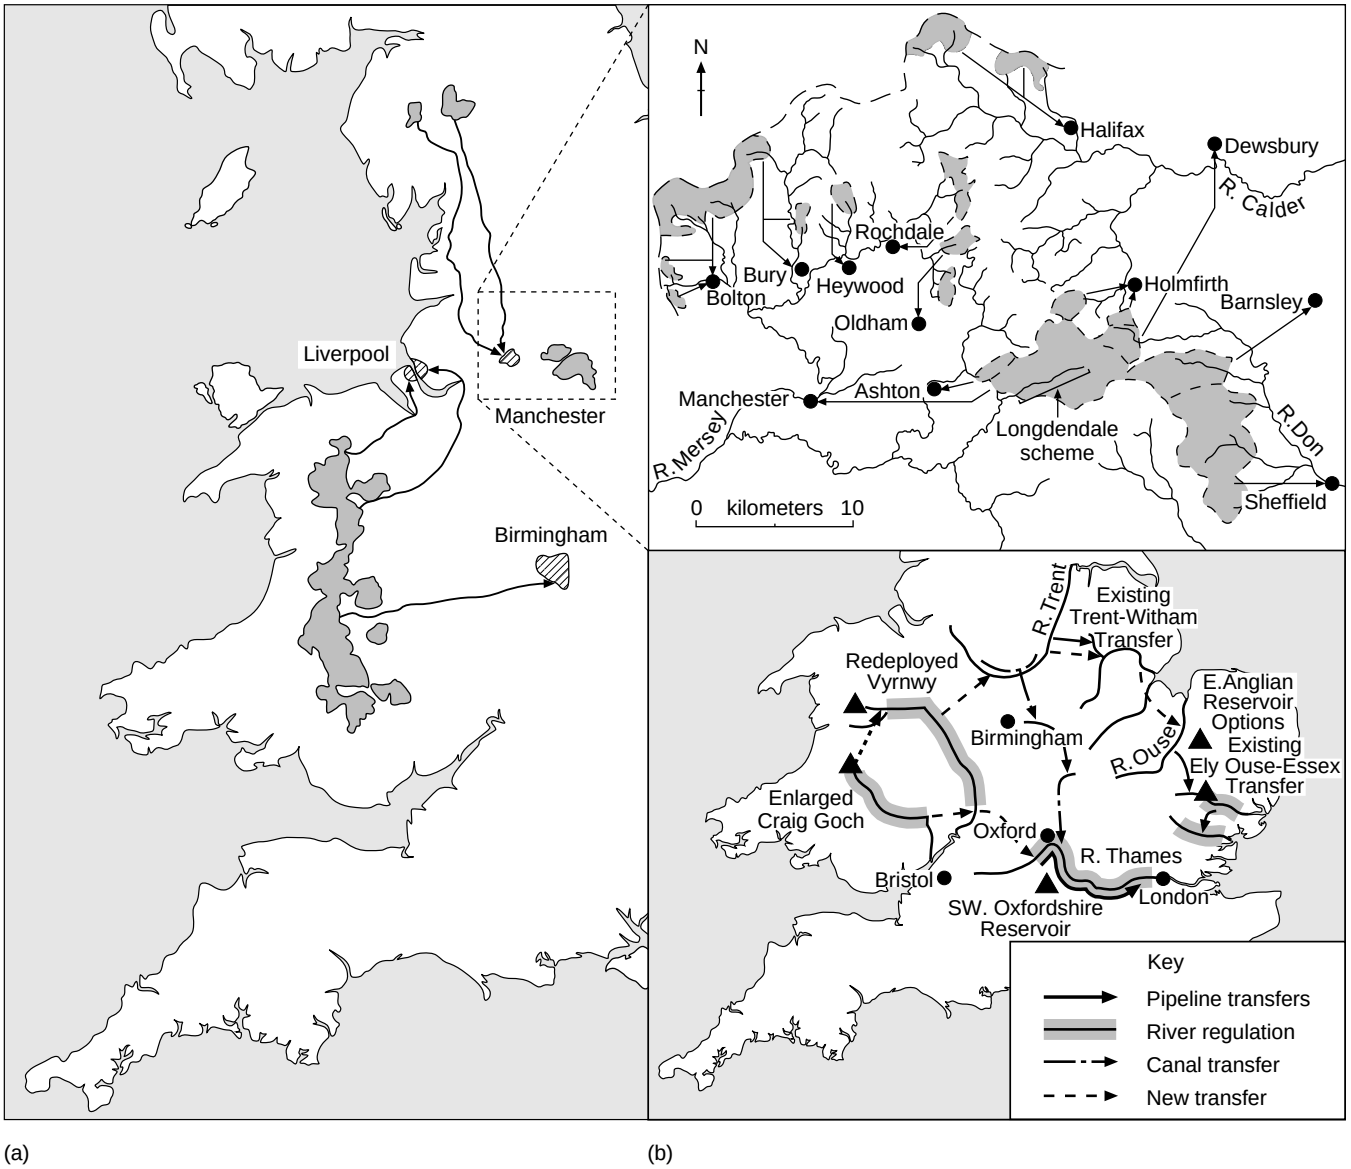

Figure 1 (a) IBTs to supply Central and Eastern England: 19th century catchwater schemes and associated transfers in the southern Pennines and longer-distance schemes to supply Manchester and Birmingham; and (b) possible future scenarios to meet the needs of the growing population in South-east England

500 Mld of effluent from Birmingham s two major water recovery works, and this has markedly altered the pattern of flows in the river, especially during dry summers when artificial inputs represent up to 130% of the natural flow! Following the improvements in water quality, one solution to the deficits projected for Eastern England is to further exploit the enhanced flows in the River Trent through new transfers.

GLOBAL EXAMPLES

The relatively small-scale IBTs that have been developed to counteract regional inequalities of water resources are mirrored by much larger schemes, both existing and proposed, worldwide (Golubev and Biswas, 1985; Petts, 1994). The exploitation of catchwaters to increase the water yield to a storage reservoir is widespread practice, especially for hydro-electric power generation. In Switzerland, the Grande Dixence Scheme, completed in 1965, links intakes on mountain and proglacial streams by 90 km of tunnels to the Lac des Dix, thereby increasing the reservoirs catchment area to 357 km^2 and its water yield to about 420 million m^3. La Grande Riviére hydroelectric complex in Quebec provides a second example: its catchment has been increased by 43% by IBTs from adjacent basins.

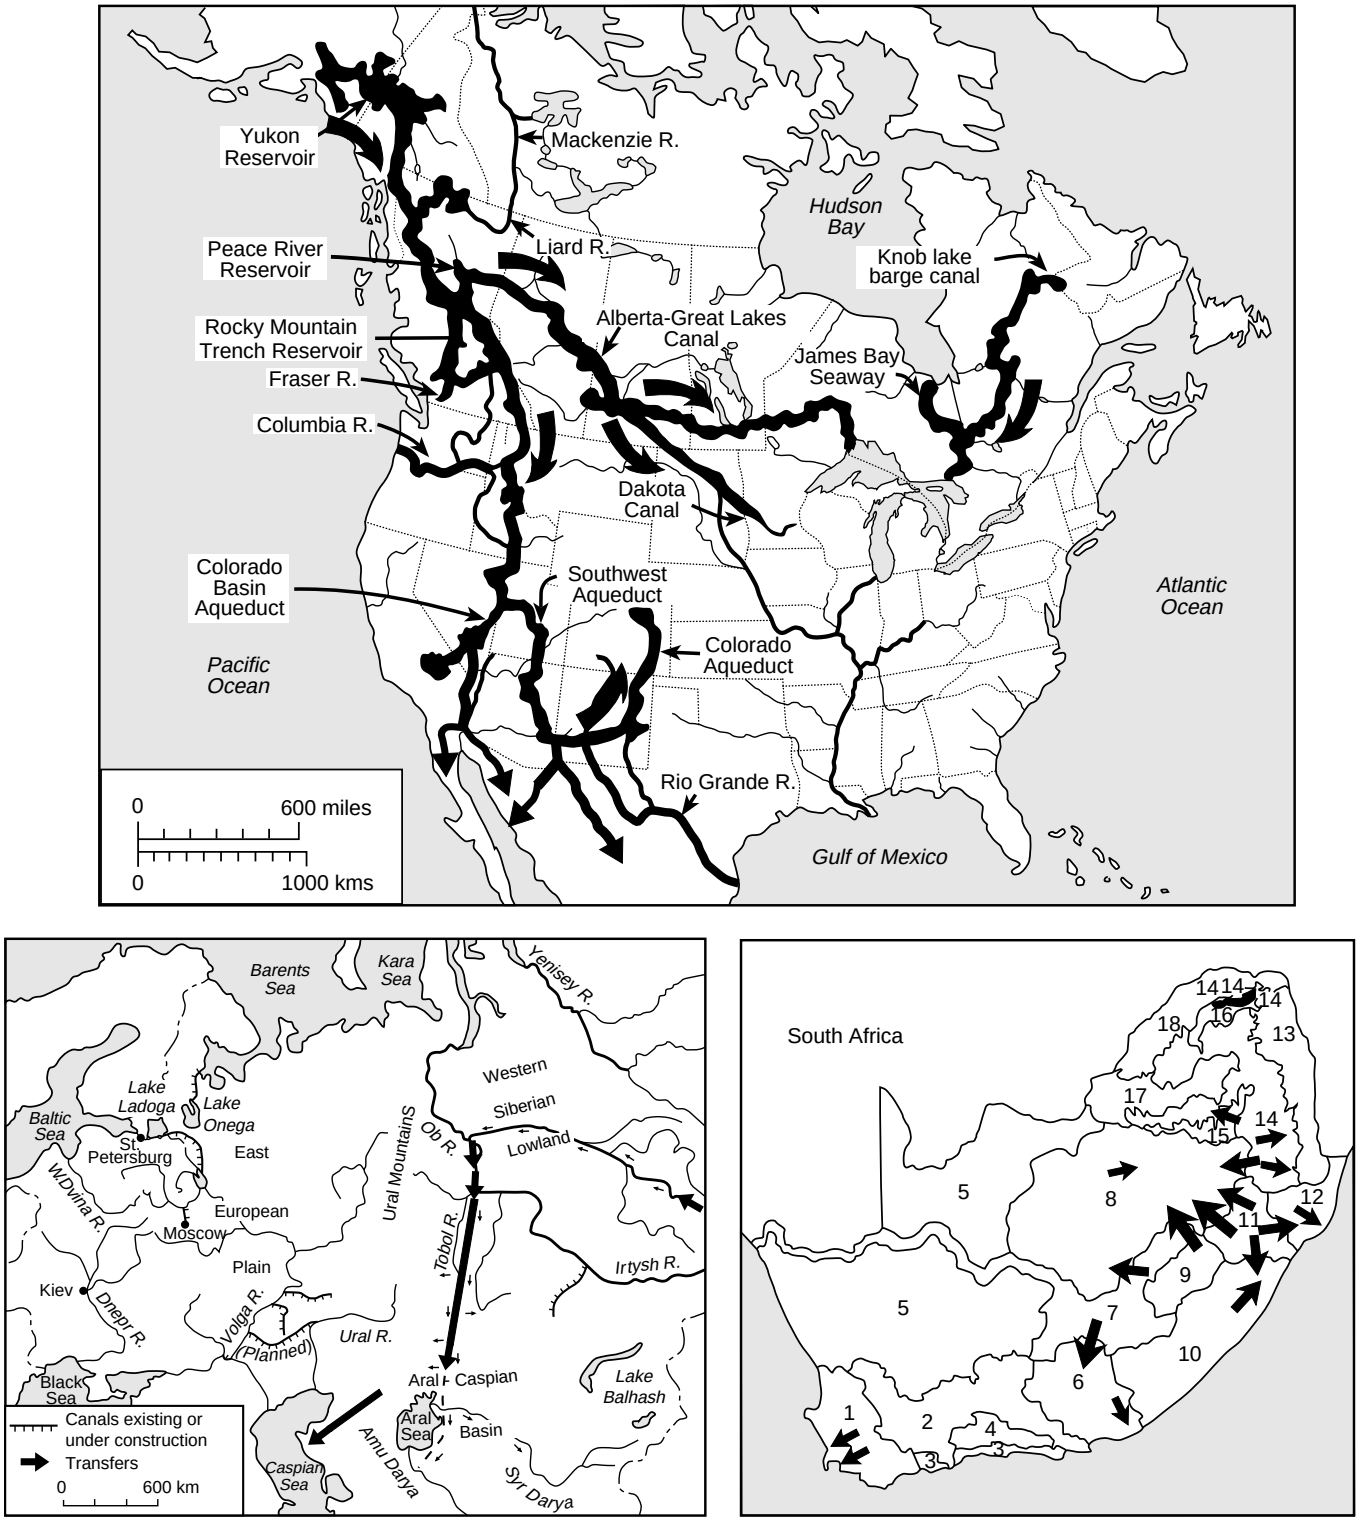

Figure 2 Examples of IBTs plans for North America and Siberia-Central Asia, and inter-eco-region transfers in South Africa (eco-regions are labeled 1–18). (Reproduced from Davies *et al.*, 2000)

Schemes to meet regional water deficits include California s State water project built between 1963 and 1973, which diverts flow from better-watered northern areas to the drier central and southern parts of the state. Again the scheme involves water storage reservoirs and river regulation in the north, and a 715 km aqueduct and pumping stations to redistribute the water. Plans for an even larger scale, long distance IBTs have been proposed. One of them was the North American Water and Power Alliance (NAWAPA) scheme (Figure 2), put forward in the 1960s as a comprehensive solution to North America s water supply problems. The project was designed to transfer 136 km^3 of water each year and would have required 240 reservoirs the largest impounding 693 km^3 of water and the highest dam would have been 543 m high! However, it is now highly criticized, especially in Canada and is unlikely to proceed.

A similar gigantic solution to regional water shortages has been proposed for Central Asia (Figure 2). The expansion of irrigation agriculture and population growth in the Aral Sea basin has led to a severe water deficit, manifest by a 20 m fall in sea level since 1960 causing the shoreline to recede by over 100 km in places (*see* Aral Sea, Volume 4). Large-scale, long distance water transfers have been considered since the 1930s as a solution to water deficiency in the region. The Siberian Rivers Diversion Project of the 1970s proposed a north-south, 2500 km-long, transfer of up to 200 km^3 of water each year. At the present time, such large-scale proposals have not been developed.

ECOLOGICAL IMPACTS

River basins are often seen as the fundamental units of landscape, the watersheds that divide basins effectively separate one river system from another. Within a catchment, water flow from headwaters to mouth with declining altitude creates a succession of in-stream and riverine habitats associated with a longitudinal sequence of animals and plants. The transfer of water between basins can have a range of impacts upon both the donor and receiving rivers, not least by disrupting the natural pattern of ecological change (Davies *et al.*, 1992; 2000).

Abstractions from donor streams can cause these rivers to become dry, especially during summer periods. Thus, the La Grande Scheme in Quebec caused about 1000 km of donor river to experience reduced flows. It was estimated that the proposed Siberian Diversion Project would have reduced levels along the River Ob by between 1.5 and 2.5 m, reducing the area of floodplain and severely impacting fish production which is dependent upon floodplain habitats for spawning and feeding for juveniles, and extending the duration of the winter freeze in the lower river and Ob Gulf. On other donor rivers, flows are augmented by reservoir releases, often eliminating important marginal habitats, such as water-water shallows for fish fry or mud banks for wading birds. Similar impacts can arise in the recipient streams, but flow releases can be pulsed and seasonal, causing additional stresses on biota. A suite of water quality and physical changes are coupled to the releases, including changes in nutrient concentrations and altered thermal characteristics.

Physical processes drive ecological processes across a range of spatial scales from the region to the basin, the reach and the habitat patch. IBTs break down the barriers between regions, basins and reaches, and water transfers can cause the passive transport of animals and plants across natural divides.

Large-scale transfers can cross divides between eco-regions. Climate, geology and landscape history control the physical processes that drive ecological processes and the patterns of biological productivity and diversity. Consequently, river basins can be grouped geographically into eco-regions, each with distinctive ecological characteristics (Omernik and Bailey, 1991). Thus, in South Africa 18 aquatic eco-regions have been defined using biotic distributions. IBTs have crossed divides between eco-regions especially in the east (Figure 2) and particularly involving four donor eco-regions (Orange, Montane, Tugela and Northern Uplands) and four receiving eco-regions dominated by the Vaal, but also including the Drought Corridor, Eastern Seaboard and St Lucia Complex. In Australia, there are 16 IBTs that cross eco-region boundaries and in the USA, 111 IBTs cross water-resource sub-regions (Davies *et al.*, 2000).

The loss of species through altered flows in the donor and recipient streams, the mixing of gene pools, the risks associated with the transfer of non-indigenous species, disease vectors, parasites and invasive species, are significant but as yet there is little information available. In one example, from South Africa, fish species passed through an 82 km-long tunnel between the Orange River and the Great Fish River where they successfully established themselves (Cambray and Jubb, 1977).

Since the 1970s, the rising concern for the environment and the realization of the huge cost of large-scale IBTs has dampened enthusiasm for them. Nevertheless, the looming water crisis, with many areas of the globe expected to be suffering water stress by the middle of this century, may lead to renewed enthusiasm for IBTs. Carefully planned operational rules governing the timing and volumes of abstractions and releases, and rate of change of flows can mitigate many ecological impacts but, as yet, there appear to be no technologies available to prevent biological transfers. It has been argued (Davies *et al.*, 2000) that biological transfers through IBTs will not only severely impact the speciation process

but also evolution itself; an impact, they suggest, that may be as serious as the release of genetically modified organisms!

Analyses of the possible effects of climate change on water supply systems suggest that most systems could be highly vulnerable to changes in climate inputs and that a small change in inputs could lead to large changes in system performance. The magnitudes of such changes vary greatly according to the scenarios used. Isolated single reservoir systems, including those dependent on small-scale IBTs, such as the 19th century works in the English Pennines, could be the most vulnerable. Larger, integrated schemes, using a variety of sources, including major IBTs, would be more resilient, especially if water demand management became more effective.

International Rice Research Institute (IRRI)

R D Hill
The University of Hong Kong, Hong Kong

Founded in 1960, the Institute is located at Los Baños, south of Manila, Philippines. It continues to play a major role in researching technical aspects of wet rice production and management.

IRRI has played a notable role in raising rice crop yields at periods when Asian populations, especially, were growing rapidly and where the prospects for increasing production to meet basic food needs by expanding the cultivated area were limited by lack of suitable land and by high costs of developing the little that there was.

The Institute was founded in 1960 at the initiative of the Ford and Rockefeller Foundations whose directors were well aware of the economic wisdom that foresaw burgeoning populations and a potentially serious food supply crunch with rice yields stagnating at around 1.5 tons ha^{-1}, except in Japan and other temperate-country producers. They were equally aware of the possibility of national strife/revolutions and their appeal to hungry people; and they saw green revolutions as an alternative. Six years after the Rockefeller Foundation s George Harrar and Warren Weaver proposed a rice research institute, it became a reality, occupying its present site at Los Banos, near Manila. Its initial success in rice breeding and management led to support from governments internationally, whose representatives sit on the corporate Board of Directors responsible for overall policy and control.

The need for rapid expansion of production at first led to decisions to concentrate upon the relatively easy-to-solve problems of raising yields by improved water control, controlling pests, and enhancing fertilizer response by designing a series of high-yielding varieties that were to change the very architecture of the plant. Later work aimed to enhance grain quality without sacrificing yields, still with the aim of matching environment to the plants as much as the plant to the environment (some would say more). Consequently some of the more intractable problems have received less attention. Improving drought resistance is inherently difficult in rice, for it is by origin a swamp plant. Varieties grown on flat land fed only by rainfall and trapped water have been difficult to improve, even though globally, most rice-farmers occupy this environment. IRRI has not been notably successful in developing cold-tolerant varieties, in which field Japanese breeders excel, or in

breeding types that give good yields where grown in brackish water, an area in which Chinese breeders have succeeded. One persisting criticism of IRRI s approach is that some of its improved varieties require rather precise conditions to achieve good results, with very poor yields should those requirements not be met, whereas traditional varieties, though low-yielding, can cope better with the vagaries of the weather.

Further criticisms are that improved rices mainly benefit relatively wealthy farmers, who alone can meet the greater cost of inputs, and that the benefits of greater output flow mainly to those supplying inputs such as insecticides, herbicides and fertilizers. It is also argued that the rice HYV (High Yielding Variety) package has led to environmental damage, seen for example in increased eutrophication, reduction in the quality and quantity of rice-field fish and in increased vulnerability to new kinds of pests as a result of the reduction of biodiversity consequent upon the use of single varieties over very large areas.

In response to these criticisms, it may be remarked that research, like much else, is driven, at least in part by basic economic considerations. The pay-off, in the form of keeping food production in Asia substantially ahead of population growth for four decades, has been a substantial one. It is also a moot question whether any major technological intervention in agriculture can be socially neutral. Eutrophication and soil toxicity are partly matters of over-use of fertilizers, herbicides and pesticides, in much the same way as improper use of agricultural chemicals poses health risks to users. Where double cropping of rice replaces single cropping, conditions certainly become adverse for rice-field fish and they may become positively dangerous to eat where chemicals are overused. Rice-field ecology is unquestionably modified by IRRI varieties and new techniques. Once relatively minor pests have become major the brown planthopper is an example. But further work has shown that it is possible to breed a degree of resistance into rice plants in the same way as it is feasible to improve fertilizer response genetically or to create varieties more tolerant of low or high temperatures at flowering. The number of rice HYVs has increased greatly since the days of IR6, the Institute s first major release some 40 years ago, so that biodiversity in HYV rice is steadily improving. This is much assisted by the Institute s collection of rice genotypes, many no longer grown.

The Institute s tasks are thus far from completion. While human population growth rates have fallen in Asia, the number of new stomachs to be filled is still many millions a year. Competition for the best rice land from urban growth, from other, more remunerative forms of rural production is increasing, so that the Institute s role in environmental change continues and is as pressing as ever.

Irrigation: Environmental Impacts

Peter Crabb
Australian National University, Canberra, Australia

Irrigation is the arti cial application of water to soil, to supplement natural precipitation and so overcome any soil moisture de ciencies that would inhibit plant growth. It can permit crop production where none would be possible under natural conditions. It can extend the natural growing season, ensure that moisture is available at critical periods in plants' growth cycles, and increase both the quantity and quality of crop production. Because irrigation alters the length, characteristics and effectiveness of plants' growing periods, it creates an arti cial environment. In turn, new agricultural landscapes are created, with new socio- economic communities, their particular nature depending largely on the crops that are grown. The new landscapes are in marked contrast to adjoining areas of non-irrigated agriculture, or no agriculture at all. Irrigation has been described as a catalyst for rural change. Few human activities have brought about more environmental change than irrigation, locally, regionally and globally. It is a form of environmental change with a long history, making possible population growth and urban development, but in turn resulting in considerable environmental damage.

THE GROWTH AND GLOBAL EXTENT OF IRRIGATION

Irrigation is an ancient activity, dating back perhaps 8000 years at Jericho in the Jordan Valley (Hillel, 1994). It was

the basis of many of the earliest hydraulic civilizations in the Tigris Euphrates, Orontes, Nile and Indus Valleys. For the Sumerians on the Mesopotamian Plain, irrigation made possible increased food production and the development of the world s earliest urban society. Irrigation was critical to the pre-Hispanic civilizations on the coastal plain of Peru, in Mexico, and in what is now the USA states of New Mexico and Arizona. Whilst the irrigation systems were simple, their development, maintenance and water allocation arrangements required social stability and a high degree of communal organization. This was perhaps even truer for the terraced irrigation areas found in many Asian countries. This remains a valid observation, both in long-established societies, such as those of Japan and many Southeast Asian countries, and in the more recently established irrigation areas.

By the year 1800, an estimated 8 million ha of land were being irrigated. Over the next 100 years, the figure increased to over 40 million ha, much of the growth being due to the construction of large projects in the Indian sub-continent. The real expansion in the world s irrigated area, the *Blue Revolution*, was from the 1950s to the early 1970s, with the annual growth rate of between 2 and 4% being higher than that of the world s population. On a *per capita* basis, the area of irrigated land reached its peak of 48 ha per 1000 people in 1979. Since then, the situation has been reversed, with the irrigated area growing at no more than 1% a year and, with continued population growth, a continuing decline in the *per capita* figure (Table 1). Estimates of the United Nations Food and Agriculture Organization (FAO) indicate that in 1995, there were 258.9 million ha of irrigated land in the world. This was 17.3% of the total area of land classed as arable and under permanent crops, some 1499.9 million ha.

Table 1 Global expansion of irrigated land and population since 1800[a]

Year	Irrigated area, in millions ha	Population, in billions	Irrigated area in ha per 1000 people
1800	8	1.00	8.0
1900	40	1.50	26.7
1930	80	2.00	40.0
1950	94	2.50	37.6
1961	139	3.07	45.3
1965	151	3.35	45.1
1970	169	3.71	45.5
1975	190	4.08	46.6
1979	209	4.37	47.8
1980	211	4.45	47.4
1985	226	4.86	46.5
1990	239	5.30	45.1
1995	255	5.69	44.9

[a] Ghassemi *et al.* (1995); Rhoades (1997); FAO (1987).

Among the individual countries with one million ha or more of irrigated land in 1995 are some very high figures, especially for a number of developing countries (Table 2). However, lower figures in both developed and developing countries must not be taken to suggest that irrigation is of less importance. There are very few countries where irrigation is not undertaken.

Asia has 179 million ha of irrigated land, some 69.1% of the world s total; India, China and Pakistan alone account for 121.1 million ha, 46.8% of the world total (*see* Water Use: Future Trends, and Environmental and Social Impacts, Volume 3). In North and Central America, the largest areas are in the United States and Mexico. In Africa, much of the irrigated land is in the Nile basin, notably Egypt and Sudan. Irrigation is widespread in Europe, but particularly in countries in the south east of the continent and those bordering the Mediterranean. Brazil, Peru, Argentina, and Chile are the South America countries with the largest irrigated areas. Australia is one of 24 countries with over 2 million ha under irrigation. However, there is considerable variation from one country to another, especially in terms of irrigated land as a percentage of all arable and permanently cultivated land.

The area of irrigated land is an indirect indicator of the extent and growth of water use by agriculture. Globally, agriculture accounts for some 65% of withdrawals and 87% of consumption, with irrigation accounting for all but a small portion. Unfortunately, data on actual water use are unreliable in many ways and have to be treated with extreme caution (Engelman and LeRoy, 1993).

THE BENEFITS DERIVED FROM IRRIGATION

Globally and nationally, the greatest benefit of irrigation is its contribution to the production and security of food supplies. It is estimated that some 36% of the world s crop output comes from the 17% of the total arable area that is irrigated (Upton, 1994), including almost 30% of all food and 46.5% of all grains. As Postel (1993) noted, irrigation is now a cornerstone of global food security. The higher yields farmers ••• get with a controllable water supply [are] vital to feeding millions added to our numbers each year . For many countries, such as China, India, Indonesia, Israel, Japan, North and South Korea, and Peru, irrigation supports over half of domestic food production; in Pakistan and Egypt, 80 and 100%, respectively. The importance of irrigation for domestic food production is reflected in the fact that, based on FAO data, close to 60% of the world s total irrigated area is devoted to paddy rice (FAO, 1987; Jones, 1995, 112 113). It is also seen in the development of irrigation for domestic food supplies and export commodities in water-scarce countries in the Middle East and North Africa. In some developing countries, such

as Bangladesh and Pakistan, irrigated commodities provide the bulk of their export earnings (Ghassemi *et al.*, 1995).

Whilst the contribution of irrigation to food supplies and the alleviation of poverty is particularly evident in the developing world, irrigation s wider benefits are perhaps more clearly evident in the developed world. On farms, there is greater diversity and stability of production. The increased quantities and often higher value agricultural production support processing and farm service industries, such as the manufacture, installation and maintenance of irrigation equipment. High-value agricultural commodities frequently require other high-value farm inputs, such as planting and harvesting equipment, fertilizers, and pesticides. Their provision creates additional employment and larger rural communities. In the Canadian province of Alberta, only 4% of its arable land is irrigated, but this accounts for 20% of its agricultural production. Of the overall economic benefits derived from irrigation, Canadian farmers receive 15%, with the remaining 85% shared by local communities, the province, and Canada as a whole. Twenty years ago, an Australian study indicated that in New South Wales, each $1.00 (AUD (Australian Dollar)) of irrigation farm output and income generated $5.00 worth of output and income beyond the farm.

Irrigation development often brings associated benefits, such as hydro electricity generation, flood mitigation, and opportunities for recreation. Whilst it is difficult to put accurate values on many of these benefits, some estimates can be made: for example, sport fishing in Alberta s irrigation waters is worth some $17 million (CAD (Canadian Dollar)) a year.

Many governments have seen such rural development and the associated multiplier effects as the key benefit of irrigation and the major reason for their direct involvement. Especially in the past, government influence in irrigation was all-pervasive in many countries, and not simply in terms of the large subsidies provided for the establishment and operation of irrigation schemes, as in the western United States and Australia s Murray Valley. More recently, in Egypt, there have been moves to establish irrigation on the shores of Lake Nasser in Aswan Province, one of the least developed parts of the country and which has benefited little from the huge reservoir, and in the Western Desert (Pearce, 1997).

THE COSTS OF IRRIGATION

The benefits of irrigation are substantial; over 1/3 of the global harvest cannot be ignored. However, the benefits have not been achieved without wide-ranging and substantial costs, at farm, regional, national and even international levels.

The capital costs of irrigation schemes, covering water storage and reticulation (water distribution networks), land preparation, and the on-farm irrigation systems, are substantial and increasing (Yudelman, 1994). On top of these are the operating costs. Especially at the farm level, costs will vary depending on the nature of the schemes and the commodities produced. In the developing world, labor inputs are high and costs low; in the developed world, sophisticated equipment replaces high-cost labor. Energy is a significant component of both capital and operating costs. The construction of dams, storages and reticulation schemes consumes large quantities of energy. So, too, does the operation of irrigation schemes, either through fossil fuels or human or animal labor, especially for pumping. In the United States, about 10% of the total energy expended each year in crop and livestock production is used to pump irrigation water (Pimentel *et al.*, 1997). With the intensification of agricultural production, the increased inputs, such as fertilizers and other chemicals, all involve higher energy costs.

The establishment of irrigation brings major changes in terms of population, new communities and social conditions. With the intensification of agriculture comes the intensification of communities, demands for a new range of support services, and even different lifestyles, not least because of the inflexible nature of irrigation farming (crops have to be watered just as dairy cows have to be milked). The creation of large reservoirs and the establishment of irrigation schemes can result in the costly disruption and relocation of existing communities, as has happened in many parts of Asia and Africa.

A critical cost issue is the price irrigators pay for their water. In both developed and developing countries, it is evident that the economics of water use for irrigation have been distorted by enormous subsidies. Data from different countries indicate subsidies of 50 90% of costs (Falkenmark and Lundqvist, 1998). In hardly any situation are the full costs covered and, in many cases, water charges do not even cover the operating costs of the supply systems (see for example, Postel, 1999, 230 232). When water is essentially free or low priced, its waste is encouraged, as there is no incentive to improve the efficiency of its use. In many cases, the situation is further complicated by the fact that the value of the commodities that are produced is less than the real cost of the irrigation water that is used to grow them. On top of this, the agricultural commodities may also attract government subsidies. In South India, electricity for water pumps is free. Such situations reflect government attitudes to agriculture in general and irrigation in particular. Their attitudes are extremely difficult to change. Farmers in California pay about two per cent of what urban users are charged per unit of water (Pimentel *et al.*, 1997). In spite of their general unwillingness to do so, there is clearly a need for irrigators to pay a realistic price for the water they consume.

The impacts of the introduction of irrigation on a region s land and water resources are equivalent to a change of climate. Most of the impacts and their costs stem from excessive and inefficient water use. Irrigation requires a reliable water supply (though it can never be absolutely drought proof), made possible by engineering works of all kinds, from simple pedal pumps that laboriously lift water from a river to the most substantial and sophisticated storage and reticulation systems. The result is substantial alteration of the natural hydrological cycle, with significant environmental consequences for both surface water and groundwater. The demands of irrigation often result in major reductions in overall river flows and significant changes to river flow patterns, including the elimination of many flood flows. These and other changes have devastating impacts on all aspects of aquatic ecosystems (Postel *et al.*, 1996). Examples include the Murray, Colorado, Tigris Euphrates, Nile, Ganges, Huang He and Chao Phraya rivers, though among the most dramatic are the diversions from the Syr Darya and Amu Darya to expand cotton production and the consequent virtual destruction of the Aral Sea (Precoda, 1991; Postel, 1999) (*see* Aral Sea, Volume 4). Northern Nigeria provides more recent examples of environmental costs exceeding the benefits of irrigation (Barbier and Thompson, 1998).

The excessive extraction of water for irrigation is not confined to surface sources. Many groundwater resources are being used beyond their recharge rates, a practice that is not sustainable. At huge cost and with few benefits, Libya s Great Manmade River Project is pumping water from aquifers under the Sahara Desert to irrigate its coastal areas (McLoughlin, 1991; Pearce, 1991) (*see* Groundwater Withdrawal and the Development of the Great Manmade River Project, Libya, Volume 3). In Saudi Arabia, fossil water is being used to grow wheat, which is exported at a loss, though cuts in subsidies reduced production by more than 60% over 1994 1996 (Postel, 1998). Quite apart from the waste of a non-renewable asset, questions are being raised about the geological impact of using so much fossil water. On the US High Plains, depletion of the Ogallala Aquifer has contributed to the termination of irrigation on about one million ha, the significant reduction of surface stream flows, and threatened this semi-arid area s entire economy. However, with institutional and technical innovation, educational campaigns, and land and water stewardship of most farmers, long term irrigation appears likely in the High Plains (Kromm and White, 1997).

Paralleling the costs of water extraction are the consequences of water application. Because of inefficiencies of the reticulation systems (especially seepage and evaporation from open channels), as much as 60% of water is lost between its source and the crop root zone; in developing countries, the figure reaches 80 90% (Barrow, 1987, 202). Further losses occur on the farms, as excess water passes through the root zones and, where drainage is non-existent or inadequate, contributes to rising water tables, inevitably resulting in water logging and salinisation. Salinisation of land and streams is the scourge of irrigation (and increasingly of many dry land farming areas, such as Australia s Murray-Darling Basin (MDBMC, 1999)). Salinisation and associated soil degradation resulting from irrigation have a long history of causing the demise of irrigation schemes, from those of the Middle East in ancient times to India, China, and the United States in the 20th century (Hillel, 1994; Ghassemi *et al.*, 1995; Postel, 1999). Between 20 and 50% of the world s irrigated land is affected. In California s San Joaquin Valley, land is being permanently taken out of production because of salinisation. This is tragic, yet more cases are being added. In the West African Sahel, some 150,000 ha were under rice by the mid 1990s. It has become the chief staple as a result of the establishment of irrigation along the Senegal and Niger rivers. However, the soil and water conditions are not suitable, land being rendered useless in some areas after only one season by a concrete-like salt crust, essentially due to the absence of drainage (Madeley, 1993). This is but one illustration of the way that irrigation alters a region s society, economy and ecology.

Downstream, other water users and the aquatic ecosystems have to cope with the polluting and damaging effects of saline drainage water from the irrigation schemes, as well as the higher salinity levels that come with reduced flows. In addition, there are often other water-born pollutants from intensive irrigation production, some of which can be toxic. The downstream environmental impacts of such exported pollution are rarely, if ever, taken into account in the costing of irrigation agriculture.

Health problems are also often associated with irrigation, especially in tropical and sub-tropical areas, including bilharzia (as along the Nile and Volta) and malaria (as in Indus Valley).

IS IRRIGATION SUSTAINABLE?

Given the enormous economic, social and especially environmental costs of irrigation, there is much evidence to support the view that irrigation is not sustainable. Yet it has survived in some regions. For example, the rice terraces of Benaue, northern Luzon, were built at least 2000 years ago to maximize production in this very hilly region. Despite concerns being expressed about deforestation and soil erosion, the continued existence of the terraces depends on a sophisticated social organization for their labor-intensive operation and maintenance.

Whilst much of the world s irrigation continues to be undertaken in ways essentially similar to those practiced for hundreds of years hence creating the unsustainable situation dramatic changes are taking place that bring into question an unqualified negative response to the critical

question. Irrigation sustainability is technically possible, but only by making the changes that are needed to sustain and rejuvenate it (Rhoades, 1997).

As has been indicated, present patterns of water use, in terms of both consumption and contamination, are unsustainable. In particular, excessive water withdrawals for irrigation are contributing to a growing number of major environmental problems, quite apart from such disasters as the Aral Sea (Postel *et al.*, 1996). Issues of water allocation and priority of use will have to be addressed by governments and societies. Even the movement of a relatively small quantity of water out of irrigation would greatly benefit other users, including the environment, with little or no cost to irrigation.

Water will have to be used more efficiently, especially by irrigators. The performance of many irrigation schemes is sub-optimal, in economic, social and environmental terms, in both developed and developing countries. Not only do poorly managed schemes create serious problems, the reduction or elimination of management deficiencies would mean improved resource use, especially of water, and a reduction in the perceived *need* for further irrigation developments. For example, Chilean farmers now irrigate 22% more land with the same amount of water as before.

Significant improvements can be made to water distribution. The replacement of open channels by pipes virtually eliminates seepage and evaporation losses. With a pressurized system, farmers can take delivery of water when they require it, rather than on the basis of a pre-determined schedule that may bear no relation to crop needs. On the farm, various methods are available to improve water application efficiency, such as micro-jet sprinklers, drip hoses and underground systems, and the use of tensiometers. As important as the irrigation technology are the management skills of the farmers, as studies in the Riverland and Sunraysia districts of Australia s Murray Valley have shown. Investigations of differences in rice yields between research stations and farms showed that water control was responsible for 23% of the difference between maximum and actual yields (Yudelman, 1994). Excessive watering is not only wasteful but also unnecessary. Provided it does not occur at critical stages in a plant s development, water stress can lead to higher yields, lower costs and spectacular increases in water use efficiency (Jerie *et al.*, 1992; Upton, 1994). Benefits can also be gained from partial irrigation, the practice of scientifically under-irrigating crops to reduce yield in a controlled way. The last increment of water applied to a crop results only in a small yield increase. With limited water, the water saved through partial irrigation can be applied to other land where the incremental yield increase is large (Trimmer, 1990).

Paralleling improved efficiency in the delivery and application of water is the need for drainage to remove excess water from the plants root zone and prevent its addition to the groundwater (Letey, 1994). Many irrigation schemes have no drainage facilities, while those that do exist are often inadequate and inefficient. The absence of efficient drainage is the major cause of water logging and salinisation.

There are other issues. In terms of crop management, greater emphasis will have to be given to high value crops and to those that use less water (Pimentel *et al.*, 1997). For example, should rice be grown in semi-arid areas? As water is an economic good, pricing structures will have to be changed to reflect accurately the real cost of irrigation water. Realistic prices would be a major incentive for greatly increased water use efficiencies. With the development of water markets, almost all other users are able to pay much higher prices for water than irrigators, except for those farmers producing high-value agricultural commodities. Given the decreasing availability of fresh water, recycling irrigation drainage and other water provides an additional source (Shuval, 1987), though the use of marginal quality water requires much more careful management, while the long-term cumulative effects are largely unknown (Tanji, 1997). The same observations apply to the use of saline water for irrigation. In many locations, marginal quality water is blended with fresh water, though this reduces the available quantity of good quality water (Rhoades, 1997).

Critical to the future of irrigation is the rehabilitation of existing schemes. Even though irrigated agriculture has led to increased output, most irrigation systems are operating well below their capacity and are giving much lower increases in agricultural output than planned (Yudelman, 1994). Further, Because fewer and fewer new sources of water are available, the emphasis of irrigation investment has shifted away from new facilities towards rehabilitating and upgrading existing ones (Jones, 1995: xi). Because of the increasing problems with many existing schemes, as much land is being lost through water logging and salinisation as is being added by new schemes. More than 20% of the world s irrigated area is affected by salinisation, which is spreading by up to 2 million ha a year (Postel, 1999, 92 93). In both developed and developing countries, there are tremendous benefits to be gained from the rejuvenation of under-performing irrigation schemes of all kinds, including those that may seem to meet the best standards (Yudelman, 1994).

CONCLUSION

Irrigation is a major dilemma. On the one hand, in order to feed the world s increasing population, it needs to expand by some 2.25% a year, while appropriate intensification and expansion of irrigated areas may account for more than 50% of food requirements by the year 2025 (Pereira *et al.*, 1996). To these views must be added the likely impacts

of global warming, which could increase world irrigation needs by 26% to maintain current production (Pimentel *et al.*, 1997). On the other hand, global patterns of water use are unsustainable (Postel *et al.*, 1996). Climate change is already making its impact on irrigation. For example, irrigation water supplies are drying up in Mediterranean Europe. Water availability will be a serious constraint to achieving the food requirements projected for 2025. The need for irrigation water is likely to be greater than anticipated, and the available supply of it less than anticipated (Postel, 1998). Already, there are serious regional water problems, in many cases largely due to the huge demands of irrigation, as in California and parts of China.

Clearly, There is a point in water resources development when water can no longer be matched to the economy, but the economy must be matched to the water available (Teclaff, 1985, 568). This is true for all natural resources, in terms of both their use and the environmental consequences of their use. At current rates of expansion, by 2025, all the water resources now considered to be available for irrigation will have been exploited. In the view of Postel (1999: 259), irrigation agriculture is unprepared for the era of water scarcity and competition . Further, as Goodland *et al.* (1991: 2) state, sustainable development has to be development without growth in throughput beyond environmental carrying capacity , with development meaning getting qualitatively better not quantitatively bigger .

This is the critical point for the future sustainability of irrigation. It requires change in both the biophysical, cultural and political environments of irrigation. Irrigation and irrigators will have to change. Ultimately, the need to balance the conflicting water interests of urban residents, farmers, industry and natural ecosystems now evident in California will have to be faced worldwide (Engelman and LeRoy, 1993; Reisner, 1986). It is inevitable that water will have to be re-allocated to other uses from irrigation (including garden watering), in California and in many other parts of the world. In particular, the absolute necessity of maintaining environmental integrity has to be accepted. New water supplies will have to come from conservation, recycling, reuse, and improved water use efficiencies. In turn, such measures will reduce the long-term environmental damage that is so often associated with irrigation.

Change in the cultural and political environments of irrigation is equally critical. Irrigation is not only a form of agricultural production and land use but a human activity. In particular, it involves human decisions about how water is allocated, managed and valued (NRC, 1996). This must change. The continuation of current practices will not even maintain current levels of food production, let alone increase them. A major United States study, *A New Era for Irrigation*, concluded: It is critical that the same resourcefulness that has made irrigation such an important economic and cultural activity over the past 100 years be brought to bear in the future (NRC, 1996, 7).

Irrigation: Induced Demise of Wetlands

A Dennis Lemly
Virginia Tech University, Blacksburg, VA, USA

Irrigation is essential to support agricultural production in many arid and semi-arid regions of the world. However, there is often an important trade-off. The bene ts from irrigation can be offset by environmental costs, particularly to wetlands, and the many functions they provide to society; for example, water, food, and aesthetic uses. The intensive irrigation practices typically used in modern agriculture place high demands on water supplies. Native wetlands and their associated wildlife populations can be eliminated in a short period of time because water removal for use in irrigation robs wetlands of their source of water and they shrink in size or dry up. For example, in the western US, wetland losses due to agricultural irrigation exceed 90% in many locations, and have been occurring largely unimpeded for the past 100 years (Reisner, 1986).

In addition to the direct loss of wetland areas, wetlands can lose their capacity to function normally if agricultural pesticides and herbicides in the surface run-off from irrigated elds or subsurface irrigation drainage contaminate the water sources. Subsurface drainage was identi ed in the United States in the early 1980s as a major cause of wetland change. Irrigation water trapped by shallow clay lenses must be removed or drained away, otherwise it saturates the root zone and kills crops. The resultant drainage contains elevated concentrations of soil trace elements, salts, and other constituents, and ultimately reaches major wetlands, streams, and rivers. Fish and wildlife populations have been poisoned by drainage water contaminants at several locations and human health has been jeopardized (Lemly et al., *1993; Lemly, 1994). Thus, although reductions in water supplies have caused the demise of wetlands for centuries, there are more recent threats that are just now being identi ed and investigated.*

Wetlands continue to play a direct role in supporting many human populations through their varied functions, products, and attributes (Hruby et al., *1995). There are also numerous indirect roles. For example, wetlands are important in removing greenhouse gases, such as carbon dioxide, from the atmosphere. The global assimilation of these gases may be detrimentally affected by wetland losses associated with irrigation. Wetlands are a sensitive public issue because they provide a habitat and staging grounds for migratory birds, which have important aesthetic, recreational, and conservation values.*

Major irrigation-related impacts to wetlands have continued to take place throughout the world during the past 25 years despite international conservation efforts, such as the Ramsar Convention and the Rio Conference (Lemly et al., *2000). One thing is certain - nding an environmentally acceptable balance for irrigated agriculture is more complicated, yet more necessary, than ever before.*

GLOBAL EXAMPLES

Africa (Table 1; Figure 1)

The most extensive wetlands within the African continent are the large seasonally inundated floodplains. These

Table 1 Some examples of the impact of irrigation on Africa's floodplain wetlands

Wetland	Status	Cause of impact	Period of impact	Effects on wetland and wildlife	References
Logone Floodplain, Cameroon	Includes the Waza National Park	Upstream barrage for irrigation and riverside embankment to protect irrigation scheme	1970 to present	Reduced wet season inundation and loss of grazing for wildlife, including ungulates and elephants	Drijver and Marchand (1985); Wesseling *et al.* (1996)
Floodplain of the Benue River, Cameroon	Close proximity to three NPs	Large dam and reservoir for 29 000 ha of irrigation	1982 to present	Loss of important wildlife habitat beneath the reservoir, reduction in downstream inundation, disruption of migration routes of large mammals, including buffalo, antelope and elephant	Drijver and Marchand (1985)
Hadejia–Nguru Wetlands, north-east Nigeria	Partly NP and nature reserves	Two large dams, one barrage and two large-scale irrigation schemes upstream. Expansion of small-scale irrigation within the wetlands	1971 to present	Reduced wet season inundation leading to declines in wildlife habitat. Removal of natural vegetation cover. Reports of river pollution with agricultural chemicals	Hollis *et al.* (1993); Thompson and Hollis (1995); Thompson (1995)
Phongolo Floodplain, South Africa	Includes the Ndmu Game Reserve	Dam constructed upstream for 40 000 ha of irrigated land	1970 to early 1990s	Changes to hydrological regime of the floodplain, including reduced flood flows and inundation extent. Recently, an artificial flood regime has been established	Acreman (1994); Bruwer *et al.* (1996)
Senegal Delta, Senegal	Includes the Djoudj National Park, a Ramsar site, World Heritage site and NP	Upstream dam for irrigation and hydropower, downstream barrage to prevent saline intrusion, river embankments to prevent flooding, expansion of irrigated agriculture	1985 to present	Loss of wetland habitat to numerous rice schemes. Reduced water supplies to some wetland areas, reduced fish populations, encroachment of freshwater vegetation into areas of open water	Drijver and Marchand (1985); N'diaye (1997); Vincke (1996)

NP, national park.

wetlands, including the Inner Delta of the Niger in Mali, the Sudd of the Sudanian Upper Nile and Zambia s Kafue Flats, provide valuable habitats for wildlife. They support a huge variety of bird life and are vital for many migratory species that winter within them. The presence of water within many floodplains during the dry season provides important grazing areas for wild ungulates during periods when the surrounding drylands are desiccated.

In addition to their importance for wildlife, Africa s floodplains play a vital life-support role for a significant

Figure 1 Major African floodplain wetlands that have been detrimentally affected by water management schemes implemented for agricultural irrigation

proportion of the continent s population (Drijver and Marchand, 1985). Human populations have, for centuries, utilized the agricultural, fisheries, hunting, grazing and water resources provided by floodplains (Adams, 1996). These wetlands have rightly been termed *the heart of Sahelian life systems*.

Historically, the different uses of floodplain resources were integrated economically and ecologically. Floodplains have been able to support wildlife and people. However, over the last 40 years, many dams have been built as part of large-scale schemes of water management for irrigated agriculture (Thompson, 1996). In 1987, Van Ketel and others identified 114 dams which were detrimentally affecting wetlands within West Africa alone. Drijver and Van Wetten (1992) stated that by the year 2020, all Sahelian wetlands would be subject to the impacts associated with upstream dams. These impacts will have profound consequences for the wildlife and human populations which depend on wetlands.

At a local level, the expansion of small-scale irrigation has led to the replacement of natural vegetation or rainfed agricultural land with small plots (typically 1 4 ha), in which relatively high value crops, such as wheat, peppers, onions, sweet potato and tomatoes, are grown. The expansion of this form of agriculture was aided by a sharp rise in wheat prices in the 1970s and 1980s resulting from a ban on wheat imports into Nigeria (Kimmage, 1991). This coincided with the dissemination of approximately 70 000 portable irrigation pumps by the Kano State Agricultural and Rural Development Program. This change in agricultural practices enabled areas previously considered as marginal for cultivation to be cropped. The quality of wetlands and their suitability for wildlife have been altered due to shifts in vegetation and increased salinity. Muslim and Umar (1995) indicated that agricultural intensification has also resulted in increasing concentrations of chemical pollutants, largely from fertilizers, within the wetlands.

Table 2 A sample of 20 key wetlands in Australia that have been changed by irrigation

Wetland	Status	Cause of impact	Period of impact	Effects on wetland and wildlife	References
Barmah/Millewa Forest	Ramsar	Diversion and regulation of water for irrigation. Timber harvesting. Flows in the wetland regulated	1936 to present	About 50% of wetland lost. Decreased flood frequency and changes in season of flooding. Wetland vegetation less reliant on flooding; replaced by more aquatic vegetation	Bren (1988, 1992)
Wetlands of the Border Rivers	No reserve status	Diversion and regulation of water for irrigation	1980 to present	Decreased wetland flooding	Kingsford (1995)
Bowling Green Bay	NP, Ramsar	Water augmentation to inflowing rivers from irrigation			Blackman *et al.* (1996)
Carrum Swamplands		Swamps drained for agriculture	1870–1950	Wetland area declined from 4050 ha to 81 ha	Norman and Corrick (1988)
East coast Wetlands of New South Wales	Includes Kooragang Island Nature Reserve	Drainage schemes to limit flooding damage to agricultural and urban land	1900–1980s	Drainage affected 96% of wetland area on Macleay river floodplain	Goodrick (1970); Pressey (1989)
Gwydir Wetlands		Diversion and regulation of water for irrigation. Seventy percent reduction in floods of 100 Gl per month. Flooding frequency declined halved, from 1 in 2 to 1 in 4 years. Drains and channelization. Elevated levels of herbicides and insecticides (endosulfan) detected		Reduction in areas of aquatic vegetation, reed beds from 4000 ha to 250 ha. Abundance and diversity of waterbirds declined from 58 to 45 species	Debus (1989)
Hattah–Kulkyne Lakes	NP, Ramsar, Biosphere reserve	River regulation has reduced inflows to the lakes from the Murray River	1900 to present	Increased blooms of cyanobacteria. Reduced flood frequency	Hull (1996)
Herbert River Floodplain	NP (part), wetland reserves, fish habitat reserve	Decline in water quality caused by agriculture. Sugar cane production destroyed most of wooded swamps and many other wetlands. Drains replaced natural watercourses			Blackman *et al.* (1996)
Kerang Wetlands	Ramsar site wildlife reserves	Water levels held permanently high in wetlands. Increased salinity. Levees to control flooding, channeling of water courses. Saline water disposed in some wetlands	1936 to present	Prolonged inundation caused a loss of aquatic vegetation adapted to wet and dry cycles. Increased salinity affected fauna and flora	Hull (1996)
Koo-wee-rup Swamp		Drainage for agriculture		No wetland remains, declined from 40 000 ha. No aquatic plants or animals	Norman and Corrick (1988)
Lake Albacutya	NP, Ramsar site, national heritage	Historical records indicate reduced flooding because of upstream diversion of water for irrigation. Rising saline groundwater	1920s to present	Degradation of vegetation communities	Hull (1996)

Macquarie Marshes	Nature reserve, Register of National Estate, Ramsar	Diversion of water upstream mainly for irrigation	1969 to present	Reduced wetland size by at least 40–50%. Number of waterbirds and species in decline. Wetland vegetation in decline	Kingsford and Thomas (1995)
Menindee Lakes	Included in Kinchega National Park	Water levels kept artificially high for irrigation and public water supply. Tandou Lake no longer a wetland	1950s to present	Aquatic vegetation killed by too much flooding. Reduced numbers of waterbirds. Waterbird community dominated by piscivores. Erosion of lakeshores	Kingsford (1995)
Murray River Wetlands		Water levels kept artificially high for irrigation on 35% of wetlands	1900 to present	Death and deterioration of floodplain vegetation	Bren (1990); Pressey (1990); Smith and Smith (1990)
Murrumbidgee River Wetlands		Water levels kept artificially high; 62% of wetland area with water levels controlled locally		570 ha of floodplain eucalypt trees killed; ducks did not breed where water levels were highly controlled. Breeding of herons, egrets, and cormorants dependent on flooding of red gum. Loss of some breeding habitat for egrets	Briggs *et al.* (1994); Thornton and Briggs (1994); Briggs *et al.* (1997)
Narran Lake	Nature reserve	Water diversion for irrigation	1985 to present	Reductions of flow by 31%	Kingsford (1995)
Ord and Parry River Floodplains	Nature reserve and Ramsar site	Building of reservoir (Lakes Argyle and Kununurra). Reduced flooding. Ord irrigation scheme diverts water.	1972 to present	Prevented migration of fish; impact on downstream wetlands. Submerged seasonal wetlands (e.g., Packsaddle Swamp)	Lane and McComb (1988)
Swan Coastal Plain		Drainage of wetlands for agriculture, roads, urban development. Increased water levels	Up to 1964	Seventy percent of wetlands lost or significantly altered by clearing of vegetation	Halse (1989)
South-west Western Australia	Affected nature reserves include Lakes Toolibin (Ramsar site); Dumbleyung, Coyrecup, Pinjarrega, Nonalling, Beverley Lakes	Clearing of dryland vegetation for agriculture	1900–1960s	Salinization of wetlands is common	Lane and McComb (1988); Froend *et al.* (1987)
Lower South-east Wetlands of South Australia (include Bool Lagoon)	Bool and Hacks Lagoon (Ramsar site; conservation park)	Drainage to increase availability of lands for grazing livestock	1863–1981	Loss of wetlands; affected 53% of flood prone areas; more than 93% loss of permanent lakes and swamps	Lane and McComb (1988)

At a regional and continental level, a far more significant impact on the acreage of wetlands has resulted from the construction of large-scale irrigation schemes and associated dams. For example, in the Hadejia Nguru River Basin in Nigeria alone, there are currently over 20 dams, all upstream of the wetlands. The largest are associated with two major irrigation schemes located on the Hadejia River or its tributaries. The Kano River Irrigation Project (KRIP) is the biggest scheme at present. Tiga Dam, the largest dam in the basin, which was constructed during the period 1971 1974, provides irrigation water. The plan for KRIP envisaged its development in two distinct phases. A total irrigated area of 27 000 ha was planned for Phase I (KRIP-I) while Phase II (KRIP-II) would add a further 40 000 ha. The construction of Phase I began in 1977, and to date, around 14 000 ha have been completed.

The second major irrigation scheme, known as the Hadejia Valley Project (HVP), is under construction. The scheme involves a barrage across the Hadejia River just upstream of the Hadejia Nguru Wetlands and a planned 12 500 ha of formal irrigation. At present, around 7000 8000 ha have been completed. Challawa Gorge Dam on the Challawa River, upstream of Kano, is linked to the HVP. The dam, which was completed in 1992, is designed to store water during the wet season and subsequently release it downstream for use on the HVP.

The development of these large-scale schemes has had a tremendous impact on the hydrology of the river basin. These impacts have been concentrated in downstream areas. By retaining and utilizing water upstream, the schemes have reduced the magnitudes of downstream flood discharges and thereby reduced the area inundated within the floodplain. Any further expansion in the area of large-scale irrigation within the basin will clearly have tremendous implications for wildlife and human communities within the wetlands. In particular, plans for 84 000 ha of irrigation and a massive dam at Kafin Zaki on the, as yet, undammed Jama are River will reduce flood extents and associated wetlands by an average of over 50% (Thompson, 1995).

Australia (Table 2; Figure 2)

Agricultural irrigation has caused major changes in the wetlands of Australia. Hydropower generation and urban development have destroyed wetlands, but agriculture has caused most wetland loss.

The 1960s marked the beginning of the great development of water resources within Australia. In New South Wales, for example, a 25-year plan was initiated in 1971 to spend A$723 million (about US$60 million, in 1997 dollars), primarily on building dams (WRIC, 1971). Australia now boasts the largest per capita water storage in the world

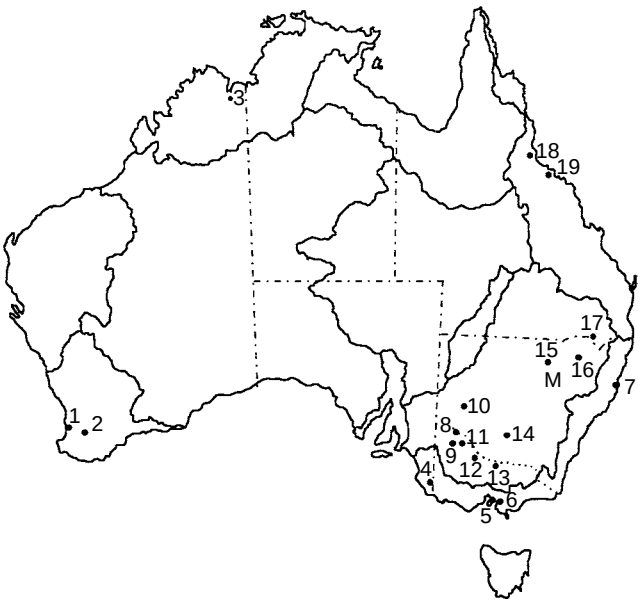

Figure 2 A sample of significant wetlands in Australia that have been detrimentally affected by irrigated agriculture. Lines mark the major drainage divisions in Australia. M marks the location of the Macquarie Marshes and the numbers refer to the following wetlands: (1) Swan Coastal Plain; (2) Lake Toolibin; (3) Ord and Parry River Floodplains; (4) Bool Lagoon; (5) Carrum Wetlands; (6) Koo-wee-rup Swamp; (7) Macleay River Floodplain; (8) Murray River Wetlands; (9) Lake Albacutya; (10) Menindee Lakes; (11) Hattah–Kulkyne Lakes; (12) Kerang Wetlands; (13) Barmah–Millewa Forest; (14) Murrumbidgee Wetlands; (15) Narran Lake; (16) Gwydir wetlands; (17) Wetlands of the Border Rivers; (18) Herbert River Floodplain; (19) Bowling Green Bay Wetlands

(Wasson *et al.*, 1996). In New South Wales, there are 144 large storage reservoirs, each with a capacity of greater than 1000 Ml (10^6 l) (Kingsford, 1995). These have had a significant impact on wetlands and water resources in the country. The management of water for irrigation, mainly with large dams, has severely affected river flows (Maheshwari *et al.*, 1995) and wetlands (Pressey and Middleton, 1982). With the changed water regime, many wetlands now store water permanently, which has killed aquatic vegetation adapted to wet and dry cycles.

A more insidious problem is the impact of the diversion of water upstream on the extent and duration of flooding. A notable example is the Macquarie Marshes. In 1896, the first weir was built on the Macquarie River to manage water. Nine large dams, five major weirs and several minor weirs, a water transfer scheme, and numerous other regulatory structures (Kingsford and Thomas, 1995) store water for later release to a large irrigation industry. About 89% of the water diverted from the Macquarie River is used for irrigation. Irrigation increased after Burrendong Dam was built in 1967. Burrendong Dam has a storage capacity 70%

larger than any other regulatory storage in the Macquarie Valley. Irrigated cotton was first grown in the valley in 1967 (McHugh, 1996), and now accounts for more than half of the water use for irrigation. It peaked in 1993/1994 when 543 000 Ml were diverted for irrigation. Originally flooding up to 1 280 000 ha, the Macquarie Marshes now inundate only about 130 000 ha during large floods (Kingsford and Thomas, 1995).

The impact of irrigated agriculture on the wetland and its water birds is profound. The total amount of water reaching the Macquarie Marshes is a highly significant predictor of wetland size (Kingsford and Thomas, 1995). Due to reduction in flows as a result of the diversion of water upstream, mainly for irrigated agriculture, the wetland is now conservatively 40 50% smaller than it was before water was diverted (Kingsford and Thomas, 1995). Before the Burrendong Dam was built, about 50% of the water, which passed the upstream gauge at Dubbo, reached the Macquarie Marshes. Now only about 21% of this water reaches the Marshes, despite no changes in the catchment rainfall in the period 1944 1993 (Kingsford and Thomas, 1995). Wetland trees, such as river red gums, have declined by about 50% during the period 1934 1998; reed beds experienced similar declines between 1963 and 1972 (Brander, 1987). Water couch (*Paspalum paspaloides*) has declined by 40% in some areas during the period 1949 1991, with exotic dryland vegetation replacing it. The numbers of water birds and the numbers of species declined in the period 1983 1995 (Kingsford and Thomas, 1995). Reduced flows have also impacted the size of breeding colonies of Ciconiiformes. Conservatively, this has probably meant that there are now about 100 000 fewer nests over a period of 11 years as result of water that was diverted from the Macquarie River. Fish surveys also indicate a substantial decline in diversity and biomass.

Irrigation upstream of the Macquarie Marshes is also raising water tables, which has caused salinity problems that are contributing to long-term increases in the salinity of water reaching the Macquarie Marshes (*see* Irrigation: Environmental Impacts, Volume 3; Salinity and Agriculture, Volume 3). Four pesticide products occur in the river: endosulfan, atrazine, prometryn and parathion. Sampling during the summer of 1994 1995 at two sites at the beginning of the Macquarie Marshes detected levels of endosulfan greater than $0.01\,\mu g\,l^{\bullet\,1}$, which is above the threshold at which toxic impacts to aquatic ecosystems begin to occur.

North America (Table 3; Figure 3)

Limited availability of water was one of the major obstacles to early settlement in many arid and semi-arid regions in western North America (Reisner, 1986). In the US, the shortage of water and perceived need to homestead on desert lands led to the establishment of the US Bureau of Reclamation in 1902 (then named the Reclamation Service). The primary mission of this agency was to *reclaim* unproductive lands by bringing water to arid regions and turning desert into farmland. This reclamation began in earnest with the completion of the Newlands Water Project in Nevada in 1915 and reached a peak with the building of such massive water storage/diversion projects as the Hoover Dam on the Colorado River, the California Aquaduct across the Mojave Desert, and the Central Valley Irrigation Project in California (Reisner, 1986). However, the price for this reclamation and associated increase in agricultural production was a sharp decline in the amount of water available to native wetlands.

A combination of reduced freshwater inflows and contaminated subsurface irrigation drainage has seriously degraded wetlands throughout western North America. The impacts to wildlife have been severe, and the conservation benefits provided by these wetlands have dropped precipitously (Lemly *et al.*, 1993; Lemly, 1994). Battles for water rights between settlers, agriculture, urban developers, and water authorities have raged for well over a century (Reisner, 1986), but only in the last few years have the water needs of remnant native wetlands gained attention and become the focus of water management policies. A notable example is the wetlands located in the Lahontan Valley of northwestern Nevada.

An extensive wetland ecosystem, comprising some 70 000 ha, existed in low areas of the Carson Desert of northwestern Nevada prior to the completion of the Newlands Irrigation Project in 1915. Of this amount, 14 000 ha in Stillwater Marsh, 11 000 ha in Carson Lake Marsh, and about 11 000 ha at the mouth of the Carson River in the Carson Sink (Fallon NWR) were terminal drainage areas for the Carson River and were directly impacted by the Newlands Project. Since the initiation of the project in 1905, the quantity and quality of the water reaching the terminal wetlands has declined precipitously. The water quantity has been reduced due to the diversion of water from the Carson River for use in irrigating crop land, primarily to grow alfalfa that is harvested and sold as livestock feed in Nevada and neighboring states. The water quality has declined because of saline, contaminated subsurface drainage formed as a by-product of irrigation. The net effect has been the elimination of 59 000 ha of wetlands in exchange for the water used to irrigate 22 000 ha of land. A total of 84% of the native wetlands are gone and the remaining marshland receives water that contains up to 100 times the historic concentrations of dissolved solids, including toxic trace elements such as mercury, arsenic, and selenium (Hoffman *et al.*, 1990; Hallock and Hallock, 1993). The changes in water quality have led to extensive declines in marsh vegetation in the remaining wetlands (Hoffman *et al.*, 1990; Lemly, 1994).

Table 3 A sample of wetlands in North America that have changed due to irrigated agriculture

Wetland	Status[a]	Cause of impact	Period of impact	Effects on wetland and wildlife	References
Stillwater Marsh	NWR, Ramsar, hemispheric reserve for shorebirds	Water diversions for crop irrigation resulted in • 90% reduction of inflows and produced contaminated subsurface drainage	1915 to present	Loss of 71% of wetlands; production of shorebirds cut by • 60%; death and deformity of birds and fish due to contaminants in irrigation drainage; mortality of endangered species	Hoffman *et al.* (1990); Hallock and Hallock (1993); Lemly (1994)
Kesterson Marsh	NWR	Contaminated subsurface irrigation drainage	1978–1985	Death and deformity of thousands of waterfowl and shorebirds; all marshland (2388 ha) drained and sediments excavated. No wetlands remain	Zahm (1986); Hoffman *et al.* (1986); Marshall (1985)
Grasslands Marshes	NWR, SWMA, 70% private ownership	Freshwater inflows replaced by contaminated irrigation drainage	1950 to present	Accumulation of drainwater contaminants in shorebirds to toxic levels for reproduction	Ohlendorf *et al.* (1987); Hothem and Welsh (1994)
Rasmus Lee Lake, Goose Lake Wetlands	SWMA	Contaminated subsurface irrigation drainage	1986 to present	Bio-accumulation of selenium to toxic levels; death and deformity of waterfowl and shorebirds	Peterson *et al.* (1988); See *et al.* (1992a,b)
Ouray Wetlands	NWR, SWMA	Contaminated subsurface irrigation drainage	1960 to present	Bio-accumulation of selenium to toxic levels; death and deformity of waterfowl, shorebirds, and fish; mortality of endangered species	Stephens *et al.* (1988, 1992); Waddell and Stanger (1992); Hamilton (1998)
Benton Lake Wetlands	NWR	Freshwater inflows replaced by contaminated irrigation drainage	1970 to present	Bio-accumulation of trace elements to toxic levels in waterfowl, shorebirds, and fish; reproductive impairment in birds	Knapton *et al.* (1987); Lambing *et al.* (1987)
Mexican Riverine Wetlands	WP, SWMA	Diversion of freshwater inflows for irrigation; salinization of surface and ground water supplies	1963 to present	Loss of • 50% of wetlands and shallow water habitat; local loss of up to 68% of native fish species; total extinction of 15 rare or endangered fish species	Conteras-Balderas and Lozano-Vilano (1994)
South Saskatchewan Basin Wetlands	NP, PP, PWMA	Diversion of freshwater inflows for irrigation; salinization of surface and ground water supplies	1940 to present	Loss of • 40% of wetlands and shallow water habitat; declines in bird usage and production	Livingstone and Campbell (1992); Gilbert and Ramey (1995)

[a] NWR, national wildlife refuge; SWMA, state wildlife management area; WP, wildlife preserve; NP, national park; PP, provincial park; PWMA, provincial wildlife management area.

Figure 3 A sample of significant wetlands in North America that have been detrimentally affected by irrigated agriculture. L marks the location of the Lahontan Valley Wetlands, which include Stillwater Marsh, and numbers identify the following wetlands: (1) Kesterson Marsh; (2) Grasslands Marshes; (3) Rasmus Lee Lake and Goose Lake Wetlands; (4) Ouray Wetlands; (5) Benton Lake Wetlands; (6) Mexican Riverine Wetlands; (7) South Saskatchewan River Basin Wetlands

The irrigation-induced effects on wildlife have been severe. Fish populations are greatly reduced, and the species composition has changed since historical times. For example, the Lahontan cutthroat trout (*Oncorhynchus clarki henshawi*), a Federally listed endangered species, has been totally eliminated. The largemouth bass (*Micropterus salmoides*), an introduced species that once supported an extensive recreational fishery, has also entirely disappeared. Most of the native species are now absent from the wetlands and those that remain are pollution-tolerant fishes, such as common carp (*Cyprinus carpio*) and mosquitofish (*Gambusia af nis*). The once diverse fish forage base supporting American white pelicans has been greatly reduced. The river otter (*Lutra canadensis*), mink (*Mustela vison*), frogs, and turtles characteristic marsh species that were once numerous are all gone. Other species have experienced precipitous declines in numbers, to the point that they are now uncommon e.g., the American curlew (*Numenius americanus*). Muskrats (*Ondatra zibethicus*), freshwater clams and aquatic snails were once abundant throughout the wetlands, but only small, remnant populations remain. Freshwater clams, for example, are only present in Stillwater Point Reservoir, which is the area with the lowest dissolved solids concentration (Hallock and Hallock, 1993).

Waterfowl production is now much reduced compared with historical conditions. The numbers of nesting birds, as well as the percentage of successful waterfowl and shorebird nests, have steadily declined due to a loss of wetland acreage and emergent vegetation, coupled with exposure to contaminants in irrigation drainage water. Only about 25% of nests succeed in hatching even one chick, and the birds that do fledge contain elevated concentrations of mercury and selenium. Moreover, the water in many marsh areas is toxic to aquatic life because of the accumulated salts and trace elements that are leached out of crop land during irrigation and carried to the wetlands in drainwater (e.g., selenium, boron, molybdenum, lithium, arsenic). There are also public health concerns. Selenium, for example, accumulates in biota to concentrations that are 10 000 times those present in water, resulting in tissue residues in waterfowl that are four times the safe levels for human consumption (Hallock and Hallock, 1993).

OUTLOOK FOR THE FUTURE

The degree of wetland change caused by irrigation over the past century has reached a critical point on a global scale. Many key wetlands have lost the ability to sustain the critical hydrological and biological functions responsible for multiple benefits to the environment and society. Particularly troubling is the possibility that future changes in global climate will affect precipitation patterns and increase the extent of arid and semi-arid regions. This would increase the need for irrigation to support agriculture and accelerate declines in remaining native wetlands. The repercussions are significant. Loss of wetlands may contribute to alterations in climate by reducing the amount of carbon taken up and sequestered in wetland plants, thereby enhancing atmospheric CO_2 and the greenhouse effect. Climate change means alteration of agricultural practices and crops. Thus, there is an intricate cycle in operation; wetlands are detrimentally affected by water withdrawals for irrigation, but at the same time, destroying wetlands may contribute to climate changes that detrimentally affect agriculture. It is important to recognize that the agricultural systems we now depend on are directly affected by what society does to wetlands.

Loss of wetlands also translates to reduced biodiversity on a global scale. This fact has not gone unnoticed. Recent developments, such as the United Nations Biodiversity Convention (Denny, 1994), show a willingness to resolve environmental issues related to wetlands. Agenda 21, a global partnership for sustainable development in the 21st century, was established at the UN Conference on Environment and Development in Rio de Janiero in 1992. Although the goals are noble, conferences such as this may merely establish *political correctness* rather than institute meaningful changes in environmental management policy. Care must be taken that the euphoria born at the

Rio Conference is not allowed to degenerate into a series of platitudes in which words like *biodiversity* and *sustainable development* become political words of convenience rather than words of true meaning. (Denny, 1994) This quote highlights the key failing of past efforts much is said and written, but little is done. Moreover, the track record established over the past 40 years suggests that *sustainable development* is often a political code name for *perpetual growth*, used strategically to make development more palatable to those who would oppose it (Willers, 1994).

Irrigation threats to wetlands are often disguised within a sustainable development scenario i.e., that continued growth and development are compatible with environmental constraints. As noted by Pearce *et al.* (1989), sustainable development has come to mean whatever suits the advocacy of the individual or group concerned. Advocacy for sustainable agriculture under a false pretense of environmental compatibility has been a principal factor guiding water policy decisions for decades. Environmental management has been intense and largely in one direction toward the expansion of irrigation. Yet, the recurring result has been that so-called sustainable development has guaranteed the deterioration of wetland ecosystems and loss of biodiversity.

Recent surveys reveal that a steady growth of irrigated agriculture is continuing to occur (e.g., Anonymous, 1997). Water demands for domestic and industrial use will no doubt expand substantially over the next 30 years (Postel *et al.*, 1996), making the issue of wetland values more important than ever in resolving problems. Detailed economic valuation of wetland resources and application of the resultant ecosystem *capital* in water negotiations is being used to develop management plans that protect wetlands. For example, the New South Wales government in Australia reached decisions for managing the Macquarie Marshes based in a large part on ecological grounds (values associated with wildlife preservation) despite considerable lobbying by the irrigation industry with arguments that about A$35 million (about US$3 million) and about 500 jobs would be lost (Morrison and Kingsford, 1997). With cooperation and strategic planning, local citizens and wetland managers are having a significant effect on how water policies are developed and implemented. This is a positive sign that historic trends in wetland change due to irrigation are beginning to reverse.

Karst

Karst is landscape or topography dominated by surface features produced by the dissolving of rocks by water passing over and through them and by development of underground passages and cavern systems. Usually the term is restricted in use to carbonate rocks (limestone or dolomite) that are characterized by sinkholes, caves, sinking streams, springs and solution valleys. In this case the dominant dissolving action is by dilute carbonic acid in the water formed by the combination of water with carbon dioxide derived from both the atmosphere and biotic activity in vegetation and soils.

Among the world s most celebrated karst areas are those of Slovenia and Croatia (where the word comes from), the Guilin tower karst along the Li River in southern China and the Mammoth Cave area of the US. However karst underlies many important populated regions, including much of Florida, the Kuala Lumpur area of Malaysia and large areas of Cuba and northern Vietnam.

Karstic landscapes are particularly sensitive to environmental degradation. Problems such as modifications to groundwater supply, contamination of groundwater, and inducement of land instability abound in populated karst regions.

IAN DOUGLAS *UK*

Kovda, V A

(1904- 1991)

Viktor Abramovich Kovda, corresponding member of the USSR Academy of Sciences, Professor, was born in Vladikavkaz into a post office clerk s family. He graduated from Kuban Agricultural Institution (Krasnodar). After post-graduate studies he became a student of Professor Wigner in Switzerland.

Kovda worked in the Dokuchaev Soil Science Institute and in Moscow State University, where he was Chairman of the General Soil Science Department (1953 1981). In 1969 1970 he founded the Agrochemistry and Soil Science Institute in Pushino (Moscow region), where he worked until his death. Throughout his lifetime Kovda worked in many different international organizations, whose focus was centered around the problems of soil science and environment conservation.

He was the Head of the United Nations Educational, Scientific and Cultural Organization (UNESCO) Department of Natural and Exact Sciences (Paris, 1959 1965). During this period he raised and solved some important global scientific problems (soil reclamation, aridization, relationships between the biosphere and human activities, and construction of a soil map of the world). In 1968, Professor Kovda was elected President of the International Soil Science Society. From 1973 up to 1976 he was President of the Scientific Committee on Problems of the Environment (SCOPE).

Due to his encyclopedic knowledge of foreign and Russian literature and his numerous trips abroad, Kovda gained a deep insight into the problems of global soils and biosphere changes as a consequence of anthropogenic influences and global climatic change.

Kovda played a leading part in the world scientific community directed towards understanding the role of soils and soil cover in the planetary biosphere, people s responsibility for maintaining biosphere functioning, and the need to handle nature conservation problems on a global scale.

Kovda is one of the founders of the contemporary theory of desertification, aridization and soil salinity. He developed the scientific principles of the origin of saline soils, he solved both theoretical and practical problems of chernozem irrigation, and he worked out the concept of the prevalence of paleohydromorphism on the Great Plains and its influence on the formation of soil cover. Following V I Vernadski, he stimulated the world community to

study the whole complex of environmental conservation problems.

Kovda demonstrated for the first time that aridization and desertification are global processes. In 1974 at a SCOPE meeting, Kovda stressed that the problem of the biochemical cycles of chemical elements, both natural and anthropogenic, is very important. In his activities Kovda constantly adapted fundamental scientific developments to the needs of practical users.

L

Lahars

Lahar is an Indonesian word for a rapidly flowing mixture of rock debris and water, a volcanic mudflow or debris flow that originates on the flanks or slopes of a volcano particularly in the wet tropics. As a hazardous volcanic event, lahars occur in the presence of large quantities of water in association with any type of volcano. Lahars form in a variety of ways: from crater lakes; the rapid melting of snow and glaciers; intense rainfall on loose volcanic rock deposits; breakout of a lake dammed by volcanic deposits; as a consequence of debris avalanches and predominantly by the rapid melting of snow and ice by pyroclastic flows. Once a pyroclastic flow mixes with a stream or rainwater mixes with a still hot pyroclastic material a hot lahar forms. Lahars consist of fluids of water and volcanic particle mixtures comprised of particles 50% less than sand-sized with the remainder ranging from clay-size to boulder-size. Lahars travel great distances ranging up to 300 km traveled mostly in valleys and have a viscous consistency of wet concrete capable of a range of velocity activity. Their spontaneous but disastrous impact can be deadly. The velocity of a lahar depends on the slope and water content; the lower the viscosity, the faster it flows. They attain speeds of $1\,\mathrm{m\,s^{-1}} = 2{\bullet}55\,\mathrm{m\,h^{-1}}$ and on steep slopes velocity ranges from $1.3\,\mathrm{m\,s^{-1}}$ to $40\,\mathrm{m\,s^{-1}}$. Flows of lower viscosity are therefore more dangerous because of the drowning risk compared to high viscosity flows that are only capable of removing vegetation and causing structural failure. Lahars become increasingly diluted with water after interacting with pyroclastic surges downstream from snow and ice and transform into regular floods. This was experienced during the eruption of Nevado del Ruiz, Armero, Colombia in 1985 that caused the death of 21 000 people. This first occurred at Mount St Helen s, US, where hot pyroclastic surges transformed to lahars, to hyperconcentrated streamflow and then to normal floods. Besides the initial destruction and altered river courses, lahars subsequently leave deposits that impede local river channels. These deposits of volcanic sediment require dredging to allow navigation to resume and are often used as construction materials. Lahars do not necessarily happen at the time of the eruption, they may occur many years later. Unfortunately, lahar prevention is only possible by use of barriers similar to those used for lava flows, this provides only minimal protection. Some Indonesian villages position artificial mounds so that people can quickly access higher ground away from the flow. However, this preventive measure requires an adequate warning system. To determine the threat of mudflows, rain gauges or flow sensors are used to monitor the amount of precipitation.

MARY KEARNEY *Canada*

Lake Baikal

Anson W Mackay
University College London, London, UK

Lake Baikal, located in southeast Siberia, is one of the most unusual freshwater ecosystems in the world. It formed within a series of rift zones over 30 million years ago, making it by far the oldest living lake. Lake Baikal is also the deepest lake in the world, with a maximum depth of 1642 m. This great depth ensures that the lake contains the world's largest volume of surface freshwater, some 20% of global resources, and 80% of resources found within the former Soviet Union (fSU). Lake Baikal has a remarkable freshwater ora and fauna: over 2500 animal and plant species have been identi ed; of which it is estimated over

75% are endemic (that is, they are found nowhere else in the world today). Biodiversity levels in the lake are extremely high, principally because of its great age allowing evolutionary processes to proceed, but also because the entire water column is saturated with oxygen, allowing extensive, deep-water, endemic faunal communities to exist.

Over the last 30 years, Lake Baikal has been one of the fSU's environmental causes celêbres, due to both increasing exploitation of resources within the lake, and perhaps more importantly, increasing contamination of its water by pollution from industrial growth in the catchment. In recognition of Lake Baikal's global ecological signi cance, the United Nations Educational, Scienti c and Cultural Organization declared it a World Heritage Site in 1996.

Lake Baikal consists of three basins of differing geological age within a series of rift zones. The basins are separated by two underwater highs, the Selenga Shallows in the south (separating the south and middle basins), and the Academician Ridge, separating the middle and north basins (Figure 1). The rift zones are associated with intense seismic activity, and are currently expanding at a rate of c. 20 mm year^{-1} (SB-RAS, 1996). Accordingly, Lake Baikal also occupies the deepest continental depression at 1164 m below sea level (Table 1).

In terms of area, Lake Baikal is the world s seventh largest freshwater lake, but it contains the world s largest volume of freshwater (over 23 000 km^3) because of its great depth (Kozhov, 1963). Lake Baikal is, therefore, an important freshwater resource. The majority of water enters the lake through some 365 rivers, although there is only one outflow from the lake, the Angara River in the south basin. The Angara flows northwards through the heart of Russia, before it eventually merges with the Yenisei River and then enters the Arctic Ocean. Two-thirds of the water entering Baikal is contributed by just three rivers: the Selenga, the Upper Angara and the Barguzin Rivers which yield 47, 13 and 6% of water input, respectively. The largest, the Selenga River, has its source in the Mongolian highlands.

Lake Baikal is strongly influenced by a continental climate: mean daily temperatures in January fall to an average of c. $-25\,^{\circ}$C, whilst in July they are in the region of c. $+18\,^{\circ}$C. Winters are long, cold and dry, whilst summers are relatively hot, short and wet. The surface of the lake freezes every winter (late December in the north basin to January in the south basin) until the following May (in the south basin), and June (in the north basin). Ice thickness during this time reaches between 80 120 cm. Ice formation and cover are affected by local and regional climatology, although influences from the North Atlantic Oscillation have also recently been found. The lake itself promotes local temperature differences, with the formation of a local climate within 25 km^3 of its shores, with slightly warmer winters and slightly cooler summers.

Table 1 Major morphological characteristics of Lake Baikal

Length (km)	636
Mean width (km)	49.3
Total area (km^2)	315 000
Maximum depth (m)	1642
Mean depth (m)	738
Volume (km^3)	23 000

The catchment area of Lake Baikal is vast (over 540 000 km^2), spanning south-eastern Siberia and northern Mongolia (Kozhov, 1963). It has recently been split into zones, defined by both physical and economic geographies, which has been important in securing World Heritage Site status (SB-RAS, 1996). It is also a UNESCO Biosphere Reserve (*see* Biosphere Reserves, Volume 2). The zones are defined as: (i) the central zone, which includes the lake and natural parks and reserves around the lake; (ii) the buffer zone, which includes the rest of the physical catchment area both within Russia and Mongolia; and (iii) the zone of atmospheric impact, which occupies an area immediately outside the physical catchment area to the west and north-west of the lake. All three together comprise the Lake Baikal Region, which lies at the junction between several biogeographically distinct regions (e.g., taiga, steppe, tundra and high mountain deserts). Approximately 10% of the 2500 species of vascular plants in this region are endemic, whilst the faunal communities are even more diverse, and in the mountain regions at least, endemism is especially common (SB-RAS, 1996). The biota in Lake Baikal is derived from three principal sources: (i) local endemics; (ii) marine immigrants; and (iii) Asian immigrants (Kozhova and Izmest eva, 1998).

Lake Baikal is home to the world s only freshwater seal, or nerpa (*Phoca sibirica*), which is also Baikal s only mammalian endemic. It is thought that the nerpa are descended from the ringed seal *P. hispida*, (i.e., that they have marine ancestry) and have been inhabitants of Lake Baikal since the last Ice Age (Kozhov, 1963). Population levels are in excess of about 70 000 individuals, of which up to 6000 are culled annually. Adults generally live to an age of 50+ years. In recent decades, the fluctuating populations of seal have been the focus of environmental concern, outlined in more detail below. The majority of species within the fish population are also endemic, although there have been some recent introductions of more common species such as perch and roach. Some fish species are extremely unusual and have very specific adaptations to their environment. For example, the *Abyssocottus* genus only exists in the very deep waters of Baikal, whilst another genus, the *Comephorous*, is specifically adapted to live in the open water, has large pectoral fins, and a scaleless, translucent

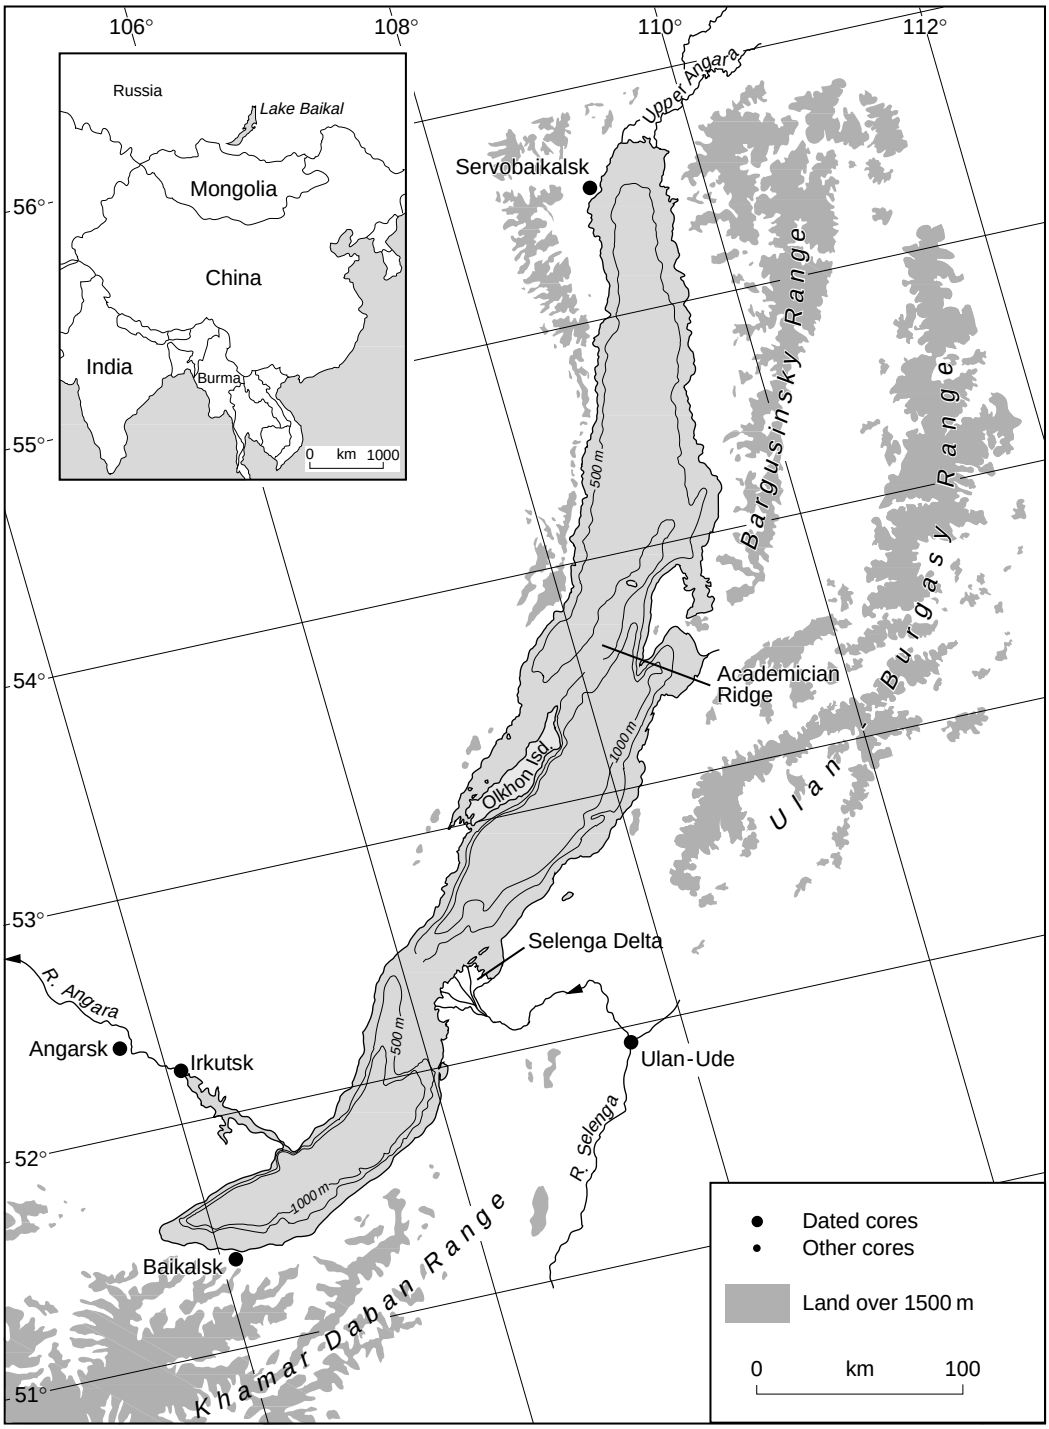

Figure 1 Map of Lake Baikal and its immediate catchment. Major towns are indicated, as are the rivers, Selenga and the Angara, and the two underwater highs, the Selenga Delta and the Academician Ridge

body and reduced ossification. Relatively few species of fish are commercially exploited in Lake Baikal, the most important one being the omul, *Coregonus autumalis migratorius*.

Levels of endemism increase further in the invertebrates, especially the crustaceans (e.g., gammarids), the molluscs (e.g., gastropods), the annelids (e.g., polychaetes) and free-living flat worms (e.g., Platyhelminthes).

Along the coastlines of Baikal, there are few species of higher plants, except for local occurrences of *Myriophyllum*, *Potomogeton*, and *Elodea canadensis*, a recent

introduction. Lower plants, especially the algae, are more diverse, of which perhaps the diatoms (Bacillariophyta) are the most important and interesting group. Diatoms are unicellular plants encased by ornamented silica shells, or valves. The hundreds of endemic diatom species in Baikal ensure that they are important primary producers in the lake, comprising approximately 57% of the lake s planktonic community. Diatoms are by far the dominant producer of biogenic silica, contributing around 98% of all sedimentary silica.

Lake Baikal is an important site for studying past global climate change for a number of reasons: (i) it is sensitive to changes in insolation patterns caused by orbital forcing; (ii) it is close to the boundaries of two globally important weather systems (the Siberian High and the Asiatic Monsoon); and (iii) Lake Baikal contains one of the few very long lacustrine (i.e., lake) records of environmental change that is comparable to marine records. The Baikal rift zone has never been glaciated, and since its formation, over 7500 m of sediment have accumulated. The sediments are composed largely of biogenic silica (from diatoms) and clastic and fluvial input from Baikal s catchment. These sediments contain the remains of pollen grains and fossil diatoms (amongst other environmental proxies) going back millions of years, which can be used by scientists to reconstruct past environmental change in the lake and its catchment. For example, pollen analysis can tell us when the catchment of the lake was covered by forest, e.g., in warmer climates such as the present-day one, or when steppe vegetation was dominant, indicative of cooler climate. The diatoms can provide information on past climate change around Lake Baikal from as little as c. 150 years ago (e.g., Mackay *et al.*, 1998) to as far back as 5 million years ago (e.g., Williams *et al.*, 1997). Past climate in the Baikal Region has responded to both global changes relating to the earth s orbit, and to changes in the Earth s ice-cover, despite the continentality of its location. These changes not only manifest themselves on biological activity in the lake, but have also had direct influences on lake-water levels, which have risen and fallen in the past by hundreds of meters.

Human influence around Lake Baikal has been evident since at least the Neolithic period, as small populations hunted nerpa on a seasonal basis. Asian populations, such as the Buryats and the Mongols have also existed around Baikal for centuries, but the first Russian settlers did not arrive until the mid-17th century. However, only since the 1950s have environmental concerns for the lake developed into national and international issues. These concerns focus mainly on point-source pollution from two paper and pulp mills (built in the 1960s 1970s) in the towns of Baikalsk in the southern basin, and Selenginsk on the Selenga River. During the 1980s, the environmental campaign against these industries gathered pace, and extended to include logging in the catchment, over-fishing, the dumping of effluents from other factory waste products and partly treated sewage, and atmospheric contamination from recent increases in industrial emissions. The largest sources of sulfur dioxide (SO_2) and particulates are from oil-fired power stations at the town of Angarsk. It has recently been established that pollutants indicative of fossil fuel combustion, i.e., spheroidal carbonaceous particles (SCPs) have increased in the Baikal region over the last 50 years (Rose *et al.*, 1998). SCPs are only produced by high temperature combustion, and are, therefore, unambiguous indicators of anthropogenic contamination. Concentrations of these particles in Baikal show spatial differences, with highest concentrations found in the southern basin, where industrialization and urbanization are highest. Small increases are also evident in the north basin, where, in recent decades, new centers of urbanization have been developed, e.g., the town of Severobaikalsk. These increases closely mirror levels of fossil fuel combustion in the catchment. As well as SCPs, heavy metal input into the lake is also increasing, such as quantities of lead, copper, zinc and vanadium. However, attributing heavy metal concentration increases solely to anthropogenic contamination is more difficult than for SCPs, as these metals are also produced naturally in the catchment, and will increase in the lake as the catchment is disturbed. Current levels of metals in Baikal are greatest in the southern basin, but the effects of these pollutants are still debated. For example, it is well known that toxic levels of mercury and cadmium can cause immuno-suppression in animals, and whilst these poisons can be detected in Lake Baikal, their concentrations are still low, and are similar to those of Northern Hemisphere background sites, such as the Arctic region.

Perhaps the greatest threat to the lake s biota, especially the nerpa, lies with increasing levels of persistent organic pollutants (POPs), polychlorinated biphenyls (PCBs) and dichlorodiphenyltrichloroethane (DDT). It has been shown that the Baikalsk mill caused locally enhanced levels of persistent organic chlorine compounds in the southern basin. Trends are complicated however. Concentrations of POPs in the air above Baikal are similar to those in remote regions, such as the Arctic, although levels in fish are comparable to those in the Great Lakes in North America, whilst concentrations in the nerpa were similar to those in animals found in, e.g., more polluted European waters, such as concentrations in the Caspian seal (Kucklick *et al.*, 1994). In the late 1980s, thousands of nerpa died from a morbillivirus, and environmentalists suggested that the seals immune systems had been compromised by increasing pollution levels, including POPs and heavy metals. On the other hand, many other scientists firmly believe that changes in the biota of the lake can be explained by natural variation, and during the 1990s, international research programs were established to collate scientific evidence on

the past and present environmental state of Lake Baikal (under the auspices of the Baikal International Center for Ecological Research).

Bioaccumulation of organic chlorine compounds, including DDT and PCBs, in the nerpa is clearly a problem, even though the physical environment of Baikal (water and sediments) contains relatively low levels of pollutants. A direct link has not yet been made between increasing organochlorine pollution and morbidity and mortality in *P. sibirica*, although mechanisms have been proposed. Much more research needs to take place, and it is encouraging in the meantime that several measures to reduce pollution in the lake have already been taken, such as converting the two pulp and paper mills into closed systems.

Further, pollution from other industrial and domestic wastes, increasing eutrophication (nutrient enrichment), uncontrolled fishing and logging of the catchment were also linked to declines in fish growth rates, the disappearance of endemic animals, and a general influx of more cosmopolitan flora and fauna. For example, *C. autumalis migratorius* is non-migratory and its numbers were severely depleted since the 1950s due to over-fishing, but since the introduction of catch controls, populations have increased significantly. One potential threat from increasing pollution of the Baikal ecosystem is the decline of numbers of endemic plant and animal species as a whole, due to deteriorating water quality. Diatoms, however, provide an excellent record of past environmental conditions, as they are very sensitive to changes in water quality (e.g., pH and nutrient enrichment) and climate. By examining diatoms in surface sediments, Mackay *et al.* (1998) found no evidence that the endemic flora in the lake had been affected by pollution. Therefore, there has been no deterioration in water quality due to pollution across the main body of water in Lake Baikal, although there is evidence for very localized eutrophication in the shallow waters of the Selenga Delta region.

Land Degradation in the Mediterranean

John B Thornes
King's College, London, UK

Land degradation is the reduction of the land's capacity to grow agricultural products. It mainly takes the form of soil erosion. Globally it is an important process that has accelerated over the centuries as pressure on the land for production has increased and as agricultural technology has changed. It is intimately linked to off-site effects such as ooding, reservoir siltation and water shortage and is often viewed as an integral part of the wider problem of deserti cation.

In Europe, lands around the Mediterranean Sea are most affected, especially the areas with low rainfall totals, high summer temperatures and seasonally concentrated rainfall. These climatic factors, which vary greatly in space and time, lead to a poor vegetation cover, particularly when they are linked to land husbandry practices unsuitable for the environment. Poor soils and steep mountain slopes exacerbate the problem. The changes in land management over the last century, related to North European markets, have also accelerated it.

The major approach to mitigating land degradation is to reconstruct the land cover. Forestry, the generally preferred option, may not be an optimal solution. Aside from the technical xes, such as terracing, check dams and reservoirs, it is the human dimensions that have to be addressed by policy makers.

LAND DEGRADATION AND DESERTIFICATION

Land degradation is the progressive reduction of the land s capacity to grow agricultural products. It comprises two main processes, the loss of the soil itself that acts as a framework for plant growth, and the loss of fertility. The latter normally accompanies the former because most of the nutrients are stored near the soil surface. This means that a modest amount of erosion may lead to a substantial loss of fertility. Soil erosion has other impacts. The lost material is transported by surface water and rivers to off-site locations where, by its accumulation, it may cause other problems. For example, it may cause siltation of reservoirs, burial of crops or of irrigation equipment. Accumulation of deposits in channels increases the risk of flooding and may cause direct damage to residential property. Soil degradation is inseparably linked to hydrology. Soil acts as a sponge for rain and, if its storage capacity is reduced by soil erosion, more of the rain is lost to runoff and therefore more erosion occurs. Therefore, there is a vicious circle of feedback. The more erosion that occurs, the more that is expected to occur. The end of this cycle is only reached when all the soil has been stripped and the surface largely compromises bare rock, from which rainwater runs off more or less instantaneously. Not only does more water run off into rivers, but it also gets there more quickly. Water on the surface can reach speeds of $1\,\mathrm{m\,s^{-1}}$. Water traveling through the soil may reach $1\,\mathrm{m\,day^{-1}}$. Water traveling through rock may take one day to travel 1 cm, depending on the type of rock.

Deserti cation is land degradation due to climate and human causes, but this definition, from the United Nations (UN), includes water and vegetation in the term land, so it refers not only to soil erosion, though this is generally thought of as the main indicator of desertification. Countries and even international agencies have often tended to exaggerate the extent of land degradation for political purposes, and there has been a lively debate about this in recent years. Thomas and Middleton (1994) claimed that desertification was a myth perpetuated by United Nations Environment Programme (UNEP), to draw attention to its International Convention, though they themselves were contributors to UNEP s *Atlas of World Deserti cation*. It is, however, extremely difficult to obtain accurate estimates of erosion because of the huge variety of conditions and the crude methods of its measurement. Often rates of erosion are estimated from small plots inadequate in size. Sometimes they are very few in number so that it is impossible to obtain a statistically representative sample. Sometimes the rates are generated by simulated artificial rainfall that fails to replicate the characteristics of real rainfall. The plots have strong biases arising from their construction, with water and sediments leaking down the cracks where the metal edge has been installed. Another approach is to estimate the total load of sediments carried by a river from a basin. Potentially this is the more accurate approach. It involves multiplying the discharge (flow rate of the river) by the concentration of sediment in the flow. There are many other techniques, for example measuring the depth of exposure of tree roots that appear to mark former ground surface; or fence posts, whose original placement and age is known. Not all systems are so crude and recently the concentration and profile of radioactive fall-out in the soils has been used. Generally, however, rates of erosion are extremely difficult to obtain with much confidence. What is clear is that they vary greatly over very small distances. As a consequence, estimates are made with models ranging from the empirical universal soil loss equation (USLE) to sophisticated computer models such as WEPP (Water Erosion Point Predictor) and EPIC (Erosion Point Impact Calculator). These models have been developed and tested mainly by the United States Department of Agriculture, but despite the vast resources involved in their production they can still only give rough estimates that are little better than those obtained from field experiments. So we really do not know how much or where or when land degradation has occurred.

Computer models (Kirkby and Neale, 1987) and field data converge on the view that Mediterranean regions have some of the highest erosion rates in the world. The general plot of erosion against mean annual rainfall adjusted for evapotranspiration is shown in Figure 1. Although this is for North American data, the overall relationship represents causal factors and should hold in the Mediterranean as well (see discussion). The curve is highest where effective rainfall is about 300 400 $\mathrm{mm\,year^{-1}}$, typical of large areas of the drier parts of the dry lands surrounding the Mediterranean Sea. The argument runs as follows. In drier areas (to the left of the peak) there is insufficient rain to create runoff. At the extreme, with no rainfall, there can be no runoff. As the rainfall increases, erosion increases relatively quickly, peaking on bare soils. To the right of the peak the continuing increase in mean annual rainfall means that vegetation (which suppresses erosion) grows faster. The increase in erosion produced by more rainfall cannot keep up with the decrease caused by more vegetation.

One important omission from this general approach is the effect of seasonality. One of the strongest features of Mediterranean environments is the strong contrast between summer and winter. Summers are hot and dry and winters are cool and wet. The stronger the seasonality, the stronger is the erosion. So much so that, as Kirkby and Neale (1987) show with model studies, where most of the rainfall falls in one month, the curve continues to rise as rainfall increases beyond the Mediterranean peak, so that with strong seasonality, the wetter areas of the Mediterranean can still have high erosion rates (see Figure 2).

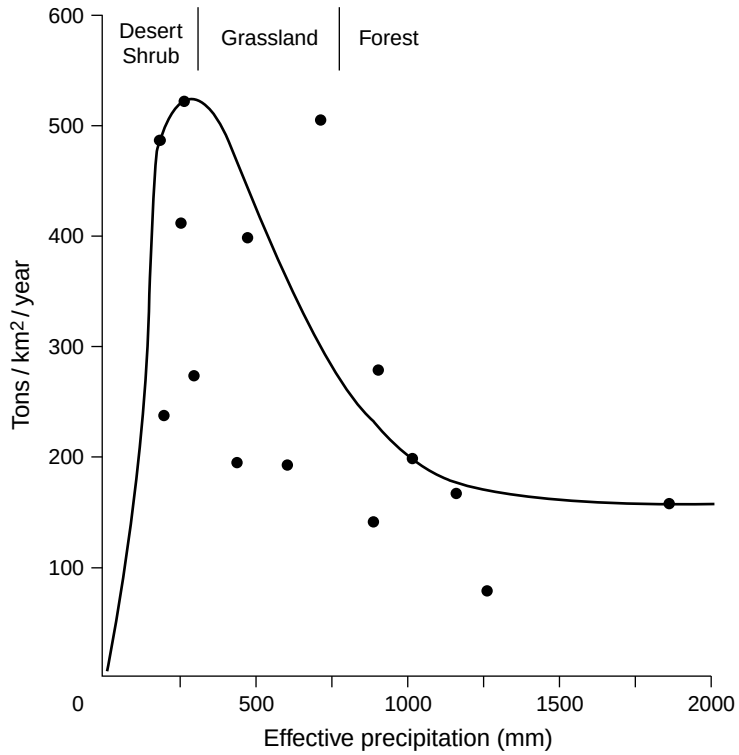

Figure 1 A general plot of erosion against mean annual rainfall, adjusted for evapotranspiration, based on data from the United States according to Langbein and Schumm (1958)

Rainfall intensity is the amount of rain that falls in a given period of time, measured in mm hour^{-1}. The more intense the rainfall, the more quickly the soil fills up and water starts to flow over the surface, because the soil is saturated (*saturated overland ow*). Alternatively, if the rain is coming down faster than it can infiltrate into the soil, it again is forced to flow over the surface (*Hortonian overland ow*). Consequently storms with higher intensity produce more erosion. It is generally true that the kinetic energy of rainfall is related directly to intensity (higher intensity, higher kinetic energy). High kinetic-energy rain detaches the soil particles by rainfall impact, a process called *splash erosion*. The splashed particles are thrown into the overland flow and carried away. Winter storms often have low intensities (20 30 mm hour^{-1}). By contrast summer storms have highest intensities (say 60 mm hour^{-1} in about 1 year in 5). Some of the most extreme intensities are found in the autumn storms when depressions, formed over the Mediterranean Sea, move inland and the air is forced to climb high mountains near the coast (orographic lifting). The intensities may reach 140 160 mm hour^{-1} and the storms may be sustained for many hours.

The strong seasonality in rainfall leads to sharp seasonal variation in soil moisture as shown in Figure 3. Throughout the winter, soil moistures are typically high, though they still respond to individual rain events, as indicated by the vertical black bars. After the spring rains, there is a dramatic fall in soil moisture as the summer heat begins to develop. Soil moisture remains low throughout the hot dry summer months, rising sharply again with the autumn rains, to winter high values.

LAND DEGRADATION AND VEGETATION

A direct consequence of this regime is that plants (agricultural as well as wild) have difficulty in producing enough growth to survive the summer drought. Roughly speaking, the amount of visible plant (above ground biomass) is directly proportional to rainfall in dry areas. So vegetation in Mediterranean drylands, that typically have 300 500 mm year^{-1} of rainfall, is quite sparse. Moreover, the vegetation comprises mainly bushes which can tap water at great depths and are ecologically suited to the overall environmental conditions, including human activity. As a result, when land is abandoned, the recovery of vegetation is often in the form of bushes, low trees and herbaceous shrubs. This is called *matorral* or *monte* in Spain, *maquis* in France, *macchia* in Italy and *phrygana* in Greece. This vegetation has a variable impact. Bushes may concentrate overland flows to cause higher rates of erosion and tiny stream channels called *rills*. They also provide a good general cover, sometimes almost as good as small pine

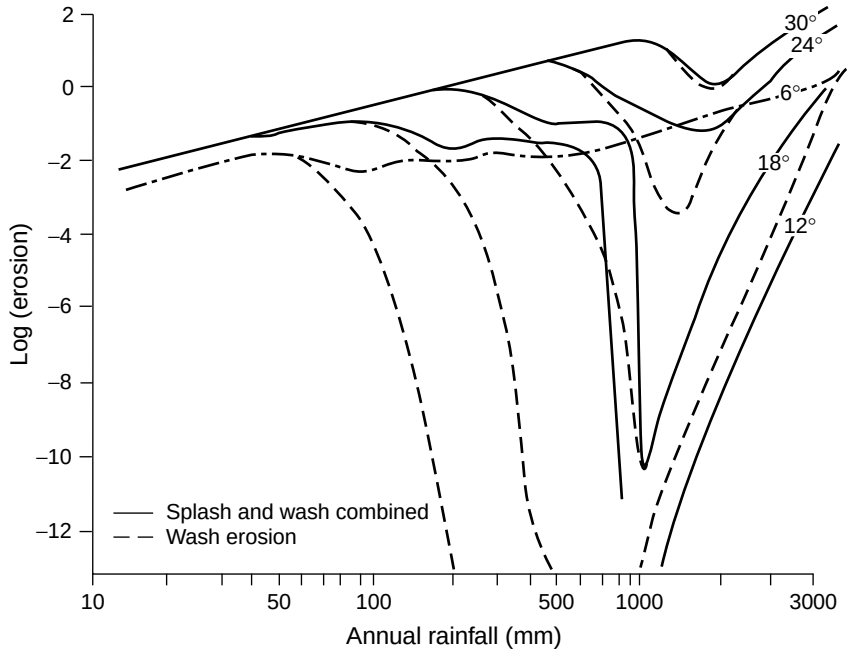

Figure 2 Kirkby and Neale's model output on the relationship of erosion and rainfall that emphasizes the effect of the concentration of rainfall into certain months of the year and the direct effects of temperature (T °C). *Wash* refers to erosion caused by water running over the soil surface. *Splash* refers to the process whereby soil is detached by the impact of falling raindrops. *Erosion* is the combination of the detachment of soil by splash and wash and its transportation away from the point of detachment. The curves are for different slope angles

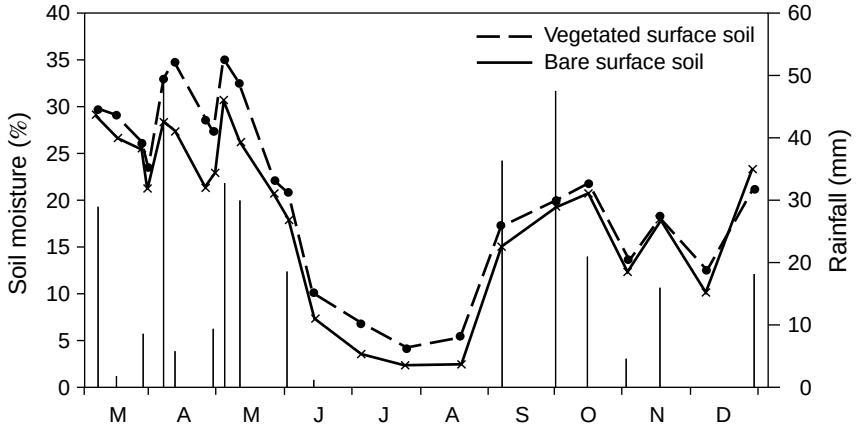

Figure 3 Soil moisture variations through time in the dry Mediterranean (Murcia Spain, 350 mm rain year^{-1}) based on data collected by Professor F Lopez-Bermudez, University of Murcia, Spain

trees, and so inhibit other forms of erosion. The vegetation breaks up the raindrops and reduces their kinetic energy. The soil organic matter creates tubes and holes in the soil. This encourages infiltration and reduces runoff.

The relation of erosion and runoff to vegetation has been established and re-affirmed for over 30 years and is shown in Figure 4. The lower curve shows that, as plant cover increases, soil erosion falls very dramatically so that, as a rough rule of thumb, by the time that plant cover has reached 30%, soil erosion has fallen to 30% of the bare soil value. This shows that soil erosion is very sensitive to plant cover between 0–30%. This relationship is quite sensitive to rainfall intensity and the curve is most dramatic for LI and less dramatic for HI. As a result, quite moderate amounts of biomass can be as effective in reducing erosion as large amounts of biomass. Matorral or grass may be as good as trees. Conversely, anything that reduces cover in the 0–30% danger zone for vegetation can have a quick and dramatic impact on erosion rates.

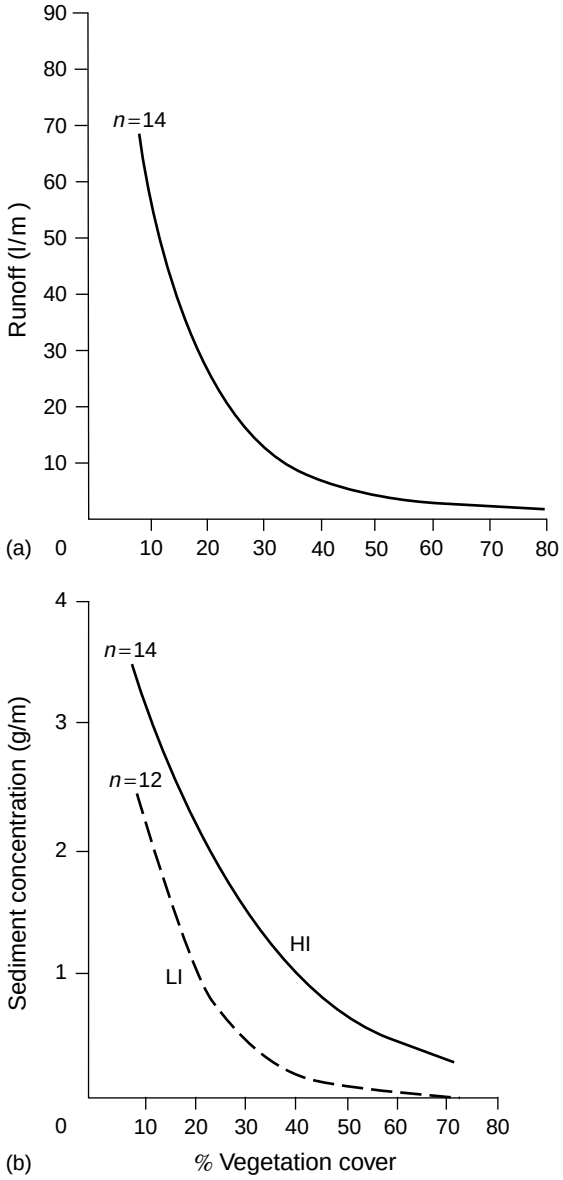

Figure 4 (a) the relationship of vegetation (x, cover percent) to erosion (y, proportion of bare soil erosion rate) according to Elwell and Stocking (1976). (b) The effects of high intensity (HI) and low intensity (LI) rainfall, as well as vegetation cover, according to Francis and Thornes (1990). The horizontal axis is the percentage of the ground covered by plants when looked at in plan view (i.e., from above). The vertical axis is the erosion rate as a fraction of that on bare soil

LAND DEGRADATION AND CLIMATE CHANGE

The impact of climate change on degradation is very complex. Given the estimated 3 °C warming, the carbon dioxide (CO_2) doubling and the expected reduction in winter rainfall that coupled models anticipate for the Mediterranean, Diamond and Woodward (1998) have modeled the expected impact on semi-natural vegetation in the Iberian Peninsula and have estimated the likely consequences for soil degradation. They indicate a marked reduction in vegetation biomass for bush and grass by 2050 AD, especially in areas where the vegetation is already quite marginal (those that have less than 30 mm of mean annual rainfall and more than seven months year^{-1} dry). These are notably in the provinces of Almeria, Jaen, Murcia and Granada. The effects on both bush and grass are much less dramatic in the more humid areas, such as the Autonomous Region of Catalonia and the Basque country of the northwest. In the dry areas, small changes in the already marginal vegetation cover must lead, according to the arguments made earlier, to substantial increase in runoff and erosion as the cover falls to less than the 30% critical amount. On the other hand, the response is likely to be complex, with a boom and burst type oscillation as the rainfall varies enormously from year to year and erosion and plant growth compete for dominance.

THE HUMAN IMPACT ON LAND DEGRADATION THROUGH THE CENTURIES: THE IBERIAN PENINSULA

Early man seems to have had little impact on erosion in the Western Mediterranean. Research suggests that the main features of erosion that we see today (the gully systems) were already in existence in Bronze Age Spain. Therefore, the widely held idea that erosion is mainly due to forest clearance has to be questioned. However, six millennia of traditional Mediterranean farming have resulted in significant amounts of soil erosion since prehistoric times. The traditional combination of bush and tree crops (vines and olives), animal grazing (goats and sheep) and cereal crops (wheat and barley) have taken their toll. The tree cropping is usually accompanied by the removal of weeds and grass between the trees to conserve water and nutrients and this reduces the cover. Grazing directly takes off the protective leaves and compacts the soil under the hooves of animals that may be in large flocks. In the mesetas of Central Spain, the ancient system of *mesta*, herding sheep and cattle along public trails, could lead locally to complete devastation of soils.

A major shock to the west Mediterranean system came with the Moorish invasions at the end of the first millennium, which brought citrus fruit cultivation and traditional irrigation practices. Irrigation had already been introduced in the form of Roman aqueducts, but Moorish irrigation meant that an economy already based on scarce water resources was moved further towards the margin and that the extensive agricultural economy was replaced by a more intensive one. The Moorish concept of the landscape as

a garden, however, meant that there was an emphasis on better land husbandry. The terrace as a device for water and soil conservation was already widespread, extending the possibilities for agriculture. As the Moors were expelled in the late 15th century, new immigrants from other parts of the Mediterranean took over the land and the struggles for production and ownership commenced and continued for half a millennium.

By the end of the 18th century in Spain, major land holding changes were in progress. The Royal Decree of 1793, applicable in Extremadura, attempted to increase cereal output by allowing farmers to plow up their pasturelands and saw the beginning of the end of the mesta system. Between 1798 and 1808, the first sales of church properties occurred. These changes were accelerated by the invasion of the French army that brought about major changes in land husbandry in the Spanish landscape. The population rise (12.5% between 1780 and 1820) forced the pace of agricultural production. By 1820 this surge had ended, as demonstrated by the increased exportation of agricultural products. Many more changes liberated land in the 19th century. Some of these changes had profound consequences for land degradation, particularly the redistribution of church lands, the best of which went to capable wealthy large landowners, whilst the poorest went into the public domain as common land that continued to be degraded by over-grazing well into the 20th century.

The next huge changes occurred in the middle of the 20th century. Mountain areas under vines, such as Eastern Andalucia, were impoverished by pestilence and emigration, so that land care became almost non-existent and terraces began to fail from lack of maintenance. The initiation of serious degradation in the Sierra Nevada can be traced back to the early years of the 20th century.

In the better agricultural areas, the pressure to increase production with the expansion of regional and global markets, coupled with the rise of tourism with its insatiable demand for water and market garden products, led to strong intensification of agriculture in the 1950s. Other technological changes mechanization, improved pumping systems and fertilization all added to the pace of modernization, adding pressures to land that had suffered the ravages of centuries. By 1965, the stamp of contemporary agriculture, and its attendant consequences for land degradation, had already been imposed. Entry to the European Community further added to these pressures through the last 30 years of the 20th century, as the emphasis on competitive productionist agriculture prevailed until the end of the millennium.

Spain and the other Mediterranean nations were already aware of their plight. But water received more attention than land, even though the two are inextricably related. By 1879, the Water Law allowed tax concessions on newly irrigated land and the consequent demand for water led to a boom of reservoir construction, exacerbated by the Spanish law of 1883 that allowed a 50% state subsidy for all major construction work. Other Mediterranean countries were quick to follow, though the early emphasis was on canals rather than on reservoirs. A slower uptake of irrigation resulted from the need for farmers, as well as engineers, to learn the techniques and skills of irrigation agriculture. Not least of all, they had to learn about the dangers of salinisation, a serious cause of land degradation in susceptible Mediterranean drylands and in coastal areas.

Although the Common Agricultural Policy (CAP) of the European Union (EU) strives to maintain the sustainability of rural populations, decrease the disparities between the gross national productivity of member states and incorporate measures that protect the environment, over the years there have been measures that have exacerbated the land degradation problem. The most general and most important of these policies have encouraged agricultural intensification by subsidies that have led to increased production in marginal areas, most notably for the support of mechanization and livestock farming (Papadimitriou and Mairota, 1998). A specific example is the generous economic support given to seed oil (sunflower oil) producers by the EU. It is claimed that it has led to the collapse of olive oil prices relative to sunflower oil and, in turn, to the abandonment of olive groves in southern France and the Aegean Islands. Land abandonment does not invariably lead to land degradation, but can lead to an increase in animal husbandry, more intensive grazing and selective management of the vegetation cover, all of which increase the risk of degradation.

MITIGATING LAND DEGRADATION

The land degradation problem has now been recognized and highlighted in the UN s International Convention on Combating Desertification and Drought (ICCD), which has a special annex referring to the drylands around the Mediterranean. The ICCD has called upon affected countries (including Portugal, Spain, Italy and Greece) to set up National Focal Points and National Committees to establish the nature and causes of the problem and to develop National Action Plans to mitigate the problem.

Mitigation is a broad activity that can range from restoration to reclamation and rehabilitation. The US National Academy of Sciences defined these terms 25 years ago, according to the effects of these actions in relation to the initial conditions in the context of mining. At the simplest level, *rehabilitation* means that the land will be made useful, but with a different land-use and different species. *Reclamation* means that the site will be similar in ecological functioning after disturbance and will be habitable for similar, but not necessarily the same, species. *Restoration* means that the exact conditions before disturbance due to agriculture will be replicated after the remedial action.

Allen (1988) prefers the word reconstruction, a compromise term meaning to build an image of what something was in its original form. Although these terms were originally introduced for land disturbed by mining, they are useful in reminding us that mitigation involves more than simply covering the ground with vegetation to make it look visually more appealing.

Because most Mediterranean states have a land husbandry policy almost invariably dominated by a forestry ethic, it is especially important to be clear about what is understood, and intended by, mitigation. Forestry seems the obvious resort to providing cover and is usually the first option to be considered. A recent investigation of the action taken by Mediterranean governments indicates that they have almost invariably turned to forestry as the solution (Burke and Thornes, 1998). Because the original objectives of the action were never clearly specified, it is impossible to judge their success. The difficulties of evaluating the impacts of afforestation on runoff have been well documented (Rodda, 1976) on the basis of experiments carried out in the USA in the 1920s and 1930s. Moreover, in the face of public criticism, afforestation has been justified *post-hoc* on the basis that it sustains rural activity and is economically viable, both of which are debatable.

If we take the view that the primary objective is to reduce the loss of nutrients and to minimize off-site effects, then the major task is the reduction of soil erosion to a natural rate. Because erosion is a natural geological process that has varied through geological history, it is inconceivable that it can, and should be, reduced to zero. Because the rate of soil production is slow, it is essential to conserve what remains for future generations. At the same time, we have to reckon with achieving the sustainability of rural communities, especially agricultural production. This is a complex activity especially in the mixed farming economies that are widespread in the Mediterranean lands. Soil conservation also implies catchment water retention and hence reduced flooding and reservoir siltation and is certainly more than ecological reconstruction.

The restoration of plant cover is the highest priority, and this is naturally taking place as a result of a very widespread problem land abandonment throughout the Mediterranean, as in the rest of Europe. There have been strong objections, on aesthetic and practical grounds, to the use of exotics such as *Eucalyptus* spp., especially in Portugal. The problem is not only which species to use, but also where and when to plant. Computer simulations have shown that different patterns of planting in space and time have different success rates, but that these also depend on the climate history in the first decade or so after planting. If there is a drought punctuated by heavy storms, then regeneration can be very slow, the cover taking 13 20 years to reach the desired 30%. If regeneration is concentrated in the lowest third of the catchment, reductions in runoff and sediment yield are much more significant than if the upper third of the catchment is abandoned. A ramped (steadily increasing) abandonment is more effective than a steadily declining abandonment and so on. Of course, these are model results, though we are confident that the model fairly represents the plant growth and erosional processes.

These factors are beyond the control of foresters who do not usually have a choice in the matter, certainly not over the weather. Usually the least desirable land is abandoned first, often rocky land at the head of the catchment, difficult to access and farm, and so this is the first to receive attention from foresters on a lowest cost, least argument basis. Political and economic constraints will usually determine the rate of abandonment. In Italy, the reduction in the male population in World War II led to a rapid increase in land abandonment.

Other technical fixes are used as well as forestry. Where land is abandoned, terraces that were built hundreds of years ago are prone to collapse and serious soil erosion may ensue. Maintenance of these structures is part of the required husbandry package.

In water and drought management, hard solutions have generally been preferred, in the form of reservoirs in good (winter) times and check dams to slow down or halt the loss of sediment to downstream areas. The great emphasis on large dams to resolve water resource issues over the last 200 years continues today, even though world-wide, the emphasis has shifted to land husbandry and integrated catchment management as the preferred strategy.

Above all, given that land husbandry has been promoted and practiced since the times of Plato, we feel obliged to ask why land degradation is still a serious problem. Part of the answer at least must rest in the failure of politics and politicians to recognize the essential need to involve those directly engaged in land husbandry in the formulation and implementation of policies based on sound planning. Above all, an integrated, holistic view of the catchment must be taken to ensure that changes made in one place do not create fresh problems in another. European-wide directives and spatially uniform agricultural subsidies are not appropriate instruments for the temporally, spatially and socially extremely variable mosaic of Mediterranean landscapes.

Land Reclamation from Seas

Iris Möller
University of Cambridge, Cambridge, UK

Land reclamation from seas refers to the arti cial drainage of coastal areas and their subsequent enclosure and conversion to freshwater land. The newly created land surface is used as a sea defence and/or for agricultural, industrial, or residential purposes and has to be continuously drained to prevent the reversion to brackish or saltwater wetland. Land reclamation for agricultural purposes dates back to 2000 BC and has occurred in many parts of the world, leading to fundamental changes in the con guration of the world's sedimentary coastlines and contributing signi cantly to global environmental change over the past century.

Methods of coastal land reclamation differ with respect to the intended use of the reclaimed land, the nancial and technological means available, and the socio-political framework within which the reclamation scheme is carried out. Schemes range from the enclosure of existing wetlands by dykes and the construction of small brushwood groynes on intertidal mud ats to the arti cial planting of coastal wetland vegetation, the construction of docks or arti cial islands. Land reclamation from seas can have many undesired, local, regional, and global ecological and socio-economic side effects. Increases in coastal population combined with global sea-level rise and a fundamental uncertainty about the long-term sustainability of such large-scale human intervention in the natural evolution of the coast are likely to provide an unprecedented global challenge.

THE GLOBAL CONTEXT

Low-lying estuarine and coastal areas with their rich fishing grounds, fertile alluvial soils, and potential for transport and trade route development have attracted human settlement since the early days of civilization. Globally, more than 50% of people currently live within 60 km of the sea. As a result, human society has had to develop a variety of ways of dealing with the challenging nature of the sea while harnessing its many resources. On the one hand, the development of sea defense systems has been necessary to protect human lives, buildings and agricultural land from the destructive effects of waves and tides. On the other hand, the need for food and thus agriculturally productive land and space for settlements and industry has driven the development of methods of land reclamation from the seas. This has been particularly important in areas such as the southern North Sea, where the presence of shallow-sloping intertidal flats favors natural accretion of sediment. More than 20% of the land surface of the Netherlands consists of land that has been reclaimed from the sea (Stuyfzand, 1995) (Figure 1). The increasing industrial development of the world s coastlines over the past few decades has introduced a new dimension to land reclamation schemes. In addition, new scientific insights into the complexity of natural coastal processes have increased awareness of the potential environmental and economic impacts of reclamation schemes.

A BRIEF HISTORY OF LAND RECLAMATION FROM SEAS

It is not clear when and where the first attempts to claim new land from the sea began. There is no doubt, however, that early civilizations such as the Sumerians of lower Mesopotamia succeeded in draining the low-lying alluvium deposited by the rivers at the coast as early as 2000 BC for agricultural purposes. These societies also used the salt-tolerant vegetation of the intertidal areas seaward of their enclosure dykes as food and for medicinal purposes (Wagret, 1968). It is likely that the early hydraulic knowledge developed by the Sumerians in Mesopotamia made its way to Italy where, 1500 years later, the Etruscans transformed the swampy marshland of, e.g., the Po valley into productive market gardens. The Etruscans passed much of this knowledge on to the Romans but significant land reclamation in Northern Europe did not start until the seventh and eighth centuries when it became common practice in the region

of Flanders and Zeeland (now the southern part of the Netherlands).

Early land reclamation in Northern Europe was initially linked to the initiatives of individual farmers. By the 13th century, however, much land was reclaimed by monks who were encouraged by the local nobles and thus, land reclamation became closely linked to the national importance of the church and local and national politics. Land reclamation schemes continued to be predominantly driven by the need for agricultural land until the growth of regional and world trade in the Middle Ages increased the need to expand ports and related industrial development at the coast. It could be argued that land reclamation for industrial and residential purposes began as early as the 12th Century in the Netherlands. At this time, the practice of land reclamation was actively encouraged by wealthy merchants from the flourishing Flemish market towns of, e.g., Ghent and Bruges. Most of the reclaimed land on which the first settlements developed in Flanders and Zeeland, however, were initially reclaimed for agricultural purposes.

Land reclamation for the sole purpose of industrial use is a more recent development associated with the expansion of a large number of ports and port cities around the world. In the Netherlands, for example, large areas of intertidal wetland were reclaimed near Rotterdam to expand its internationally important port and related industries. Between 1950 and 1970, the port was extended by reclaiming an area of 11 km^2 from the sea (Pinder and Witherick, 1990). Other large-scale reclamations for the purpose of port development have occurred around the world, e.g., in New York, Marseilles and Le Havre in France, Southampton in the UK (*see* Shipping: Harbors and Ports, Volume 3), Zeebrugge in Belgium, Hong Kong, and Singapore. Nowhere has there been a more urgent need for land reclamations for urban use than in Japan. This is exemplified by the development of Tokyo metropolitan area with a population of over 20 million (Figure 2) (Pinder and Witherick, 1990).

Most recently, the increasing industrial need for reclamation of land from the sea has ceased to be limited to the simple seaward displacement of the shoreline and has involved new schemes that focus on the building of offshore islands in deeper water. One example of such a scheme is Kansai International airport in Osaka Bay, Japan, built entirely on such an artificial island. The increasing economic and industrial development at a global scale has led to large-scale wetland reclamation in previously less developed countries. In China, for example, some 1.19 million ha of tidal lands were reclaimed for agriculture, salt production, shrimp ponds, ship berths and other uses during 1950 1985 (Yu, 1994).

In addition to the potential agricultural and industrial use, land reclamation has been driven by the need for flood protection and to prevent the spread of disease. This was the case in Lagos lagoon, Nigeria, for example, where almost 400 ha of swamp were reclaimed between 1900 and 1946 (Mabogunje, 1968).

METHODS OF LAND RECLAMATION

Methods of land reclamation from the sea have varied through time and depend to a large extent on the natural characteristics of the coastal environments, the purpose of the reclamation, and the technical, financial and organizational means available. Initially, coastal land reclamation did not involve the artificial planting of vegetation or the placement of material in the intertidal zone but focused either on draining existing coastal wetlands (such as salt marshes or mangrove swamps) or on encouraging natural sedimentation and the formation of coastal wetlands before draining.

The earliest reclamation schemes focused on draining existing vegetated coastal wetlands, making them suitable for agriculture and protecting their inhabitants from flooding. Thus the Sumerians created ditch and canal systems to drain the low-lying alluvium deposited by the Mesopotamian rivers (Wagret, 1968) and the early land reclamation in the Netherlands began with small individual projects by local landowners who would construct mounds (terpen) to protect themselves and their cattle from coastal flooding (Knights, 1979). Causeways were constructed between these mounds and formed the first dykes (embankments) and *polders* (enclosed low lying

flat areas with controlled water levels and protection from surrounding higher water levels).

In addition to draining existing wetlands, methods were later developed to encourage the formation of wetlands from non-vegetated mud flats. Such methods rely on the successful accumulation and retention of sediment on the tidal flat. This can only be achieved in conditions of ample sediment supply and low wave and tidal current velocities. Furthermore, vegetation growth is only possible if surface elevations are raised sufficiently to allow enough exposure of plant seedlings between individual inundations and if sufficient drainage is available.

Simple breakwater/ditch constructions started to be used as early as the 13th century in the Netherlands and Northern Germany, to take advantage of the favorable natural conditions (i.e., ample sediment supply and hydrodynamic conditions favoring the settlement/retention of sediment and vegetation establishment). Brushwood breakwaters and small banks were used seaward of dykes to decrease tidal currents and waves in the intertidal zone and thus encourage sediment deposition and the colonization of the mud surface by vegetation. These methods are still being used and have led to the creation of approximately 160 000 ha of reclaimed land in the northern part of the Netherlands and Germany (the Waddenzee and Schleswig-Holstein) (Knights, 1979).

In addition to schemes that encourage the natural sedimentation and vegetation colonization of mud flats for the purpose of land reclamation, the artificial planting of coastal wetland vegetation in the intertidal zone has been attempted in many parts of the world. In 1996, e.g., the government of Bangladesh launched a large-scale program of planting mangrove trees outside coastal embankments. Although the aim was to provide added protection from tidal surges and create an economic resource and wildlife habitat, circa. 60 000 ha of the newly created wetland areas have subsequently been drained and used for cattle, goat, and buffalo grazing (Saenger and Siddiqi, 1993). In Europe, the planting of salt marsh vegetation, such as *Spartina townsendii*, to encourage the progression from mud flat to salt marsh became common practice in the early 20th century (Wagret, 1968).

Throughout history, technological development has had a large effect on methods of reclamation. This is well illustrated in the history of the Netherlands. While early reclamations were carried out on a small scale and by using simple ditches to drain the land, technical advances in the 16th and 17th century led to improved pump drainage driven initially by more efficient windmills, then by steam engines, and most recently by diesel and electric pumps. Such new technologies allowed a much larger scale approach to land reclamation. This type of drainage and enclosure method spread to a large number of areas within Europe. Over 29% of the total current land area (3.4 million ha) of the Netherlands is now pump-drained (compared to circa. 400 000 ha that are drained by gravity) (Knights, 1979). Further advances in technology have led to more advanced ways of land reclamation. The artificial placement of large amounts of sediment near the shore, for example, has been used to raise surface elevations before or after enclosure. This has been successfully used in the construction of artificial islands (e.g., in Osaka Bay, Japan) and industrial port developments (e.g., in Southampton, UK, where 1090 ha of the estuary were claimed in this way (Doody, 1992)).

REGIONAL AND GLOBAL ENVIRONMENTAL IMPACT

The success and long-term sustainability of coastal land reclamation can only be achieved if the methods and designs of such schemes are based on a thorough understanding of the natural (local and regional) conditions of erosion, accretion, wave and tidal action. Ignorance of the natural conditions and processes can not only lead to the failure of the land reclamation scheme itself but can also contribute to coastal environmental problems on a regional and global scale (Viles and Spencer, 1995) (Figure 3).

Undesired ecological and economical consequences have resulted from many land reclamation schemes. In the case of the mangrove plantation scheme of Bangladesh, for example, accretion has been so rapid that much of the land no longer supports mangroves and the objective of creating intertidal habitats and optimal timber production has had to be compromised (Saenger and Siddiqi, 1993). Other studies have shown that the reduction in intertidal area caused by reclamation in estuaries or partially enclosed tidal inlets may significantly alter the tidal prism (the difference between maximum and minimum amount of water stored in the tidal section of the estuary) and the balance between tidal flood and ebb currents. Such changes can lead to the silting up of tidal channels and rivers and this in turn can have implications for the navigability of these waterways and the dredging of channels may become necessary. An example of this can be found in the Westerschelde in the Netherlands, where embanking and poldering has led to a reduction in the tidal prism, increased sedimentation and the need for continuous maintenance dredging of the access channel to the port of Antwerp (Smit *et al.*, 1997). In addition to these physical effects of land reclamation, the conversion of saline intertidal environments to agricultural land can alter the chemical composition of adjacent ground and coastal waters. In natural coastal wetlands, for example, dead organic material gets broken down into iron sulfide or iron pyrites by bacteria that thrive in the waterlogged, anaerobic, conditions. When

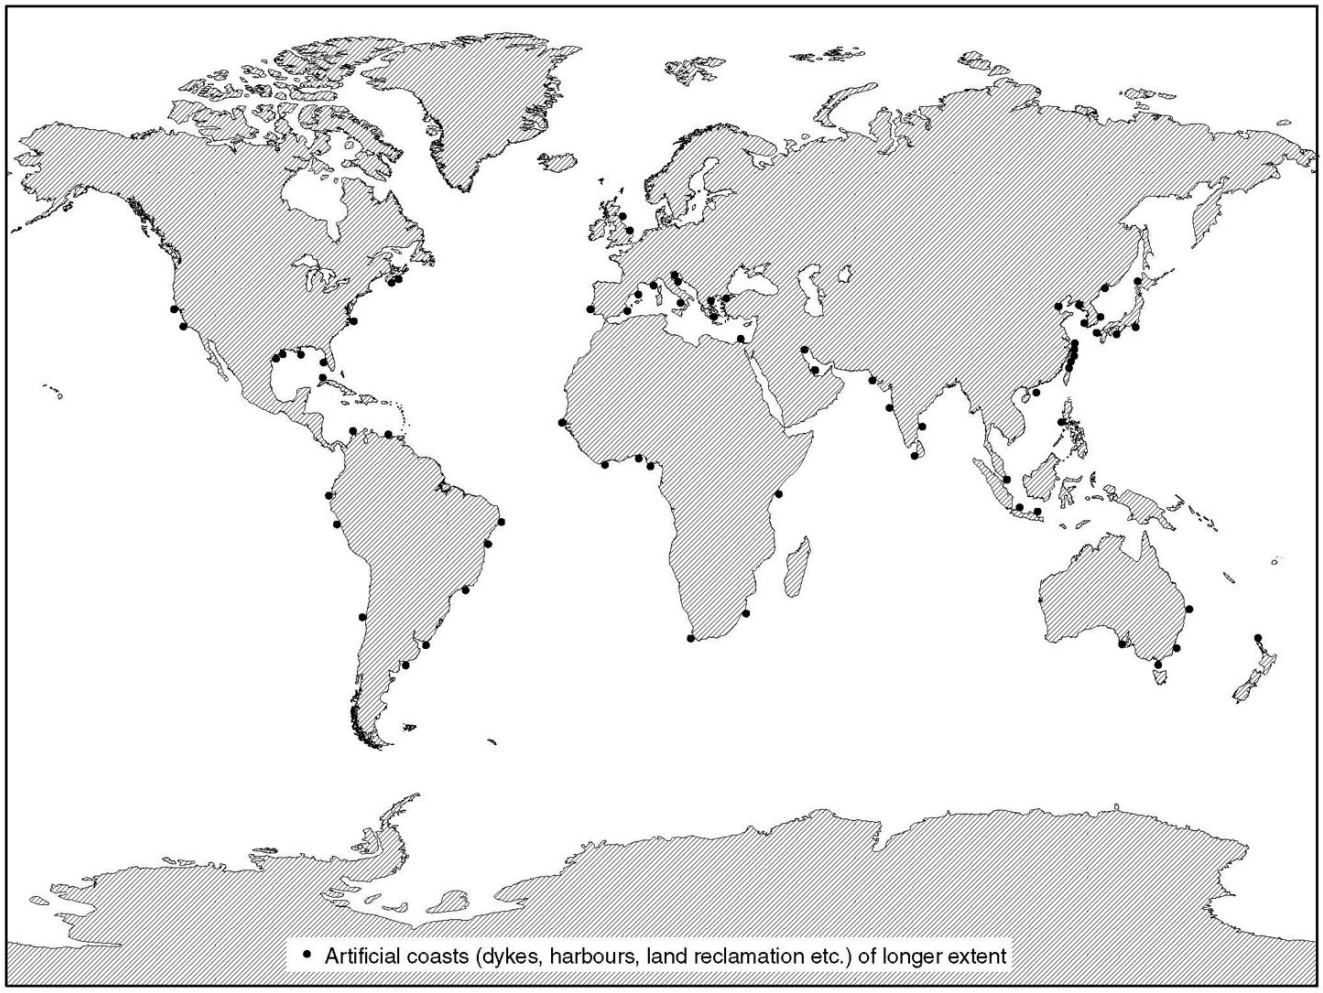

Figure 3 World distribution of major coastal problems related to artificial coasts (land reclamation, dykes, harbors, etc.,) of large extent. (Reproduced by permission of Arnold Publishers in Viles and Spencer, 1995)

these soils are drained as part of reclamation schemes, the iron pyrites come into contact with air and oxidize to form sulfuric acid (*see* **Acid Sulfate Soils**, Volume 3). When this acid reacts with clay in the soil, aluminum hydroxide ($Al(OH)_3$) may form and asphyxiate fish. This effect has been observed in relation to the mangrove areas of Southeast Asia that have been converted to rice fields or other agricultural uses (Anderson, 1991). Other chemical and hydrological problems may result from the intrusion of polluted water from adjacent rivers or saline water from the adjacent coast into the groundwater in continually drained reclaimed areas that lie below sea level (Stuyfzand, 1995).

The loss of intertidal, vegetated or non-vegetated, habitat, as a result of land reclamation itself can have important environmental impacts. Significant losses of intertidal wetlands due to reclamation have been reported from many parts of the world. In the UK, for example, over 56 000 ha of intertidal salt marsh have been reclaimed for agriculture (Doody, 1992) and in China the total area of mangroves declined from 50 000 ha to less than 20 000 ha between 1991 and 1994 (Yu, 1994), largely due to reclamation for agricultural use. In Korea, 1070 km^2 of intertidal land has been reclaimed mainly for agricultural purposes (Hong, 1991). As wetlands have a range of important functions at the local, regional and global level, such large-scale wetland losses are a matter of some concern. At the local level, wetlands act as important wave energy buffers (Knutson, 1988; Möller *et al.*, 1999), sediment stores and traps/filters for pollutants and toxic substances (Williams, 1991). At a more regional level, coastal wetlands provide habitats for a large range of plant, bird and invertebrate species. More than two-thirds of the commercially used fish and shellfish species of the Gulf and Atlantic coasts of the US, for example, depend on coastal or estuarine marshes as spawning or feeding grounds (Williams, 1991). Globally, tidal wetlands and estuaries are thought to constitute 3.18% of the total aquatic primary production

(De Vooys, in Bolin *et al.*, 1979) and there is growing evidence for the importance of coastal wetlands as part of the main biogeochemical cycles. In terms of the global carbon (C) cycle, it is thought that the uptake of carbon by the natural organic soils of temperate wetlands lies between 57 and 83×10^6 tons per year (Armentano and Menges, 1986). The large-scale loss of these environments due to reclamation is likely to have significant effects on global climate through influencing atmospheric carbon concentrations.

LAND RECLAMATION IN THE CONTEXT OF SEA LEVEL CHANGE

In most cases the reclaimed land (whether it is used for agricultural or industrial purposes) needs to be actively prevented from reverting back to land that is liable to flooding by the sea and/or periodic inundation by the tides. If land reclamation has taken place in areas where sea levels are rising relative to the land surface, such protection can require costly engineering structures such as, e.g., the extensive dyke systems of the Netherlands.

While many coastal areas experience a regional isostatic sea level decrease (due to a regional increase in the elevation of the land), others experience sea level rise (due to a regional decrease in the elevation of the land). In addition, global climate change may cause future global eustatic sea level rise (due to a change in the volume of water in the oceans). In 1995, the IPCC (Intergovernmental Panel on Climate Change) estimated that the latter effect could result in an increase in global sea level of 15 50 cm by the year 2100.

In the context of such potentially high rates of sea level rise, the protection of reclaimed land from inundation by the sea may become economically and environmentally unsustainable on some coastlines. In such circumstances, it is not unknown for reclaimed land to revert back to intertidal sand/mud or marshland. In some countries, the option to abandon reclaimed land and to recreate mud flats and/or saltmarshes is strongly supported by conservationists and is becoming an integral part of coastal management schemes. If such abandonment is approved by coastal management authorities (and involves the deliberate breaching of sea defenses or the failure to repair storm damage), however, a multitude of political, economic and social issues (such as, e.g., compensation for the loss of agricultural land), need to be addressed.

Increasingly refined estimates of future sea level change and an increased knowledge of coastal morphological evolution will be required if the sustainability of particular past and present coastal land reclamation schemes is to be assessed in the context of sea level change.

CONCLUSIONS

The reclamation of land from the sea has remained an important means by which to harness coastal resources and satisfy human demands for space in the coastal zone. On a regional scale, however, the socio-economic driving forces behind this have changed through time. While the need for agricultural land dominated early land reclamation schemes, the need for industrial developments and residential space has become more urgent in many industrialized countries over the past few decades. Similarly, the geographic focus of land reclamation from seas is shifting. Throughout history, Northern Europe (and especially the Netherlands) has been the region with the most significant gain in land due to reclamation from the sea. In recent years, however, the increasing economic development of low-lying coastal regions of previously less developed countries is likely to increase the need for agricultural, industrial, and residential coastal land in other parts of the world. The regional and global rise in coastal population and future predictions of global sea-level rise are likely to exacerbate the problems that are associated with the large-scale losses of intertidal habitats that inevitably result from land reclamation from the seas.

Land Subsidence

Land subsidence is the lowering of the land surface elevation as a result of changes that take place underground. Common causes of land subsidence from human activity are: pumping water, oil and gas from underground reservoirs; dissolution of limestone aquifers (sinkhole formation); collapse of underground mines; drainage of organic soils; and initial wetting of dry soils (hydrocompaction). Land subsidence causes many problems including: (1) changes in elevation and slope of streams, canals and drains; (2) damage to bridges, roads, railways, storm drains, sanitary sewers, canals and levees; (3) damage to private and public buildings; and (4) failure of well-casings from forces generated by compaction of fine-grained materials in aquifer systems.

Traditional surveying techniques to monitor subsidence, such as global positioning systems campaigns, provide accurate point measurements over limited areas. Synthetic aperture radar interferometry is now used to monitor small-scale surface displacements over large areas, such as major sectors of cities, providing a denser coverage and more complete information of surface height changes.

Land Transformation in China: 3000 Years of Human Ecological History

Rusong Wang
Beijing, China

Land transformation from natural ecosystems to croplands in China started 7000 years ago and has been ourished for the last 3000 years in the middle reaches of the Yellow River. Based on the well-developed human ecological tenet that " Man and nature be as one" , China has enabled nearly a quarter of the world's population to survive for thousands of years on about one- fteenth of the world's farmland.

Dramatic land use and land cover changes have taken place in China in the last two decades since the country was opened to the world and began the transition from a planned to a market economy. Although bringing prosperity and hope to the people, the pace, depth, and magnitude of this transition have exerted severe ecological stresses on both local human living conditions and regional ecosystems.

Faced with the sharp con icts between old traditions and the new transition, an eco-development campaign towards sustainable development has been initiated in some regions of the country aimed at physical and human ecological restoration.

THE OLD TRADITION: HUMAN ECOLOGICAL THOUGHTS ON SUSTAINABILITY IN ANCIENT CHINA

China is a huge country with a population of 1.2 billion, and an area of 9.6 million km^2, two-thirds of which are in highland, hillside or marginal land areas. Its one million km^2 of farmland is mainly located in the eastern and southeastern parts of China. Based on the geographical and demographic conditions, the country can be divided into three regions: the coastal region with 48% population, 13.5% land, 62% gross domestic product (GDP); the interior region with 41% population, 25% land, 32% of GDP; and the remote region with 11% population, 61.5% land, and 6% of GDP. The country s *per capita* farmland amounts to only 0.1 ha. China s climate is characterized by the summer monsoon, which brings high rainfall in July and August, but dry winter conditions. Water and land are the two limiting factors for the life-supporting system. The ecological disasters of flooding, famine and pest outbreak have beset the Chinese for at least 3000 years. In part they are caused by overloading of the carrying capacity of the land in densely populated areas, such as the middle and lower reaches of the Yellow and Yangtze River Basins. As a traditional

agricultural society, ancient China paid more attention to land sustainability. To survive from the marginal water and land, people had to plan, design and manage their environment in accordance with nature by resorting to making efficient use of resources from their native ecosystem. There were no wastes in ancient China, either in towns or rural areas: all wastes were degradable and used as fuel, forage or fertilizer for local ecosystems.

An example is Chinese agriculture. With 7000 years history, Chinese agriculture has maintained sustainable production and soil fertility with the holistic human ecological view has played an important role. The traditional, widely accepted practice of agro-ecological engineering plays a key role in maintaining this densely populated land. Its purpose is to design and maintain a sustainable agricultural ecosystem by enhancing the mechanism of material regeneration and recycling, maintaining ecological integrity and self-reliance. Measures include intercropping, interplanting, total metabolism farming (combination of cropping, husbandry, fishery, forestation and agro-products processing), integrated pest management, soil cultivation through organic and green manure, and biogas systems. In hundreds upon hundreds of villages in China agriculture was sustainable for centuries and the people enjoyed a harmonious country life with nature, with cities and with each other.

Contrasted with the mechanical thoughts dominated in western industrial societies, ancient Chinese human ecological thought emphasized system nexus and dialectical thinking, advocating that man and nature were as one. The ideas of Tian (heaven or nature), Di (earth or resources) and Ren (people or society) and their relationships have been accepted for thousands of years and formed the concept of Chinese human sustainability. The most fruitful period was from Spring and Autumn Time (770 476 BC) to Warring States Time (475 221 BC), when various philosophical schools, including Confucianism, Taoism, Legalism, Yin Yang, Logicianism, etc., flourished. The result is an organized set of principles for managing the relationship between people and the environment. These principles include: Dao-Li (physical relationship with the universe, geography, climate, etc.); Shi-Li (planning and management of human activities, such as agriculture, warfare, politics, medicine.); and Qing-Li (ecological ethics, psychological feelings, attitudes, motives and values towards the environment). Other important principles are: Yin Yang (negative and positive forces playing upon each other provide the basis for all ecological relationships); Wuxing (five fundamental elements and movements within any ecosystem promoted and restrained by each other); Zhong Yong (things should not go to their extremes but take a moderate way) and Feng Shui theory (Wind Water in Chinese expressing the geographical and ecological relationship between human settlements and their natural environment).

The theory of Yin Yang and the Five Elements is the main theory about the structure and origin of the universe, including the relationships of Man and nature. Yin Yang is a theory on the relationship and rules of things and phenomena. Yang originally referred to the sun or the heaven, while Yin refers to the moon or earth. Yang means male, positive, hot, bright, dry, hard, etc.; Yin represents female, negative, cold, dark, damp, soft, etc. The interaction between Yin and Yang produces all things and phenomena and maintains a specific balance. The interdependence and transformation between Yin and Yang result in the dynamics of nature and human society (Wang and Qi, 1991).

Wuxing theory (the Five Elements) divides nature into five agents, i.e., wood (living organism), fire (energy), soil, metal (chemicals) and water. They are promoted and restrained by each other. Wuxing theory was used to explain the network relationships within nature, society and the human body. All natural phenomena and human activities are in this network and connected with each other. Any component either too strong or too weak will put negative impacts on other components as well as on itself through feedbacks. For example, inappropriate behaviour towards nature will be punished by nature. Social change and dynasty succession are also related to the Five Elements. The holistic view implied in the theory of Yin Yang and the Five Elements claims that Man is nourished by nature, grows up as the seasons change, exchanges energy and materials with the environment and thereby is always affected by nature. Meanwhile, Man is also able to adapt and reform the environment.

The principle of Zhong Yong, a common philosophy of Confucianism and Taoism, claims that a contrary result would occur if something developed to an extreme. Therefore, it is recommended that one be Chongho (appropriate, harmonious, neither too hurried nor too slow), and Yongchang (taking things easy and moderate, adapting to nature), Mingcheng (showing good sense in natural laws and social activities). The great tolerance of the Chinese people to difficult times was affected by the thought of Zhong Yong.

Feng Shui theory, despite its superstitious components, is a kind of ecological theory for landscape planning and design. It deals with the ecological integrity between Man and the land as follows (Wang and Hu, 1999):

- totality: geographical continuity, hydrological cycling, ecological integrity, and cultural consistency;
- harmony between structure and function, internal and external environments, implicit and explicit layout, nature and Man, objective being and subjective value, material and spiritual goals;
- mobility: constant wind and flowing water, vertical and horizontal flow, meandering streams, undulating and far reaching;

- vitality: luxuriant, flourishing and productive fauna, flora, soil and aquatic biomes;
- purity: clean and transparently clear water and air, quiet and secluded surroundings, carrying capacity never overloaded;
- safety: spacious, open, easy to disperse and defend, disaster resistant;
- diversity and heterogeneity of landscape, ecosystem, species, society and culture;
- sustainability: negative and positive interlocking feedbacks, self-reliance, self-maintaining, sufficiency and efficiency, appropriate exploitation and development.

The first part of the Chinese word *sheng* means Man on the land . The modern landscape is a kind of human-dominated ecosystem driven by technological and social behaviour, sustained by natural life support systems, vitalised by ecological processes. Shijun Ma termed it a social-economic-natural complex ecosystem (Ma and Wang, 1984) that is driven by energy, money, power and the human spirit. The ten eco-cybernetic principles in ancient Chinese human ecological philosophy fall into three groups: competition for resources and available living space; symbiosis among: (1) Man and nature; (2) different groups of human beings; (3) any human ecological unit and its upper level ecosystem; and (4) self-reliance to sustain the structural and functional stability of an ecosystem through self-organization and recycling (Wang *et al.*, 1990; Wang and Hu, 1994).

THE NEW TRANSITION: RAPID LAND TRANSFORMATION IN RECENT DECADES

China is experiencing rapid growth through regional urbanization and rural industrialization. During the past 20 years, the GNP and the number of cities and towns have increased threefold. Nearly all types of environmental pollution experienced in industrializing countries and of ecological deterioration characteristic of poor developing countries have emerged in China. During the past 50 years, for example, the total farmland was reduced by a quarter.

The Yellow River, the second largest river in China, first began periodic cessations of flow in 1972 due to the excessive human impacts on the upper and middle reaches resulting from urbanization and industrialization (*see* Yellow River, China: a Case Study in Water Resources, Volume 3). Thousands of reservoirs, waterworks, canals and huge engineering schemes in the upper and middle reaches have weakened the river s vitality, mobility and eco-service functioning. As a result, the frequency, duration, and length of cessation have increased year by year, and the date when flow ceases has become earlier and earlier every year since 1972. The average annual duration of no flow was 21 days in the 1970s, 36 days in the 1980s, 122 days in 1995, 133 days in 1996, and 226 days in 1997. The cessation started 85 and 102 days earlier in 1996 and 1997, respectively, than in 1995. Urban and industrial demands for water have been met at the expense of water use to maintain natural ecosystems and agriculture. This in turn has led to severe regional ecosystem degradation.

The long duration, widespread flooding in the middle reaches of the Yangtze River basin in 1998 is another significant example of Feng Shui deterioration. Though the total rainfall in the watershed in 1998 was close to the median level over the last 100 years, and less than that in 25 other years, the river level at most stations exceeded or approached the highest ever recorded. The damage was much heavier than before with a direct economic loss of more than 166.7 billion yuan Ren Min Bi (RMB). The direct causes of this disaster are eco-capital loss, eco-service function degradation, blocking of eco-throughput and the ecological fragmentation of Feng Shui integrity (deforestation, inappropriate hydrological engineering construction, wetland reclamation, biodiversity loss and sedimentation of rivers and lakes). For example, 14.4 million m^3 of forest timber were cut every year in Sichuan and Yunnan provinces in the upper reach of the Yangtze. The total area of soil erosion increased from 0.36 million km^2 in the 1950s to 0.57 million km^2 in the 1990s, a 57% increase in 30 years. The area of Dongting Lake has decreased from 6000 km^2 in the 19th century to 2600 km^2 now. Its capacity decreased from 29.3 billion m^3 in 1949 to 17.8 billion m^3 in 1998. One hundred and twenty thousand km^2 of lakes were transformed into cropland. Of 1066 lakes in the 1950s, only 182 remained in the 1990s. A total of 56.7 billion m^3 of the capacity of 22 main lakes were lost in the Yangtze river basin. As a result, the flood disaster frequency in the basin increased dramatically from once every 83 years during 276 1524, 20 years during 1525 1851, five years during 1852 1949 and four years during 1949 1980s to once a year in the 1990s (Wang *et al.*, 2000).

Though drought and flooding are contrasting disasters, they have both resulted from the deterioration of Feng Shui in both the Yangtze and the Yellow River Basins. Inappropriate resource exploitation, wetland reclamation, deforestation, short-term and localized engineering project and inappropriate settlement construction, have destroyed or disrupted the integrity of the landscape ecosystem. The ecosystem s ability to retain water, conserve the soil and purify wastes has been reduced. The vitality of flora, fauna and soil communities has been weakened. The diversity of the landscape, ecosystem and culture has been greatly reduced. The harmony between people and nature has been destroyed by the misleading attitude that Man has to conquer nature. As a result, the Qi of the basins either were exhausted or stagnated, and the natural service functions declined dramatically. The desire for short-term economic profits has overwhelmed the need to preserve long-term

ecological benefits. The disasters that have happened in the two watersheds are warning signs of more severe disasters in the future.

The Yangtze River Delta, with a population of 73.71 million and an area of 99 530 km^2, has a crucial role in the national economy. Its area, population, GDP and revenue are 1.04, 6.09, 15.42 and 21.8% of those of all China, respectively. For more than 3000 years, it has been the richest economic and cultural area and most beautiful landscape in China. The area used to be the land of rice and fish , the hometown of gifted scholars and beauties , and the paradise on earth due to its marvelous natural and artificial landscape or Feng Shui. The industrialization of China was initiated from this region at the beginning of the 20th century, resulting in the emergence of the megacity of Shanghai, the Suzhou Wuxi Changzhou urban complex and many small towns in the area.

In the last 10 years, dramatic social, economic and environmental changes have taken place in the region especially along the Suzhou Wuxi Changzhou corridor. Flexible development policies, viable decentralized institutions, the long tradition of industrialization, strong technical support from large cities such as Shanghai, and rich human and natural resources all stimulated the extraordinary growth of the local economy. The area has become one of the most rapidly urbanizing and rural industrializing areas in China. Its annual growth rate of GDP has been 50% higher than that of the country as a whole since 1992. The urban population in the region has increased by 60% and population in small towns has increased by 2.7 times; around eight million workers have migrated into the region after 1980.

Compared with that of the mid-1980s, the urbanized area in the Yangtze Delta in 1993 increased by 17.57%, much higher than that of the state average level of 2.5%, and road traffic has increased by 46.67%. In Shanghai, the built-up area was 86 km^2 in 1949, 276.35 km^2 in 1984, 324 km^2 in the early 1990s, and presently 365 km^2; more will be added after the construction of the new Pudong development area is finished. In the same time, agricultural production in the region has been shrinking due to the great shift of arable land into urban and industrial use. Accordingly, the percentage of agriculture in the total production is declining year by year, and food export has been replaced by food import in most areas of the region.

Rural industrialization in the Yangtze delta is proceeding much faster than that of the cities and the average income *per capita* of the region is nearly twice that of the whole country. The economic development in this region is based on township and village enterprises (TVE), which have become a significant source of both income and pollution. According to a statistical survey in 48 small towns around the Taihu Lake watershed, the total annual amount of sewage discharge is $3{\bullet}7 \times 10^8$ t $year^{-1}$, of which industrial wastewater discharge occupies 90%. The quality of Taihu Lake has been reduced by one grade every 10 years since the 1970s. In 1995, 70% of the Taihu water failed to reach the national grade III standard. In 1992, more than 50% of the water in the Dianshan, Yangcheng and Gehu lakes failed to meet the national grade III standard. Only 1.8% of treated wastewater meets the state environmental standard. Due to over-exploitation of underground water and deforestation, the land has visibly been degraded. The over-exploitation of underground water has caused a severe fall in the water table. Subsidence caused by over-exploitation of underground water in the region affects about 8000 km^2. As a result, human health has been significantly affected. The outbreak of hepatitis in Shanghai in 1988, where 230 000 citizens were infected due to food pollution is just one example of the consequences of degraded environmental conditions.

A main driving force for this transition is the replacement of Chinese human ecological traditions by high consumption and high impact activities. Ecological farming is being replaced by petroleum agriculture, with organic manure being displaced by chemical fertilizers, and pesticides replacing the traditional integrated pest control methods. Household excrement and urine are being carried away through pipes mixed with domestic chemicals. A deluge of plastic bags, packaging materials and advertisement papers is taking the place of traditional organic garbage. Frozen or preserved food from supermarkets is consumed instead of fresh meat and vegetables from the free markets. Some enterprises are following the development strategy of other industrializing countries: pollution first, treatment later; speed first, efficiency later; and chaos first, sustainability later . In one word, reductionism is replacing holism, diversified human ecosystems are being replaced by mono-production and mono-culture, the self-reliant life style is being displaced by a modern life style involving high energy consumption and high environmental impacts (Wang *et al.*, 1996).

ECO-DEVELOPMENT: A NEW TRANSITION BASED ON AN OLD TRADITION

Fortunately, based on the long tradition of human ecological thought in China, an eco-development movement led by ecologists and supported by local government has been operating in several villages, counties and towns in China since the 1990s. The essential idea of eco-development is to plan, design, manage and construct the human ecosystem s function of production, living, and sustenance according to ecological cybernetics. The ultimate goals of eco-development are wealth, health and faith. *Wealth* measures the structural state of the monetary assets, natural assets (minerals, water, forest, soil, air and biodiversity), human resources and social resources (institution, arts, etc.). *Health* measures the functional state: individual and social health,

economic health and ecosystem health. *Faith* measures the behavioral mode: attitudes, traditions, customs, perceptions, ideas, concepts, values, beliefs, ethics and life styles. Systematically responsible planning, totally functioning engineering and ecologically sound management are the three determinants of sustainable development (Wang and Ouyang, 1996).

Several pilot projects have been initiated, including more than 50 provincial and 29 national Comprehensive Experimental Communities for Sustainable Development (CECSD), 51 national Eco-Agricultural Counties (EAC) and 100 Ecological Demonstration Districts (EDD). Some fruitful theoretical and applied results have been obtained. Local engineers, planners, and managers have adopted sustainability measures and recommendations, which will be the model for the development of other regions. The project focuses on the comprehensive use of natural resources; comprehensive management of the environment; and comprehensive development of people. It operates by introducing effective appropriate technology, developing systematically responsible institutions, and cultivating an ecologically sensitive culture (Wang *et al.*, 1998).

As one of the new sustainable development strategies, ecological agriculture has been implemented in many of these pilot studies since the early 1980s. There are more than 2000 eco-agricultural experimental sites in China ranging from village to county level which cover 123 000 km^2 and 23.92 million people. By 1995, the annual increase of crop yield was over 15%, the yield per unit of arable land increased by 10% since 1980, respectively, 4.5 and 9.2 times higher than those of counties without eco-agricultural development. *Per capita* income at the experimental sites was 12% higher than the average of neighboring regions. For example, the *per capita* income in 105 eco-agricultural experimental sites in Hubei province in 1995 was 32% higher than the average level in the province.

Baiquan county in Heilongjiang province which has suffered severe soil erosion due to intensive land reclamation, is one of the EACs. The reclamation ratio of soil in the county before 1990 reached 77.1%. Sixty percent of the total territory and 71% of the arable land were subject to erosion before 1990. Water eroded 6 mm of topsoil per year and wind eroded 4 mm $year^{-1}$. The organic matter in the soil was reduced from 8% at the beginning of reclamation to nowadays 2 3%, the lowest one being even below 1%.

Since 1990, an eco-development aimed at harnessing soil erosion has been initiated throughout the county. Approximately 150 eco-restoration zones and 32 comprehensive resource-based zones were established. More than 7000 gullies have been regulated, 36 000 ha terraced fields have been restored, 40 000 ha of sloping land has been cultivated along contour lines and 13 000 ha of ridges have been planted in 10 years. Four thousand, seven hundred and thirty-three ha of former cultivated steep slope cropland has been restored to grassland and grass forestry ecosystems. This has stimulated local livestock husbandry. Approximately 15 000 tons of wood were saved through widespread use of firewood-efficient stoves and solar energy houses. One thousand, four hundred and thirty energy-efficient tobacco curing houses were built, which saved 1430 tons of coal annually. Additionally, there are 84 solar energy houses, totaling about 7621 m^2, and 5150 solar energy hog cotes, which increased pig weights by 250 g. Finally, the area of fuel wood has reached 26 000 ha, and the recycling of crop residues and straw to fields resulted in an increase of organic content in the soil by 26.9% in 10 years (Wang and Yan, 1998).

Through 10 years implementation of eco-agriculture, agricultural gross output, gross income and *per capita* income have increased by 190%, 360% and 540%, respectively. Forest cover increased by 19.7%, 5% higher than in neighboring areas. Soil erosion control areas covered 67.7% of the total eroded area, resulting in a 37% reduction of surface runoff, a 50% decrease in soil loss, and a decrease in wind speed by 10.14%.

Before 1980, Xishan village in Shandong province was a poor village where food had to be imported. The village was subsidized by the government. The *per capita* income was less than 90 yuan RMB and the total fixed assets of the village were less than 20 000 yuan RMB in 1978. The eco-village development initiated in 1985 started from courtyard planning, with a 160 m^2 lotus pond in front of each house, and a 64 m^2 grape garden in front of the lotus pond. Around the village, a 2 km long and 30 m wide river was dug, outside of which was planted an orchard of 66.7 ha. There is also a 1 ha park at the back of the village, which makes the environment of this village more beautiful and viable. Pigs and chicken are raised in a piggery where pigs are kept in the basement, while chickens are on the upper floor. In the basement there is an 8 m^2 methane pond. The excrement of people and livestock are placed in this pond to produce biogas. Fermented waste is used as fertilizer in the yard. In this way, the *per capita* household income exceeded 2000 yuan RMB, some households have even reached 6000 yuan RMB, which is 20 70 times higher than the income in 1978 (Lu *et al.*, 1995). In 1990 a series of methane fermentation ponds, covering 2200 m^2, were built to treat the excrement of 5000 pigs, 6000 ducks, and 300 cows. The ponds provide about 400 m^3 biogas per day for residents use and about 7500 kg of high quality organic fertilizer per day for agriculture.

The eco-village development has changed this village dramatically in 10 years. Grain production increased from 12 900 kg ha^{-1} in 1987 to 19 770 kg ha^{-1} in 1995, with a *per capita* output of 1305 kg. The *per capita* income increased from 870 yuan RMB in 1987 to 2511 yuan RMB in 1995. The land productivity has multiplied from 14 505 yuan ha^{-1} in 1987 to 54 520.5 yuan ha^{-1} in 1995. The organic matter

in soil increased from 1.1% in 1987 to 1.3% in 1995. Meanwhile, the chemical fertilizer input was reduced from 1290 kg ha^{-1} in 1987 to 765 kg ha^{-1} in 1996.

Another example of the CECSD is the eco-county development in Dafeng, a middle-size county located in the northern part of Jiangsu Province with 740 000 people and 2367 km^2 of land. It is also one of the EACs and the EDDs. The county s economy was less developed in comparison with counties in the southern part of the province, where rapid industrialization started in 1978. The severe environmental problems in South Jiangsu province warned the people of Dafeng that they must search for an alternative way of realizing industrialization while maintaining a harmonious relationship with nature (Wang *et al.*, 1990).

The main goal of the Dafeng eco-county development is the promotion of a synthesis of the biophysical, socio-economic and psycho-cultural factors of production, consumption and sustainability in a long term, large scale and holistic policy-making framework. In striving towards this target, technological, institutional and cultural instruments are used together with cultivation of the mechanisms of competition, symbiosis and self-organization. A compromise between decision-makers, entrepreneurs, experts and the public is as important as the exploitation of the external and internal potentials. The evaluation indicators are: production efficiency; quality of life; institutional harmony; people s capability; ecological order. Twenty-two demonstration sites for ecological engineering have been organized in the county including ecological agriculture, ecological industry, ecosystem conservation, and community development. One hundred technological societies and 10 technological service networks have been set up. Considerable progress has been achieved in social, economic and environmental development since Dafeng eco-county planning was adopted, by the Yancheng municipal government in 1989. The county s gross domestic production in 1996 was nearly eight times greater than that of 1986 before the plan was initiated. Environmental quality has improved or has been maintained at the same level as that of 1980 when there were few industries, and the soil organic content has increased from 1.19% in 1986 to 1.23% in 1996. At the same time, the forest cover has increased by 15.7%. The county has won more than 10 national awards for its eco-development by relevant ministries and international agencies since 1989.

Low Concentration Methane Bearing Gases

Edan Prabhu
FlexEnergy Inc., Mission Viejo, CA, USA

Methane, a major constituent of natural gas, is generated from many sources related to human activities. Enormous

quantities of such methane are emitted each year, most commonly as part of the carbon cycle, through the anaerobic decomposition of vegetable and animal matter. Over time, methane in the atmosphere converts into carbon dioxide, and the carbon dioxide is then photosynthesized back into vegetable matter. Examination of its prevalence and sources suggests potential uses for the low concentration methane now emitted into the atmosphere. If low concentration methane can be captured and converted into carbon dioxide and water, useful energy could be extracted, providing an important step towards sustainable energy supply.

METHANE IN THE ATMOSPHERE: A MAJOR GREENHOUSE GAS

Methane (CH_4) is the principal constituent of natural gas, but is also generated in large quantities as a by-product of various natural and human created systems. Methane is created by anaerobic decomposition of biological matter, such as in rice fields, landfills, farms, wetlands, termites and other sources. Methane is also released during coal, oil and natural gas production, the result of decomposition of biological matter in geological time, possibly under far more aggressive conditions.

In some cases, methane is available in relatively high concentrations, between 40 100% of gas flows, such as in natural gas production systems, large landfills and large water treatment facilities. Such sources of methane are being successfully used on a commercial basis today. In most circumstances, however, the methane is available only in very low concentrations (10% or less), levels at which energy recovery is thought to be economically unfeasible (*see* Methane: Industrial Sources, Volume 3).

The US Environmental Protection Agency (EPA) states: As a contributor to climate change, methane is second only to carbon dioxide . The EPA also states Over the last two centuries, methane concentrations in the atmosphere have more than doubled from about 700 parts per billion by volume (ppbv) in pre-industrial times to 1730 ppbv in 1997 largely due to human-related activities (Figure 1). The doubling of methane concentrations corresponds to a four-fold increase in world population. The EPA rates methane s global warming potential (GWP) as 21 on a scale where carbon dioxide has a GWP of 1. Thus, methane is 21 times more potent as a greenhouse gas than carbon dioxide. The EPA also states that a reduction of about 10% in methane emissions from sources due to human activities alone would halt the annual rise in methane concentrations, thereby significantly contributing to mitigation of climate change (*see* Methane, Volume 1).

Total global annual methane emissions estimated by the EPA for 1990 were about 350 teragrams, or 350 million tons, of which about 70% came from anthropogenic sources and 30% from natural sources.

Anthropogenic activities such as fossil fuel production, animal husbandry (digestive processes of ruminant livestock and manure), rice cultivation, and landfills release significant quantities of methane (Figure 2), fundamentally altering the composition of the earth s atmosphere. In industrial nations such as the US, methane is primarily generated by decomposition of wastes in landfills, manure and enteric (intestinal) fermentation associated with domestic livestock, natural gas systems, and coal mining. In developing nations, the methane is produced primarily by rice cultivation and enteric and manure decomposition in ruminant livestock (*see* Cattle Grazing: Impacts on Land Cover and Methane Emissions, Volume 3).

Natural sources of methane include wetlands, gas hydrates and permafrost, termites, oceans, freshwater bodies, non-wetland soils, and other sources such as wildfires.

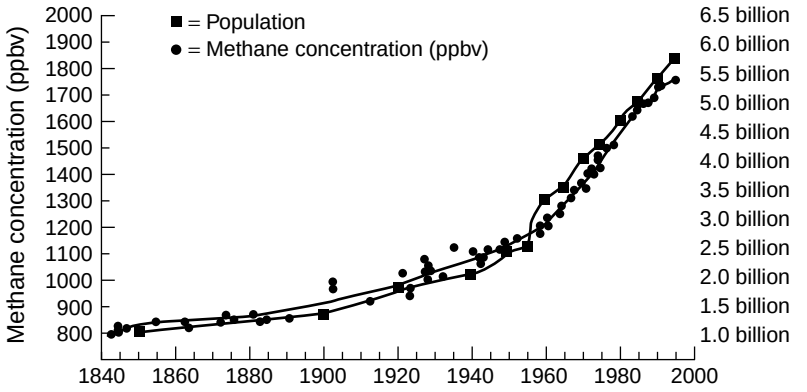

Figure 1 Increases in methane concentrations compared to world population growth (1841–1996)

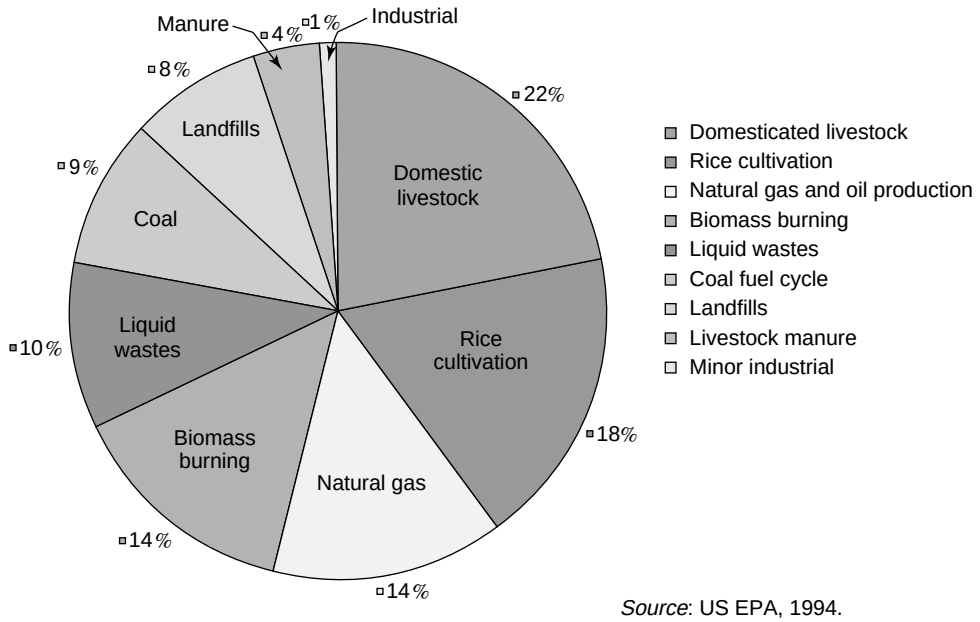

Source: US EPA, 1994.

Figure 2 Sources of total global methane emissions from anthropogenic sources

In an ironic twist, in some localities, global warming may actually increase the natural production of methane by creating larger wetlands and swamps, exacerbating the emissions problem. The emissions from natural sources are roughly divided 50% from wetlands and 50% from other sources. The two largest anthropogenic contributors are domestic livestock with 22% and rice cultivation with 18%, together a staggering 40% of anthropogenic emissions.

The US EPA and other government agencies around the world have rigorous programs to reduce methane emissions. The EPA focuses on the main anthropogenic sources in the US, on high concentration methane emitters such as landfills and animal manure, with the goal of capturing and recovering the gas. There has also been some effort to prevent formation of low energy methane emission, for example, by altering cattle feed to reduce their methane production.

TECHNOLOGIES FOR USING METHANE TO PRODUCE USEFUL ENERGY

How much of this methane could be recovered as fuel, and how significant a fuel would it be? The 350 million tons of methane emitted each year are the equivalent of roughly three billion barrels of oil a year, or three percent of total world energy consumption. Obviously there would be a large payoff if this energy could be recovered. Even if only a tenth of it could be used for power generation, it would greatly dwarf all solar and wind energy combined. How possible and feasible would this be?

The existing programs by the EPA and others focus on those streams of methane that are easily recoverable; these are generally those where the methane is produced and recovered in relatively high concentrations. For example, the best landfills generate gas with about 40 50% methane, and anaerobic digesters for cattle manure generate gas with about 50 80% methane. The fuel is sometimes captured for use in reciprocating engines, gas turbines and in some cases used to produce heat and steam for electricity. In a few instances, the methane is piped to other locations for industrial or commercial uses. However, most of the methane emissions are simply vented into the atmosphere. If a significant portion of this methane is to be captured, it will most likely be recoverable only in much lower concentrations. In order for a fuel to be converted into useful energy, its chemical energy must be converted into heat and then into useful mechanical or electrical energy. Traditional combustion engines developed for using petroleum based fuels, require a methane concentration of at least 10%, but prefer no less than 100% methane.

While traditional engines cannot utilize the low concentration methane, there are fresh approaches that can make a difference. Technology developed during air pollution research has made catalytic converters and combustors available that remove very low concentrations of hydrocarbons from tailpipe and other gases, down to the parts per million (ppm) threshold. Theoretically, a catalytic combustor could actually reduce the 1730 ppbv of methane in ordinary air, but doing so is impractical and the process would not be self-sustainable. However, it may well be feasible to usefully recover the energy from methane concentrations as low as 1 2%. Modern microturbines routinely

operate in these fuel ranges. They generally begin with a highly concentrated fuel that is diluted after combustion. By converting the turbines to catalytic combustion, it will be feasible to run them directly on low concentration methane fuel gases. Such catalytic combustion is already in use for certain large turbines, and one company is now developing the Flex-Microturbine™ to use catalytic combustion for very low methane fuels. Should that effort be successful, the path to recovery of low energy gases could be radically altered.

COLLECTION AND LOCAL CONSUMPTION OF LOW CONCENTRATION METHANE GAS

How feasible is it to collect gases from methane emitting sources such that the resulting concentrations are at least 1 2% of methane? One percent methane is 10 000 ppm, which is over 2000 times the concentration of methane in ambient air. However, methane rises from landfills, rice fields, animal pastures, animals themselves, coal mines, oil and gas drilling, production and transport operations often in concentrations of 10 000 ppm or greater. Can simple collection systems be devised? Perhaps landfills could be covered with large sheets to collect the emanating gases; methane-bearing gases from coal mines could be diverted rather than diluted; oil and gas operations could be adapted to collect these waste fuels; large feedlots could be enclosed and the methane collected.

Size becomes a critical issue. It would be prohibitively expensive to cover very large areas, or to transport low energy gases through long distances to central power plants. It would also be prohibitively expensive to develop means to boost the methane concentrations by treating the gas stream. However, microturbines are small and easy to move. It may be feasible to install small portable power plants, so-called distributed generation, that locally converts the methane into electricity and useful heat. Distributed generation is one of the fastest growing new means of power generation and could very well become a major part of the generation mix in the next ten years. Microturbines, in particular, are rapidly becoming commercial with a marked increase in production in the last few years.

THE BENEFITS OF LOW CONCENTRATION METHANE RECOVERY

In addition to the immense value derived by consuming methane for greenhouse abatement, several other benefits will accrue.

The most immediate benefit would be the generation of electricity. Electricity is inexpensive to transport and easy to use. It is by far the most desired fuel on the planet, the true engine for growth. In addition to the electricity generated, in some instances the waste heat from individual small power plants may be useful for space or water heating or pasteurizing milk. In a world of rapidly fluctuating fossil fuel prices, the fuel, for the present, at least, is free for the taking.

The catalytic combustion needed for recovery of low concentration methane assures virtually no NO_x. NO_x, formed in most other engines, is the main ingredient of urban smog and a contributor to acid rain.

Many rural areas lack electricity. It may become feasible to supply those areas directly using local fuels. For example, many developing nations that grow rice, have large herds of cattle, or contain swamplands may be able to capture and convert the methane. Methane is considered non-toxic; a rice field could simply be covered with a transparent sheet to collect the gas. The methane-laden air inside may actually be breathable, at least for short periods.

The environmental impact of such power plants would be almost entirely beneficial. No new major structures would be needed, no wastewater, no solid disposal problems. The new energy would displace fossil fuels that cause damage during their production, use and disposal. Small power plants could be sited with no need for complex licensing review. The footprint of these plants on their local environment would be less than that of fossil power plants, solar or wind energy systems. They would tap nature s energy in the least obtrusive way, making them the most environmentally friendly source of renewable energy. Unlike wind and solar power, electricity could be generated any time of day or night to deliver dependable power to small, remote villages without need for a large central grid. The recovery of this waste fuel would have the potential to provide at least one percent of the world s energy needs, perhaps much more.

THE FUTURE

In the eternal carbon cycle, all carbon goes from carbohydrate in plants to carbon dioxide in the atmosphere and back to carbohydrate in plants. Along the way, some of it is first converted into methane. This methane may be a valuable source of energy for sustainable living. It is recommended that public policy programs place heavy emphasis on its recovery and use. There may be value in developing means to increase such methane production by mimicking and enhancing natural digestion processes. Even more methane could then be generated and used, unobtrusively tapping into the eternal cycle for comfort and growth.

M

Malnutrition, Infectious Diseases and Global Environmental Change

David Pimentel
Cornell University, Ithaca, NY, USA

Global climate change is likely to have major effects on public health. Higher than present temperatures may encourage the spread of mosquito vectors and other public health pests. In addition, heavy rainfall and ooding may encourage increases in mosquito populations, leading to outbreaks of diseases such as malaria.

Droughts may reduce crop production, intensifying the malnutrition problem that currently exists (WHO, 1996a,b; Conway, 1997). Malnutrition itself is a serious disease but equally important is the fact that malnourished people are also more susceptible to infectious diseases, such as malaria and cholera, and the effects of environmental stresses, such as smoke and chemical pollution (Pimentel et al.*, 1998).*

Climatologists project that greenhouse gas emissions will probably increase average global temperatures by approximately 3 °C in temperate regions within the next 50 years or so, increase rainfall in some regions and cause droughts in others, and intensify hurricanes and other tropical storms (Rosenzweig and Hillel, 1998). In addition, sea levels may rise about half a meter.

In this article, the potential effects of global climate change on malnutrition and other diseases are assessed.

GLOBAL CHANGE

Assessing the impact of carbon dioxide and other greenhouses gases on the world s climate is difficult because at this juncture, we have not fully defined the size of atmospheric, biotic, and oceanic reservoirs as sources and sinks of carbon dioxide and other greenhouse gases (Hominick, 1993; Rosensweig and Hillel, 1998). Nonetheless, it is well documented that burning fossil fuels and removing and burning forests does increase the levels of atmospheric carbon dioxide and other greenhouse gases. Levels of atmospheric carbon dioxide have risen from 280 ppm in the 1850s to more than 350 ppm today, and are expected to reach 400 600 ppm by the year 2035 (Hominick, 1993; Rosensweig and Hillel, 1998). Without significant societal changes, concentrations of atmospheric carbon dioxide and other gases will continue to increase.

Atmospheric and other scientists conclude that if present trends continue, the combined effect of atmospheric carbon dioxide and other greenhouse gases will increase the earth s average temperature by 1.5 4.5 °C before the middle of the century, with warming most pronounced in the Arctic. Rosensweig and Hillel (1998) have reported that average global temperatures have already risen approximately 0.5 °C in the past century. Although this temperature increase seems indicative of global climate change, others question whether a significant global temperature increase has occurred, and instead attribute any warming to the natural climate variability on earth.

Exactly when and how much the climate will change depends on the complex interactions of the atmosphere, oceans, and biosphere. Climate changes will not be uniform over the different regions of the earth. Winter temperatures in the middle and high latitudes can be expected to rise to more than twice the world average rise (Rosensweig and Hillel, 1998). Summer temperatures will also rise, but less than during other seasons. Furthermore, rainfall is expected to increase significantly in some regions, such as the eastern portion of Africa, and decrease in others, such as the central portion of the United States (Hominick, 1993; Rosensweig and Hillel, 1998).

MALNUTRITION WORLDWIDE

Undernutrition

Malnutrition, which includes inadequate intake of calories, protein, and numerous essential vitamins and minerals, is a major disease and is in part related to environmental degradation and rapid population growth. Malnutrition prevails in regions where the overall food supply is inadequate, where populations lack economic resources to purchase

food, and/or where political unrest and instability interrupt food supplies. In addition, rapidly expanding human populations intensify food supply problems by diminishing the *per capita* availability of cropland, water, and biological resources (Pimentel and Pimentel, 1996).

In 1950, 500 million people (about 20% of the world population) were considered malnourished (Grigg, 1993). Today more than three billion people (about 50% of the world population) suffer from malnutrition (WHO, 1996a). This is the largest number and highest rate of malnourished people in history. Each year, between 6 and 14 million people die both directly from malnutrition and from malnutrition related diseases (Murray and Lopez, 1996). Malnutrition problems are also on the increase in the United States, especially among the poor.

In many parts of the world, especially in developing countries, severe shortages of vitamin A cause prevalent blindness, illness, and death. For example, in the Sahelian region, as well as in West and East Africa, *per capita* consumption of vitamin A has been declining during the last 10 20 years, while associated serious eye problems have been increasing (ACC/SCN, 1992). Worldwide, approximately 250 million children are vitamin A deficient (WHO, 1996b). Each year, vitamin A deficiency causes approximately two million deaths and three million serious eye problems, including blindness (Murray and Lopez, 1996).

Similarly, *per capita* iron intake has been declining during the last 10 30 years, especially in sub-Saharan Africa, South Asia, China, and South America, primarily because of the overall shortages of food that are resulting in widespread inadequate nutrition (ACC/SCN, 1992). Globally, more than two billion people are iron deficient, severely enough in most cases to suffer from anemia (WHO, 1996b). An estimated 20% of global malnutrition deaths are attributed to anemia (Murray and Lopez, 1996). In general, people with anemia have difficulty working, as well as limited resistance to other diseases. In addition, about 1.6 billion people live in iodine deficient environments and suffer from iodine deficiency disease (WHO, 1996b).

Malnutrition is frequently complicated by parasitic infections, and is typically found in poverty-stricken areas with inadequate sanitation. Malnourished individuals, especially children, are seriously affected by parasitic infections, because these infections can further reduce the amount of nutrients a person can obtain from his or her food. Intestinal parasites frequently diminish both appetite and food intake. Their presence increases loss of nutrients by causing diarrhea and dysentery. Hookworms, for instance, can suck as much as 30 ml of blood from an infected person each day, gradually weakening individuals and lowering their resistance to other diseases (Hotez and Pritchard, 1995). Because an estimated 5 20% of an infected individual s daily food intake is used to offset the effects of these parasitic illnesses, the overall nutritional status of a parasite-infected person is greatly diminished over time (Pimentel and Pimentel, 1996).

Decreasing Food Production

Based on current rates of increase, the world population is projected to double to more than 12 billion in less than 50 years (PRB, 1998). As the world population continues to expand at a rate of 1.4% per year, with more than a quarter million people added each day, providing adequate food becomes an increasingly difficult problem. Conceivably, the numbers of malnourished will reach 4 5 billion in future decades.

Reports from the Food and Agriculture Organization (FAO) of the United Nations and the US Department of Agriculture, as well as numerous other international organizations, further confirm the serious nature of the global food supply problem (RS and NAS, 1992; NAS, 1994; WHO, 1996a). For example, the *per capita* availability of world cereal grains, which make up 80 90% of the world s food supply, has been declining for the past 17 years (Kendall and Pimentel, 1994).

Thus, as the world population continues to expand, more pressure than ever before is being placed on the finite basic resources that are essential for food production. Unfortunately, while the human population grows exponentially, food production can only increase linearly. Furthermore, degradation of land, water, energy, and biological resources, all vital to agriculture, continues unabated (Pimentel *et al.*, 1997a; Pimentel and Pimentel, 1996).

More than 99% of the world s food supply comes from the land; less than 1% is from oceans and other aquatic habitats (FAO, 1991). The continued production of an adequate food supply is directly dependent on ample quantities of fertile land, fresh water, energy, and natural biodiversity. Obviously, as the human population grows, the requirements for these resources will escalate. Even if these resources are never completely depleted, their supply will decline significantly on a *per capita* basis because they must be divided among more people.

Throughout the world, fertile cropland is being lost from production at an alarming rate. While true for all cropland, it is best illustrated by the diminishing amount of land now devoted to cereal grains. Soil erosion by wind and water, in addition to overuse, has been responsible for the loss of about 30% of the world s cropland during the past 40 years (WRI, 1994; Pimentel *et al.*, 1995). Once fertile soil is lost, it takes 500 years or more to form a mere 25 mm (1 inch) of fertile soil. For crop production, at least 150 mm of soil is required (*see* Soil Deterioration and Loss of Topsoil, Volume 3).

Most of the replacement for eroded and unproductive agricultural land is coming from cleared forests and

marginal land. The need for more cropland accounts for more than 60% of the world s deforestation (Myers, 1994). Despite such land replacement strategies, available world cropland *per capita* is declining and now stands at only 0.27 ha *per capita*. This is only about 50% of the 0.5 ha *per capita* considered the minimum for the production of a diverse diet, similar to that of the US and Europe (Lal and Stewart, 1990). China now has only 0.08 ha *per capita*, or about 15% of the accepted minimum.

Rainfall and its collection in rivers, lakes, and vast underground aquifers provides the water needed by humans for their survival and diverse activities. Ample supplies of fresh water are critical for all vegetation, including crops. All plants use and transpire massive amounts of water during the growing season. For example, a hectare of corn, producing about 8000 kg ha^{-1}, will transpire more than five million l of water during one growing season (Pimentel *et al.*, 1997b). This means that more than 8 to 10 million l of water must reach each hectare of corn during the season. In total, agriculture consumes about 70% of the world s fresh water supply, far more than any other human activity, thus leaving relatively little available for other uses (Postel, 1996).

Water resources are currently under great stress as densely populated cities, states, and countries increase their withdrawal of water from rivers, lakes, and aquifers every year. For example, by the time the Colorado River reaches Mexico, it is diminished to a trickle into the Gulf of California (Sheridan, 1983). Also, the great Ogalla aquifer in the central US is suffering an overdraft rate that is about 140% above recharge rate (Gleick, 1993). Water shortages in the US and elsewhere in the world are already reflected in the *per capita* decline in crop irrigation during the past 20 years.

To compound the water problem, about 40% of the world s population live in regions that directly compete for shared water resources (Gleick, 1993). In China, for example, more than 300 cities already are short of water, and these shortages are intensifying as Chinese urban areas expand (WRI, 1994). Competition for water resources among individuals, industries, and regions both within and between countries is growing throughout the world community (Gleick, 1993).

In addition to the quantity of water available, its purity is also important. Diseases associated with impure water and unsanitary systems rob people of their health, nutrients, and livelihood. Again, these problems are most serious in developing countries, where about 90% of diseases can be traced to a lack of pure water (WHO, 1992). Worldwide, about four billion cases of disease are contracted from impure water and approximately six million deaths are caused by waterborne disease each year (Pimentel *et al.*, 1997b).

Energy from many sources (especially fossil energy) is also a prime resource used in food production. Nearly 75% of the fossil energy used each year throughout the world is consumed by the people living in developed countries. Of this, about 17% is expended in the production, processing, and packaging of food products (Pimentel and Pimentel, 1996). In particular, the intensive farming technologies characteristic of developed countries rely on massive amounts of fossil energy for fertilizers, pesticides, irrigation, and for machines that substitute for human labor. In contrast, developing countries use fossil energy primarily for fertilizers and irrigation to help maintain yields, rather than to reduce human labor inputs (Giampietro and Pimentel, 1993).

Because fossil energy is a finite resource, its depletion accelerates as populations expand and their food requirements increase. The US Department of Energy warns that the United States will exhaust most or all of its oil reserves within the next 15 20 years (BP, 1994).

Worldwide, *per capita* supplies of oil resources show a significant decline since 1979 and this trend can be expected to continue (Duncan, 1999). Fossil energy, especially natural gas, for fertilizer production is having a negative impact on available amounts of fertilizers. For example, *per capita* fertilizer use has declined about 23% during the past decade (IFDC, 1998).

In addition to all these problems forcing the decline in per person food production, future global climate change will further depress food production. The projected higher temperatures will increase some insect pest, weed, and plant pathogen problems that are already causing the loss of more than 40% of all potential food production despite all the pesticide being applied worldwide (Pimentel, 1997; Rosensweig and Hillel, 1998; Chakraborty *et al.*, 1998). In addition, water shortages will also intensify (Postel, 1999). Higher temperatures will increase evapotranspiration from plants and land, and rainfall in some regions will decrease (Postel, 1999). These complications will result in some decline in global crop yields.

INFECTIOUS DISEASES

Waterborne infections account for about 80% of all infectious diseases worldwide, and 90% of all infectious diseases in developing countries (Epstein *et al.*, 1994). With global warming, projections suggest that many of these waterborne diseases will increase. For example, cholera, a well known waterborne disease, continues to be a serious global problem. *Vibrio cholerae* outbreaks are closely associated with climatic cycles (e.g., El Nino) and ocean plankton blooms (Colwell, 1996). These associations suggest that a potential influence of global warming will increase the spread and incidence of certain diseases, such as cholera (Colwell, 1996). In 1988, there were about 50 000 cases of cholera,

but by 1991 the number of cases had risen to 600 000; deaths from the disease rose from 2000 to 18 000 over the same period (Gleick, 1993). However, from 1991 to 1995, the number of cholera cases declined worldwide to about 210 000 per year, due to effective public health efforts.

Schistosomiasis, which is associated with contaminated fresh water, is also expanding worldwide and currently causes an estimated one million deaths annually (Gleick, 1993). This expansion is due to an increase in suitable habitats for the snail intermediate host population due to various human activities, including the construction of dams and irrigation channels (Shiklomanov, 1993). Global warming will probably contribute to the increase in schistosomiasis because the availability of suitable habitats, including warm water ecosystems, for the snail intermediate host will also increase (Martens *et al.*, 1997).

Mosquito-borne malaria is also associated with aquatic ecosystems. This disease infects more than 500 million people each year, killing, approximately 2.7 million (Marshall, 1997; Travis, 1997). Approximately 90% of all malaria cases occur in Africa, as do 90 95% of the world s malaria-related deaths. Between 1987 and 1994 in Rwanda, the increase in malaria incidence was greater than 500% and it continues to rise (Loevinsohn, 1994).

In some regions of Asia and South America, malaria is also on the rise. For example, in 1991, Peru recorded about 34 000 cases, but by 1992 that number had increased to about 55 000 cases per year (WHO, 1996c). Similarly, in Bangladesh, malaria prevalence increased from about 33 000 cases in 1988 to 64 000 cases in 1991; and to 125 000 cases in 1993 (WHO, 1996d).

Environmental changes, including more polluted water, have fostered the high incidence rates of malaria. Future global warming will also favor the spread and breeding of malaria-transmitting mosquitoes (Loevinsohn, 1994; Lindsay and Birley, 1996; Martens *et al.*, 1997; Woube, 1997; Lindsay and Martens, 1998; Kindson and Indaratna, 1998). Also, with some African populations doubling every 20 years, more people are living in close proximity to the water ecosystems most suitable for mosquito breeding. Concurrently, mosquito vectors are evolving resistance to insecticides (insecticides that also are polluting aquatic ecosystems), and the protozoan pathogens are evolving resistance to anti-malarial drugs, making control efforts less effective than before (Georghiou, 1990; Olliaro and Cattani, 1996).

In addition to its effects on global climate change, deforestation can cause other global changes. For example, deforestation in parts of Africa has exposed land to sunlight and promoted the development of temporary pools of water, thus favoring the breeding of malaria-transmitting mosquitoes, *Anopheles gambiae* (Coluozzi, 1994). Changes in human activities associated with deforestation can also change the incidence of exposure of humans to vectors (Walsh *et al.*, 1993). For instance, deforestation can expose humans to vectors that were previously zoophilic, leading to the transmission of various zoonotic agents, and can change the ecology of the land, providing new and different larval breeding sites.

Other infectious diseases transmitted by insect vectors that may increase with global climatic change include: onchoceriasis, filiarasis, dengue, yellow fever, Japanese encephalitis, and equine encephalitis (McMichael, 1993; McMichael and Beers, 1994; Murray and Lopez, 1997; Martens *et al.*, 1997; Lindgren, 1998; Patz *et al.*, 1998) (*see* Infectious Diseases, Volume 2; Urban Poverty and Environmental Health, Volume 3; Policy Responses to Public Health Issues Relating to Global Environmental Change, Volume 4).

LAND DEGRADATION AND DISEASE

Humans can acquire chemical pollutants and pathogens directly from the soil, by direct contact with it and/or indirectly through consumption of contaminated food and water. For example, sometimes soil particles themselves can be pollutants, entering eyes, nose, and mouth and acting as an irritant and/or allergen. Increases in temperature and an increase in wind intensity will intensify human exposure to these types of pollutants.

Cleared and exposed soil is especially susceptible to wind and water erosion. Wind erosion can cause serious health problems by blowing soil particles and microbes into the air. These wind-borne particles irritate respiratory tracts and eyes and aggravate allergies and asthma. Erosion can also disperse toxic chemicals, such as heavy metals and pesticides, leading to increases in contaminated food and water. Furthermore, erosion strips soil of its nutrients, lowering food crop productivity and ultimately reducing human nutrition. Professor R. Lal of Ohio State University reports that the addition of carbon dioxide of soil organic matter exposed because of soil erosion each year is 10 times greater than that contributed by all fossil combustion world wide.

As people invade more and more natural ecosystems and increasing amounts of land are cleared exposing more soil, the chances of humans becoming infected by helminths (like hookworms), and microbes (like pathogenic *Escherichia coli*), increase (WHO, 1992). Such increases were observed in Nepal, a mountainous country that experiences serious soil erosion and severe disease problems; 87% of the population was infected with helminths in 1984 (Suguri *et al.*, 1985; Metz, 1991). Children suffer greater morbidity from helminthic infections than adults because children need more protein than adults per kilogram of body weight, and under severe parasitic infections may be unable to utilize protein efficiently enough to remain healthy.

In addition, many species of helminths that infect humans are found in soil contaminated by human feces, thereby increasing the cycle of exposure. Worldwide, approximately two billion people are estimated to be infected with one or more species of helminths, either by direct penetration or by consumption of contaminated food or water (Hotez *et al.*, 1996). The most prevalent helminths are hookworms (*Necator americanus* and *Anclostoma duodenale*), *Strongyloides stercoralis*, and *Ascaris lumbricoides*. In locations where sanitation is poor and people are overcrowded, as in parts of urban Africa, up to 90% of the population may be infected with one or more helminths (Stephenson, 1994).

CONCLUSION

Global climate change will probably increase the prevalence of human diseases and the number of deaths caused by these diseases (*see* Environmental Change and Human Health: Extending the Sustainability Agenda, Volume 3). The ecology of increasing disease is exceedingly complex because of the diversity of infectious organisms and the impacts of environmental degradation on the prevalence of diseases. Rapid expansion of human populations has become a major factor in the rise of human diseases. Humans living in crowded urban areas provide an ideal ecosystem for the resurgence and rapid spread of old diseases, as well as the development and spread of new diseases (Pimentel *et al.*, 1998). Unprecedented increases in air, water, and soil pollutants, including organic and chemical wastes, further stress humans and increases disease prevalence. In particular, malnutrition enhances the susceptibility of humans to infectious pathogens and other diseases. Global climate change will probably improve the environment for growth of many vectors and intermediate hosts of diseases, thereby also increasing the spread and prevalence of diseases.

Global climate changes are also improving the environment for the development of some other diseases, such as malnutrition. Climate changes can be expected to further increase the susceptibility of food crops to certain pests, which could intensify food shortages and malnutrition. A concurrent problem is the rapid expansion of the number of environmental refugees and refugees from wars, floods, and other problems (Myers, 1993). These people, living in poverty and desperate for food, flee their homes in their search for survival. Their prevalent malnutrition and dislocation-related stress provide ideal conditions for further development of various diseases in these dense populations under environmental stress (*see* Refugees and Human Conflict, Volume 3; Environmental Refugees, Volume 4).

Many factors influence the ecology of the increasing number of human diseases now occurring worldwide. Currently, 40% of disease-related deaths result from diverse environment factors, including chemical pollutants, tobacco, and malnutrition. This growth in diseases is expected to continue as the global climate changes. Infectious diseases, which cause 37% of all deaths throughout the world, also are expected to increase.

To prevent diseases, poverty and malnutrition from worsening, the growing imbalance between an escalating human population and the earth s limited amount of natural resources must be dealt with. The crowding of people into urban areas; movement of populations into new environments; increased use of chemicals that pollute soils, water, and air; misuse of antibiotics that foster resistance in disease microbes; and growing malnutrition are all contributing factors to the ecological increase of human diseases worldwide.

Marine Mammal Exploitation: Whales and Whaling

C Scott Baker[1] and Phillip J Clapham[2]
[1]*Auckland University, Auckland, New Zealand*
[2]*Northeast Fisheries Science Center, Woods Hole, MA, USA*

The utilization of marine mammals for subsistence or pro t has a long tradition in human history. Seals, sea lions, walruses and sea otters have been hunted for their fur, meat and oil since Neolithic times. Some of these species were later the target of organized commercial hunting, primarily for their pelts. Other coastal species, such as dolphins, manatees and dugongs have been hunted on an ongoing, if limited, basis by many societies around the world. In general, this exploitation did not differ markedly in scale or method from the hunting or trapping of terrestrial mammals, although in the case of the now extinct Stellar sea cow, the result was nonetheless devastating.

The hunting of whales stands out in the history of human resource exploitation because of its global expanse, its dependence on progressive technical innovation and the sheer scale of the slaughter. From its origins along the shores of the Basque province during the 11th century through to the factory whaling eets patrolling the Southern Ocean during the 20th century, commercial whalers have exploited an international biological resource for short-term gain, even when this was clearly at the expense of a long-term, sustainable utilization. In acting as though the oceans were an inexhaustible resource, the whaling industry brought about a tragedy of the commons on a grand scale. Time and again, agreement on limits to this exploitation was reached only when it was no longer pro table to hunt depleted species or populations. In the case of illegal whaling by the Soviet Union, even these belated agreements were ignored. With the measures of protection now in effect, some populations of whales are increasing in numbers and a few are approaching their pre-exploitation abundance. Other populations, however, remain precariously small and may be drifting towards extinction.

THE WHALERS' PRINCIPAL PREY

Although directed hunting of cetaceans has often involved smaller species such as dolphins and porpoises, the focus of commercial whaling was the great whales. This includes only one odontocete (toothed cetacean), the sperm whale, a pelagic species that underpinned the expansion of the New England whale fleet in the 18th and 19th centuries. Beaked whales, including the northern bottlenose whale and Baird s beaked whales, have been the target of more localized hunting at times during the 20th century. All of the other hunted large whales were mysticetes (baleen whales), a group that includes the largest of all animals, the blue and fin whales. There are 11 recognized species of baleen whales, divided into four families. These include the rorquals (blue, fin, sei, Bryde s, minke and humpback whales), the balaenids (the bowhead whale, as well as both northern and southern right whales), the gray whale, and the pygmy right whale. Several unresolved taxonomic issues exist concerning species or subspecies designations in blue, Bryde s, minke, bowhead and right whales.

Most of the baleen whales have a cosmopolitan distribution, but there are four exceptions. The bowhead is a Northern Hemisphere species that spends much of its life in the Arctic and is usually closely associated with sea ice. The Bryde s whale is found in all major oceans, but is the only mysticete whose distribution is concentrated in tropical or subtropical waters year-round. The gray whale is found today only in the North Pacific, although a population

existed in the North Atlantic as recently as the 1700s. The cause of its extinction is unknown, and may have been related to either whaling or natural factors, or a combination of the two. Finally, the pygmy right whale, a poorly understood Southern Hemisphere species, is the only mysticete to have never been a regular target of exploitation.

Most baleen whales undertake seasonal migrations from productive high-latitude summering areas, where they feed, to mating and calving grounds in warm waters, where fasting generally occurs. Some migrations, such as those of the humpback and gray whale, are the longest recorded for any mammal. Bowheads never leave high latitudes and, as noted above, Bryde s whales remain in warm water year-round. In other species, migratory patterns vary. Because the oil content of whales was greater during the summer feeding season or during migration from the feeding grounds, whalers tended to focus their hunting at these times. Whales on the return migration from the winter breeding grounds were dry, having lost between one-third and one-half of their renderable oils from fasting.

OPPORTUNISTIC ENCOUNTERS AND SUBSISTENCE HUNTING

Historically, the utilization of large whales took a variety of forms. Many primitive societies took advantage of occasional drift (stranded) whales as a supplement to other sources of nutrition and a source of material (bone and baleen) for tools, utensils and ceremonial items. The Wampanoag of the northeastern coast of the United States (US) and the Maori of New Zealand, for example, frequently availed themselves of beached animals, but did not actively engage in directed hunting of whales until colonial times. A relatively small number of societies took to sea in pursuit of whales. For these people, particularly the Inuit of the Arctic, whaling was, and continues to be, a central part of both their diet and culture. The origins of this aboriginal whaling probably date back thousands of years. A carving on a sandstone wall in southeastern Korea made about 6000 BC clearly shows a boatload of men harpooning a whale.

Methods of capture varied in directed aboriginal whaling. A variety of cultures in the Pacific region used darts tipped with the poison aconite to kill whales. This must have been a wasteful hunt: given the delayed effect of this poison, the number of animals eventually caught probably represented a small percentage of those actually struck and killed. Early harpoon-based fisheries used shafts tipped with stone points; in some Arctic hunts, sealskin floats were attached to the harpoon line to make the submerged whale easier to follow, and to impede its ability to move and dive, thus hastening the lethal strike with a lance or other weapon. Directed aboriginal whaling relied mainly on slow coastal species such as humpback, right, gray and bowhead whales. A number of cultures exploited the herding instinct of pilot whales by driving them into shallow bays where they could be killed easily; in addition, Arctic peoples often made use of ice entrapments (sassats) to kill entire pods of toothed whales, notably narwhals and belugas.

Examples of aboriginal whale hunts survive today in places as far apart as Indonesia, Greenland and North America. Many native societies that came into contact with the expanding European commercial whale fishery adopted its more efficient methods. By the late 1800s, this included the replacement of hand-thrown implements with guns or explosive harpoons. In some cases, modern subsistence hunting was initiated after contact with commercial whaling (as occurred during the 19th century in the Caribbean island of Bequia and the South Pacific Kingdom of Tonga), or was resumed after a long hiatus (such as with the Makah Indians of the northwestern coast of the US). Japan, which has a long history of opportunistic and directed whaling, developed systematic commercial hunting in the 17th century based on entangling whales in nets. This allowed villages to take species that had previously been difficult to capture by harpooning alone, including gray, right, humpback and fin whales.

EARLY EUROPEAN AND YANKEE WHALING

The earliest sustained commercial whaling, for which reliable records exist, was the Basque right whale fishery in the Bay of Biscay. Market records and tax documents indicate that this enterprise was operating as early as the 11th century in southern France and northern Spain. The Basques were instrumental in the expansion of European whaling into the New World: their whalers were operating by 1530 in Labrador, where they killed right whales as well as bowheads. Declining catches combined with general European exploration resulted in the opening of new whaling grounds in the Arctic in the early 17th century. This expansion was led by the Dutch and Germans, closely followed by the British and French, with the Basques often employed as harpooners. Bowheads were the principal targets of the Arctic fishery, and exploitation was so intense that the species was effectively extirpated from some areas, notably Spitsbergen. During the same period, colonial settlers in New England began hunting right whales. This pursuit began in earnest in the late 1600s and crashed by 1750, when few whales remained in the coastal waters of the region.

Early European whalers, although using large sailing vessels to find whales, had relied on towing the carcasses to shore for processing, a practice that limited them to coastal or ice-edge species. Despite this limitation, the slow moving right and bowhead whales were depleted (and the gray whale was extinct) in the North Atlantic by the late 18th century and whalers were forced to look to other

oceans and species for profit. This expansion was led by the Yankee whalers of New England and aided by technological improvements, including larger vessels fitted with a central brick furnace and large iron pots, referred to as the try-works, used for rendering the oil from the blubber and scraps of the whale. In 1791, Thomas Jefferson, in his role of Secretary of State, wrote of the American whalers, They followed the whales farther and farther into the ocean, enlarging their vessels to 60, 100 and 200 tons. Having extended their pursuit . . . , they fell in with the spermacaeti whale.

At the beginning of the 19th century, New England whalers were venturing into the Southern Hemisphere in pursuit of right and sperm whales. In 1835, the first North Pacific right whales were killed in the Gulf of Alaska, and soon after, the fishery expanded to the western side of the ocean and the Okhotsk Sea. By 1849, right whales were sufficiently scarce in areas of the North Pacific to cause many whalers to switch their focus to the Bering and Beaufort Seas, where newly discovered stocks of bowheads were being plundered. Later in the 19th century, and continuing into the 20th century, shore stations on the west coast of North America sprang up, taking abundant humpback and gray whales for a few years before local depletion caused the stations closure.

MODERN WHALING AND THE SOUTHERN OCEAN

During the 1860s, two resourceful whalers (one Norwegian, the other American) independently introduced an innovation that was to change forever the methods of whaling. The harpoon gun (fired from the shoulder or mounted in more powerful form on the bows of catcher boats) permitted whalers to dispatch whales more swiftly than had ever been possible with hand-thrown harpoons and lances. This invention, together with the equally revolutionary replacement of sail with steam power, rendered even the fastest rorquals fair game, and ushered in the modern era of industrial whaling. Additional improvements in efficiency resulted from use of the compressor to inflate carcasses that would otherwise sink and be lost. Finally, in 1925 the introduction of the factory ship freed whalers from any remaining dependence on land stations for processing and thus permitted independent, fully mechanized whaling on the high seas.

The technical advances of modern whaling coincided with the discovery of the richest whaling grounds on Earth. In 1904, a Norwegian whaler ventured into the Southern Ocean near the island of South Georgia and noted with astonishment, I see them in hundreds and thousands. Every species of baleen whale except the bowhead, gray and Bryde s existed in vast numbers in the extraordinarily productive feeding grounds of the Antarctic. With this discovery, the stage was set for a slaughter that has few parallels in the history of wildlife exploitation. Between 1904 and 1980, approximately two million whales were killed in the Southern Hemisphere.

Although catch reports to international agencies for this period showed rapid declines in most species, the full extent of this exploitation was not revealed until 1994 when a group of Russian scientists presented the true catch records of several Soviet factory ships. From shortly after World War II until the late 1970s, the Soviet vessels systematically falsified their records, vastly under-reporting the true catches of some species. For humpback whales, the reported catch was 2710 but the true catch was 48 477. For the southern right whale, which had been depleted in the 19th century and protected by international agreement since the 1930s, the reported catch was four but the true catch was 3354. Accounting for these newly available records shows that the true extent of modern whaling in the Southern Hemisphere included over 200 000 humpbacks, 350 000 blue whales, almost 400 000 sperm whales and a staggering 725 000 fin whales. Although we will never know the true abundance prior to whaling, it is probable that between 80 and 95% of the pristine populations of these species were killed during this period.

THE MORATORIUM AND STATUS OF STOCKS

The International Whaling Commission (IWC) was established 1947 in recognition of the interest of the nations of the world in safeguarding for future generations the great natural resources represented by the whales stocks. Unfortunately, this admirable objective was not quickly or easily achieved. Although whale stocks were already in decline, and a few species had been protected by previous international agreements, the IWC made little effort and had little power to imposed catch limits. By the 1960s even the seemingly boundless stocks of rorquals in the Southern Hemisphere, particularly the humpback and blue whales, had all but disappeared. In 1972, the United Nations recognized the need for urgent action and called for a moratorium on whaling to allow the recovery of stocks. Not until 10 years later, however, did the IWC admit failure of its past management and agree to the need for a moratorium. This moratorium took effect in 1986, banning all commercial whaling and providing time to formulate an adequate management plan for any future hunting. Following several years of development and debate, the IWC agreed to a Revised Management Procedure based on a computer model to determine levels of allowable catch for any future hunting.

Today, some whales are recovering from overexploitation, although few have begun to approach their pre-exploitation abundance. The California gray whale is an exception: after nearly a century of protection, it is now

thought to number 26 000 individuals, equaling or exceeding pre-exploitation abundance. Some humpback and southern right whale populations appear to be experiencing strong growth, despite the massive damage inflicted upon them in the 20th century. Nonetheless, a number of exceptions exist involving populations that remain dangerously small. Among the most critically endangered are the North Pacific and North Atlantic northern right whales, bowhead whales of the eastern Arctic, western Pacific gray whales and most blue whale populations. In addition, some local populations appear to have been almost entirely extirpated; examples include the humpbacks and blue whales that once fed in huge numbers around South Georgia, New Zealand humpback whales, Spitsbergen bowheads, Gibraltar fin whales, North Atlantic right whales, and blue whales off Japan.

The reasons for the variability in recovery of stocks are unknown but could include a loss of cultural tradition or fidelity to specific migratory destinations. Recent behavioral and genetic studies indicate the importance of a calf s early experience in determining migratory traditions. If these traditions are lost by local extinction, the pattern of recovery will be patchy. Another possibility is the as yet poorly understood consequences of past illegal or pirate whaling. With the exception of the former Soviet scientists data, which are still being evaluated, most illegal whalers kept poor catch records. Finally, even low levels of ongoing illegal hunting could be depressing recovery in some stocks. Molecular genetic surveys of whale meat markets of Japan and Korea show that protected species and stocks are still available more than a decade after the moratorium.

ENVIRONMENTAL CHANGE AND THE FUTURE

The ecological impacts of whaling have been much debated, especially for the Antarctic ecosystem where whales were the dominant predator. The principal prey for virtually all mysticetes in the Southern Ocean is krill (euphausiid crustaceans). Even a moderate size whale, such as a humpback, probably requires more than a ton (900 kg) of krill a day for much of the 90 120 day feeding season. By some estimates, the depletion of whales has liberated more than 150 million tons of krill a year into the Antarctic marine ecosystem. This is several times more biomass than taken each year in all the fisheries of the world (estimated to be 60 70 million tons in 1980). Although there is evidence that populations of other predators (such as penguins and some pinnipeds) have expanded as a result of increased krill availability, it is unlikely this has replaced the role of whales. In particular, these other predators do not migrate and the incidental transport of nutrients to tropical waters by formerly abundant whale populations is now vastly reduced. Data on possible density-dependent effects in surviving whale populations are more equivocal, and there is little evidence to support the hypothesis that the recovery of some whale populations is inhibited by interspecific competition from others.

Humans do not as yet colonize the oceans; consequently, unlike many terrestrial mammals, competition for habitat space is not strictly an issue for whales. However, cetaceans are increasingly threatened with human competition for food resources, as well as with habitat degradation from pollution, noise, ship traffic and proliferation of fishing gear. The North Atlantic right whale population, depleted by whaling prior to the 20th century, is now struggling due to mortality from collisions with ships and entanglement with fishing nets in the busy coastal waters of the northeastern US and Canada. The impacts of global climate change on whales (and thus on whaling) are more difficult to assess but could constitute a serious threat in the Southern Hemisphere. Studies have shown that increased ultra violet radiation from ozone depletion can inhibit growth of phytoplankton on which krill feed. Independently, global warming may be influencing the ecological dynamics of invertebrates in the Antarctic marine system. In some areas, salps (tunicates), which are not a dietary component of whales, seem to be displacing krill. Interestingly, data on whales and whaling also provide an indication of global climate change. Whaling records (collected since 1937) appear to show an abrupt southerly movement of the sea-ice edge between the mid 1950s and early 1970s. This suggests a decline of some 25% in the area covered by sea ice, and could imply changes in Antarctic deep-water formation and, consequently, biological productivity. The actual impact of these changes on the recovery of whales remains to be seen. Like all other life on Earth, however, whales are now unwitting participants in a great and uncontrolled experiment in global ecology and climate change which began with the onset of the industrial revolution.

Marine Pollution: the GESAMP Definition

see GESAMP (Joint Group of Experts on the Scientific Aspects of Marine Environmental Protection) (**Volume 4**)

Marsh, George Perkins

(1801 - 1882)

George Perkins Marsh, US diplomat and scholar, provided one of the first extensive examinations of environmental degradation, in *Man and Nature; or, Physical Geography as Modi ed by Human Action* (1864). In this book he discussed the extinction of species, the consequences of forest clearing for streamflow, and other topics. Based on extensive study and travel, his portrayal was of a harmonious world torn apart by greed and ignorance. To check the abuse of nature, it was necessary, Marsh argued, not to reject all exploitation, but to exercise foresight, guided by a scientific understanding of the world.

Marsh s essential message was not entirely novel. Writers in France, Germany, Italy and elsewhere in Europe (especially the geographer Alexander von Humboldt), as well as scientists in India and other colonies, had expressed concerns during preceding decades about human impacts on the environment, particularly the effects of forest clearing on species, streams, and local climate. Marsh drew on many of these writers (he could read in 20 languages), and also observed conditions while traveling in the Mediterranean region and Europe. Thus, *Man and Nature* was especially significant because it brought together an array of existing knowledge and experience, synthesizing in an accessible format the perceptions of scientists in various parts of the world, and explaining their relevance to North America and other temperate regions.

Marsh s views were also shaped by his personal experience of land clearing and settlement in his home state of Vermont. By 1847 he had noted the consequences of clearing: erosion, streams in which droughts alternated with floods, impoverished fish communities (Marsh, 1848). Ten years later he advised the Vermont Legislature on the declining fisheries of the state. In his report he anticipated *Man and Nature*, describing a nature in the shorn and crippled condition to which human progress has reduced her (Marsh, 1857).

Although quoted elsewhere, Marsh was especially influential in North America. *Man and Nature* sold well, and within a decade was described as a classic. His critique of the once widespread view of deforestation as improvement proved persuasive: many Americans became convinced that clearing led to unregulated streamflow, deterioration in climate, and poorer conditions for farming. In response, Congress established a national forestry commission and forest reserves in 1873. His influence was also eventually felt by 1900 through the progressive conservation movement, when Gifford Pinchot of the US Forest Service, with others, advocated efficient use of resources through professional management. Closely linked to the advocacy of scientific management in business and government, the conservation movement accelerated the application of expertise to the management of forests, water and other resources. More recently, with the widespread emergence of environmental concerns since the 1960s, *Man and Nature* has been recognized as a prescient warning of the hazards of environmental degradation.

Marshes, Anthropogenic Changes

Pat Hutchings
The Australian Museum, Sydney, Australia

Tidal marshes occur on sheltered shores between approximately mean high water level of neap tides and the highest high waters of spring tides, and are periodically inundated with water ranging from fully marine to brackish waters. They are often referred to as salt marshes. Tidal marshes occur worldwide, from subpolar regions to the tropics, and depending upon latitude they may be dormant for varying periods of time in the winter, or may continue growing all year although often at varying rates.

No detailed worldwide inventory of tidal marshes exists although the largest area occurs in North America where extensive *Spartina* marshes are found along the east coast (occupying in excess of two million ha; Frey and Basan, 1985) and marshes dominated by *Distichlis* are present on the west coast (Dawe and White, 1986). Australia has more than one million ha of salt marsh (IPIECA, 1994). Tropical marshes have fewer plant species than temperate ones (Adam, 1990), although whether this relationship is also valid for the associated fauna and microflora is not known. Attempts to classify the vegetation of marshes based on floristic and vegetational criteria have been made by Chapman (1977). Within a tidal marsh, plant species are commonly zoned according to tidal height. The zonation may be dynamic with the marsh plants facilitating deposition of fine sediments, leading to increasing height relative to tidal datum and changes in species composition. Similarly, the distribution, abundance and species composition of the fauna are related to plant species distribution and structure as well as latitude, although local factors such as leaf litter, surface topography, salinity, sediment

characteristics and the distribution of surface microflora all play a major role (Hutchings, 1994). However, there are relatively few quantitative studies on the distribution and abundance of the macrofauna of tidal marshes, and many species exhibit major fluctuations in populations over time.

The terrestrial and seaward boundaries of tidal marshes fluctuate as sediment patterns and tidal regimes change. Along the New England coast, accretion rates in salt marshes over the last few thousand years have kept pace with increases in relative sea level. This has allowed the salt marshes to extend both landward over previously terrestrial or freshwater wetlands and seaward onto mudflats (Niering and Warren, 1980). However, landward encroachments of marshes are increasingly prevented by the presence of seawalls and other barriers. Encroachment of adjacent mangroves into salt marshes may lead to loss of such habitats unless active measures are taken to maintain the marshes (Burchett *et al.*, 1998). The reasons for this mangrove encroachment in parts of Sydney Harbor are not fully understood, although increasing urbanization of the catchment and with it increasing sedimentation may be a contributing factor. In coastal areas experiencing tectonic subsidence such as SE Australia and Irian Jaya, fringing mangroves are encroaching into the salt marshes as land levels drop (cited by Bird, 1993).

So not only do we not have a detailed inventory of the areas currently occupied worldwide by this important ecosystem (Adam, 1990, and references therein), we have limited knowledge of how these areas have fluctuated globally since the last major sea level rise, 6000 years ago (Adam, 1990; Bird, 1985; Viles and Spencer, 1995 for specific examples), although we have some detailed studies of individual areas during the last 100 years or so. For example, in the Fal estuary in SE England, the salt marsh advanced seawards by up to 900 m between 1878 and 1973, while its landward margins were colonized by scrub and woodland vegetation (Bird, 1985). This clearly illustrates the potential dynamic nature of salt marshes both in terms of distribution and species composition. So it is unclear as to whether the total area occupied by tidal marshes has increased or decreased globally since the last major sea level rise, although changes have certainly occurred within regions. A variety of processes control the distribution of tidal marshes, including sea level and associated tidal regimes and sedimentation and accretion processes. Knowledge of the distribution of tidal marshes prior to 6000 years ago is limited, as marshes provide few fossilized deposits. Kennish (1986) has suggested that the available area for the development of tidal marshes was small before this time, and the period of rapidly fluctuating sea levels between 15 000 and 6000 years ago would also have prevented their development.

The hydrological and topographical conditions which enable tidal marshes to develop are often identical to those needed for ports and associated settlements. For example, in Australia all but one of the capital cities and most other cities and large towns are located on an estuary or a sheltered bay and have associated ports. This means that tidal marshes are often in close proximity to centers of human population, and are therefore subjected to anthropogenic impacts. Such impacts may have occurred over many centuries. In addition, in many countries coastal populations are generally increasing, e.g., in California and the east coast of Australia.

The following is a brief summary of the impacts of humankind on tidal marshes:

1. A long established use of salt marshes has been the clearing of vegetation for the creation of ponds in which sea water is trapped and then allowed to evaporate to produce salt, a practice still prevalent in many countries.
2. Tidal marshes are often reclaimed by dredging and or drainage for developments such as marinas and port developments (Pinder and Witherick, 1990). Such major development may require the redirection of wave energy, changing tidal and wave patterns in the area. Wave-deflecting barriers incorporated into the development of Port Botany, Botany Bay, redirected waves across the Bay leading to massive erosion of tidal marshes.
3. The proximity of tidal marshes to ports makes them vulnerable to oil spills, and they are efficient at trapping oil. The ability of the marshes to recover varies and in some cases it is suggested that it is preferable to allow the marsh to recover naturally (IPIECA, 1994) than to try to remove the oil either physically or chemically. Hopefully, an increasing use of booms will reduce the numbers of oil spills or at least the extent of cover.
4. Tidal marshes are affected by changes in freshwater input and storm water discharges, both in terms of quantity and quality of input. Redirection of storm water in the Swan River, Perth has led to a loss of tidal marshes and increases in the area occupied by the sedge *Typha* (Thurlow *et al.*, 1986). Such changes will also presumably affect the microalgal and meiofaunal communities and this may impact on the macrofaunal communities. Storm water runoff with high levels of nutrients will also impact on these communities.
5. Increasing damming of rivers for fresh water may lead to the salinity wedge encroaching further upstream, changing salinity patterns and so modifying marsh communities, both animals and plants.
6. Deliberate plantings of *Spartina* in southern England in the late 1800s and the accidental formation of a hybrid *Spartina anglica* which is now the dominant saltmarsh species throughout Northern Europe, has drastically altered the ecology of this area (see Adams, 1990 for a discussion). As this species is tolerant of some tidal submergence, it has colonized mud flats and may have

reduced the value of these sites for wading birds (Davis and Moss, 1984; Millard and Evans, 1984). The hybrid has been planted in New Zealand, southern Australia and China, and forms extensive colonies replacing endemic communities. At least in Australia such a practice has stopped, but the species is still colonizing new areas.

7. While tidal marshes are relatively weed free because of the salinity conditions which prevail, some introduced species have become pests. In Australia these include the sedge *Juncus acutus* and the American species *Baccharis* ssp. which has been declared a noxious weed in Queensland and has been implicated in causing asthma.
8. Pumping offshore for oil and gas and extraction of ground water has led to subsidence along some coastal areas which has then led to sea level rises and flooding of coastal areas (see Bird, 1993 for details). In other areas, offshore mining for sand has modified rates of accretion in coastal areas.
9. Tidal marshes have been used for livestock grazing for centuries, which is important in northern Europe (Dijkema, 1984), eastern Canada (Roberts and Robertson, 1986) and Japan (Ishizuka, 1974), primarily cattle and horses, although the practice is slowly declining in these areas. The grazing regime is a major factor controlling diversity of plant species (see Adam, 1990 for discussion of impact of grazing).
10. As tidal marshes often occur near populated areas, they may be subjected to frequent spraying of insecticides to control mosquitoes and biting midges, which also impacts on other invertebrates as well; in addition, the physical damage occurs as a result of trampling through the marsh. In the past, swamps were often drained to control these insects.

While the above impacts could potentially be quantified for particular regions, this has not been done. It is far more difficult to evaluate the impact of global warming and associated rising sea levels and increased frequency of storms, and to separate the impact of these factors from the naturally dynamic nature of tidal marshes, which fluctuate in area and species composition over time. In addition, tidal marshes are impacted by a variety of localized anthropogenic impacts as discussed above. So several factors, natural and anthropogenic, are responsible for changes in area or type of tidal marshes. Separating these factors is not a feasible option at this stage as there is no detailed global inventory of tidal marshes or changes over time. Certainly in some areas, loss of tidal marshes has occurred but whether losses have been cancelled out by gains elsewhere is not known. However, tidal marshes are diverse systems and a system in SE Asia cannot be equated with an Arctic marsh.

While in the past, tidal marshes could migrate landwards with rising sea level, increasingly this will be prevented by the construction of seawalls. Although some data from the Gulf of Mexico and the Atlantic coast of the USA suggest that rates of accretion in most cases exceed rates of sea level rise, where land is available for boundary movement. With increasing temperatures, the species composition of tidal marshes will change, not just in terms of species, but also in terms of structure and presumably associated changes in the microflora and both macro- and microfauna. Limited data suggest that this will affect bird populations that either roost in the tidal marsh after feeding on nearby mud flats or those species which feed in the marshes. Increasing storm activity may lead to changes in sediment distribution and erosion, and the ability of them to recover will in part be dependent on the frequency of such events.

Certainly global warming and changes in sea level, together with other anthropogenic impacts discussed above, will change the distribution and structure of tidal marshes. Whether these changes will lead to a reduction in the areas occupied by this habitat is unclear. However, certainly in tidal urbanized areas physical barriers will curtail any expansion of marshes inland and this will lead to losses of this habitat on a regional scale. But will these losses be compensated by expansion in non-developed areas? Also unclear is the impact of either physical loss of tidal marshes, or changes in species composition and how this will affect nearby tidal waters. Expanding tidal marshes tend to function as net carbon importers but as the marsh matures, it may become a carbon exporter as well as being important in the transformation of compounds (Adam, 1990 and references therein), with considerable variation occurring between marshes. So changes in species composition of tidal marshes induced by rising sea levels and global warming will certainly change the productivity of the marshes. However, few attempts have been made to construct budgets for individual tidal marshes, let alone regional or global ones, so the impact of changes in the distribution and composition of these habitats is difficult to assess or how these will impact adjacent ecosystems. One should therefore practice the precautionary approach and attempt to prevent any further loss of tidal marshes, and to undertake further studies to complete our understanding of the role of various types of tidal marshes.

Materials Flows for Mining and Quarrying

Ian Douglas and Nigel Lawson
University of Manchester, Manchester, UK

The materials ows due to mining and quarrying directly link industrial activity to the sustainable use of resources and are a major component of land surface change. To the minerals or ore extracted must be added all the overlying rocks and soils that are removed and dumped elsewhere, even temporarily. The total mass of material moved in these extractive industries exceeds the mass of sediment carried annually by all the world's rivers to the sea and is approximately three times the amount of mineral matter actually entering industrial processing streams. The hidden ows of overburden removal and ore processing waste have to be taken into account when considering the contribution that mining and quarrying make to global environmental change.

INTRODUCTION

Mining and quarrying involve some the greatest transformations of the landscape through human activity; often creating huge pits and waste heaps. Mineral extraction is broadly divided into three basic methods: open-pit or surface, underground, and solution mining. Open workings are the dominant form of extraction of the main commodities mined or quarried: coal and aggregates. Surface, or open-pit mining requires rock, soil and vegetation removal to reach mineral deposits. The waste rock, or overburden, is piled near the mine. The workings have large energy requirements and produce emissions to the atmosphere and discharges to nearby water bodies. For any particular mine, these hidden flows are often greater in magnitude than the mass of mineral or ore extracted for processing. This extraction of materials from the natural environment and their transfer to urban and industrial areas has to be considered as a geological and geomorphological agent contributing to global environmental change.

Despite having relatively static total populations, the industrialized economies are increasing their use of materials, particularly construction materials, as households become smaller but more numerous and individuals acquire more possessions. In the rapidly industrializing countries, urban and industrial building and the construction of roads and other infrastructure are proceeding apace. For example in China, the production of aggregates and associated hidden flows more than doubled in seven years, rising from 2313 million metric tones (Mt) in 1989 to 5403 Mt in 1996

(Chen and Qiao, 2000). However per capita flows remain highest in the wealthier countries, the flows associated with aggregates being approximately 10 metric tonnes (t) per person per year in the US and approximately 4.2 t per person per year in China.

The key quantities to be addressed in establishing the materials flows due to mining and urbanization are the annual masses of rock and earth surface materials extracted, including overburden and mineral processing residues. In addition, account should be taken of pollutant releases to the atmosphere, water and the soil, as well as of the chemicals, fuels and materials in machinery used in the mining and mineral processing activities.

CALCULATING THE OVERBURDEN AND HIDDEN FLOWS

National mining and quarrying statistics record the net amounts of material produced for each commodity extracted, the run of mine production. However, these figures do not account for all the overburden removed before extraction can start and the waste created during mineral processing, the hidden flows associated with mining and quarrying (Adriaanse *et al.*, 1997; Douglas and Lawson, 1997). Whilst it can be argued that during open pit mining, especially coal mining, much of the overburden and locally stored waste is eventually replaced in the hole from which it came, even that local temporary shift of materials involves a large energy consumption and a change in the nature of the ground surface. In addition, there is always a risk that some of the stockpiled overburden will be eroded or lost through drains to nearby streams and that the final land restoration will result in a somewhat different landscape from that which existed before mining. The quantities of material shifted by mining and quarrying will vary with the mineral being extracted, the technology used to extract it, the geological situation of the deposit, the age and life of the mine, and the precise management policies of the mine operator. Nevertheless, this ecological rucksack of mining and extractive industries has to be estimated.

Researchers, including Sherlock (1922) and Hooke (1994), have tried to gain an idea of these *hidden* flows using estimated multipliers of the mineral production to obtain a figure for the total amount of materials shifted by mining and quarrying. For each mineral product, a given additional quantity of earth surface materials is removed as overburden or as waste from ore treatment. The ratio of this additional quantity to the amount of mineral produced can be used as a multiplier to obtain the total volume of material moved. To obtain the multipliers used in this article, case study examples of mine overburden quantities cited in the literature were examined for more general applicability; and approximate multipliers were established for as many mineral commodities as possible. These approximations (Table 1) were then extensively revised through consultation with a wide range of experts involved with the mineral industries (Douglas and Lawson, 1997). This provides a list of multipliers based on commodities that can be applied to world figures. Their application to individual countries may be less safe, particularly if a single mine, or group of mines, in an unusual geologic formation is responsible for virtually all the production of a particular mineral in that country.

The multiplier for coal plays a major role in the magnitude of the global figure of total material extracted. Many argue that because the excavated material in open pit mining is usually replaced in the same hole, it should not be included in the calculations of hidden flows. However, we assume no overburden replacement in this assessment of earth surface change even though good site restoration programs can, in time and in certain locations, successfully return the land to up to 80% of original productivity. Energy and machines have to be used to dig out and later replace the material. The nature of the replaced material is not exactly the same and a local change has occurred which contributes to the overall global change caused by extractive industries.

INFORMAL AND UNRECORDED MINING ACTIVITY

National mineral production statistics vary in accuracy, and there is probably a certain amount of unrecorded, and often illegal, removal of gravel and rock in every country. Some countries have a large amount of small-scale artisanal mining, some of which may be unregulated and unrecorded. Gold Fields Mineral Services of London s estimate of 175 t of gold being produced in 1975 by informal miners worldwide may be an underestimate. Three million carats of diamonds may be mined informally each year in Africa. Because of low recovery rates when informal artisanal gold and gem miners open up sites with very low yields, these operators probably shift more than twice the mass of material per net tone of pure mineral extracted than do their formal mining counterparts. The overburden: mineral ratio may be as high as 3.7 M to 1 for artisanal gold mining in the Amazon, as compared with a ratio of about 1 M to 1 for large mechanized gold mining. These operations alone could easily result in the movement of over 400 Mt of material per annum, equivalent to nearly 1% of the global mass moved during mineral extraction.

In many parts of the developing world, building materials are worked as small enterprises. People seek the clay, sand, gravel and stone that they need in the nearest most

convenient place and it is inconceivable that these activities are accurately recorded. In Vietnam, for example, at headlands along the coast, individual entrepreneurs quarry granite, while around towns and cities, small brick clay pits leave a series of derelict hollows and degraded soils. In inland China, villagers operate small crushers making aggregates from rock quarried from tiny rock outcrops near their fields. Around Beijing, many farmers have removed a depth of 1 2 m of clay from their fields to feed local brickworks and have then resumed cereal or vegetable cultivation on the lowered surface. Many hundreds of thousands of tones of material are worked in this way and in inefficient

Table 1 An example of the development of multipliers to calculate the hidden flows in mining activity

Commodity	Multipliers from the literature	Expert opinions	Recommended multiplier	Sources
Copper bearing ores: Cu content of copper ores and concentrates and all other copper bearing ores and concentrates intended for treatment of copper recovery	Copper ore = 1000% waste (Sherlock, 1922)	1% copper in ore and need to move 5 tons per 1 ton ore, i.e., ×500 (Highley)	×450	Highley = ×500
	1.23% = average of six mines (Mining Annual Review, 1996)	Bingham Canyon 0.7% copper in ore (Gilluly, *et al.*)		Accept Tilton and Highley average
	Bougainville quoted 1 ton waste to 1 ton ore (Winslow)	×337–×550 (Tilton in Eggert quoting US Bureau of Mines)		
	Freeport ore = 2.5% copper (Mitton)	0.49% average for US production in 1990–1994 (US Bureau of mines)		
	Copper content of ores hardly 1%, 165 material to one refined metal (Masini and Ayres)	0.77% concentration (Blackburn and Dennen)		
		×603 in US (Ayres and Ayres)		
Nickel bearing ores: (Ni content of nickel ores and concentrates intended for treatment for nickel recovery)	1.3% concentration (Blackburn and Dennen)	3% Ni content, and predominantly opencast and 1 : 15 ore/overburden (Manning)	×560	Basis 2% Ni content in ores and 75% opencast
	1.89% = average Ni content of eight mines (Mining Annual Review, 1996)			
Gold bearing ores: (Au content of gold ores and concentrates and all other gold bearing ores and concentrates intended for gold recovery)	8 grams per ton of ore (Blackburn and Dennen)	0.9–4.0 grams Gold per ton of ore, but 1 : 9.5 ore to waste, in the Andes (Fox)

unauthorized mines. Road construction in remote areas, such as logging roads in Borneo, uses up to 370 t of gravel per kilometer (km), and may involve the unrecorded quarrying of over 4000 t of rock per year in each major Borneo logging concession (assuming some 10 km of road construction or repair each year).

The global amount of material moved by these informal, and largely unrecorded, mining activities is difficult to assess. Assuming that such mining involves 250 t per person per year and noting that in India alone about 200 000 informal miners may be shifting about 50 Mt of material each year, about 2.5% of all mining related materials displacement in India (Lawson and Douglas, 1997). Whilst these activities result in substantial amounts of earth movement, they probably add no more than 1 5% to the global mass of materials moved during the extraction of minerals.

THE RELATIVE MAGNITUDES OF NATURAL AND EXTRACTIVE INDUSTRY MATERIALS FLOWS

The masses involved in these deliberate shifts of material at the earth s surface are globally more than double the amount of material transfer to the oceans by rivers (Table 2). In North and Central America, Europe and Australasia, the mining of hard coal alone shifts more material than is carried by river erosion processes to the sea, including the products of soil erosion induced by human activity. Only in Asia, where the steeplands and intense human occupancy of the land cause extremely high rates of river erosion, does natural erosion exceed the movement of materials by the mining of just three commodities: coal, iron ore and copper ore.

The comparison suggests that deliberate human activity, in terms of excavation and filling of sectors of the earth s surface, is the most efficient geological agent on the earth at present. Natural processes of erosion vary greatly in space and time, with enormous local transformations when earthquakes or volcanic eruptions occur. Even so, most of the world s river basins are greatly affected by human activities, their sediment discharge including eroded soil from cultivated fields and waste discharges from homes and factories. Few river basins have no human interference. Natural rates of erosion range from less than $10\,t\,km^{-2}\,year^{-1}$ in lowland rivers on resistant rocks, to over $1000\,t\,km^{-2}\,year^{-1}$ on the slopes of volcanoes or in the steep, earthquake prone uplands of New Guinea. Erosion rates in areas affected by human activities may be one or two orders of magnitude greater.

Even if we take those accelerated rates of sediment discharge of major rivers, we find that individual rivers such as the Mekong, Ganges and Yangtze discharge a smaller mass of material annually than the global production of an individual mineral commodity in a single year and that the fluvial sediment discharges to the oceans from the continents are either similar to, or less than, the total movement of materials for minerals production on those continents. Thus, when we compare river loads with mineral production and overburden movement, we are examining the similarity of people accelerated natural process activity to deliberate shifting of material. The comparison brings out the magnitude of the materials fluxes involved.

River basin based analyses of natural and people driven materials flows offer an alternative to regional accounts. Investigations in the moist temperate environment of Northern Spain and in the humid tropical environment of Puerto Rico indicate the scale of materials shifted by extractive industries against the work of natural fluvial processes. The Spanish Besaya Basin has 13.9 million Mt per year of material excavated for mining, but the river only removes 0.07 Mt of sediment per year to the sea. For the Rio Loiza in Puerto Rico, 1.24 Mt of sand and gravel are dug out of the river channel for urban construction each year, while the

[a] Source of production figures, net weight (unless otherwise stated): Department of Economic and Social Affairs, Statistical Division of the United Nations.

[b] Oil won from oil bearing shales and sands is included in the net figure for production of Petroleum, crude. However, oil from these sands and shale deposits requires additional materials movement of 22 times the net quantity of oil produced. Oil products produced from oil bearing shales and sands by the major producing countries amounted to 17 857 thousand tons in 1994 (United States Bureau of Mines, 1994).

[c] Aggregates and building stone production accounts for over 52% of the net weight of all mined or quarried material. Published UN data only cover 22 countries that produce about 50% the aggregates and building stones used. There are few figures covering the developing world. The only available global estimates of aggregates and building materials production have been made by correlating US production figures with gross domestic product (GDP) (Evans, 1993; Hooke, 1994). AS GDP includes exports, it is a variable predictor. Alternatively, an extrapolation could be based on population or energy consumption. As development involves building roads, housing and industrial facilities that use both aggregates and energy, data on energy consumption may be a good predictor of aggregate use. Absence of efficiency considerations in energy figures may be compensated for by the additional labor use. Available production figures for national, United Nations aggregate and building stone production correlate better with energy consumption than with GDP or population. Aggregates – energy: 80% of results range 9% $\pm$ the median. Aggregates – GDP: 80% of results range 43% $\pm$ the median. Aggregates – population: 80% of results range $>$100% $\pm$ the median.

sediment yield to the river is 2.80 Mt (Douglas and Lawson, 1997).

CONCLUSION

Globally, the total mineral production recorded in published data for 1995 was 19.7 billion tons (see Table 3), but the actual total amount of material mined or quarried from the earth s surface was of the order of 57.5 billion tons, i.e., some 37.8 billion tons of waste, overburden or spoil were also moved indicating that the hidden flows are about three times greater than the recorded ones (Douglas and Lawson, 1997).

Methane: Industrial Sources

Lee Beck

United States Environmental Protection Agency, Research Triangle Park, NC, USA

Methane concentrations are increasing in the Earth's atmosphere. The exact mechanisms responsible are not known well enough to quantify the individual types of sources. Part of the increase is due to natural processes such as decay of organic material, and some of the change is caused by chemical reactions in the atmosphere. However, the greatest part of the increase in atmospheric concentrations is due to anthropogenic (human) activity. Part of this increase is the result of direct activity (e.g., fossil fuel combustion) and part is indirect activity (e.g., partial thawing of permafrost due to anthropogenic global warming). The industrial sources described in this article are part of the direct component.

One of the dif culties in quantifying methane emissions from industry is the inconsistent treatment of source characterization within the industrial sector. Industrial wastewater treatment lagoons and the petroleum industry are the most signi cant sources of methane emissions presented in this article. Some sources that could have been included (e.g., from the natural gas industry) are not treated here.

SCOPE OF MATERIAL PRESENTED IN THIS ARTICLE

Treatment of methane emissions from the industrial sector is not consistent across publications. Several authors include coal mining and/or natural gas production in the industrial sector (e.g., Sapoundjiev *et al.*, 1999: 805). In fact, many sources refer to natural gas production, transmission, and distribution systems as the natural gas industry. Electricity production, agricultural sources, and municipal solid waste (MSW) landfills are sometimes also included in the industrial sector. Sometimes sources are mixed even within the same report. For example, the *industry* module of the US Environmental Protection Agency s (EPA s) global model called the Atmospheric Stabilization Network includes only non-combustion industrial sources. Industrial combustion is accounted for in the *energy* sector (Lashof

and Tirpak, 1990: VI-15 VI-18). This is to allow for emissions accounting in the model by balancing energy supply with energy demand. When quantifying methane emissions elsewhere in the report however, the industrial sector includes combustion sources (boilers, heaters, lighting, etc.) (Lashof and Tirpak, 1990: IV-15). Methane from landfills is included in the industrial sector (Lashof and Tirpak, 1990: IV-19 and VI-18) as is agriculture (Lashof and Tirpak, 1990: V-48). Landfills and agriculture are treated separately in most other studies (e.g., Adler, 1994; Hogan, 1993).

Some studies separate stationary fossil fuel combustion from other industrial sources (Berdowski *et al.*, 1993: 133). The Intergovernmental Panel on Climate Change (IPCC) Working Group II publication considers energy production to be part of the industrial sector when characterizing the sector in the part of the report presenting mitigation assessment options (IPCC, 1996: 655), yet treats them separately in the section which assesses impacts and adaptation (IPCC, 1996: 367). As with Lashof and Tirpak (1990), this is probably due to the different objectives of the different sections of the report. However, these inconsistencies illustrate the difficulty in defining industrial sources.

There are also different methods for reporting individual sources within manufacturing operations, even when they clearly are part of the industrial sector. Some reports on greenhouse gas emissions combine all fossil fuel combustion into one category, which includes electricity generation as well as industrial boilers and other industrial fossil fueled processes. Other works group demand by common sources such as lighting and motors into their own separate categories that include both residential and industrial sources.

A primary rationale for deciding what to include in this article is to minimize redundancy. For this reason, coal mines, the natural gas industry, and MSW landfills are not covered here. (For methane from landfill, *see* Urban Wastes, Volume 3). Peat mining is included here since it is a methane source characterized in the referenced literature but is not included elsewhere in this volume.

Sources covered in this article are categorized as:

1. industrial combustion sources;
2. the petroleum industry (a significant methane emitter in the industrial sector);
3. coke production (also individually cited in the literature as a methane emission source);
4. peat mining;
5. wastewater treatment lagoons and industrial landfills;
6. miscellaneous industrial processes.

Some of the data presented are *emission factors* (amount of emission per source or activity). Some data are presented as total emissions, taking into account the number of sources. Further, some emission estimates are global totals and some are for the US only. This is because there frequently is insufficient information to extrapolate the US estimates to global totals. Because of the overlap or exclusion of sources presented in this article, compared to other presentations of methane and/or the industrial sector, it is imperative that the reader confirms the scope of material herein with the scope from other sources prior to any attempt to use the data to quantify anthropogenic methane emissions. Failure to do so may result in double counting of some sources and/or not counting of others.

INDUSTRIAL COMBUSTION SOURCES

This segment of the industry includes industrial boilers, process heaters, and other devices that burn fuel for heat. There are a number of ways to estimate methane emissions from these sources. A method used by the EPA is to apply an emission factor of 1.4 kg methane per $2.8 \times 10^4\,m^3$ of gas consumed to the annual consumption rate of about $2 \times 10^8\,m^3$ (Hogan, 1993: 7-7). This yields about 0.01 Tg annually for this source. That same study estimated methane emissions from wood-fired equipment used in the industrial sector as 0.2 kg of methane per kg of non-methane volatile organic compounds (NMVOCs). For the reported annual rate of 0.485 Tg of NMVOCs (Hogan, 1993: 7-7), this yields an annual methane emission rate of about 0.1 Tg methane from this source.

Energy usage is another way to estimate the greenhouse gas emission contribution of the sector. One major study estimates the following breakdown of energy usage for the US industrial sector: process heat applications, 40%; boilers, 30%; electrical requirements, 15%; and feedstocks, 15%. In that study, boilers are defined as steam producers, and process heat applications are defined as industrial non-steam producers such as ovens, furnaces, dryers, and kilns (Lashof and Tirpak, 1990: IV-15).

THE PETROLEUM INDUSTRY

The petroleum industry can be divided into five segments:

1. Production: this includes emissions at the oil well and at the pumps, tanks, and compressors associated with the well. Some equipment such as compressors used to transport natural gas to sales are not included here. They are considered part of the natural gas industry.
2. Transportation of crude oil: this segment includes all movement of crude oil from the production segment to the oil refinery. This includes truck, marine, rail, and pipeline transportation.
3. Refining: this segment includes all equipment that transforms the crude oil into fuels such as gasoline.

Crude storage, refinery operations and equipment, and product storage tanks are included here. It does not include chemical plant operations such as ethylene manufacture, plastic/rubber operations, and specialty products, even though these operations are sometimes integrated with the refinery operations. These latter operations are included under the chemical industry.

4. Product transport: this segment includes the truck, marine, rail, and pipeline transport of products and/or intermediate products from the refinery to the end-user.
5. End use: this segment includes the final distribution (e.g., gasoline filling stations) and use (e.g., in cars and trucks).

Information on methane emissions for this sector is available from only the first three categories listed above (Harrison *et al.*, 1999: 8). In other words, emissions are estimated for sources from the wellhead to the exit from the refinery.

Methane emissions from the petroleum industry can be characterized as fugitive, vented, and combusted. *Fugitive emissions* are unintentional leaks from equipment or storage vessels. These include pump packings, seals, pipelines, and leaks. *Vented emissions* are those typically released to the atmosphere as normal operating practice. Examples are dehydrator vents, tank vents, gas operated pneumatic devices, and maintenance practices such as blowdowns. *Combusted emissions* are unburned methane fuel from sources such as engines, burners, and flares.

Emissions from the US petroleum industry were estimated by determining how many emitting items there are, called the *activity factor*, and how much methane is emitted from each item, called an *emission factor*. The activity factor and emission factor are multiplied to determine the emissions.

Harrison *et al.* (1999) used 1993 as the base year for which the most recent complete data were available. For comparison purposes, the study also estimated emissions for the years 1986 1992. This was done by applying the 1993 activity data to the activity profiles for each of the prior years. Emission factors were assumed not to have changed over the study period. Only the 1993 data are presented here.

The production segment of the US petroleum industry emitted 1.7 Tg of methane in 1993. This represents about 90% of the emissions characterized by the study. Within the production segment, about 35% of the emissions were from oil tank venting, 17% from pneumatic devices, and 13% from compressor fugitives (Harrison *et al.*, 1999: 46).

Refineries emitted about 9% of emissions (0.18 Tg) and transportation the remainder (0.027 Tg). Of the total industry emissions, about 60% were vented, 30% were fugitive, and 10% were combustion related (Harrison *et al.*, 1999: 48 52).

MANUFACTURE OF COKE

Metallurgical coke is produced by heating coal to drive off the volatile material. The remaining residue, coke, is almost pure carbon. It is used primarily in the steel making process as a reducing agent and for fuel. The process takes place in coke oven batteries, which consist of a series of refractory lined ovens. In a typical battery, 7370 kg of coke and 1500 kg of coke oven gas are produced from 10 000 kg of coal (EPA, 1984: 3 8). The coke oven gas is cleaned at a by-product plant where the hot gas is quenched with water and the resulting tar separated. Usually this tar goes through additional fractionation and separation to produce products such as naphthalene and other heavy organics. About 40% of the cleaned gas from the by-product plant is returned to the underside of the ovens to provide the fuel for the coking process. The cleaned coke oven gas is approximately 50% hydrogen and 32% methane by volume, with carbon monoxide, carbon dioxide, nitrogen, and other trace gases making up the remainder.

Though most of the process takes place under negative pressure, there is some leakage of methane to the atmosphere. These leaks amount to about 3.2 tonnes of methane per million tonnes of coke produced (Adler, 1994, 7). Another author reports methane emissions of 0.319 Tg globally (Piccot *et al.*, 1996: 22 764).

PEAT MINING

World peat production was reported by Lacroix (1993) to be 23 million tonnes per year. About half of the production reportedly occurs in the former Soviet Union, with practically all of the additional production taking place in Finland and Ireland (Adler, 1994: 7 9). The mining operations produced emissions of about 2 ± 1 Tg of methane per year. However, the methane emission estimate is highly uncertain. Lacroix (1993) reports that it may be low, given that it does not include emissions from the total peat production cycle and does not include dewatering and briquetting, which likely produce additional methane (Lacroix, 1993, 530). One author reports concern over the accuracy of Lacroix s estimate (Piccot *et al.*, 1996: 22 762).

WASTEWATER TREATMENT LAGOONS AND INDUSTRIAL LANDFILLS

Emission from industrial wastewater treatment lagoons is highly uncertain. The source is generally associated with facilities which have a large organic content such as food processing industries. The methane is produced as a result of organic decomposition. The EPA reports that by extrapolating emissions from individual lagoons, global methane emissions from this source may be on the order of 20 25 Tg per year, and are expected to increase over the next decades

(EPA, 1990: A-8). Another EPA report estimates 25 Tg per year from this source (Hogan, 1993: 1 4). Most of the increase, as with most other sources of greenhouse gases, is expected to take place in developing countries. By contrast, emissions from domestic (municipal) wastewater treatment facilities are much lower than from industrial sources. Emissions from wastewater treatment facilities in the US are reported as 0.2 Tg each year from 1990 1997 (EPA, 1999: 7-4 and 7-5).

One study assumes that the methane emission from wastewater treatment lagoons is a function of the organic content of the wastewater, expressed as biochemical oxygen demand (BOD). This study provides global estimates of methane by multiplying the global wastewater outflow by wastewater BOD concentrations, using industry-specific concentration factors. This number was then multiplied by the fraction of anaerobically digested wastewater and a methane emission factor of 0.22 kg methane per kg BOD for the anaerobic fraction. References are given for the BOD estimates for various industrial waste waters. The global estimate of methane emissions for industrial wastewater treatment obtained using this method was 26 40 Tg per year (Adler, 1994: 10-3 10-11).

Much information has been published on methane emissions from MSW landfills; however, industrial landfills are not as well characterized. The EPA greenhouse gas inventory cites emissions from industrial landfills annually for the US from 1990 (0.7 Tg) to 1997 (0.9 Tg). The EPA study assumed that emissions from industrial sites are 7% of total emissions from MSW landfills. Methane emissions from MSW landfills totaled 10.6 Tg in 1990 and 12.6 Tg in 1997. 1.5 Tg of methane from all landfills was recovered and combusted in 1990 and 1.8 Tg was recovered/combusted in 1997. No information is given on how much of this recovery took place at the industrial sites (EPA, 1999: 7-2 and 7-3).

MISCELLANEOUS INDUSTRIAL PROCESSES

The scientific literature reports several other industrial sources as having an as yet unquantified potential for methane emissions. In some cases, it is because methane (usually from natural gas) is used as feedstock. Such is the case for the manufacture of hydrogen, ammonia, methanol, and various organic chemicals. In most of these processes, hydrogen is stripped from the methane molecule. The remaining carbon is oxidized to carbon monoxide or carbon dioxide. Production of methanol may increase as cleaner transportation options are pursued. Methanol can be used both as a direct fuel and as a source of hydrogen in fuel cells. In the US, nearly $340 \times 10^9\ m^3$ of hydrogen is used in ammonia production, $900 \times 10^9\ m^3$ by refineries, and $25 \times 10^9\ m^3$ for methanol production (IPCC, 1996: 660). Though emissions were not estimated, one publication reports methane emission factors, in kilograms per tonne, for the following industrial processes: 11 for carbon black, 4 for styrene, 2 for methanol, 1 for ethylene, and 0.4 for ethylene dichloride (EPA, 1999: 3 15).

Kraft paper manufacturing processes, printing and publishing operations, organic chemical manufacturing, and miscellaneous unnamed manufacturing sources are estimated to emit about 0.5 Tg of methane annually (Piccot *et al.*, 1996: 22 763).

The manufacture of silicon carbide, an abrasive, also has the potential to emit methane. In this case, quartz reacts with carbon from petroleum coke, and methane is produced. Emissions from this process for the US are estimated to be 0.001 Tg annually (EPA, 1999: 3 16).

There is also a potential for significant emissions from the non-fuel mining industry. Methane concentrations ranging over several orders of magnitude (0.0012 to $9.3\ cm^3\ kg^{-1}$) are present in various rock types and in mineral and metal ores (Lacroix, 1993: 530 531).

Table 1 summarizes emissions estimates presented in this article.

FUTURE PROSPECTS FOR INDUSTRIAL SECTOR METHANE EMISSIONS

IPCC (1996), 655 cites four driving forces that will affect future emissions of greenhouse gases from the industrial sector:

Table 1 Summary of Information on methane emissions from industry

Source	Scope	Annual emissions (Tg)	Reference
Industrial combustion	US	0.1	Hogan, 1993
Petroleum industry	US	1.7	Harrison *et al.*, 1999
Coke manufacturing	Global	0.3	Piccot *et al.*, 1996
Peat mining	Global	23	Lacroix, 1993[a]
Wastewater treatment	Global	25	Hogan, 1993
Wastewater treatment	US	0.2	EPA, 1999
Paper, chemicals and miscellaneous	Global	0.5	Piccot *et al.*, 1996
Silicon carbide manufacturing	US	0.001	EPA, 1999

[a] Unconfirmed, see text.

1. growth in industrial production (quantitative changes);
2. changes in the sectoral pattern of industrial growth (qualitative changes);
3. reduction in the energy used to produce specific products (energy efficiency improvements);
4. changes in energy carrier composition, which relates primarily to fuel switching (e.g., coal to natural gas, fossil to renewable sources).

The IPCC (1996) conclusions cited above address all greenhouse gases; however, the same drivers apply to methane emissions from the industrial sector. Certainly changes in production and/or the kinds of materials produced (items 1 and 2) will affect the quantity of methane emitted. Also changes in fuels used (item 4) will affect methane emissions (e.g., switching to natural gas will increase leakage to the atmosphere). Reduction in energy usage (item 3) will reduce methane emissions to a lesser extent than carbon dioxide emissions but will have the added benefit of fewer opportunities for natural gas leakage.

Most of the *per capita* quantitative increase in the industrial sector will occur in the developing countries. However because of the potential for qualitative changes in industrial development, the quantitative increases may not be proportionally as great as would otherwise be expected (IPCC, 1996: 657 658). This contention is sometimes referred to as *leapfrogging* (*see* Leapfrogging Technology, Volume 4) to indicate that new technology can learn from the past and not be subject to the same evolutionary trends (Lashof and Tirpak, 1990: V-50).

Migrations: The Environmental Challenge of Population Movements

Ronald Skeldon

University of Sussex, Falmer, UK

The relationship between human migration and the environment is complex. Often, environmental change is seen as a root cause of population movement. Periods of desiccation in Central Asia have long been considered a factor in stimulating the great movements of nomad hordes that wrought so much devastation to the civilizations of Europe, the Middle East and China from the 12th to the 15th centuries, for example. Soil erosion, or the destruction of the

tropical forest, have been seen as factors creating more local movements of peoples in our own day. In very different contexts, the image of environments over owing with milk and honey, or land and gold in the Americas, to generations of Europeans and Chinese, attracted mass migrations to these open lands. However, the very movement of peoples, both pushed and pulled, causes environmental change through the spread of new technologies and new ideas, or simply through the introduction of increased numbers of people into environments unsuited for such an in ux. Yet, it is not a simple equation of population numbers and resources, but a complex matrix of institutional and political factors, in addition to the measures of population and environment.

It must also be made clear, however, that it is not only the great migrations that can represent a signi cant challenge to human and physical environments; small numbers of movers, too, can bring profound change. There can perhaps be no more dramatic example than the introduction of the human immunode ciency virus (HIV) and AIDS (acquired immune de ciency syndrome) into the United States, possibly by a single short-term visitor. The resulting rapid diffusion of the disease, the climate of fear among large sections of the population, and the eventual massive policy response changed people's behavior irrevocably in the West. In those areas in developing countries worst af icted, the disease is diffused rapidly along trucking routes, again by a minority of migrants, and the resulting high mortality has led to the virtual abandonment of lands and villages in parts of sub-Saharan Africa.

Throughout history, trading diasporas have linked small numbers of circular migrants and the exchange of goods, ideas, genes, and microbes that have generated profound change, both positive and negative, in the global environment. Four great human migrations of the past and present are identi ed for discussion: the migrations out of the Eurasian continent; movements from rural to urban areas; refugee and forced movements; and the new migrations of the late 20th century. This simple typology should not be seen as establishing four mutually exclusive forms of migration, but they form convenient divisions through which to examine the challenges for the environment posed by the movement of peoples.

THE MIGRATIONS OUT OF EURASIA

The Great Migration refers to the movement out of Europe, across the Atlantic, from the second half of the 19th to the early 20th century. Between 1860 and 1914, some 52 million people left Europe, mainly for the Americas but also for Australasia (Baines, 1991; Nugent, 1992). Many returned to their home countries, but this wave of migration was critical to the peopling of the North American continent, the transformation of once subsistence economies and the emergence of the United States as a major world power. That great migration, however, was but part of the much longer, and continuing, interchanges of population between Europe and Asia and the Americas. Beginning in a persistent form from the late 15th century, that Columbian exchange (Crosby, 1972) transformed the global environment through the introduction of new diseases, staple food crops, types of human settlement, and ways of doing things (*see* Biological Invasions, Volume 2).

The great human migrations in and to the Americas need to be placed within the overall context of the expansion of Europe that saw the ultimate creation of global empires. Smaller groups of European migrants traveled to literally every part of the world, not just as settlers but also as administrators and captains of commerce and industry. The resultant network of communities provided the human framework for the so-called global system in which large parts of the world are interrelated in a functional economic system. Small groups of migrants within colonial systems transformed rural landscapes through the expansion of commercial cropping. Perhaps the most dramatic example of this environmental transformation was the introduction of the plantation system, which brought a visual unity of coconut palm, sugar cane, or rubber trees to vast stretches of once heterogeneous forest. One account of the significance of the movement of plants, not just plantation crops, is given in Hobhouse (1985).

The conditions created by European expansion allowed for the vast movement of other peoples, some forced but others more voluntary. Movements of slaves out of Africa, later of indentured servants out of India and China, and of independent laborers seeking their fortunes, also from China, contributed to a transformation of the world as it was then known. Perhaps as many as 10 million slaves were landed alive in the Americas by the late 19th century, with an equal number having died between their place of capture and their destination (Lovejoy, 1989). Large parts of Africa suffered economic and demographic decline as a consequence, even if other parts of the continent undoubtedly profited as a result of the trade. By the early 20th century, some 1.5 million Indians had been moved outside the subcontinent as indentured laborers, and some three million Chinese were shipped out of China between 1801 and 1925 (Clarke *et al.*, 1990; Pan, 1998).

The global networks of European, Indian and Chinese communities that were established through these great migrations by the end of the period of European expansion laid the basis for the subsequent transformation of our environment today by human movements. An integral part of the demographic expansion out of Europe, however, was the establishment of urban centers for administration, trade, and the exploitation of resources. These laid the foundation for much of the second great human migration: the movement from rural to urban areas.

RURAL TO URBAN MIGRATIONS

Great cities long predate the colonial age in Africa, Asia, and South and Central America. The size, wealth and splendor of cities in China from the 12th century, and in India in the 16th and 17th centuries, overshadowed those of Europe before the industrial revolution. From the middle of the 18th century, however, Europe led the world in the growth and economic and political power of its cities. The overall level of urbanization in the developing world in 1800 was probably no more than about 8.3% compared with almost 12% in Europe (Bairoch, 1988). The change in the proportion of population that is urban by region from 1800 is shown in Figure 1. Of a total world population of around 978 million in 1800, about 50 million lived in towns. Since then, the world s population has risen more than six-fold to exceed six billion, while the numbers living in urban areas in the year 2000 have increased some 60-fold to almost 2.9 billion (United Nations, 1980, 1998b).

The explosive growth in the size of cities and in the level of urbanization occurred in Europe in the 19th century, but in developing countries that growth started essentially after the end of the Second World War. Currently, about 65 million people are being added to the world s urban population every year, compared with about 15 million being added to the rural sector. Over 60 million of the annual increase in urban population is being added to cities in countries of the developing world. Thus, the environmental challenge of population growth as we move into the 21st century is essentially one of the growth of the urban population in the developing world.

While migration is critical to the emergence of rapidly growing urban centers, mortality in early European cities was so high that the growth of these cities could only be sustained through the constant supply of migrants from the countryside, but migration is only one of three components of urban growth. The natural increase of the urban population itself is often the major component and currently accounts for about 58% of global urban growth (McGee and Griffiths, 1998). The reclassification of formerly rural areas as urban is also an important contributor to the total increase in urban population in any area, but one notoriously difficult to measure with any accuracy. The movement of people from village to town was, however, fundamental to the shift in the relative balance from a rural to an urban society. The rural to urban migration brought about the concentration of population at specific locations and the eventual depopulation of other regions.

The migration from village to town should not be thought of in terms of a simple, unilinear movement of people abandoning their rural homes for a life in the city. Rural to urban migration is a complex system that involves much return movement back to the villages and human circulation between town and country that binds the two into an integrated economic system (Skeldon, 1990). Wealth flowing in cash and kind back to the villages has been

shown to be a support to rural life, initially at least, in both developed and developing worlds during the transition to more urban societies.

An integral part of this process has been the emergence of very large urban areas, or mega-cities, which are often the capital and single largest city in a country or large region. While most of these used to be in the countries of the present developed world, the majority now are to be found in poorer parts of the world (Table 1). These cities have posed, and continue to pose, some of the major challenges facing our environment. The problems of supplying adequate housing, transportation, health services and sewage disposal, as well as providing the means to earn a basic living for densely packed and rapidly growing populations, have taxed the minds of city administrators in all these huge metropolises. Between 70 and 95% of all new housing in the cities of the developing world is estimated to be constructed illegally, and the average number of persons per room ranges between three and five times that of the developed world; up to 66% of urban populations in the developing world have no adequate systems of sanitation and several hundred million have no access to clean drinking water (Satterthwaite, 1998) (*see* Urban Population Change, Volume 3).

Pollution of air and water and the rapid spread of disease among the squalid conditions of the urban poor are thus as characteristic of the Calcutta, Lagos or Rio de Janeiro of today as they were of Cobbett s early 19th-century London the great wen ... The monster called the metropolis of empire . The teeming masses of the underemployed and unemployed have provided crowds to threaten and overthrow governments and the conditions of the urban poor have generated such a multitude of informal activities for survival that the criminal activities among them are seen as a threat to social order and decency. Yet, despite all the problems, the great cities have survived and prospered as one of the most enduring symbols of our time.

It would be unfair to attribute all these ills either to migration or to migrants. In the developing world of today, the city-born are usually found to have higher levels of unemployment than migrants from the rural sector, and the city-born, too, are often shown to have greater involvement in criminal activities. Yet, migration brings different groups together, facilitating the emergence of new identities while at the same time creating tensions over the perceived fear of the outsider. The resulting ferment has seen many of the environmental challenges met through the concentration of minds and wealth in the great centers of learning, commerce, and industry that are the mega-cities. While many challenges remain, particularly in the cities in the developing world, it is no exaggeration to say that the migration to the cities has provided the human foundation for the transformation of our environment to an urban world.

FORCED AND REFUGEE MIGRATIONS

Warfare, the destruction of crops and property, and the capture of slaves have been integral parts of the history of civilizations everywhere, so too has flight from these depredations been a universal response. More recently, however, the emergence of the nation state as the basic political unit of the modern world institutionalized flight on an unprecedented scale. With the nation state s emphasis on common identity, any group deemed to be outsiders is at risk of persecution and expulsion. State conflicts, the emergence of new nations, and the ethnic or ideological cleansing of the 20th century have generated another of the great human migrations: the flows of refugees. Some 30 million people were displaced in Europe alone by the Second World War (Moch, 1992), between 15 and 17 million people moved upon the partition of India and Pakistan in 1947, and some 10 million people fled to India in 1971 from what is now Bangladesh to escape the civil war in that area which had been aggravated by cyclone damage and famine conditions.

Although the world has ostensibly been at peace since the early 1950s and has subsequently experienced a period of continuous and rapid economic growth, the number of refugees rose substantially from under two million in 1965 to 13.2 million in 1996. The number of people considered to be of concern to the United Nations High Commissioner for Refugees in 1996 was double this number, or 26 million, which included the 13.2 million refugees, plus 3.3 million prior refugees who had since returned home, 4.7 million internally displaced, and another 4.9 million in danger of being displaced by conflict (United Nations, 1998a). Most of these people are to be found in the poorest countries of the world in sub-Saharan Africa and western South Asia,

which often incorporate marginal environments, with environmental concerns looming large as both cause and consequence of the displacements (*see* Refugees and Human Conflict, Volume 3).

It is perhaps in the area of forced migrations that the link between the environment and population movement is most explicit in the literature (*see* Environmental Refugees, Volume 4). Natural disasters caused by typhoons and hurricanes, floods, volcanic eruptions, and earthquakes illustrate the challenges posed to populations by the environment, although the effects are more likely to be seen in increased mortality than in migration, with population displacement, while intense, being localized and short-term. Famine, the disaster most capable of displacing large numbers of people, is likely to be more the result of human mismanagement and political ambition resulting in conflict than of natural factors. Famine and its accomplices, disease and war, make up a triple affliction that sees migration as a basic survival strategy resulting in the movement of hundreds of thousands of people and, as indicated above, was as common in the history of Europe as it is in much of sub-Saharan Africa today. The environmental refugee, or the person apparently forced to move for environmental reasons, is likely to have moved for a combination of reasons (Black, 1998).

The forced migration of such large numbers moving in so short a period of time is also seen to create intense pressure on the environments to which the people move. Those fleeing toward towns for protection are faced with finding adequate food in non-agricultural economies, making worse the already over-crowded and unsanitary conditions in the urban centers. Those displaced to rural areas are seen to exceed the carrying capacity of the often marginal environments to which they are moved, leading to the destruction of local resources, specifically forests, land, and groundwater. As in the case of those who fled to urban areas, the closely packed populations create severe problems for the adequate disposal of human waste and provide ideal conditions for the spread of disease. While such situations do exist and severe environmental destruction can result from the forced movement of populations for whatever reason, dispassionate analysis suggests that these conditions are neither characteristic of all refugee settlement areas nor necessarily inevitable (Black, 1998).

Displaced migrants have the capacity to help themselves and it is incumbent upon relief agencies to provide the conditions that can best allow the displaced to achieve these objectives. Such a strategy is similar to that proposed to provide the urban poor, many of whom are rural-to-urban migrants, with another path to development (De Soto, 1989), the means to help themselves. Given the large numbers of forced migrants and the fact that they are not an exceptional type of population movement in our modern world, it is perhaps best to consider them as an integral part of the total pattern of migration. As such, their challenges for the environment can be seen within a more general development framework. The issues then blend with those that have come to dominate concerns over international population movements since about the mid-1960s, or the new global migrations.

More long-term environmental changes leading to migration, such as desertification and future rises in sea level as a result of global warming, have the potential to displace very large numbers indeed. For example, in 1995, the Intergovernmental Panel on Climate Change projected a rise in sea level of 20 cm by 2020 and 30 100 cm by 2099. A rise of this magnitude would inundate almost one fifth of the present land area of Bangladesh within a century, directly affecting some 70 million people. Some small island countries would virtually vanish. The disappearance of densely settled, low-lying cultivable land, however, would merely be one of the more obvious direct effects of such a rise in sea level. The encroaching sea would also contaminate lenses of fresh water and gradually intensify the effects of tropical storms in populated areas.

The impact of global warming on a rise in sea level is still a matter of considerable debate and it is difficult to convince governments to plan for long-term shifts that may appear to be hypothetical when more immediate issues are at hand. However, the mere possibility that such an event might occur can undermine confidence, discourage investment and lead to long-term movements away from small island countries. For example, the prospects are dire indeed for large, densely populated areas such as those around the Bay of Bengal or the Gulf of Siam, where there is neither the tradition of building defenses against the sea (as in the Netherlands, for example) nor the capital available to do so.

THE NEW MIGRATIONS

Our present age has been called the age of migration (Castles and Miller, 1993). Although the absolute number of international migrants, as measured by migrant stock in each country, increased from 75 million persons in 1965 to 120 million in 1990, the annual rate of increase was only slightly higher than for the population as a whole and the proportion of people remaining outside their countries of origin is small, fluctuating between 2.1 and 2.3% over this entire period (Zlotnik, 1998). The reasons for designating our era as the age of migration lie elsewhere. The direction and composition of international population flows changed markedly over the period, with the movement to the settler societies of North America and Australasia being dominated by migrants from non-European sources, and Europe itself emerging as a significant destination for migration from developing countries.

These changes in the direction and composition of migration were associated with the transition to persistent low

fertility among European peoples that brought about a slowing in the growth of the labor force and an ageing of populations. With the post-war economic boom in progress, immigrants, initially from southern Europe and later from further afield, met the demand for labor. The societies of the developed worlds of Europe, North America and Australasia thus experienced a major transformation through ethnic mixing on a scale unprecedented in recent history. Such mixing had characterized societies at various stages prior to the emergence of the ideal of the nation state, and the late 20th century has seen a return to a polyethnic norm (McNeill, 1986).

The creation of multicultural states presents one of the greatest challenges to our modern world and one in which the environment looms large. The bringing together of peoples with very different attitudes to the environment and to its use can provide a basis for conflict. Different consumption patterns, attitudes towards trees, the interpretation of local building and zonation codes, or the disposal of garbage can create tensions between long-standing residents and new immigrants. Migrants from highly urbanized and affluent Hong Kong, for example, have difficulty understanding local Canadian sensitivities towards their approach to house styles and neighborhood trees that in Hong Kong is normal but in Vancouver is considered crass and uncaring. That many of the landscapes being altered by migrants are more romanticized than real, and have themselves been imposed by previous generations of European migrants on native populations, simply illustrates the complex relationships between the environment, the relative wealth of migrants, and attitudes that can be seen as racist (Ley, 1998).

Scapegoating and resentment toward wealthy immigrants on the part of the local population at the local level can find broader national expression, as they have in Australia where environmental concerns have been used as a justification to limit immigration altogether. Increased consumption of scarce resources raises Malthusian fears of the limits to growth and a limited carrying capacity (*see* Carrying Capacity, Volume 4) that, if exceeded by a future generation of migrants, will threaten the lifestyles of existing citizens (Hugo, 1996). In Australia, the fear of the culturally different outsider bringing environmental destruction has been a vocal, if as yet largely ineffectual, dimension of the immigration debate. While such local and national attitudes ignore the very real positive contribution that migrants make to their host economies and societies, they clearly reflect the difficulties of creating a single nation out of many peoples living in one environment.

A significant component of the modern migration flows is the short-term movements of tourists. The annual number of tourists increased from 69 million in 1960 to 454 million in 1990. The rising affluence of the developed countries and the advent of rapid and cheap air transportation facilitate movement for recreation to all parts of the world, including Antarctica. While almost three-quarters of the number of tourists visit developed countries, increasing numbers are going to remote and often fragile environments in search of the exotic. High mountain and island ecosystems are particularly at risk from any unregulated influx of visitors and an enduring challenge remains to ensure adequate plans for the conservation of heavily used sites and the preservation of other wilderness areas (*see* Tourism and Ecosystems, Volume 3).

Human migration is, along with fertility and mortality, one of the basic components of demographic change and, as such, must be included as a critical factor in the equation relating population size and resource use. With the decline of fertility, migration has emerged as *the* variable in causing populations to increase or to decline in some areas. For example, international migration accounted for almost 88% of the population growth of Europe between 1990 and 1995 but only 33% for North America (United Nations, 1998a). More important than its impact on growth, however, is its effect on the distribution of populations, concentrating people in urban areas and leading to the depopulation of rural areas, and its effect on the composition of populations, spreading ideas and patterns of consumption around the world and bringing very different peoples together. Human migration has been, and remains, one of the major forces behind environmental change and is an integral part of overall development (Skeldon, 1997).

National Responsibilities for Greenhouse Gas Emissions

Ian Douglas
University of Manchester, Manchester, UK

When considering the human drivers of global environmental change and discussing what can be done to reduce the pace of such change, responsibility for greenhouse gas emission reduction always comes to the fore. One measure is to simply look at national tonnages of gas emitted and then to call for a percentage reduction in that tonnage. However, more equitable measures look in each country at the amount of gas emitted per person, per unit of gross domestic product (GDP) and per unit land area and the deviation of those individual country gures from the global averages per person, per unit GDP and per km^2. Reliable data are not available on a standard basis for all gases, but those for fossil fuel derived carbon dioxide are considered reliable. For some countries, data for the three main greenhouse gases (carbon dioxide, methane and nitrous oxide) are now available.

Many factors affect differences in the emissions per person in a country, for example, the types of fuel used for heating or cooling, cooking or to generate electricity, population density, degree of industrialization, availability of private cars and vehicle kilometers traveled (people tend to drive longer distances in sparsely populated areas), and whether fossil fuels are extracted or processed within the state.

Differences in emissions per unit GDP (here expressed as per $1000 GDP) re ect contrasts in economic conditions between countries, the type of economic activity, and the ef ciency with which energy is used throughout the country. Differences in emissions per km^2 re ect population density, land use and the intensity and type of industrial activity. Some countries have vast areas of thinly populated, inhospitable land, while others are highly urbanized and have intensive agriculture.

ADEQUACY OF DATA FOR EVALUATING FAIRNESS AND EQUITY OF RESPONSIBILITY FOR EMISSIONS

Notions of fairness and justice underpin international negotiations to reduce greenhouse gas emissions. The United Nations Framework Convention on Climate Change (UNFCCC) (*see* United Nations Framework Convention on Climate Change and Kyoto Protocol, Volume 4) contains concepts of burden sharing and common but differentiated responsibilities (*see* Common but Differentiated Responsibility Principle (Stockholm/Rio), Volume 4) that are based on the idea that nations that have contributed most to the problem of climate change should do most to solve it. This is inherently the polluter pays principle (*see* PPP (Polluter Pay Principle), Volume 4). Application of this notion suggests that national targets for the reduction of greenhouse gas emissions should be based on the historical contribution of each nation to global emissions. The most important factor in determining this contribution is the level of emissions *per capita*.

Although investigations of burden sharing or differentiation usually make emissions *per capita* as the foremost criterion on which emission reduction targets should be based. However, other criteria to be considered include: the ability to pay (usually measured by GDP *per capita*), emissions per unit GDP, dependence on fossil fuels and emissions per unit land area. Clearly, emissions may be high in particular countries because they are burning fossil fuels to manufacture commodities widely used elsewhere in the world, such as the petrochemical industries of the Netherlands, Venezuela and the US.

Due to measurement difficulties and lack of data, the figures for emissions *per capita* usually used refer to carbon dioxide emissions from fossil fuel burning, cement production and gas flaring only. Such figures suggest that the US has the world s highest emissions *per capita*. However, the provisions of the UNFCCC require the industrialized countries that have signed up to emissions reduction targets to compile and submit to the United Nations systematic and comprehensive inventories of emissions from all sources and sinks. This additional information

includes the impact of agriculture, grazing, wetland use and forest management, some countries removing greenhouse gases from the atmosphere through these activities, others releasing them. Some of these data now permit more comprehensive evaluations of greenhouse gas emissions for some countries. Nevertheless, the only analysis for all countries deals solely with carbon dioxide emission from fossil fuel burning, cement production, and gas flaring.

FOSSIL FUEL BURNING, CEMENT PRODUCTION, AND GAS FLARING CARBON DIOXIDE EMISSIONS

The Largest National Gas Emitters by Total Tonnage

The US continues to be the largest single source of fossil fuel related carbon dioxide emissions reaching an all time high of 1447 million metric tons of carbon in 1996. In fact, US emissions are approximately 58% higher than those of the world s second largest emitter, the People s Republic of China. Over the past 20 years, China s fossil fuel carbon dioxide emissions grew at an annual rate of 5.3% reaching almost 918 million metric tons of carbon in 1996. From 1990 1996 alone, emissions from fossil fuel consumption and cement production rose 40%. Growth has occurred largely in the use of coal, not surprising given that China is the world s largest coal producer. In 1950 coal use contributed 99% of the total Chinese energy-driven carbon dioxide emissions, but only 77% in 1996. Liquid fuels now contribute 14% of emissions and have grown appreciably over the past decade. Since 1992, total carbon dioxide emissions from Russia have dropped 19% to 431 million metric tons of carbon, still the third largest emitting country in the world and the largest emitter of the republics comprising the former USSR. After 1987, Japanese carbon dioxide emissions grew by 30% to almost 319 million metric tons of carbon in 1996. Recent growth reflects a return to late 1970s consumption levels for liquid petroleum products and continued contributions from coal and natural gas. Japan is the world s largest importer of coal (126 000 metric tons) and liquefied petroleum gas (15 000 metric tons), and second largest importer of crude oil. India has experienced dramatic growth in fossil fuel carbon dioxide emissions, which have increased 6.1% per year since 1950, as India has climbed to the world s fifth largest fossil fuel carbon dioxide emitting country. Since 1990 alone, total emissions have risen 47.7% to 272 million metric tons of carbon in 1996. Fossil fuel carbon dioxide emissions from the UK in 1996, 152 million metric tons of carbon, are comparable to emission levels of the 1950s. Since 1950, the UK has dropped from third to seventh in rank among fossil fuel carbon dioxide emitting nations.

The Highest Per Capita Emitters

Several small states with major refineries and petrochemical operations, such as the US Virgin Islands with 33.22 tonnes *per capita* ($t\,cap^{-1}$), Qatar 18.19 $t\,cap^{-1}$, United Arab Emirates 9.40 $t\,cap^{-1}$, and Netherlands Antilles 8.75 $t\,cap^{-1}$, head the ranked list of countries by *per capita* emissions. Of the countries with the 30 largest total emissions (Table 1) the US heads the list at 5.48 $t\,cap^{-1}$. *Per capita* values for the US are the highest of the industrialized world but remain well below the 1973 high, roughly equivalent to late 1960s levels, and only 22% higher than the 1950 level. In 1996, 40% of US fossil fuel emissions came from the consumption of petroleum products.

Russia has a 1996 *per capita* emission rate of nearly three metric tons of carbon per person that is almost three times the global average and represents the third highest rate of the region behind the Czech Republic (3.37) and Estonia (3.04). Japan s *per capita* fossil fuel carbon dioxide emission rate has risen in 1996 to an all time high of 2.54 metric tons of carbon. China s population has doubled over the past forty years and now exceeds 1.25 billion people. *Per capita* emissions increased by a factor of almost eight over this period but their 1996 rate of 0.7 t carbon *per capita* is well below the global average. With the world s second largest population of nearly one billion people, India s *per capita* emission rate for 1996, of 0.29 t carbon cap^{-1} is well below the global average (1.13). It is the smallest *per capita* rate of any country with fossil fuel carbon dioxide emissions exceeding 25 million metric tons of carbon.

This contrast in per capita emissions between the world s two largest countries in population terms, China and India (0.76 and 0.29 $t\,cap^{-1}$, respectively) and the two biggest emitters, the US and Russia (5.48 and 2.65 $t\,cap^{-1}$, respectively) illustrates the great gulf in responsibility for release of carbon dioxide to the atmosphere between the people of relatively poor countries and those that are wealthy or have a highly developed industrial base (Figure 1).

The Lowest Per Capita Emitters

Forty out of the 210 countries in the database emit less than 0.10 $t\,cap^{-1}$. The majority of them are in Africa, but they include countries with large cities and substantial populations such as Kenya, Ethiopia and Mozambique. Pakistan which emits 0.18 $t\,cap^{-1}$ and ranks 158th in *per capita* terms, is ranked 37th in terms of gross national emissions. Indonesia is 22nd in national tonnage of emissions but 138th in *per capita* terms while India is 5th and 142nd, respectively (Table 1). The two sets of figures tell different stories.

Table 1 Carbon dioxide emissions from fossil fuel burning, cement production, and gas flaring in 25 of the top 30 total emitting countries in 1997 expressed as tonnes of carbon

Country	Tonnes per capita	Tonnes per 10 km^2	Tonnes per $1000 GDP	Total (tonnes)
US	5.48	1.62641	0.23	1 489 648
China (PRC)	0.75	0.983498	2.15	913 768

Sources: emissions total and per capita from Marland *et al.*, 2000; land area and GDP from http://www.wri.org.

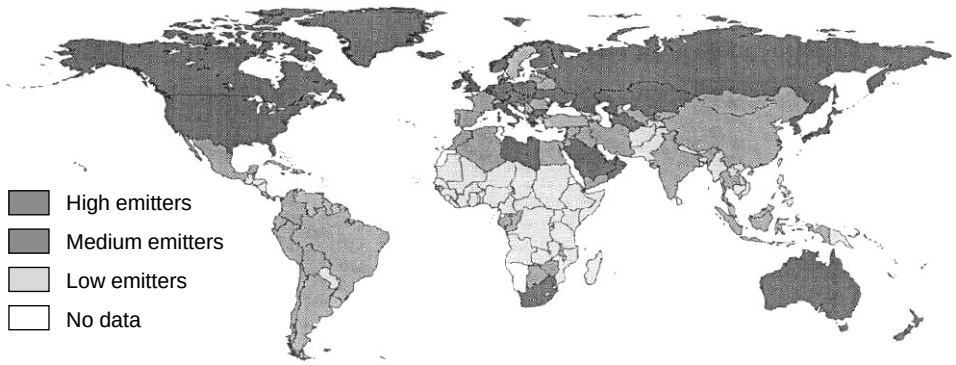

Figure 1 Per capita emissions of carbon dioxide by country 1996. The map shows the countries in which the 20% highest emitters live (high emitters) and the 20% lowest emitters (low emitters)

The Highest Per Unit GDP Emitters

Among the 30 largest emitters, China is by far the biggest emitter of carbon dioxide per unit GDP at 2.15 t per $1000 (Table 1), reflecting a great reliance on coal for transportation, industry and domestic cooking and heating. Other countries with heavy industrial structures, such as Poland, the Czech Republic and the Russian Federation follow China. India also has heavy industry, but a relatively small GDP in relation to its total population and thus has a similar emissions per unit GDP to the Central and Eastern European countries at 1.12 t per $1000 GDP.

The Lowest Per Unit GDP Emitters

Japan and France (0.08 and 0.074 t per $1000, respectively) have low carbon dioxide emissions per unit GDP

because they have considerable reliance on hydropower and nuclear power for energy. Many Western European nations, such as the UK, Italy and Germany have emissions of 0.11 0.14 t per $1000, while Canada, Australia and the US are in the range 0.23 to 0.30 per $1000.

The Highest Emitters Per km^2 Land Area

With emissions of 13.0 t km^{-2} the Netherlands has the highest rate among the 30 countries with the largest emissions, followed by South Korea with 11.8 t km^{-2}. These figures may reflect the high population densities and the concentrations of petrochemical and steel making industries in those countries. Japan, Germany and the UK are the next three highest countries with emissions of 8.38, 6.51 and 5.88 t km^{-2}, respectively.

The Lowest Emitters Per km^2 Land Area

Large countries with arid, cold or mountainous areas and relatively small populations are the lowest emitters per unit area, Australia emitting 0.11 t carbon dioxide km^{-2}, Argentina, 0.13 and Canada 0.14. While the Russian Federation emits 0.23 t km^{-2}, China emits 0.98 and the US 1.62.

CALCULATIONS OF TOTAL GREENHOUSE GAS EMISSIONS PER CAPITA

New calculations of greenhouse gas emissions per person for all 35 Annex B parties to the Kyoto Protocol (the industrialised nations that have signed up to emissions reduction targets) cover emissions of the three main greenhouse gases (carbon dioxide, methane and nitrous oxide) in 1995 from all sources and all sinks measured in carbon dioxide equivalents (CO_2-e) (Turton and Hamilton, 1999). On this basis, Australia has the world s highest greenhouse gas emissions per person at 26.7 tonnes; this is twice the average level for all other wealthy countries (13.4 t cap^{-1}) and 25% higher than emissions per person in the US (21.2 t cap^{-1}). While the US has higher emissions from energy (20.6 t cap^{-1}

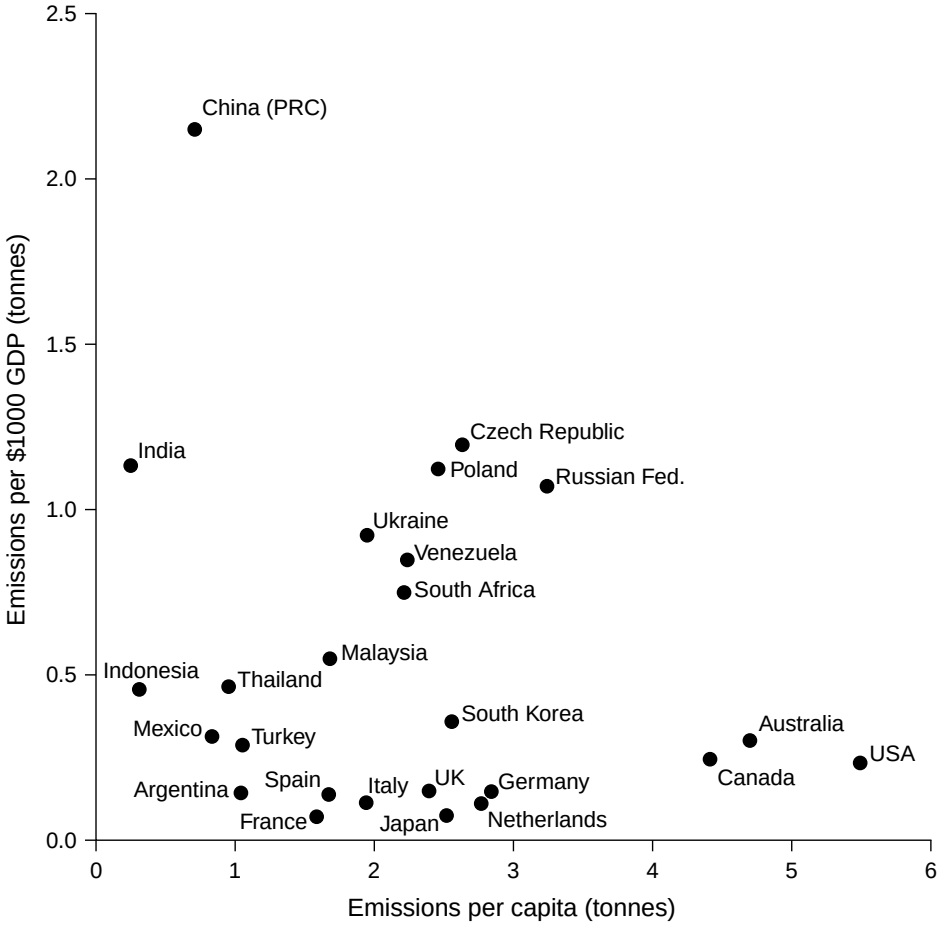

Figure 2 Plot of tonnes carbon dioxide emissions per $1000 GDP against tonnes carbon dioxide emitted per capita for the countries in Table 1

compared to Australia s 17.6 t cap^{-1}), Australia has much higher levels of emissions from agriculture and land-use change.

In descending order, the six nations with the highest per capita emissions are: Australia (26.7), Luxembourg (24.2), US (21.2), Canada (20.6), New Zealand (17.3) and Ukraine (16.7). The next five countries have emissions per capita of 14 15 tonnes. Luxembourg s very high emissions are due to the presence of a large steel plant. New Zealand has low energy emissions (due to the predominance of hydroelectricity) but very high emissions from agriculture (due to the large number of sheep). These are offset to some extent by the net sink provided by forests in that country.

Among larger countries at the other end of the scale, France (7.8 t cap^{-1}), Germany (12.6 t cap^{-1}), Spain (7.1 t cap^{-1}), Italy (9.0 t cap^{-1}) and Japan (9.5 t cap^{-1}) are notable. Their low emissions are due to a combination of energy efficiency, industrial structure and the use of nuclear power.

CONCLUSION

Plots of emissions per $1000 GDP against emission *per capita* for 25 high total emission countries (Figure 2) show the contrasting positions of the three countries with the highest total emissions. China is high per unit GDP and fairly low *per capita*. The Russian Federation is moderately high in both per unit GDP and *per capita* terms, while the USA is low in per unit GDP terms, but highest in *per capita* terms. Countries like Thailand, Mexico and Argentina are low on both criteria.

When emissions per $1000 GDP are plotted against emissions per km^2 (Figure 3), the majority of the 25 countries crowd into the lower left-hand corner of the figure, but the densely populated industrial countries, like South Korea and

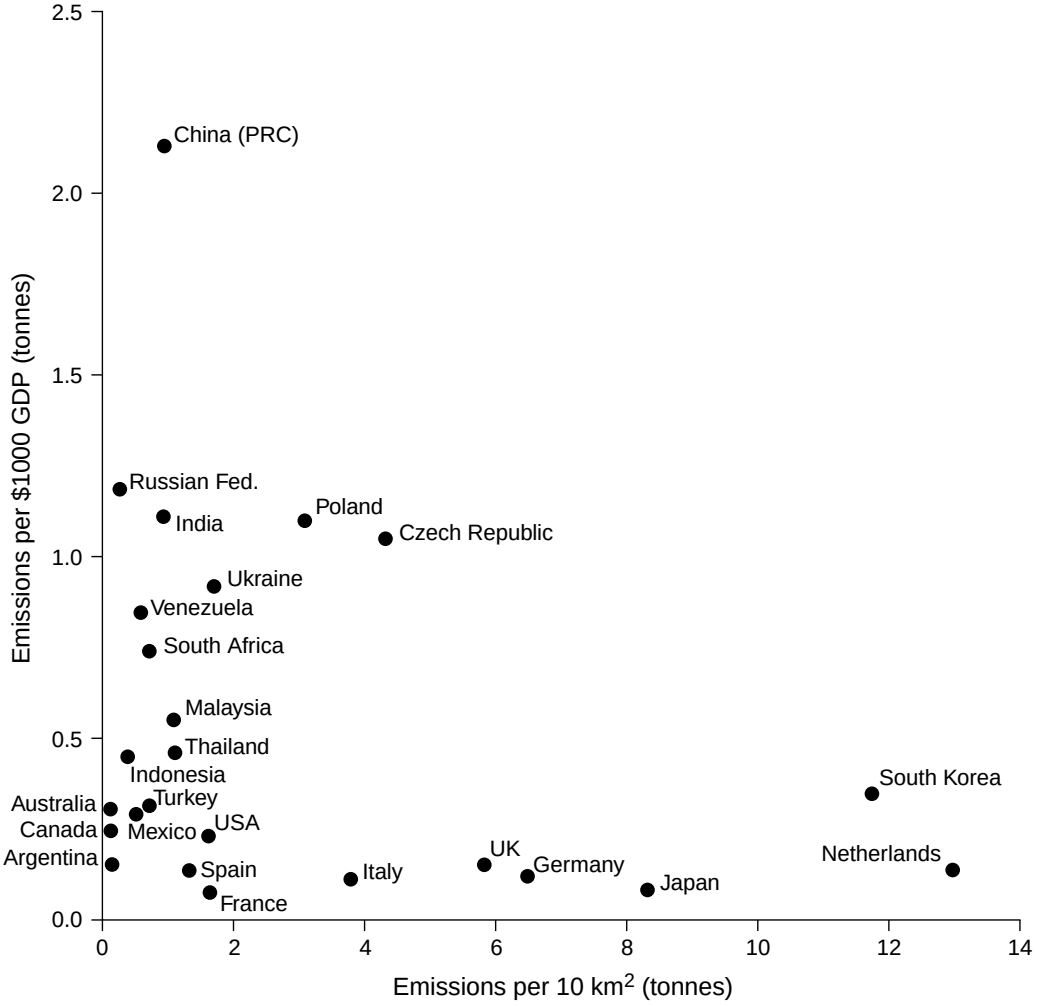

Figure 3 Plot of tonnes carbon dioxide emissions per $1000 GDP against tonnes carbon dioxide emitted per 10 km^2 for the countries in Table 1

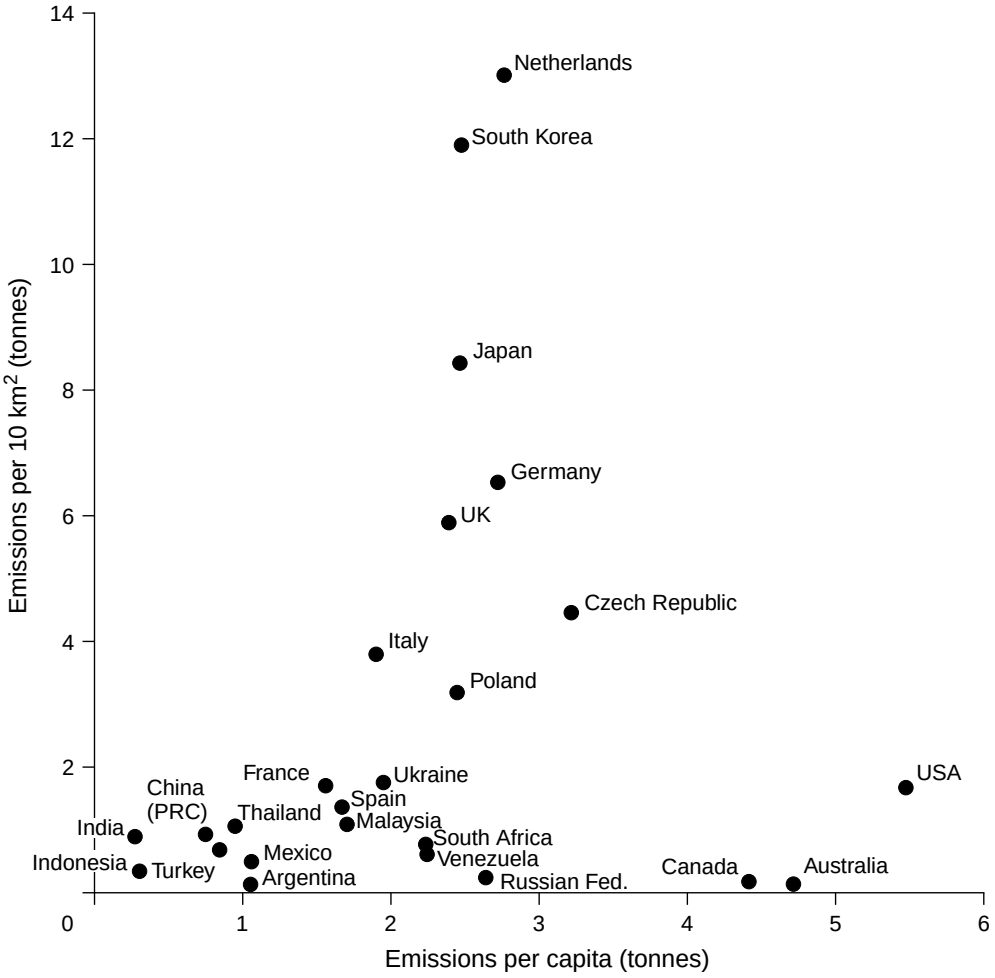

Figure 4 Plot of tonnes carbon dioxide emissions per 10 km^2 against tonnes carbon dioxide emitted per capita for those countries in Table 1

the Netherlands plot towards the lower right. The countries with enormous reliance on coal and relatively old and less efficient industrial facilities plot towards the top left-hand corner.

The plot of carbon dioxide emissions per $1000 GDP (Figure 4) separates the 25 countries more clearly, with the high *per capita* countries in the lower right corner and the high per GDP countries in the lower left. Interestingly, the newly industrialising countries, such as Malaysia, Thailand and Venezuela, plot towards the centre of the graph.

These graphs and tables demonstrate that responsibility for greenhouse gas emissions is extremely unequally distributed amongst countries. One fifth of the world s population accounted for almost two thirds (62%) of all emissions in 1996 while another, much poorer, fifth accounted for less than 2%. Industrialized countries, with relatively slowly growing populations, have the largest *per capita* emissions, as Tables 1 and 2 show. Growth in *per capita* emissions, by contrast, tends to be most rapid in less wealthy countries, many of whose populations are growing rapidly. The gap in *per capita* emissions by nation is narrowing, but so slowly that there is no reason to expect relatively equal *per capita* emissions at any point in the future.

The fifth of the global population collectively contributing less than 2% of all greenhouse gas emissions (over a billion people) could rightfully argue that they are not contributing to climate change at all. Since their modest *per capita* greenhouse gas emissions, if emulated by everyone else in the world, would result in stable or even falling greenhouse gas concentrations in the atmosphere. This poor population is growing rapidly, however, and in escaping poverty, their descendants greenhouse gas emissions are likely to come closer to the global average and be less sustaining of the global climate. The more people there are in the world, the lower the average *per capita* emission will have to be if climate change is not to accelerate.

Table 2 Total emissions of the three main greenhouse gases (carbon dioxide, methane and nitrous oxide), breakdown by source and per capita emissions for Annex B countries, 1995 (Mt CO_2-e)

Source: Turton and Hamilton, 1999.

These contrasts between nations pose severe problems in negotiations that affect the causes of climate change. They need to be understood in order to appreciate the difficulties which negotiators face. Some argue that emissions rights should become proportional to people rather than remaining proportional to accumulated income and environmental impact (Global Commons Institute, 1999). Others make the case that there have always been centers of high consumption of energy *per capita* and per unit GDP and that these centers change over time. According to them, setting a common *per capita* standard would stultify the industrial activity which has over the last 200 years made it possible for the world to support a six-fold expansion of its human population.

Natural Hazards

Kenneth Hewitt
Wilfrid Laurier University, Waterloo, Canada

Natural hazards refer to conditions or agents in the planetary environment that have caused damage to life and property, and are likely to do so again. They include extremes of heat and cold, hurricanes and droughts, earthquakes and landslides, forest fires and locust swarms. They are natural in the sense of occurring spontaneously, as processes of the planetary environment. Objective physical or biological relationships and laws govern their behavior. They may occur whether humans are present or not. Of course, human activity can, and increasingly does, intervene to modify the incidence and severity of these dangers, or the damaging events associated with them.

Used strictly, the term hazard has an interactive and an evaluative meaning. Natural conditions become hazards where a potential exists for harm to humans - a function of their exposure to destructive forces and their vulnerability or lack of defenses against such forces. However, most studies treat the hazard as, literally, a natural process such as volcanism, a virus or a flood wave. The field is organized in terms of natural agents, with specializations in geophysical, biological and environmental hazards. Moreover, the work has mainly addressed the more extreme or calamitous dangers.

The importance of natural disasters is reflected in continuing large death tolls and property losses. In the late 20th century, agencies like the Red Cross and the United Nations Disaster Relief Organization recognized some 210 natural disasters in an average year, worldwide. These involved annual death totals of about 128 600 and 90 000 people severely injured. Some 4.8 million people were made homeless and, in all, about 137 million directly affected. The evidence suggests that the global losses have been growing over recent decades. Although notoriously hard to define, economic costs in the 1990s were put at about US$88 billion annually (IFRCRCS, 1997). This takes no account of thousands of other less destructive episodes not reported in major disaster inventories.

Global environmental change may increase the intensities and/or change the temporal and geographical incidence of natural hazards such as droughts, storms and floods. Trends, such as sea-level rise, or degraded ecosystems, may be dangerous in themselves. They can also magnify other hazards such as storm wave impacts, or wildfires and insect infestations, respectively. There are dangerous interactions with novel human technologies and activities, as demonstrated in photochemical smogs, acid precipitation, Arctic haze, drug-resistant diseases and biocide-resistant pests.

In this context, the need for detailed and reliable knowledge of natural processes and environments, has never been more urgent. However, risks from nature, or the dimensions of natural conditions that we need to address, are altered and complicated by societal change. Of singular importance are the redistribution of populations and intensification of land uses, rapid urbanization, megaprojects, ecological abuses and disruptions occasioned by warfare (UN/DHA, 1994). Hazards research increasingly recognizes the complexities resulting from changing technologies and activities, and changing human exposure or vulnerability to hazardous agents.

While trying to retain a sense of the latter here, we will focus mainly on the characteristics and scope of dangerous geophysical agents and related disasters. Problems arising from global environmental changes, examined in more detail elsewhere in these volumes, will be indicated throughout.

NATURAL HAZARDS AND DISASTERS

Natural conditions can cause harm over a broad range of scales and intensities. There are everyday hazards and chronic forms of damage. They include most weather-related traffic accidents, common childhood infections and the almost imperceptible, repetitive deterioration of buildings by weathering and molds. These tend to be tolerated or dealt with routinely by citizens, communities and well-established agencies.

There are also extreme and unusual conditions that cause sudden, extensive bouts of damage and may lead to natural disasters. Usually, they become threatening and destructive because they exceed manageable magnitudes, intensities, or thresholds. It might be extremes of heat and cold, the height of floodwaters, winds above a certain speed, or the length of time and/or area covered by drought conditions.

Other distinguishing features and problems of natural disasters relate to casualties or property damage highly concentrated in space or time (Quarantelli, 1998). The harm may overwhelm local or regional, sometimes national, capacities to respond, or to sustain acceptable living conditions. Extraordinary measures are required. As a distinctive field of enquiry, the study of natural hazards has mainly addressed these more extreme or disastrous conditions.

Damage and disaster can also occur with unusual or untimely combinations of conditions, not individually threatening (see the section on compound hazards). There are geographic or out-of-place dangers: conditions common in some places but so rare, or formerly absent, in others, that people lack the capacities and experience to withstand them. Conversely, activities, equipment, or domesticated plants and animals that are well suited or adapted to one environment, may not be in another.

In none of these cases is a hazard a separate reality. On the one hand, every component of the natural environment may be harmful for some persons, or at certain times, including what are, otherwise, treated as natural resources. On the other hand, even phenomena we may think of as only and always destructive, like earthquakes, tornadoes, termites and forest fires, have been shown to contribute to the long-term health or renewal of the biosphere. They are not just unfortunate natural phenomena. For example, the torrential rains associated with hurricanes contribute significantly to groundwater reserves in the US southeastern states.

For these reasons, natural hazards are as much about human adaptation and preparedness against dangers in given habitats, as the intrinsic properties of natural agents. Global environmental change presents both the prospect of changes in hazardous agents, and transformed human relations to them.

Etiology of Hazards

Nevertheless, we need to have in mind just how they become hazardous, or contribute to disaster. Any damaging event will involve a series of factors, in which natural processes can be identified as:

1. Generative conditions: those that give rise to dangerous forces, agents or events. Examples include the tectonic forces in the Earth s crust, and fault mechanisms that give rise to earthquakes; conditions over the tropical mid-ocean regions that can generate hurricanes, or dry weather and the state of forest vegetation in promoting wild fires.
2. Primary damaging agents: the conditions or events that directly initiate and cause damage, such as strong ground motion with the arrival of earthquake waves, volcanic explosion, hurricane winds, or a conflagration. These are what the term natural hazards is most often used to refer to.
3. Secondary and tertiary hazards: damaging agents triggered by other hazards, such as landslides set off by earthquakes, or mass fires by electrical storms. Tertiary hazards are follow-on dangers such as disease outbreaks after floods. Often, these secondary or tertiary hazards, or their impacts, are simply lumped together with the primary agent. However, they have their own distinctive properties as hazards, and reflect the setting in which a primary hazard occurs. They show the importance of intervening habitat conditions.
4. Intervening habitat conditions: these moderate, magnify or redirect damaging agents. Examples would be the influence of topography on snow drifting or on cold air drainage in frost events; coastal zone morphology in wave action; or the age and composition of forest stands in the fire hazard. Secondary hazards and their importance, mostly reflect such intervening conditions.

The factors listed above involve the natural habitat. Equally, intervening conditions created by human activity may modify natural hazards or give rise to secondary artificial hazards. The urban mass fires that followed the San Francisco, 1906 and Tokyo, 1923 earthquakes, illustrate how such factors transform the type and severity of damage triggered by natural forces. Moreover, losses in natural disasters always depend upon whom and what are exposed to given natural agents, their state and available protections. How human exposure and vulnerability, and adjustments to and defenses against, dangers enter into natural hazards will be only briefly indicated here.

DOMAINS AND CLASSES OF NATURAL HAZARD

Hazards investigations mainly follow the division of the planetary environment into atmosphere, hydrosphere, cryosphere, lithosphere and biosphere. It will be appropriate, therefore, to review our physical understanding of hazards in such terms. Remember, however, that few destructive events are confined to just one process or natural sphere. A disaster initiated in one domain may involve more destructive processes in another: for example, floods or landslides triggered by rainstorms, forest fires set by lightning, and epidemics following drought or flood. Moreover, human activities mostly occur at interfaces of these spheres, such that harm and response in any disasters are constrained by aspects of all four.

The full range of dangers is enormous, and can only be outlined. We will then concentrate on those known to be especially damaging, or likely to be sensitive to global change, and disasters that illustrate these points.

Atmospheric Hazards

The most widespread and frequent environmental disasters are those initiated by atmospheric processes (Table 1). In part, this relates to the diversity and changeability of weather conditions, and recurring extremes. In part it reflects the continuous exposure of people and property to them.

Atmospheric hazards can be treated as single conditions such as high winds, severe cold, evaporation losses. However, in storm systems and any disaster situation, several hazardous forces usually occur together. In some, such as tornadoes, the forces involved are so great that few affordable structures or activities can be protected from destruction. In the modern world, because more or less elaborate arrangements have been put in place to

Table 1 Classes of atmospheric hazards

Single condition/process	Multiple process or event hazards
Temperature (high/low)	(Meteorological) drought
'cold spell', heat wave	Temperature inversion
Fog	
(high) Winds	Wind storm
Hydrometeors:	
Rain, rainfall	Rainstorm, mid-latitude depression
Snow, snowfall	Snowstorms, 'Whiteouts' Blizzards
Freezing rain ('glaze')	Glaze or ice storms
Lightning	Thunderstorms/hailstorms
	Tornadoes
	Tropical cyclones: Hurricanes (Atlantic Ocean) Typhoons (Pacific) Cyclones (Indian Ocean)

cushion people and property from the weather, serious harm usually results from their breakdown or destruction, or from failures of common protective measures and preparedness. Vulnerable people are suddenly exposed to harsh conditions in cities with failure of fuel and power lines, for example, on highways or in recreational areas.

The incidence and severity of dangerous atmospheric agents vary greatly in different climatic regions. Some are largely or wholly confined to particular regions. Alternatively, it is the relative frequency, or combinations, of conditions that vary. There are hazards identified mainly with certain broad zonal divisions organized in latitudinal belts, from equatorial to polar regions. There are azonal environments, such as coastal zones, mountain belts or continental interiors, which generate their own distinctive combinations of hazards.

Global Change and Atmospheric Hazards

Climate modification has the potential to alter the magnitude and frequency of hazardous atmospheric agents, their geographical scale and incidence. It is thought that a relatively greater incidence of damaging events in recent decades is, at least partly, due to more severe weather or changing weather patterns.

Recent human impacts on the atmospheric environment have undermined some of its singular benefits for life on Earth. Perhaps the most critical relate to the ways in which the atmosphere transmits and absorbs radiant energy. As an absorber of, or barrier to, incoming high-energy solar and cosmic radiation, the atmosphere shields living tissue from harmful irradiation. The critical role of the stratosphere in this regard is threatened by ozone-stripping industrial chemicals, causing unprecedented holes in the stratospheric ozone layer. Rapid increases in greenhouse gas emissions affect the atmosphere s capacity to absorb and retain thermal energy, and can induce global warming. Associated changes in weather conditions, perhaps climatic zones, threaten existing ecosystems, human economies and health.

Increases in atmospheric particulate matter from fossil fuels and other industrial activity, from desertified land surfaces or increased deliberate or inadvertent burning of vegetation, may have a range of dangerous consequences. They may block sunlight, lower local temperatures in agricultural zones, and suppress cloud formation. Meanwhile, these dangers become coupled with the beneficial roles of atmospheric circulation, in transfers of heat and moisture around the globe. The same conveyors also transport toxic materials from industrial, urbanized, war-torn, or modernized agricultural regions, to distant places.

Hydrological Hazards

Hydrology includes all aspects of the movement and storage of moisture, including water in the atmosphere (hydrometeors like rain and snow), lithosphere (ground water) and biosphere (soil, wetlands and transpiration). Moisture-related risks can arise where human society interacts with each of these. However, the focus of hydrological hazards has been on surface waters, especially streams and rivers, freshwater lakes, glaciers, and the oceans, and on acute shortages of fresh water (Table 2). Drought, the absence or deficiency in fresh water supplies, although it arises most often from atmospheric conditions, is generally examined as a hydrological hazard.

Table 2 Classes of hydrological hazards

Single condition/process	Multiple process or event hazards
Runoff (overland, stream)	Floods:
Snow-on-the-ground	Riverine
Groundwater	Lakeshore
Freeze-thaw	Coastal (marine)
Sea ice	Storm surge
Icebergs	Ice-infested waters
Wave action	Storm waves
Glaciers	Waterlogging
	Glacier 'surges'
Evaporation and transpiration	Natural dams: Glacier Landslide Vegetation
Salinization (of freshwater resources)	Droughts: Meteorological Runoff Aquifer

Danger tends to arise with extremes of occurrence or behavior; including various powerful hydrodynamic processes, excessive or deficient moisture, and high or low water conditions. These hazards may also be defined through single processes such as stream flow and evaporation, or in events such as floods, droughts, and glacier surges, that combine several hazardous conditions.

Attention to flood and drought hazards has outstripped all others. This is hardly surprising. The former comprise the single most widely reported, lethal, and costly disasters. They occur in nearly all habitable land areas. Major droughts, though less frequent than floods, when they do occur tend to affect the greatest numbers of people (UN/DHA, 1994).

The importance of floods and droughts reflects the close association between water supply or water bodies, and human populations, including most towns and cities. Risks arise mainly through the forms of human dependence on, and use of, water as a resource, including large demands for domestic, agricultural, municipal and industrial consumption. People and property may also be exposed to floods in tapping biological resources of seas, lakes and rivers; through water-borne transportation; mercantile and naval strategy; and water-related amenities and recreation. Water-borne disease, in terms of numbers of victims, is probably the greatest threat associated with these relationships and adverse effects on the aquatic environment. This is illustrated by many recent outbreaks or epidemics of cholera, bilharzias, and *Escherichia coli*, among others, and infestations by water-dependent insect vectors like malaria-carrying mosquitoes.

Global Change and Hydrological Hazards

Recent climatic trends suggest that both floods and droughts are likely to become more severe in future. Climate warming is likely to intensify the thermal and evaporative conditions in drought. However, flood risks are also likely to increase, even in the same areas. Greater warming of ocean and freshwater surfaces, and higher temperatures generally, should drive higher rates of evapotranspiration. This increases the amount of moisture entering the atmosphere and, ultimately, its turnover through condensation and precipitation. Storminess is also likely to intensify, increasing the amount of precipitation in more severe events and, hence, flood risks. Some regions, especially coastal and high mountains, are likely to see higher, if more variable, precipitation. Moreover, water quality, already tending to deteriorate world wide, is likely to be adversely affected by increased drought conditions, and larger fluctuations. Meanwhile, availability of fresh water in most regions is declining, while there is ever-greater exploitation of, and conflict over, water resources.

Table 3 Classes of geological and geomorphological (lithospheric) hazards

Single condition/ process	Multiple process or event hazards
Seismicity	Earthquake
Earth/rock materials:	
Quick clay	Liquification
Quicksand	
Radionuclides	
Radioactivity	Domestic radon gas
Geothermal heat	Volcanic eruptions
	Ash (tephra) fall
	Lava flows
	Pyroclastic flows
	Gas or vapour eruption
	Explosive eruption
Mass movement	Landslides:
	Rock slide, rock avalanche
	Debris- and mudflow
	Earthflow
	Dirty avalanche
	Density currents (lake)
	Submarine slides
Subsidence	

Geological Hazards

These arise from processes of the lithosphere or solid earth. They fall into three broad classes, seismo-tectonic, volcanic, and geomorphic or earth surface processes (Table 3). Earthquake disasters are the most frequent and destructive, followed by volcanic eruptions. Landslides are the most widespread source of damages, but less often the primary cause of disasters. Danger, usually of a more long-term and dispersed kind, may also arise where earth materials contain and release toxic chemicals, or ionizing radiation (*see* Contaminated Lands and Sediments: Chemical Time Bombs?, Volume 3).

Ultimately, the hazards arise from the large scale and continuing evolution of the Earth s crust. They depend upon isostatic, tidal and geothermal conditions, and crustal processes now interpreted in terms of plate tectonics. Of special relevance are the great stresses, volcanism and intensified erosional processes that occur at plate margins. They include the extending crust at the mid-ocean ridge systems, but especially collision zones, whether of continents as exemplified by the Alpine Mediterranean and Himalayan mountain zones, or continent sea floor margins, such as surround the Pacific Ocean.

Geomorphic hazards derive from subaerial or landscape forming processes. Most are actually triggered by atmospheric, geological or hydrological extremes. They are highlighted as geomorphic hazards when the main impacts come from erosion, transport and deposition of earth materials. The distribution of geomorphic hazards is strongly

dependent on the relief and ruggedness of land and submarine surfaces the composition, structures and weathering of rock and soil masses. Most are triggered by climatic and hydrological conditions.

The dangers and damages from landslides tend to be greatly underestimated. This is partly because few individual events affect large areas or numbers of people. Mainly, it is because the worst landslide damages occur as secondary hazards in events identified with other processes. In particular, they occur with earthquake, volcanic, flood and severe storm disasters. In more than half of all earthquake disasters, slope failure and landslide impacts are greater causes of death and destruction than primary seismic motion (Hewitt, 1997, 226).

With respect to human safety, geological hazards mainly involve processes that suddenly alter or destroy the stability of the land surface. The solid earth affects material security mainly through the sites of human settlement and, especially, the support of built structures. The destruction in earthquakes, landslides, and the more lethal volcanic eruptions, is largely to buildings. Most fatalities occur when buildings collapse on people inside or nearby, usually peoples homes. Under modern conditions, geological hazards are also identified with lifeline disasters. They commonly sever, block or destroy the built infrastructure of roads and railways, water, power and fuel lines. Geomorphic and volcanic events may also ruin more or less extensive areas of cropland and natural vegetation, burying them in ash fall, lava flows, and in mass movements, of water- or wind-borne sediments.

Global Change and Geological Hazards

Tectonics and volcanism reflect long-term geosphere developments, rather than global change over decades or centuries. Nevertheless, dramatic changes in risks from these processes are likely as a result of changes in human exposure and vulnerability. Meanwhile, global environmental change involves significant concerns in the scope and scale of geomorphic hazards.

Earth surface processes are directly affected by climatic hydrological controls. Geomorphic activity is also modified in landscape changes by human agency (Hewitt, 1989). Increases in sediment yields with intensified cultivation or urbanization, and increased land sliding after deforestation, are well documented. The artificial fragmentation of rivers is already associated with more or less severe geomorphic, as well as biotic, effects, including downstream erosion and upstream siltation following dam building (Dynesius and Nilsson, 1994). In fact, all of the more important landform-shaping processes are being drastically modified by human agency or climate change streams and rivers, glaciers, freeze thaw in soils, and the active layer over permafrost, coastal and aeolian action, and biological activity over and in the near-surface zone.

Dangerous contaminants introduced into geomorphic systems are less visible but, perhaps, more critical for human health and harder to reverse. In addition to well-known problems with contaminated ground waters, earth surface processes of all kinds may selectively pick up, carry and deposit contaminated sediments in distinctive ways and patterns (Stone and Droppo, 1994; Mallin, 2000). The sources of pollutants are industries, fossil fuels, municipalities, mechanized agriculture, factory raised farm animals, and mineral and biotic resource extraction. However, natural geomorphic processes redistribute and concentrate these dangers. Only recently have their roles in the toxic waste stream started to be fully recognized and addressed (Callow and Petts, 1994). Strictly speaking, it is part of the burgeoning problems of complex hazards at the interface of modern technologies, industries, land uses and natural processes (see following sections).

Biotic Hazards

These involve dangers to humans from other organisms or conditions in the living world. They arise both from human interdependence with the rest of the biosphere, and efforts to control or segregate parts of it for human use. The latter leads to competition with other organisms that are then called pests, weeds, infestations, etc. However, not only are damaging impacts of modern societies on the biosphere a great cause for concern, they are a large and integral part of biological hazards that come to plague society (Table 4).

Compound and Complex Hazards

Each domain of the natural environment gives rise to a variety of conditions that may threaten human societies. Each has been the focus of particular hazards studies. However, as noted, actual damaging events involve at least three, and usually all four, natural spheres. In addition to hazards in one natural domain that trigger secondary ones in another, disasters often involve compound hazards adverse combinations of atmospheric, hydrological, biotic and geological conditions (Table 5). The case studies of natural disasters provide ample illustrations.

In recent years, the idea of complex emergencies has been proposed, and the growing significance of such situations underlined. From a hazards perspective, these are events in which natural hazards combine with harmful technologies and/or social processes. Experience with severe famines in Africa give particular support for the notion. Drought and crop loss do not, alone, decide who starves, which people become refugees, and what their needs are. Usually, economic and social change are equally involved. In most cases, that includes armed conflict, misrule and developments that reduce food security. Failures of national

Table 4 Classes of biological hazards

Single condition/organism	Multiple process or event hazards
	Disease outbreak/epidemic
Bacteria (Pneumonia)	Bubonic plague
Protozoa (Giardia, Malaria)	Yellow fever
Fungal (Pneumcystas)	Influenza pandemic
Viruses (Measles, HIV, Dengue)	
Algae	Harmful algal bloom 'Red tide' (toxic algal blooms)
Sexually transmitted diseases Chlamydia, Syphilis, HIV, etc.	
Domestic animal disease: Hoof and mouth disease 'Mad cow' disease	Outbreaks
Domestic crop diseases Blights, rusts	Outbreaks, crop failures
Plant hazards or 'weeds' Water hyacinth, Prickly Pear	Plant infestations, 'Invasions'
Insects 'pests' Locust/grasshopper Lice, cockroaches	Insect plague/infestation
Animal 'pests' Rats, mice	Infestation/population explosion Rat 'plague' Rabbit infestation
Wild animal disease Rabies Shellfish poisonings Neurotoxic poisoning (e.g., whales)	

Table 5 Compound and complex hazards

Compound natural hazards
Permafrost and 'active layer' processes
Volcanic mud flows (lahars)
Volcanic floods ('jökulhlaupts')
Landslide-, and vegetation-dam outburst floods
Tsunami (seismic sea wave) coastal flood
Complex (natural + artificial agents)
Smog
Arctic haze
Acid precipitation
Artificial dambreak flood
Urban firestorms
Famines
Environmental warfare agents
Irrigation-induced waterlogging
Combustion generated greenhouse gases and global warming

and international humanitarian assistance occur for similar reasons (IFRCRCS, 1997).

Recognizing such interrelationships among hazardous processes is of singular importance for anticipating how they may change with global environmental change. Even where one sphere is mainly affected, it can magnify, redirect or alter the significance of hazards in another. Sea level rise is likely to increase the dangers from tsunamis, storm surges, and coastal erosion. Changes in weather patterns and vegetation cover will be reflected, especially, in dangers from hydrological and geomorphic processes, in earthquakes and wild fires. Each of these risks will change with changing human technologies, activity and vulnerability.

We can anticipate that modern disasters, whatever the specific agent that triggers them, become complex emergencies. Earthquakes and severe storms in urban centers are now complicated by the presence of stores of flammable and volatile chemicals. Some of the most serious and enduring dangers and losses from floods are the toxic wastes flushed from agricultural operations, chemical industries, or overloaded sewage treatment plants. Again, one can see how global change raises the prospect of more and more severe, interactions between natural and artificial systems, increasing the incidence of such complex disasters.

THE MAJOR FORMS OF NATURAL DISASTER

Tropical Cyclones

These are the greatest storms on Earth. They are known as hurricanes in the Atlantic and eastern Pacific, typhoons in the western Pacific and cyclones in the Indian Ocean. They

develop over open areas of the warm, tropical oceans, but do their greatest harm where they pass over oceanic islands, and/or strike mainland coasts. Most disasters occur on sub-tropical eastward- and equatorward-facing shores of the three oceans (*see* Hurricanes, Typhoons and other Tropical Storms – Descriptive Overview, Volume 1; Hurricanes, Typhoons and other Tropical Storms – Dynamics and Intensity, Volume 1).

The storms involve a number of destructive forces, including high winds, torrential rains, and intense electrical or lightning activity. Over the ocean, the storms may also generate waterspouts and, over land, tornadoes (Pielke and Pielke, 1997).

The high winds can cause significant property damage directly, and from the impact of debris carried by them. Power and communication lines are disrupted and fallen debris closes access routes. Usually, however, the greatest loss of life and devastation are due to the storm surge. This derives from a piling up of water in the low-pressure eye of the cyclone. On reaching land, the surge can be higher than the highest tides. It may be further elevated by wind-driven wave action.

Notorious in this respect are Bay of Bengal cyclones that reach the low-lying, deltaic coasts of the Ganga Brahmaputra delta. The surge in the November, 1970 cyclone, drowned between 400 000 and 500 000 people in Bangladesh (then East Pakistan), the most lethal of these storms in the past century.

In other cases, torrential rainfall has caused the greatest damage; usually through floods and/or landslides triggered by the rain. Hurricane Mitch, where it affected the Central American republics in November 1998, is an example.

Case Study 1

Hurricane Mitch, October 26 November 4, 1998, exemplifying the dangers of intensified tropical storms, and of increasingly vulnerable land uses and populations.

This was the most lethal Atlantic hurricane in 200 years, and the fourth strongest on record. Especially critical was the path followed by the storm and the way it stalled over the Central American republics of Honduras, Nicaragua, Guatemala, and El Salvador. Here, where the greatest damage occurred, the storm s impact was greatly aggravated by recent changes in land use, and redistribution of vulnerable populations. There were also losses in Costa Rica, Belize, Panama, Mexico and the US.

The storm attained Category 5 intensity highest on the Simpson Saffir Hurricane Intensity Scale for over 33 h, with sustained winds of over 290 km h^{-1} and gusts of over 320 km h^{-1}. Its destructive potential was maintained or recovered over 10 consecutive days. An unusually warm year, probably related to El Nino global warming, may have increased the intensity, and perhaps the likelihood, of this hurricane.

However, the heaviest rainfall was over volcanic mountain ranges, when a downgraded Mitch drifted slowly over Central America, stalled by a blocking frontal system. As much as 125 190 cm of rain fell in two to three days. Secondary hazards induced by the rainfall, especially major mud slides and flooding, caused the greatest loss of life and destruction.

Preliminary estimates of the death toll were 10 000+, with 12 000 missing. Some 50 000 people were injured. Honduras was the hardest hit with 6500 deaths, 11 760 reported missing, and 1 million made homeless. There were major agricultural losses, Guatemala lost 95% of its banana crop and 30% of its cattle. There was huge and widespread damage to the sugar cane, coffee, corn and bean crops.

Forest removal and land use changes, notably the spread of large commercial plantations in the previous two to three decades, were blamed for increased flood potential and erodibility of soil. Enforced redistribution of peasant populations into more mountainous areas also encouraged further forest clearance and destabilized slopes. Meanwhile, other poor and displaced persons were concentrated in coastal zones, and along river courses. This increased their exposure to, and vulnerability from, mud slides and floods.

Tornadoes

Unlike hurricanes, tornadoes are associated with frontal storm conditions, mainly in sub-tropical and mid-latitude continental areas. They occur with intense, convective storms, and usually in the summer half of the year. About 70% of all reported tornadoes occur in the US Midwest.

The tornado is a funnel cloud that descends to earth from intense convective storms. It comprises a vortex of whirlwinds around a central, low-pressure area. The highest known wind speeds and enormous numbers of lightning strikes to earth occur with tornadoes. All combine to magnify storm destructiveness and the problems of emergency response (Church *et al.*, 1993).

The width and length of the path where the funnel touches down is as critical as the dangerous forces in it. Rarely is the swath more than a few hundred meters wide or a few kilometers in length. Occasionally, however, a tornado may remain active and in contact with the ground for tens or even hundreds of kilometers, or repeatedly lift and descend again. The damage swath may reach 2 3 km wide. An example was the US Tri-state tornado of March 1925, which traveled more than 350 km across Missouri, Illinois and Indiana, killing 689 persons and devastating more than 20 towns and cities. Storm systems may also generate multiple funnels. In the so-called super outbreak of April, 1974 in the US, 147 tornadoes were recorded, touching down in 13 states, and killing 335 persons.

If increased heating of the atmosphere continues, it may lead to more, or stronger tornado activity, and a geographical expansion of the zones in which tornadoes are more frequent. It is difficult to judge what is happening on the basis of disaster trends, because of enormous variations in damage from tornadoes of the same size and intensity, and comparable damages from those of very different scale. More important are variations in land use and densities of human occupancy.

Winter Storms

The snow and ice storms of higher latitudes and elevations have not been as lethal or destructive as tropical cyclones. However, they are a major, and growing, source of disruption and economic loss in some of the wealthiest countries. Winter storms have become, above all, a threat to modern urban areas and infrastructure, especially to power, light and transportation services for cities.

Of particular concern are large area snowstorms, blizzards, and ice storms. *Blizzard* refers to a winter storm with winds in excess of about $56\,km\,h^{-1}$, temperatures less than $-10\,^{\circ}C$ and very low or zero visibility. Wind and temperature combine to create severe wind chill for humans and animals. There must be blowing snow involved, but actual snowfall may or may not be a large. Snow whipped up from the ground helps to cause severe snow drifting and whiteouts an extreme visibility hazard.

About half the world s land area is subject to snowfall. However, snow-related disasters and costs are overwhelmingly concentrated in major urbanized regions and, to a lesser but growing extent, in winter recreational areas. Closing of transportation routes in and between cities, typify what happens in most winter storm disasters. This is reflected in the exceptional number and share occurring in North America, where the media invariably report them as paralyzing cities.

Ice storms, also referred to as freezing rain or glaze storms, involve rain falling from relatively warm air aloft, into sub-zero air below. The raindrops may be super cooled, but remain liquid. When they fall on vegetation and exposed structures, they freeze instantly. Heavy coatings of ice on overhead wires can cause the wires to break, especially in windy conditions. Branches of trees are bent over or broken off by the weight of ice. Overhead wires, structures or vehicles on which they fall are damaged, and roads blocked. Coatings of ice on roads lead to traffic accidents or close highways.

It is likely that climatic changes will change the incidence, geography and, possibly, intensity of freezing rain events. The case study below indicates the potential of intensified or shifting patterns of winter storms, and the vulnerability to them of urban-industrial areas.

Case Study 2

The January, 1998 Ice Storm in Eastern Canada and North-eastern US (Soulard *et al.*, 1998; Phillips, 1998).

A succession of winter storm fronts moving across central and eastern Canada created exceptional conditions for the formation of freezing precipitation. In the worst-hit areas of South-eastern Ontario and southern Quebec, between 75 and 100 mm of freezing rain fell. Temperatures rarely rose above freezing at ground level throughout the episode. They dropped below $-10\,^{\circ}C$ for several days following the storms, greatly aggravating the difficulties of survivors and recovery operations. Damage also occurred in northern New York state, parts of New England and the Canadian Maritimes.

The area affected contained 18% of Canada s population and 56% of Quebec s, 19% of Canada s urban space, and 57% of Quebec s. Damages included thousands of kilometers of downed power lines, including collapse of hundreds of steel towers supporting high-tension lines. Over 4.5 million persons were without power for some time; more than 300 000 for over a week. Most highways, commuter trains, airports, telephone systems, newspaper deliveries and water filtration plants were shut down, and 2.8 million workers were unable to get to work in the worst period.

Some 25% of Canada s dairy cattle were endangered. Farms could not milk them without electricity. Most milk that was obtained could not be sent to market and was dumped. Over 5.5 million maple trees, supplying the maple syrup industry, were damaged or destroyed. Millions of other trees along city streets, in parks, wood lots and forested areas were damaged or destroyed.

About 100 000 people took refuge in emergency shelters, and 16 000 troops were mobilized for rescue work. Total economic losses were estimated at about 1.5 billion. The 35 fatalities (six in the USA) seem small, but the forms of death due to secondary hazards such as house fires, carbon monoxide poisoning from improper use of heating equipment, and hypothermia are typical dangers.

It was suggested that synoptic conditions over the North Atlantic, possibly relating to global warming or El Nino, helped intensify the unseasonal interaction of relatively warm, moist oceanic air, with cold, Arctic air. Freezing rain is common in the areas affected, which have a history of such disasters. However, most of the region has not recorded such quantities before, and the problem usually occurs in early spring. In the 1990s, however, Southern Canada experienced an unusual series of mid-winter warm spells and freezing rain episodes.

Floods

Floods are mainly a problem of riverside or coastal zones, the latter including lake and marine shores. A wide range of

generative conditions is involved. For rivers, heavy rainfall is the most common source and factors that govern rainfall-runoff relations, and flood routing in streams, have been a major focus of investigations. In higher latitude and altitude regions snowmelt or ablation of glacier ice can be an important source, tending to create flood-prone rivers.

In some cases, disasters involve natural impoundments or dam-burst floods. Natural obstructions include ice-jams of river ice in spring break-up; landslides, avalanches, lava flows, and vegetation, especially log jams. Inundation of land above the impoundments may be damaging, but the sudden failure of dams and resulting flood waves, can be highly destructive events (Schuster, 1986). The collapse of man-made dams is often brought about by natural extremes, and the behavior of resulting flood waves resembles those from natural dams.

Lakeshore floods can derive from contributing streams and may coincide with riverine floods. They also involve sieches oscillations of lake levels caused by storms or landslides. Marine coastal floods derive from exceptionally high tides, storm surges, and seismic sea waves or tsunamis (see herein). They may be magnified by wave action. These tend to be considered as part of the atmospheric or geologic hazards initiating them, yet their impacts are more like those of flood hazards.

Case Study 3

The Mississippi flooding of 1993, illustrating the dangers of intensified or changed patterns of rainfall-generated floods, interacting with more vulnerable land uses.

In 1993, floods occurred on the Mississippi and most of its major tributaries, forming the largest flood in 133 years. The main flood lasted 79 consecutive days, longer than the damaging 1971 flood, the previous record. The Mississippi at St Louis, Missouri was above flood stage from April 1 September 30, or 144 days. Some settlements were inundated for more than 160 days. Monthly mean discharges were above normal for the first nine months of 1993.

The generative conditions involved an unusual and persistent weather pattern related to jet stream position and high pressure in the northern mid-west United States. Blocked by the latter, humid air from the Gulf of Mexico produced sustained heavy precipitation. Precipitation was also above average for the first nine months of 1993, and twice the normal amounts for North Dakota, Kansas and Iowa. Moreover, an unusually cool 1992 had left water tables high and the ground in a saturated condition.

Damages affected a cluster of nine midwestern states, from North Dakota and Nebraska, to Missouri and Illinois. There were 48 deaths; 56 000 homes were destroyed or damaged and 26 000 people were evacuated. Direct losses were estimated at US$11 billion, while total losses, including indirect costs, such as lost income and production, were put at $20 billion. Some 3.2 million ha of cropland and 75 towns were completely inundated. More than 400 counties were declared disaster areas. River waters carrying, especially, sewage and agricultural chemicals contaminated water supplies. A two-month halt in Mississippi barge traffic affected a large fraction of national bulk transport, including coal, oil and grain. Inundation, erosion and sedimentation damage to roads was estimated at $500 million. There were serious damages to river control works, which led, in turn, to much of the other harm. Some 9300 km of levees were damaged, and 1083 out of 1576 levee systems broken or overtopped.

The 1993 flood is generally regarded as the most destructive flood on record for the region. However, while initiated by exceptional weather and hydrological conditions, the impacts were also attributed to dependency upon river engineering works (that failed) and land use changes. Over 80% of wetlands within the flood areas are said to have been drained since the 1940s, greatly reducing natural restraints on flooding. Meanwhile, as much as 70% of the homes and subdivisions inundated were part of urban expansion or other flood plain occupancy since the 1971 flood! This was despite past recognition of the importance of flood plain management to reduce exposure and vulnerability to floods.

The event illustrates how the combination of atmospheric extremes, land use change, failed control works, or otherwise inadequate adjustments to natural hazards, lead to disaster. This happened in a very wealthy country with, otherwise, outstanding achievements in water science and hazards research!

Droughts

Drought is, above all, a killer for agricultural crops and animals. It is increasingly also an economic hazard for urban industrial communities. Drought tends to affect human societies in substantially different ways from floods and in different phases of activity. Their link as hydrological extremes is largely incidental (Hewitt, 1997).

Droughts arise mainly from atmospheric conditions affecting wide territories. However, their effects on humans or other organisms can be felt in or through all forms of fresh water supply. Three main classes of drought hazard are recognized:

1. Meteorological drought, identified, especially, with lack of precipitation. It can also depend upon weather conditions that induce excessive evapotranspiration. The main atmospheric conditions tending to bring meteorological droughts are persistent high pressure systems with subsiding air; descending winds in the lee of mountain ranges; and air masses which, even if they contain abundant moisture, lack instabilities or cloud-, and precipitation-generating mechanisms. The world s desert regions involve one or more of these

as permanent conditions. They recur annually where there is seasonal drought. Most disasters arise where such conditions are abnormal, temporary, or of unusual duration.

2. Runoff drought, involving reduced stream flow, or drying up of surface waters including ponds and lakes. Though usually due to meteorological drought in the drainage basin or its headwaters, the impact is felt through dependence on surface waters. Low stream flow may be accompanied by declining water quality or contamination of the water that is available.
3. Aquifer drought involves loss of ground water sources due to declining water tables and drying up of springs and wells. Again, it tends to reflect meteorological drought, but may be exaggerated by human depletion of ground waters in regions or periods of drought.

Meanwhile, landforms, soils and vegetation cover are critical intervening variables that influence the moisture-conserving properties of sites. They can moderate or hasten the impact of dry spells. For this reason, the severity or the development of droughts involve fairly complex spatial patterns. The more severe consequences for agriculture also depend upon the drought-resistance of crops, cultivation practices, seasonal moisture demand and the possibilities for supplemental irrigation.

The special and severest association between drought and disaster concerns food security and famines. Most of the worst famines have been accompanied by drought and exacerbated, if not triggered, by drought-related crop and animal losses. However, not even the great, modern famines of the tropical world, or any since the early years of the 19th century, have been due to absolute food shortage in the food-producing or economic system, to which the victims belonged. Human actions, or inaction, can be decisive in whether food is provided to the needy, from areas of surplus.

Although both are treated as hydrological hazards, there are important differences between the development and impacts of drought and floods. Droughts develop slowly but may last weeks or months, even years (Smith, 1992, 246). Drought is often not recognized or declared until a dry spell has gone on longer than the time in which most floods arrive, peak and end. However, this drawn-out aspect can also provide opportunities for varied and geographically extensive human responses.

Floods are mostly linear or patchy in spatial extent, following water courses or coastal zones, and reflecting their topography. Severe droughts tend to embrace extensive regions. The areas most prone to moisture stress, or feeling its effects earlier, tend to be normally well-drained and drier areas. Those most prone to floods are poorly drained and flood plain areas usually the last to succumb to drought.

Earthquakes

Some 1.5 million people were killed in earthquakes in the 20th century, more than half after 1950. Perhaps 10 times as many suffered serious injury, and more than 100 million had their homes destroyed. The disasters follow directly from the occurrence of large earthquake events, mainly, but not exclusively, in regions with relatively high levels of seismicity.

The impacts of earthquakes on society depend on ground motion, especially so-called strong motion. This is influenced by near surface conditions, as well as the strength of, and distance from, the original seismic event. The local severity of earthquakes is modified by the bedrock and soil; by landforms and surface or groundwater conditions; and by vegetation cover. Seismic waves can be amplified by certain slope and landform conditions, at the interfaces of bedrock and unconsolidated materials, and in areas of deep alluvium. These are referred to as micro seismic conditions. Foundations may prove highly unstable in certain clay and sandy deposits, especially if wet. These are particular dangers of coastal and flood plain areas. Destructive landslides often occur in earthquakes (see herein).

In general, the more severe damages within disaster zones are associated with locally unfavorable choice of sites, and built structures made vulnerable by bad design. Most reflect a pattern of ill-advised occupation of sites that are hazardous because of microseismic conditions. This has become the critical factor of changing earthquake risk, notably through rapid urbanization. The importance of these relations between microseismic conditions and occupancy in earthquakes, are detailed in reports for the California, 1906, Kanto Plain, Japan, 1923, Alaska, 1964, Skopje, 1963, Niigata, 1964, Lomo Prieta, 1989 and Kobe 1995 disasters among others (Hewitt, 1997, 208 217).

A related concern, given the proliferation of megaprojects, is the evidence that large dams and fluids artificially injected deep into the ground can trigger earthquakes. A major disaster occurred around the Koyna Dam in India in 1967, directly related to the dam. A series of tremors around Denver, Colorado in the 1960s not very damaging, but disturbing for residents were traced to liquid wastes being pumped into a deep well (*see* Earthquakes Triggered by Human Activities, Volume 3).

Volcanic Hazards

Volcanic eruptions give rise to a variety of highly destructive forces and conditions (Fisher *et al.*, 1997). The type, scale, sequence and duration of eruptive episodes determine which forces occur, or can do the greatest harm. The main distinctions for disaster potential involve whether and how explosive the eruption is; composition of the ejected material and how this affects its behavior, and development of associated volcanic or constructional landforms.

Vulcanologists recognize 11 different types of eruption according to different combinations of these conditions (Blong, 1984; Chester, 1993).

The most lethal and destructive events involve explosive eruptions and pyroclastic (hot ash) flows. However, secondary hazards triggered by eruptions have together caused even more fatalities. There are volcano-induced tsunami and volcanic mudflows or lahars. The latter may be initiated by rapid melting of snow and ice on the summit area of the volcanic cone; where volcanic vents erupt under ice caps; or with a sudden outburst from a crater lake. Sometimes, lethal gas eruptions occur. The cloud of carbon dioxide emitted from the crater lake, Nyos, in Cameroon, August, 1986, killed over 1700 people by asphyxiation (McCall *et al.*, 1992).

Most volcanic eruptions have their main or only destructive impacts within a few kilometers or tens of kilometers of the volcano or eruptive vent. However, volcanic ash from the larger, explosive eruptions may be carried for thousands of kilometers, endangering transportation and reducing sunlight far away. Eruptions of exceptional explosive force and/or heat can loft large quantities of fine ash and smoke into the stratosphere where it can remain long enough to be transported around the globe. This can affect hemispheric or global climates over months, years, and, perhaps decades (Rampino and Self, 1982). The Tambora, Indonesia eruption of 1815, ejected some $35\,km^3$ of pyroclastic material three orders of magnitude larger than the Mt St Helens, 1980 eruption. Unseasonable cold, weak sunlight and summer frosts were reported in Europe and North America for the following two years. There were severe shortages of food and collapse of grape and other harvests (Post, 1977). This is by no means the largest known eruption in the geological record. A recurrence of such a relatively rare event, could drastically affect the pace, and possibly the direction, of climate change.

The more evident forms of increased risk from volcanoes relate to changing human exposure and vulnerability (Pflaker and Ericson, 1978). Many regions with active volcanoes show increasing concentrations of population, intensified land use or activities bringing more persons into areas threatened by volcanism. Often the volcano itself is an important resource and attraction, having exceptionally good soils and aquifers, or religious and aesthetic value. They are major tourist destinations, from the Caribbean to Japan, where volcanoes are one of the attractions. Included are active volcanic cones like Mt Etna in Sicily, whose winter snow cover supports a ski industry. Ever-growing investments in facilities and infrastructure help to attract growing numbers of visitors. Given that little or nothing can be done about eruptions when they occur, much improved monitoring and effective forecasts can save lives, but disastrous property losses are likely to continue increasing (Chester, 1993) (*see* Volcanoes and Cities, Volume 3; Volcanoes and the Environment, Volume 3).

Landslide Hazards

Landslides, resulting mainly from slope failure, are distinctive and widespread causes of disasters (Brabb and Harrod, 1989). Some of the more destructive ones involve catastrophic rockslides, debris flows, slump earth flows and mud flows. Avalanches are a concern in snow-covered mountains.

As noted above, the dangers and damages from landslides are underestimated because most of the larger examples or multiple failures tend to occur with other hazards such as floods and severe storms. The most destructive examples have occurred in conjunction with earthquakes. The larger part of the devastation, and some 180 000 deaths in the Kansu, China catastrophe of December, 1920, came from slope failures, and huge land slips in weak loess and alluvial deposits.

The May 1970 Peruvian earthquake triggered an avalanche of ice and entrained debris some 50 100 million m^3 in volume. Descending from Mount Nevados Huascaran (6665 m) in the Cordillera Blanca, it traveled 14.5 km and attained speeds in excess of $300\,km\,h^{-1}$. A tongue of the debris buried and totally destroyed the town of Yungay. Some 18 000 people were killed. Thousands of other landslides occurred and, especially coastal settlements, destructive ground failure occurred by subsidence, fissuring and liquefying. Together, these secondary effects were responsible for most losses over an area of some $103\,000\,km^2$ and the most lethal earthquake in the Western Hemisphere.

Deforestation and other forms of land use change or ecological abuse, increase the scale and likelihood of slope failures. Artificially excavated slopes along roads and other construction projects can, and generally do, increase the occurrence of destructive slope failures. Human exposure to, and damages from, landslides increase with the spread of buildings, facilities and activities over steep slope areas, especially in mountains and cliffed coastal areas. As indicated, mass movement dangers are likely to increase with intensified, changing geographies of atmospheric and hydrological hazards.

Tsunamis

Tsunami is a Japanese word meaning (great) harbor wave. These are the largest and most destructive water waves on Earth. They are usually triggered by undersea earthquakes, sometimes volcanic eruptions, occasionally great landslides or volcanic materials plunging into bodies of water. They become hazards where the waves strike and inundate coastal areas, thus combining aspects of hydrological and geological dangers (*see* Tsunamis, Causes and Consequences, Volume 1).

Most tsunami disasters occur along coasts within a few tens of kilometers of the undersea earthquake producing them. However, some result from waves that travel thousands of kilometers before striking mid ocean islands or distant coastlines. There have been some notable examples around the Pacific Ocean.

Tsunamis travel at speeds one or two orders of magnitude faster than wind-generated waves. In the deep ocean this may be from $500\,\mathrm{km\,h^{-1}}$ to perhaps $900\,\mathrm{km\,h^{-1}}$ over the deepest waters (Abbott, 1999). However, here they cause little or no danger, having wavelengths measured in tens or hundreds of kilometers. Their small rise and fall can go unnoticed by shipping. When they reach a shelving coast, however, or enter bays and inlets, they can translate into huge roll waves many meters high.

The arrival of a tsunami may be preceded by a sudden retreat of the sea. Sometimes people rush down to the shore to see what has happened, only to be engulfed by the returning great wave. Moreover, several waves are commonly triggered by the same event, arriving separately on a distant coast. In this case too, thinking that the danger is over after the first one, people are caught in a later one, which may also be the largest.

Some of the most lethal incidents of these kinds followed the Chilean earthquake of May 1960. With one of the largest magnitudes ever recorded, the undersea earthquake generated a series of tsunamis that swept back and forth across the Pacific for some days. In Chile, they killed about 1000 persons, mainly in the third and largest wave, when people had run down to the shore to try to rescue items swept up in the first two waves. In Hawaii, 61 people were drowned and 282 injured, and 165 persons died in Japan caught out, even though warnings were issued and relatively accurate predictions were made of arrival times.

The tsunami hazard itself is likely to become more severe with global environmental change, but not because there are any indications of increased, or stronger seismic and other triggers. Sea level rise can change the scale and scope of these events where they come ashore. Recall that a few centimeters of rise can actually mean huge volumes of water closer to shore, and available for incorporation in the wave.

This is also an example of how change in one sphere can alter dangers from another. Global warming leads to thermal expansion of ocean waters, and reduction of the Earth s glacier and permafrost, which adds water to the oceans. As a result, a hazard whose own geophysical generative conditions may not change is magnified. Meanwhile, ever-greater human occupancy of coastal zones is increasing human exposure. In many regions, the range of more vulnerable persons, activities and items near shorelines, is also growing.

Biomass or Wild Fires

Wild fires are out-of-control burnings, fed by forest, grassland and peat land whether started by natural or human agency. These fires have been a recurring natural phenomenon of regions that combine wet and dry seasons, or occasional drought in an otherwise cool and/or humid region. Dry conditions are generally needed to set the stage for large and extensive mass fires. However, humid conditions are required to produce sufficient biomass to feed the fires.

Especially susceptible have been forest and brush lands in mediterranean and sub-mediterranean climates winter rains, summer drought savanna and parkland in sub-humid tropical climates; steppic grasslands, and monsoonal areas with a marked dry season. Continental interiors with cool, snowy winters and droughty summers are also subject to recurring, large fires. The changeable weather and windy conditions of sub-humid and even humid mountain environments can also lead to serious fire hazards.

In addition to broad climatic variations in plant growth, and types of vegetation, the length of time needed to accumulate substantial biomass in particular, dead, dry, inflammable material can differ markedly between grassland, brush and forest ecosystems. Forests usually take much longer to regenerate from past, large fires than grassland, while brush will tend to lie somewhere in between.

Fire weather is more than just a matter of dry conditions. Lightning starts most wildfires. Windiness is an important, aggravating factor in the more serious burns and conflagrations. Strong winds aid combustion and the movement of fire. They make fire-fighting much more difficult and hazardous. The worst fires generate their own winds, the worst being the firestorm, a meteorological phenomena approaching tornado-like winds and temperatures exceeding $1000\,^{\circ}\mathrm{C}$.

Meanwhile, burnt-over areas become more susceptible to soil loss by water and wind erosion. In seasonally humid climates, when tree and grass covers are lost, the returning rains are likely to generate more, or worse floods, landslides or mud and debris flows.

It is widely thought that global warming will increase the forest fire hazard in mid-latitude and boreal forests. The problem is thought to be particularly severe for the great forestlands of Russia, Canada, Alaska, Scandinavia and parts of Southern Argentina and Chile. Competitive extractive industry practices, and large-scale insect infestations, may continue to aggravate the fire hazard and effects of climate change. In the tropical lowlands and highlands even areas that are humid for much of the year environmental abuse has rendered surviving forest areas much more susceptible to fire. There are very few forest areas left that have not been opened up to greater fire risks from human activity, including deliberate burning.

In many contexts, fire is a traditional technique of land clearance or pest control, and for slash and burn agriculture. This has often seemed sustainable with careful use in experienced hands. However, excessive, careless or deliberately destructive use of fire can be harmful. Combined with drought, it can lead to immense, out-of-control burnings, as in Central Africa and Amazonia in recent decades, and the regional fires in Indonesia, 1997 and 1998 (see herein).

Conversely, artificial fire suppression, to protect forested areas, may also be ill advised. In the end, it can increase the hazard or ultimate scale of fires by aiding the build-up of flammable biomass. This was seen as an important factor in the devastating forest fires in Yellowstone National Park, USA, in 1988 (Romme and Despain, 1989).

Thus, given the importance of weather and biomass conditions in the wild fire hazard generally, global climatic and land use changes seem likely to make the problem worse. Recent increases in numbers, or more extensive fires, have accelerated the destruction of forest ecosystems and forest resources. The fires have also become major regional health and economic dangers due to smoke, haze, and smog. Meanwhile, there is a positive feedback danger as large fires contribute to greenhouse gases. The conditions responsible suggest these hazards will continue to grow without a, hitherto unprecedented, international commitment to reversing the human practices that aggravate them.

Case Study 4 – The Indonesia Wild Fires, 1997

A total of some 5 million hectares burned in Indonesia, mainly in East Kalimantang (part of the island of Borneo), and Sumatra. Unusually dry weather was a major factor in the timing, scale and uncontrolled spread of the fires, and related to a strong El Nino event. The setting on fire of extensive peat lands was a grave concern, since they are likely to burn underground for years or decades, and flare up whenever dry conditions return. Meanwhile, the smoke and haze from the fires spread over much of South East Asia. Reduced visibility and yellow smog affected many areas for two to three months.

Damages included large losses to the forest, plantation, agricultural, and tourism sectors; enormous health threats from smoke and haze; evacuations to escape fire and smoke, and magnification of already severe ecological damage and loss of biodiversity. Direct losses in Indonesia were around US$2.2 billion, mainly in health care and loss to the timber, agricultural and tourism sectors (EEPSEA/WWF, 2000). Malaysia and Singapore lost more than US$0.6 billion, mainly in health costs and lost tourism revenues. Some argue that the real losses were much larger in Indonesia through long-term health costs, loss of indirect benefits of forests such as control of erosion and floods, lost biodiversity, loss of business confidence and withdrawal of foreign investment. This also came at a time of acute national economic and political crisis, and expanding social conflicts.

Fire is commonly used to clear land for agriculture, plantations and other developments. However, letting fires burn out of control has become much more common, as a way to cover up illegal logging; for plantation developers to clear land and force out small peasant farmers and indigenous peoples and for the latter to retaliate. The scale of the fires, including those in the peat formations of Kalimantang, also reflects two decades of massive forest clearance, vast plantation and resettlement schemes, illegal logging, and unchecked ecological abuse (Saharjo, 2000). In fact, about half the burnt area was actually in plantation and agricultural areas, and 20% or about 1 million hectares, forested land. However, much of the plantation and agricultural land, and some 30% classed as unproductive, represent recent clearance of forests.

Other reports suggest that 1997 was one of the worst years for fires elsewhere in tropical lowland forests. Large numbers of major, uncontrollable fires occurred in Amazonia, Central and West Africa as well as SE Asia. Droughts or higher temperatures were factors. However, in all areas, human activities were implicated in the scale and scope of the fires especially fire use itself, past forest clearance, land use changes and conflicts over land. Perhaps such wild fires need to be identified as a complex hazard, rather than a natural, let alone merely a biological, one.

CONCLUDING REMARKS

In the context of global environmental change, natural hazards or risks involving them, may increase due to one or more of the following:

1. intensification, or higher magnitudes of given natural forces and events;
2. higher frequencies or recurrence of given dangerous conditions;
3. combinations of adverse conditions, that become more frequent, prolonged or intense;
4. changing geographies of one or all the above.

Moreover, with or without any of these, life could become more hazardous, due to:

1. human modifications in the development or intensity of natural forces, whether intended or not, e.g., the roles of deforestation or urbanization on the frequency and scale of floods;
2. interaction of artificial processes with natural ones to create complex, perhaps novel, dangers, e.g., photochemical smogs combining weather conditions and

industrial pollution; or failures of engineered river control works in floods;
3. changing human exposure and/or vulnerability to some or all natural hazards.

Also, we need to pay particular attention to the fact that life could become less hazardous with:

1. (effective) hazard and vulnerability mitigation, including improved forecasting, defenses against hazards, risk-averting land use planning and design of the built environment, adaptive strategies, and assistance, especially, to those people and activities that are at greatest risk;
2. improvements in emergency preparedness, humanitarian assistance in, and recovery from, the disasters that will continue to occur.

On-going changes in human land uses and other activities not only modify natural processes, but also alter the ways in which humans are put at risk from age-old hazards (Blaikie *et al.*, 1993; Brookfield, 1999). We noted how snowfall hazards in North America, drought and famines in Africa, lethal storm surges around the Bay of Bengal, and wild fires, have been transformed by land use and societal changes. Broad, adverse trends such as desertification, deforestation, reduction of perennial snow and ice covers or sea level rise alter the danger from a range of other natural hazards. Often, it is difficult to decide which of the above, or which combinations, are more critical.

Techno-scientific knowledge and practice, now confronts the sense in which dangers from natural processes are as much manufactured by human activity in the language of Ulrich Beck (1999) and others as givens of the planetary setting. This is partly about environment-changing or high-risk technologies, and increased or changing endangerment of human populations. However, there are also the expectations of, and claims made for, scientific understanding, estimation and management of risks.

The need for detailed and reliable knowledge of environmental conditions has never been more urgent. But geophysical understanding has, increasingly, to be employed in creative, and interdisciplinary contexts. Not least among the complex demands now being made, are those requiring geophysical and techno-scientific work, as it bears upon human safety, to be developed in ways that are more accountable and transparent to society at large.

Forecasting how global environmental change will affect disaster incidence, or which hazards and damages should be of greatest concern, is complicated by uncertainties about the future of natural processes. But even more uncertainty surrounds human developments, whether from novel technologies and their adoption, or conflicts including those that turn violent and undermine response capabilities. Most obviously, recent struggles concerning whether, how, and how far, governments, the corporate sector, and particular regions of the world, will address climate change, have large implications for research into, and responses to, related natural hazards.

Nigeria Oil Industry – Case Study

see Oil Industry: Cultural Impacts and Environmental Risk Tolerance (**Volume 3**)

Nitrate Leaching

Leaching is the slow downward percolation of water through the soil, which results in the removal of water-soluble minerals such as nitrate, from the upper soil horizons, and their accumulation in surface or groundwater. Nitrate, the oxidized form of nitrogen, is the end-point of the two-stage oxidation (nitrification) process mediated by chemoautotrophic bacteria. Nitrate is highly oxidized, soluble and biologically available. Thus nitrate leaching leads to a deterioration of drinking water quality and undesirable effects on ecosystems.

Nitrate Protection Zones in Europe

Hadrian F Cook
Imperial College at Wye, Ashford, UK

High levels of nitrate contamination occur in parts of Europe in both surface water bodies and groundwater. There is concern where affected waters are destined for human consumption, and nitrate also contributes to eutrophication of lowland rivers, lakes and reservoirs. This article describes the de nition and operation of nitrate protection zones, designed to reduce nitrate loading of natural waters at source. This is through land use prescriptions and the management of inorganic and organic fertilizers where the origin lies in agriculture. In addition, nitrate protection policies increasingly consider nitrates from non-agricultural sources. Also discussed are uncertainties associated with scenarios of climate change. The European Union (EU) is the main focus with some discussion of the issues for Central and Eastern Europe.

A *nitrate protection zone* may be defined as a land area coterminous with the whole or part of: a surface water catchment, a groundwater capture zone around a specific source, or a vulnerable aquifer. Within this area, land management or other activities are constrained with the stated aim of controlling nitrate loading of waters. Generically, nitrate protection zones are examples of contaminant-specific water protection zones. Within the definition are included specific environmental policy schemes, such as *nitrate sensitive areas* (NSAs) and *nitrate vulnerable zones* (NVZs) (both described in this article), which are concerned with the implementation of detailed policy prescriptions for the reduction of nitrate contamination of waters from agricultural sources (*see* Nitrogen: Agricultural Uses and their Impacts, Volume 3).

The nitrate anion (NO_3^-) arises from the dissociation in water of nitrates, including those of calcium, magnesium and potassium. Nitrate in soils is essential for supplying nitrogen (N) for the synthesis of protein in plants; in waters, nitrate can present problems for both human health and the environment.

Nitrate ingestion in humans has variously been linked to stomach cancer, methaemoglobinaemia (or blue baby syndrome) and childhood diabetes. Medical scientists remain uncertain about the true risk to health, and epidemiological studies are inconclusive. There is indeed some evidence for a role for nitrate in preventing heart disease, controlling skin infections and killing certain gastrointestinal pathogens.

However, loading of the environment with nitrate, especially as the problem affects lowland aquatic ecosystems, remains a more tangible problem. Combined with phosphorus, nitrate in waters is frequently associated with eutrophication of aquatic ecosystems causing blooms of green and blue-green algae in reservoirs (the latter sometimes toxic) during the summer.

Figure 1 shows a simplified *nitrogen cycle* (*see* Nitrogen Cycle, Volume 2). In agricultural systems, nitrogen is lost through nitrate leaching from soils to water, ammonia volatilization and nitrous oxide (N_2O) and dinitrogen (N_2) losses by denitrification in soils and groundwater. N_2O is estimated to contribute around 5% of greenhouse gas warming potential in the atmosphere. Soil nitrogen (of many species) is boosted through regular inorganic and organic fertilizer application. Microbial activity is responsible for the release, in the first instance, of ammonium (NH_4^+). This arises from the ammonification or mineralization of organic matter, followed by nitrification, i.e., ammonium oxidation to nitrate. Nitrate ions are highly soluble, negatively charged (as is the bulk of charges in the soil matrix) and therefore prone to leaching; i.e., removal from soils by the passage of water. However, the proportion of soil nitrate leached directly from fertilizer applied is normally small, and considered to be controllable by careful application (*see* Nitrogen: Agricultural Uses and their Impacts, Volume 3).

Other nitrogen sources supplying nitrogen to soils and the environment include atmospheric fixation by leguminous plants, farmyard washings, slurries and silage deposition from the atmosphere (dry and wet) and sewerage, including leaking sewers and cesspools. Non-agricultural sources of nitrogen in waters are variously assessed as between 8 40%. In Southern England, nitrogen loading from the atmosphere, as ammonium, nitric acid and other forms occurs in the range 25 50 kg N ha^{-1} $year^{-1}$; comparable levels have been detected in the Netherlands.

Raised nitrate concentrations in the chalk ground water of Thanet (East Kent, England) have been detected since the middle decades of the 19th century, and were originally attributed to sewage arising from urbanization, although intensive horticulture and agriculture have long been the favored land uses. The chalk aquifer here is largely unconfined, meaning that no geological protection is afforded from overlying strata, and any leachate from the soil, or discharges of contaminated water, percolates vertically to the water table. Rising concentrations in the 1950s and 1960s in chalk sources across Southern and Eastern England were detected at a sufficient rate to cause concern; in the 1970s the link was established with the application of inorganic fertilizers in arable agriculture. However, nitrates in both groundwater and surface waters present problems across Europe.

For example, Figure 2 shows potential groundwater hotspots for nitrate contamination that were identified from model calculations by the European Environment Agency (EEA). Large areas of central and western Europe are potentially affected and, due to excess groundwater recharge from irrigation, areas of Southern Spain and the Southern Russian Federation may have a worse problem than Figure 2 predicts. Assessment of the real nitrate problem for groundwater across Europe is more difficult because data coverage, standards and sampling regimes all vary. However, EEA identifies actual hotspots within the territories of: Austria, Denmark, France, the Netherlands, Slovenia, Belgium, Finland, Switzerland, Spain, Greece, Portugal, Romania, Republic of Moldova, Hungary, Lithuania, Bulgaria, and Poland. To this list, the UK must be added. Overall, the problem is worst in the intensively farmed countries of North and Western Europe and has become an area of policy development by the EU, formally the European Community (EC).

Rising concentrations in natural waters caused a maximum admissible limit to be set at 50 mg nitrate/liter (11.3 mg nitrate-as N/liter) in the EC Drinking Water Directive 80/778/EEC. The guide level for human consumption is 25 mg nitrate $liter^{-1}$. Other relevant EC directives include the EC Urban Waste Water Treatment Directive (91/271) covering sewage effluent, and the EC Groundwater Directive (80/68) that requires protection against hazardous substances in groundwater, but does not cover diffuse pollution. The EC Nitrate Directive 91/676/EEC set the 50 mg nitrate $liter^{-1}$ standard for all waters vulnerable from agricultural pollution and requires member states to designate NVZs within their territories. Eventually, the quality of all waters may be protected by an EU-wide water framework directive.

Nitrate can be stripped from water by anion exchange systems that pass water through resin. This is increasingly common, but expensive. Alternatively, reactor systems are used; these utilize the natural process of microbial denitrification (the reduction of NO_3^- to the gases N_2O and N_2) through the use of a carbon source in anaerobic situations. Blending high and low-level water sources for public supply is another option, but only as a temporary measure. On Thanet, waters from an ion exchange denitrification plant are blended with high nitrate sources to reduce concentrations. However, stripping and blending relate to water put into public supply and cannot improve the status of natural waters *in situ*.

Although neither the sources nor the behavior of nitrate mobile in waters is open to simple description, many agree that control of the problem at source is the best sustainable option for reducing environmental loading. Point sources of nitrogen contamination are readily controllable by codes of good agricultural practice set by governments; however, diffuse nitrogen loading at source has

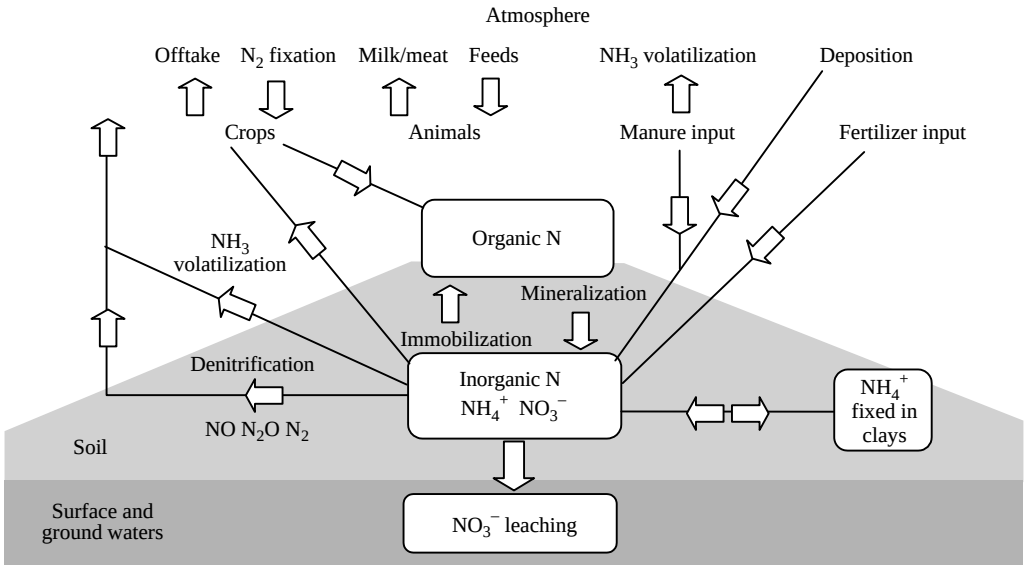

Figure 1 A simplified nitrogen cycle

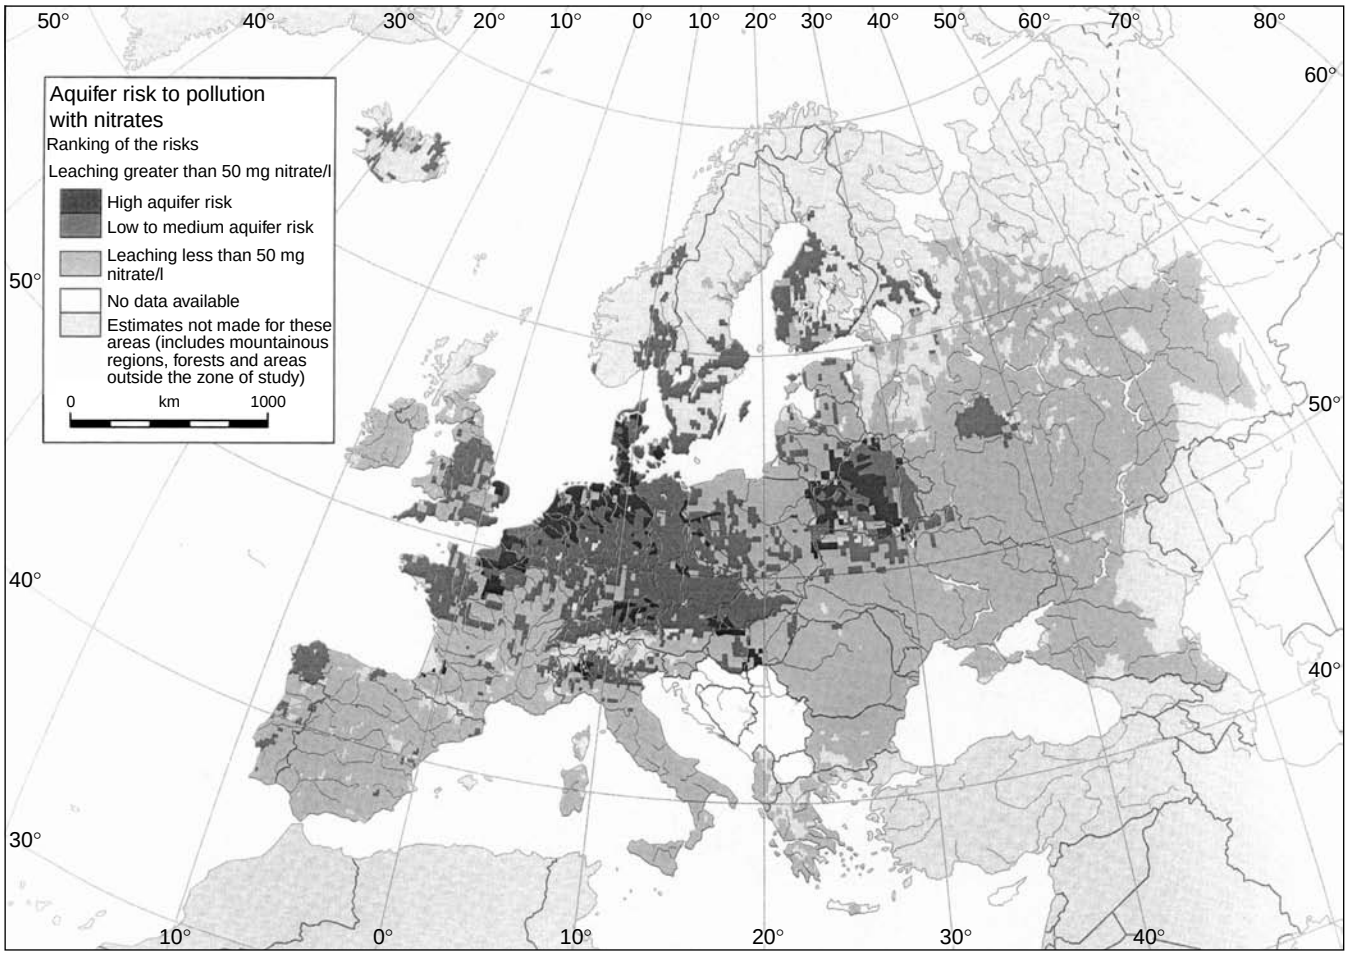

Figure 2 Potential nitrate ''hotspots'' for groundwater contamination (from Stanners and Bowdeau, 1995)

to be via land use measures. While agricultural yield is compromised, the reduction in cost of nitrate fertilizer is reduced.

EU member states have responded differently in implementing protection zone policies at the national level, depending largely on the severity of the nitrate problem within their territories. The very notion of nitrate protection zones, however, requires elaboration through the following points.

First, a nitrate protection zone suggests an uneven environmental response to what may be adverse and unsustainable agricultural practices within the catchment area for a water source. If these areas are in some way protected from the worst excesses, there remains the possibility of agricultural intensification elsewhere resulting in an expansion of any attendant problems. Nonetheless, there is a compelling argument in terms of economic efficiency for the targeting of land areas for environmental protection where farmer compensation and policing by environmental institutions is concerned.

Second, therefore, there is a tendency to protect only water sources. Ignoring the wider environment results in calls for widespread protection measures across whole aquifers and surface catchment areas.

Third, those concerned with whole-farming systems would favor the widespread adoption of measures deemed less damaging than conventional agriculture involving high agrochemical input systems and regular plowing, as in short-cycle crop rotations. Alternative systems have to be closely scrutinized, but as yet no clear benefits have been found; for example, poor management of organic farming systems produces little or no reduction in nitrogen loss.

Fourth, maximum use of available environmental information should be employed. For example, the absence of detailed soil mapping information in targeting for nitrate protection zones is an omission in Britain, yet it is known that leaching from shallow and lighter textured topsoil is great at certain times of the year.

What emerges is a convenient differentiation between source protection (aimed to protect individual boreholes, wells, springs and surface water abstraction points), and resource protection whereby larger-scale, hydrographic features may be protected, such as the entire unconfined portion of an aquifer or a surface water catchment. Some EU countries, especially the Netherlands, Germany, Denmark and parts of Belgium, have a serious nitrogen management problem due to a high density of livestock. In effect, Germany, The Netherlands and Denmark have designated their entire territories NVZs in an effort to achieve resource protection for all waters, while the UK, Belgium and France have preferred the targeted approach. In the case of France, however, the problem in certain regions is so great that the policy response has been for large areas, including the whole of Brittany, to be designated as vulnerable.

Land use policy responses to the drinking water and nitrate directives employ measures aimed at reducing nitrate losses below the soil (or horizontally into surface waters) through land use prescriptions. This is to be achieved by restricting the amounts and timing of organic and inorganic fertilizer applications, planting catch (crops that absorb nitrogen) crops, establishing low input grass on arable land and avoiding the plowing of grassland to avoid diffuse nitrate pollution. In addition, there is to be careful management of slurries and manures, according to codes of good practice, so as to avoid point source pollution.

Other effective alternative land use measures for the protection of surface waters are buffer strips and wetland areas. Nitrate that is horizontally mobile in shallow groundwater in alluvial subsoil is attenuated by the emplacement of fertilizer-free grass buffer strips parallel to watercourses, provided there is no under-drainage. The strips may be ≥ 5 m wide, and are an option promoted by several European agricultural and conservation agencies. Another approach is the use of existing, creation of new, or re-instatement of former wetland areas where relatively immobile surface waters can reduce nitrate loading in the environment.

The UK response has been to target geographical areas, and the first were NSAs under the Drinking Water Directive (*see* Nitrogen: Agricultural Uses and their Impacts, Volume 3). Since 1994, the number of NSAs was expanded to 32, incorporating 10 pilot areas (around 10 000 ha of agricultural land), initiated under the Water Act 1989. These were chosen to typify the geology and land management in areas where nitrate concentrations in abstracted groundwater was high.

In NSAs, the farmer is compensated for a supposed loss of earnings caused by a reduction in fertilizer inputs, switch of crops and even a switch to unfertilized, low-density grazing grassland under the arable premium scheme. There was an initial uptake of 86% of the agricultural land areas designated in 1991; longer-term enrollment was around 70%.

Designed to reduce the residual nitrogen in soils at the end of the growing season in autumn and winter, and to maximize nitrogen uptake during this period, the NSA scheme is a long-term experiment in land targeting, expected to run until 2003. The results are proving successful, especially where cover crops have been established before spring sowing. Under the arable premium scheme, concentrations leaving the soil at 5 mg liter^{-1} nitrate, or even less have been recorded. The basic scheme, on the other hand, provided for arable farming to continue with compensation for lower outputs in terms of yield. It has led to a variable response but around a 30% reduction in

leached nitrogen. This is attributed to cover crops and catch crops that absorb the nitrogen during autumn. Livestock farmers were asked to produce a manure plan; thereby providing some control on the storage and disposal of manure to land. There is a closed period for application depending upon soil type and crop.

Concentration of nitrate in groundwater is slower to respond than in soil water, mainly because of the longer residence time of water in the unsaturated zone of aquifers. Although certain early results are encouraging, it remains highly probable that wider-scale restrictions on land management, including fertilizer use and plowing, will be required if there is to be a widespread reduction in nitrate concentrations below the EU limit for water leaving the subsoil in agricultural areas.

A wider-ranging policy instrument in UK has involved the designation of NVZs, covering some 600 000 ha across England and Wales, with one example in Scotland in an area of intensive horticultural production (*see* Nitrogen: Agricultural Uses and their Impacts, Volume 3). NVZs derive from the nitrate directive and are concerned specifically with environmental protection from nitrates, rather than only the quality of drinking water destined for human consumption. Member states are required to identify water bodies where the EU limit for nitrates is actually or potentially exceeded, and compulsory measures must be taken to reduce pollution upstream of the sampling points.

The largest areas of designation protect surface waters, examples being the River Waveney (East Anglia), the Rivers Blackwater and Chelmer (Essex) and Rivers Leam, Cherwell and Great Ouse (a large area between Coventry and Dunstable) although groundwater is also protected, including Thanet in Kent. All the NSA areas are nested within NVZs. Compulsory NVZ measures are not always so stringent as in voluntary, compensated NSA policies. The restriction on fertilizer use is, in reality, not to exceed the economic recommendation. However, for manures good practice potentially involves additional storage and spreading over crops for some farmers.

To summarize the key NVZ rules:

- Nitrogen fertilizer applied must be according to recommended crop requirements on arable land and grass. Manures are limited to 210 kg ha^{-1} arable (to become 170 kg ha^{-1} in 2002) total nitrogen and 250 kg ha^{-1} total nitrogen to grassland.
- Closed periods for the application of nitrogen fertilizers are set at 1 September 1 February for arable land and 15 September 1 February for grassland. For organic manures on sandy and shallow soils, the closed period is 1 August 1 November for arable land, and 1 September 1 November for grassland.
- There are controls on manure-spreading during periods of waterlogged, flooded, snow covered or frozen soil and on steep slopes.
- Spreading of all fertilizers should be even and accurate.
- There are restrictions on fertilizer applications near watercourses and wells.
- There has to be adequate slurry storage.
- Good record-keeping of fertilizer applications is required.

Protection zones for surface catchments are relatively easily defined and the stretches of channel involved are easily identified. However, groundwater protection zones are more complicated. In simple terms, catchment areas from which boreholes draw water are derived from modeling subsurface flow at the water table using variable parameters. The main variables used are transmissivity, hydraulic conductivity, effective porosity and recharge. Calibration of the model is important and this is achieved by comparing output of the model runs with real water level data. By varying parameter values and their combinations, it is possible to derive various realizations of the catchments, and the NVZ boundary is based upon the line that represents the most realistic local condition.

Figure 3 shows the NVZ area designated at Moulton in East Anglia. Modeling boundaries are translated into hard boundaries in the landscape, typically field boundaries. Potentially, the final area included in a groundwater

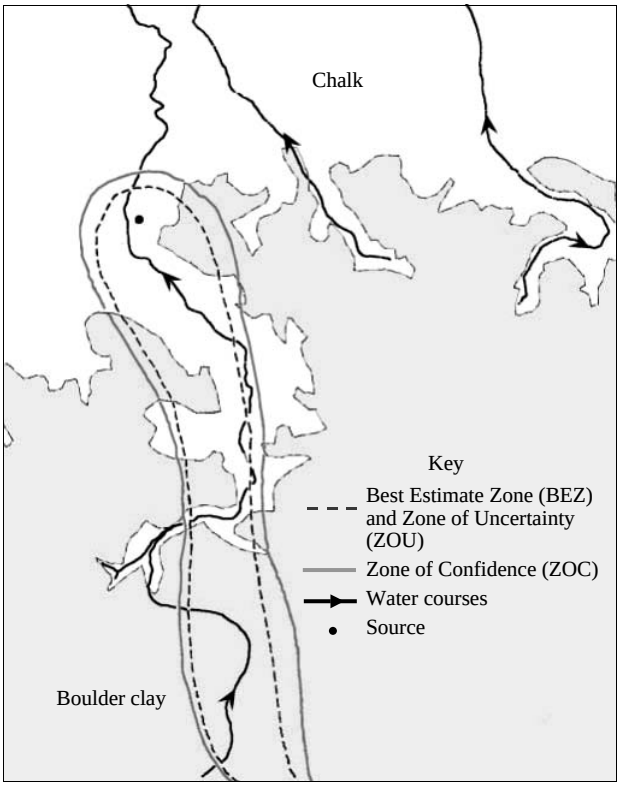

Figure 3 The Nitrate Vulnerable Zone designated at Moulton in East Anglia, UK. (Reproduced by permission of the Environment Agency for England and Wales)

NVZ may be a combination of surface water and groundwater protection zones, this being dependent upon local geology.

While the UK provides some interesting examples of policy development and implementation, it is by no means the most radical in approach. For example, Danish agriculture faces severe problems and is arguably the most regulated in Europe. Blanket restrictions under the nitrate directive have been brought about due to pollution problems affecting groundwater (the major sources of drinking water) and marine coastal waters. Around 62% of the land area is farmed, and nitrate pollution is largely attributed to the livestock sector, a problem apparent since the 1980s. Regulation of nutrients is by action plans aimed to reduce not only nitrogen pollution, but also that from phosphorus.

Disposal of manure is therefore key to the operation of successful nitrogen management, and spreading is restricted to periods of crop take-up and when risk of run-off is low. For applications between harvest and 1 February, the quantity applied must not exceed 50 kg N ha^{-1}. Danish farmers are required to prepare crop rotation and fertilizer accounts. Fertilizer must be reduced by an amount equal to the readily available manure nitrogen, i.e., assuming no losses to volatilization or leaching. For example, in the fertilization year 2001/2002 a requirement of 60% of nitrogen supplied from pig slurry or 55% cattle slurry must be used. A percentage adjustment is made in this way for each year in order to account for the residual effect of the particular organic fertilizer applied. While the policy is mostly concerned with livestock manure management, maximum available nitrogen (all sources) is set for arable crops, taking account of soil texture.

In Hungary, outside the jurisdiction of the EU, water protection zone policy is developing apace. An ambitious program was implemented for groundwater protection in 1996. Of some 1600 well fields, 643 (around two-thirds of the country s drinking water supply) with a further 78 prospective sources, are considered vulnerable to a range of pollutants. These are mostly over unconfined aquifers, hence the initial implementation of non-pollutant-specific groundwater protection zones. Around each source there are up to five concentric zones, defined at 20 days, six months, five years and 50 years travel time for subsurface flow at the water table, with the total recharge area designated if required. The policy requires assessment of current problems, their remediation and prevention of future contamination; agriculture and sewerage are included as potentially polluting surface activities.

The Hungarian Government seeks harmonization with the EC Nitrate Directive (91/676), the EC Urban Waste Water Treatment Directive (91/271) and the EC Groundwater Directive (80/68). Protection zones are designated in accordance with these directives, including not only NVZs against pollution from nitrates of agricultural origin, but also nitrates from sewage. Codes of good agricultural practice are to be implemented and there has been a thorough evaluation of the nitrate content of surface and groundwaters. In due course, there will be harmonization with the new water framework directive covering all waters.

In the states of Eastern Europe, the trend of nitrogen fertilizer use in the 1990s was downward, reflecting the poor economic conditions. Hungary also has a downward trend. In Western Europe, nitrogen fertilizer use for the same period peaked in the Netherlands, Belgium and Denmark, while it is expected that low growth will level off in the UK, France and Germany.

Yet another dimension to the nitrate issue relates to the impact of climate change in Europe. For instance, in the UK, temperatures are expected to rise from between 0.1 and 0.3 °C per decade in the first half of this century. The pattern of crop production across Europe will likely be perturbed by a northward shift in the agro-ecological zones resulting in changes in nitrogen and organic fertilizer application.

Soil organic matter loss in cultivated land, another probable outcome of climatic warming, is central to considerations of soil carbon, water and nitrogen balances and hence affects the potential for nitrate leaching. However, patterns of change in the loading of nitrate to waters are uncertain. Because raised nitrate losses may be observed following drought and storm events, it is possible that short-term increases in organic matter mineralization will result from raised temperatures. This will make areas of shallow and sandy soils over unconfined aquifers particularly vulnerable. Furthermore, changes in precipitation would increase opportunities for nutrient leaching while temperate clay soils prone to shrinkage and swelling, when exposed to a warmer climate, may also experience increased cracking, further increasing drainage rates and agrochemical losses.

There remain great unknowns for the longer term. Alone, raised atmospheric carbon dioxide has been shown to cause assimilation of soil carbon through increased primary productivity, and has the potential for nitrogen immobilization. Changes in the hydrological balance during (for example) drier summers would also reduce contaminant dilution in rivers and aquifers across Europe and wetter winters would have the opposite effect. There would also be reduced opportunities for denitrification in a drier climatic regime, while both wetter and drier soils in temperate Western Europe may also slow the turnover of soil nitrogen. Should desertification become a reality throughout Southern Europe, an accelerated loss of organic matter would be limited by its own depletion, arguably bringing an end to accelerated nitrate loss and, potentially, to cultivation itself.

The direction, severity and uncertainty of such changes will have to be reflected in policy formulation for nitrate protection zones.

The EU, and indeed certain accession states (including Hungary), are moving towards tight regulation on agriculture in order to control nitrate pollution, and many member states are working hard in order to comply with the appropriate directives. There remains an element of experiment, especially because of long residence times in aquifers and because of the need to establish workable policy instruments at the farmer/land-use interface: a situation aggravated by such variables as changing economic circumstances and scenarios of climate change. Greater success may be achieved by wider-scale measures in certain EU member states (including the UK) with better use of environmental information and further research and monitoring. Control of nitrogen loading from sewage and atmospheric deposition would also greatly assist in the control of nitrate pollution. The EC Urban Waste Water Treatment Directive (91/271) is showing the way to widening controls on nitrate pollution from non-agricultural sources; that from air pollution is more difficult.

ACKNOWLEDGMENT

Dr Grant Edwards of the Imperial College at Wye, Dr Paul A Hart of the Environment Agency of England and Wales and Dr Eunice Lord of ADAS, Ministry of Agriculture, Fisheries and Food for England and Wales, provided critical comments on the draft manuscript.

Nitrogen: Agricultural Uses and their Impacts

A L Heathwaite
University of Sheffield, Sheffield, UK

To date, environmental change related to the agricultural nitrogen (N) cycle is essentially a developed world issue but is likely to become a developing world issue unless action is taken to control elevated nitrogen losses to water and the atmosphere. Nitrogen imbalance leads to a range of environmental problems including contribution to greenhouse gases, direct damage to vegetation from nitrogen oxides, eutrophication and acidi cation. Not all problems have an agricultural source but agriculture is implicit in widespread environmental damage.

Plant production responds to increases in the supply of available nitrogen. This relationship is exploited by the agricultural system. In many developed countries, the use of nitrogen fertilizers has increased 100-fold in the post-war years but fertilizer application is generally inef cient. Thirty to 50% of fertilizer nitrogen applied may be lost to the atmosphere through denitri cation and volatilization; a further 30% may be lost through the leaching of nitrogen compounds. Such loss constitutes a major environmental problem and a source of global environmental change. There is good evidence that nitrogen pollution shifted from local to regional scale (Burt et al., *1993) when it became clear that reduction in point source inputs (e.g., industrial discharges, sewage outfalls) were not giving the expected decrease in nitrogen loading to surface waters, groundwaters and coastal seas. Today it is recognized that non-point, primarily agricultural, sources of contamination play a central role in the degradation of both terrestrial and aquatic ecosystems. Environmental management, in the form of legislation and voluntary codes of good agricultural practice has been introduced to combat the decline in the quality of*

terrestrial, aquatic and atmospheric systems. Time lags in both the agricultural system and ecosystem response mean that it may be some time before the effects on the environment of agricultural management are felt.

THE AGRICULTURAL NITROGEN CYCLE

The global nitrogen (N) cycle is described in volume 2 of this encyclopaedia (*see* Nitrogen Cycle, Volume 2). The key processes operating in the nitrogen cycle are:

- fixation from the atmosphere by bacteria;
- mineralization of organic nitrogen in soil organic matter to ammonium by soil bacteria: a key process governing the availability of mineral nitrogen for plants and leaching loss;
- immobilization through plant uptake;
- nitrification through bacterial oxidation of ammonium to nitrite then nitrate (*see* Nitrate Leaching, Volume 3);
- denitrification through reduction of nitrate to nitrite with further reduction to nitrous oxide (N_2O, a greenhouse gas) and gaseous nitrogen;
- volatilization of nitrogen compounds to gaseous ammonia;
- deposition and leaching.

Understanding the agricultural nitrogen cycle in the context of environmental change is largely a question of resolving nitrogen imbalances within the cycle and nitrogen losses from it. Climate, especially rainfall and temperature, is the key control on nitrogen loss from agricultural land owing to its effect on soil moisture, drainage, crop growth and nitrogen utilization. However, the agricultural nitrogen cycle is also driven by human action and as a consequence, land use and land management factors become important; these are discussed in detail later. Figure 1 demonstrates the changing scale of water quality problems.

Figure 2 shows a simplified nitrogen cycle for the agricultural system. Inputs (fertilizers, manures, feed) rarely balance offtake from crops and livestock produce. Furthermore, natural nitrogen inputs from atmospheric deposition have been enhanced by agricultural activity (see later). The resulting nitrogen surplus is the main source of nitrogen-related environmental change in ecosystems. Nitrogen fertilizer may be applied in urea, ammonium or nitrate form. For temperate climates, warm, moist soils mean that the various nitrogen forms are rapidly converted to nitrate that is easily lost by leaching owing to its high solubility. Nitrogen present in manures and some inorganic fertilizers may also be lost through volatilization as gaseous ammonia, with return via atmospheric deposition. If the soil is waterlogged, some nitrogen may be lost to the atmosphere through denitrification. Rivers, lakes and coastal seas act as nitrogen sinks removing nitrogen through denitrification, sedimentation and biotic uptake. The rate of denitrification varies; lakes may remove up to 50% imported nitrogen but the rate of denitrification in rivers is much lower.

ENVIRONMENTAL CHANGE: IDENTIFYING IMBALANCES IN THE AGRICULTURAL NITROGEN SYSTEM

Overview

Surplus nitrogen compounds are emitted and introduced into ecosystems as a result of three main types of human activity:

- combustion of fossil fuels (especially vehicle emissions);

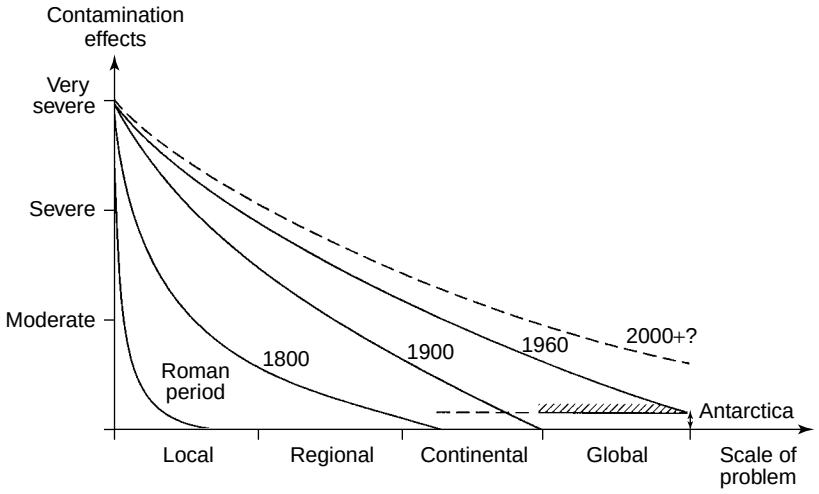

Figure 1 The changing scale of water quality problems over time. (Reproduced with permission from Burt *et al.* (1993))

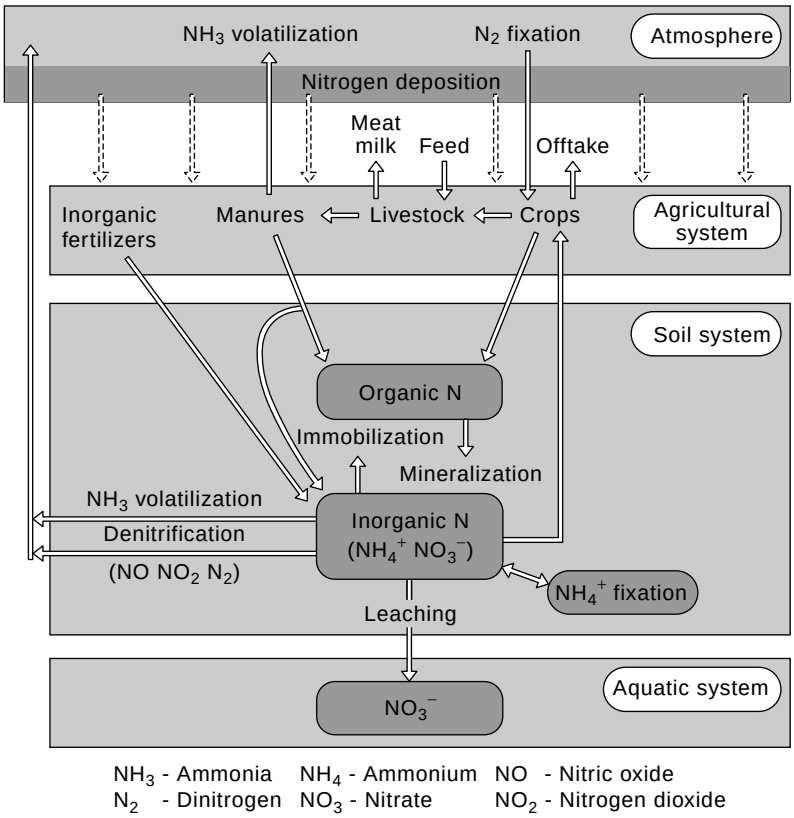

Figure 2 A simplified agricultural nitrogen cycle. (Reproduced with permission from the Ministry of Agriculture, Fisheries and Food (1999))

- direct discharges of sewage and industrial effluents;
- intensive agriculture (the focus of this article).

The introduction of higher yielding crop varieties supported by adequate supplies of fertilizer nitrogen has provided large increases in the yield of most major agricultural crops. Increases in nitrogen use similarly underpin higher livestock stocking densities. As a consequence of this intensification, agricultural land is now the main source of nitrate in most rivers and groundwaters (Burt *et al.*, 1993). Indeed, increased nitrate leaching is common to all intensive farming systems throughout the developed world. Among the other sources of excess nitrogen are increased nitrogen loading from human (sewage) sources and increased nitrogen flux from the atmosphere, although the latter has, in part, an agricultural source.

Changes in Land Use

A key problem in the agricultural use of nitrogen might be termed untimely nitrate, i.e., nitrogen present in the soil that is excess to crop requirements. Whilst climate and soil residual nitrogen are the ultimate controls on nitrate leaching, land management is becoming increasingly important. Untimely nitrogen can be directly linked to land use and land management as discussed later.

Arable Cultivation

Arable cultivation modifies soil structure and the rate of microbial breakdown of organic matter, releasing potentially leachable nitrogen. Arable land has frequently been cited as the key source of nitrogen enrichment in surface waters, lakes, and the marine ecosystem (Burt *et al.*, 1993). Critical land management practices are cultivation and drilling date and the amount and timing of nitrogen fertilizer applications. The risk of nitrate leaching from arable land increases immediately post-harvest when plant uptake is zero but nitrogen release through mineralization is high. Just as different arable crops leave different nitrogen residues in soil, research suggests that some soil types (sands and chalks) and some crops (potatoes, beans, peas, oilseed rape) are more leaky with regard to nitrogen than others.

Whilst it is possible, with careful management, for arable crops to take up the equivalent of 90 100% of the nitrogen applied from fertilizers, more commonly up to 60% nitrogen applied is lost by leaching and denitrification, with small losses though volatilization. Research has shown that the most effective way of minimizing nitrogen leaching

loss is appropriate use of cover crops coupled with careful budgeting of nitrogen fertilizer use (see later).

Grassland

Nitrogen applications to encourage high grass dry matter production are an essential part of grassland livestock management. Relative to arable crops, grassland can absorb a high fertilizer nitrogen supply. Although average nitrogen application to fertilized grass in the UK is 145 kg N ha^{-1} it may be as much as 700 kg N ha^{-1} for dairy farms. The sensitivity of grassland systems to nitrogen loss depends primarily on climate (particularly rainfall following dry spells), and mineralization of nitrogen from soil organic matter. The use to which the grass is put is also important. For example, up to 400 kg fertilizer N ha^{-1} may be applied to cut-grass before substantial leakage occurs. This is possible owing to the continuous vegetation cover, nitrogen removal in the crop and an extensive root system that directs nitrogen to the soil organic matter store. However, ploughing grassland and excessive cultivation, for example, reseeding grass leys, make a significant contribution to nitrate leaching. Nitrogen loss up to 4 ton ha^{-1} has been reported from ploughed permanent grassland although these effects are short-lived. If grassland is used for livestock production, up to 80% of all nitrogen consumed through grazing may be returned as dung and urine. Here nitrogen surpluses arise because offtake (milk, meat) relative to input is small and applications of manures and slurries coupled with direct excretion, increase the potential for nitrogen loss.

Changes in Inputs to the Agricultural System

Nitrogen fertilization is viewed as a vital part of productive grassland and arable crop management. Soils with a long history of nitrogen fertilizer application (both inorganic fertilizers and organic manures) commonly have a large mineralizable nitrogen fraction, forming a potentially large leachable nitrogen source. However, the relationship between nitrogen fertilizer application and nitrate leaching is not straightforward with factors such as climate, soil type and drainage and fertilizer timing and application rate influencing the magnitude of nitrogen losses from agricultural land. Recent research has clearly shown that two agricultural practices lead to excessive nitrogen loss: (i) use of fertilizer nitrogen in excess of crop requirement, and (ii) application of organic manures at excessive rates or at inappropriate times.

The replacement of manures by commercial inorganic fertilizers over the past 50 years is of particular significance for the agricultural nitrogen cycle. Animal manures and slurries spread on arable and grassland are commonly regarded as a waste product, with commercial fertilizers applied regardless of the nutrient content of manures. In the UK, for example, recent estimates of the potential value of animal manures are around £150 M a^{-1} but many farmers perceive the nutrient value of manures to be low relative to inorganic fertilizers, which are more convenient to use and relatively inexpensive. The manure problem is acute in northeast USA, eastern England and The Netherlands, where specialization in intensive livestock units such as pigs and poultry has produced specific problems relating to the available land area to recycle large volumes of animal waste. Current UK data show around 67 M ton animal manures are produced annually (c. 340 000 ton nitrogen) from housed livestock. A further 45 M ton a^{-1} excreta are deposited directly by grazing cattle, sheep and pigs. Manures are applied to c. 16% arable and 48% grassland.

Manure-nitrogen is mainly present as ammonium or organically bound nitrogen. The risk of nitrogen loss from agricultural land varies with manure type. Slurries and poultry manure, for example, have a high available nitrogen content and thus high potential for nitrate leaching. Two problems have recently emerged that continue to frustrate attempts to minimized nitrogen loss from livestock waste: (i) the nitrogen content is highly variable making nitrogen-balancing difficult, and (ii) ammonium-nitrogen in manures is unstable and readily volatilized as ammonia gas. Although a natural process, volatilization is greatly enhanced in intensive livestock production systems.

Changes in Atmospheric Nitrogen Loading and Emissions

Atmospheric nitrogen concentrations are increasing in developed countries as a result of emissions from vehicles and power stations, ammonia volatilization, and denitrification. Both ammonia volatilization and denitrification are enhanced under intensive agricultural production. Ammonia (NH_3) has only been regarded as an atmospheric pollutant in the last 10 years but is likely to become a major contributor to atmospheric change unless controls are implemented. Our understanding of NH_3 emissions, transport, and deposition effects remain limited. Gaseous ammonia may be returned to the soil surface through dissolution in rainwater to form ammonium. Ammonium generates acidity through release of hydrogen ions as it is oxidized to nitrate by soil bacteria. In The Netherlands, the most livestock intensive country in Europe, ammonia deposition is estimated to account for c. 20 30% of total acidification with at least 80% of these emissions coming from livestock production. Around 55% of emissions are derived from cattle, 17% from fertilizers, 11% from sheep, and 8 and 7% from pigs and poultry, respectively. Annual emissions of ammonia in Europe are c. 7 M ton $year^{-1}$ (as nitrogen) which is roughly equivalent to NO_x emissions from industry and vehicles. But whereas NO_x emissions contribute to long-range pollutant transport, most ammonia emissions are localized.

Table 1 On-farm ammonia emissions (%) by source

Livestock buildings	Liquid manure (slurry)	3–13
	Solid manure	3–12
Manure storage	Liquid manure (slurry)	2–10
	Solid manure	17–23
Field application	Liquid manure (slurry)	3–34
	Solid manure	2–18

Ammonia emissions are controlled by soil properties, pH, dry matter content and meteorological controls (especially wind speed, temperature, humidity). Ammonia emissions are greatest from slurry application to land, whilst solid manures emit more NH_3 during storage (Table 1).

Recent developments in emissions control from livestock housing include: separating urine from solid manure, improving the design of liquid manure stores, and constructing housing linked to biofilters to remove nitrogen. In the field, ammonia emissions may be reduced by up to 85% by slurry injection or incorporation rather than surface application.

AN EVALUATION OF THE CONSEQUENCES OF NITROGEN IMBALANCE

The consequences of agricultural-driven change encompass soil nitrogen saturation and soil acidification as a result of nitrogen deposition, water quality deterioration as a result of nitrate leaching, and eutrophication of coastal seas. Knock-on effects include changes in species composition in many aquatic ecosystems, mobilization of heavy metals in acidified catchments, and potential damage to human health through nitrate-rich drinking waters.

Impacts on Water Quality

Nutrient enrichment of receiving waters is undesirable owing to the resulting changes in the freshwater or marine ecosystem and the implications for drinking water affected by toxic algal growth. Nitrate reaching fresh and marine waters essentially acts as a fertilizer causing rapid aquatic macrophyte and algal growth and leading to undesirable ecological changes including anoxia, changes in species composition and loss of sensitive species.

Surface Water Quality

On a global scale, less than 10% of rivers may be classified as pristine (Heathwaite *et al.*, 1997). The average nitrate concentration in European rivers is 4.5 mg NO_3^- N per liter^{-1} compared with 0.25 mg NO_3^- N per liter^{-1} outside Europe. In the eastern USA, similar trends of increasing nitrate concentrations in rivers occur, although absolute concentrations at c. 1.0 mg N per liter^{-1} remained low until the 1990s. Overloading the capacity of forested land to retain nitrogen and elevated atmospheric nitrogen deposition is blamed for the recent increases in nitrogen concentrations in USA surface waters.

Groundwater Quality

The average concentration of nitrate is groundwater is increasing by 1 2 mg per liter^{-1} year^{-1} in intensively cultivated areas (Burt *et al.*, 1993). Shallow groundwater systems are particularly susceptible and may have nitrate concentrations in excess of 25 mg NO_3^- N per liter^{-1}. In the USA, highest nitrate concentrations are recorded in wells within 30 m of the land surface. The increased nitrogen loading to groundwater is thought to be mainly associated with fertilizer application, and is strongly correlated with land use. Owing to the time lags involved in nitrogen percolation to the groundwater table, the nitrate concentration in water extracted from bore holes for drinking water purposes is expected to continue to increase, even if fertilizer applications cease. Elevated nitrate concentrations in bore holes recorded in developing countries appear at present to be primarily related to human sewage disposal, rather than to agriculture.

Eutrophication of Marine and Coastal Waters

Elevated nitrate concentrations make a significant contribution to eutrophication in some marine and coastal waters because nitrogen is a key limiting nutrient for both phytoplankton and benthic algae in marine waters. In the 1970s, marine eutrophication was largely a phenomenon occurring in the coastal seas of northern industrialized regions. Marine eutrophication today may be considered a global environmental problem ranging from the Gulf of Mexico to Chesapeake Bay, the North Sea and the Straits of Malacca. Coastal seas such as the North Sea receive c. 1.5 M ton N a^{-1} from European Union (EU) states; nearly 70% of this input is derived from rivers carrying agricultural runoff. The symptoms of marine eutrophication include algal blooms, anoxia, formation of H_2S and fish kills.

Impacts on Human Health

Although opinion remains divided over the link between human health and nitrate in water, within the EU since 1980, the concentration of nitrate in drinking water has been regulated by the EU Drinking Water Directive. There are two main health concerns: methaemoglobinaemia and stomach cancer. Methaemoglobinaemia or *blue baby syndrome* is a well-documented medical condition thought to arise where ingested nitrate impairs the oxygen carrying capacity of the blood. Ingested nitrate is converted to nitrite in the gut. High concentrations of nitrite result in the oxidation of hemoglobin, ultimately restricting its ability to carry oxygen. The oxidation process occurs more readily in infants. Here it is compounded by a poorly developed enzyme reduction system that restricts the retransformation of methaemoglobin to hemoglobin, potentially resulting in

oxygen starvation and a characteristic bluish tinge. The condition does not affect adults because they are able to convert any nitrite formed back to nitrate, which is then excreted. The risk of blue baby syndrome is low. The World Health Organization (WHO) reported 2000 cases worldwide between 1945 and 1986. Risk is greatest in rural areas where high nitrogen fertilizer use may be enhancing nitrate concentrations in drinking waters.

The link between nitrogen and stomach cancer is poorly understood. Nitrosamine compounds possibly formed from food amines and nitrate in saliva are known to be carcinogenic but the link between nitrate ingestion and nitrosamine formation is less clear. There is little evidence to suggest a link between high nitrate concentrations in surface waters and the incidence of stomach cancer but this may be a function of the time lag for cancer to develop.

THE NEED FOR MANAGEMENT OF AGRICULTURAL NITROGEN

Much of the debate surrounding the need for control of agricultural nitrogen losses centers on who should bear the cost of any nitrogen pollution control strategy. Should the polluter pays principle be supported and largely preventative measures be adopted at a cost to the farmer? Conversely, should curative measures be imposed where the cost is borne by water supply companies and ultimately the taxpayer? A cynic might argue that the taxpayer pays in effect three times for nitrogen pollution: by subsidizing farming, by paying to clean up the resulting pollution, and through possible effects on human health.

In Europe, the critical legislation relating to agricultural nitrogen is the EU Drinking Water Directive. The Directive describes a precautionary approach to nitrogen control and provides a framework for standardizing legislation on the quality of drinking water for member states. The maximum admissible concentration (MAC) for nitrate in drinking water is 11.3 mg NO_3^-N per liter^{-1} or 50 mg NO_3^- per liter^{-1}. The MAC was reviewed by the WHO in 1997. On the basis of the latest scientific evidence, they concluded that the MAC should remain at the maximum guideline level of 50 mg NO_3^- per liter^{-1}. To achieve this level of nitrogen control, strategies preventing nitrate inputs to watercourses or treating nitrogen inputs once they have reached watercourses must be devised. These are reviewed below.

CURATIVE STRATEGIES FOR CONTROL OF NITROGEN POLLUTION DERIVED FROM AGRICULTURE

Curative strategies of nitrogen control are primarily aimed at drinking water treatment. The various approaches include water substitution or blending with low nitrogen water, and nitrogen removal through biological/chemical treatment or storage. The latter is primarily used in drinking water supply reservoirs and operates on the principle that bacteria in the bottom sediments will reduce nitrate concentrations. Biological or chemical treatment includes stimulation of denitrification whereby nitrate is reduced to N_2 or N_2O, by addition of a carbon source (e.g., methanol) to a fluidized sand bed to encourage the growth of nitrogen-removing bacteria. This approach is not without its own problems because although dinitrogen (N_2) is an acceptable end product, nitrous oxide (N_2O) is a serious atmospheric pollutant. The balance between $N_2 : N_2O$ production is largely controlled by soil factors (nitrate concentration, pH, oxygen concentration and organic matter content), and for treatment, the characteristics of the fluidized bed.

Preventative Strategies for the Control of Agricultural Nitrogen Losses

Curative strategies are essentially short-term nitrogen control measures; in the long-term, preventative measures aimed at land use control are viewed as the cheapest strategy. However, most preventative strategies will achieve only slow reductions in nitrogen loss from agricultural land. Rapid reductions may be achieved only with radical shifts in land use from intensive arable and horticultural crops to extensive, unfertilized grassland. In most developed countries such a shift is unacceptable, thus preventative controls are essentially a question of damage limitation: accepting that some level of nitrogen pollution will continue in order to maintain the productive capacity of agricultural land. Thus, in the UK, for example, whilst agricultural policy is aimed at limiting losses of nitrate and other forms of nitrogen pollution from agriculture by promoting practices that reduce such losses, restricting fertilizer use is not seen as economically viable for farmers operating on tight crop yield margins. It would also be some time before any reduction in nitrate concentrations in receiving waters was recorded owing to time lags in the system.

Essentially, three main options exist for preventative management of agricultural nitrogen to reduce nitrate concentrations in receiving waters:

- changes in land use (e.g., conversion of arable to low intensity grass as implemented in the set-aside scheme in the UK);
- changes in inputs (e.g., extensification);
- changes in management (e.g., timing of fertilizer applications).

The key proposed changes in farming practice contained in the various schemes described below are:

- accurate determination of crop nitrogen requirements;
- nitrogen fertilizer application in late spring in order to maximize crop uptake;

- split fertilizer applications rather than one or two major dressings;
- use of slow-release fertilizers;
- use of autumn cover crops to reduce the area of bare ground;
- provision of buffer zones between arable land and receiving waters.

The discussion here relates primarily to schemes promoted in the EU. Similar approaches exist in the USA, where more recently there has been a shift towards whole-farm management strategies.

Nitrate Sensitive Areas

The nitrate sensitive areas (NSA) scheme introduced by the UK Ministry of Agriculture, Fisheries and Food (MAFF) in 1990 has voluntary restrictions on nitrogen use in selected groundwater catchments and nitrate advisory areas, where good farming practice is promoted (Ministry of Agriculture, Fisheries and Food, 1998). The scheme was extended under the EU Agri-Environment Regulation to a total of 32 NSAs in 1994. Within NSAs, farmers are offered payments in return for adopting specified nitrate-reduction practices, including reductions in nitrogen fertilizer inputs below economic optimum rates, use of over-winter cover crops on arable land and conversion of arable to low input grassland. Results from the various NSA schemes show that reductions in mean nitrate concentration in drainage waters might be achieved (Burt *et al.*, 1993).

The EU Nitrate Directive

The EC Directive on Nitrate (91/676/EEC) adopted in 1991, is designed to protect waters against pollution caused by nitrate derived from agricultural sources. Member states must reduce nitrate pollution by introducing controls on agriculture in catchments where the nitrate concentration either exceeds $50\,mg\,l^{-1}$ or is at risk of doing so. The Directive provides scope for integrated controls on land use through designation of nitrate vulnerable zones (NVZs) where farming practices are restricted and the timing and application of fertilizers is controlled. To date, the UK Government has designated 68 NVZs covering 600 000 ha in England and Wales. A mandatory program of control on the amount and timing of nitrogen fertilizers and manures was imposed in the 68 NVZs in December 1998. Designated NVZs include buffer zones in riparian areas designed to reduce nitrate concentrations entering receiving waters by creating an environment in which denitrification is high. Recent research suggests that buffer zones between agricultural land and watercourses or bore holes reduce nitrogen inputs to receiving waters only if the hydrological pathways of nitrogen transport are intercepted (Haycock *et al.*, 1997). Buffer zones should perhaps be viewed as short-term measures of nitrogen pollution control. Furthermore, encouraging nitrogen removal through denitrification passes the problem from the land to the atmosphere because denitrification increases nitrous oxide emissions.

MAFF Code of Good Agricultural Practice for the Protection of Water

The Water Code (Ministry of Agriculture, Fisheries and Food, 1998) instigates voluntary controls on the application of animal manures and inorganic fertilizers to land. The Code is primarily concerned with guiding fertilizer timing and application rates and the use and disposal of animal manures. An application limit of $250\,kg\,N\,ha^{-1}\,a^{-1}$ is proposed to minimize nitrogen pollution risk; this limit does not include manure voided directly to land by livestock. Land use controls are included in the Code by limiting nitrogen fertilizer application within 10 m of a watercourse and 50 m of a bore hole or well.

THE FUTURE: AGRICULTURAL POLICY AND MANAGEMENT

The available research on agricultural nitrogen indicates two critical areas requiring further development for successful control on nitrogen loss from the agricultural system. The first is an improvement in predictive capacity to test various proposals for agricultural land use and fertilizer management. To this end, several models have been developed to predict changes in nitrogen loss as a result of specific changes in land use and management. These include NCYCLE (grassland), SUNDIAL (arable), MANNER (manures), INCA (hydrochemistry, Whitehead, 1990) and LEACHM (soils, Hutson and Wagenet, 1992). The INCA and LEACHN models are less agriculturally biased but include realistic in-river processes and groundwater/surface water interactions, respectively. In nitrogen modeling research, there is a move from sophisticated, data-hungry models towards simple semi-distributed models that estimate nitrogen loss on the basis of the limited data available. Such models commonly operate with a spatial resolution around 1 km and are driven by data availability, which in most developed countries includes land cover, livestock numbers, crops grown, climate, and soil physical properties.

The second critical area of agricultural nitrogen research is development of an integrated catchment management approach. A holistic approach is required because environmental problems unfortunately interact. Thus, buffer zones decrease nitrate leaching but they also enhance nitrous oxide emissions. Similarly, cover crops reduce nitrogen loss but increase the risk of pest and disease problems. Recent developments in farm systems studies pioneered in the USA may provide a means of developing more environmentally balanced approaches to the agricultural nitrogen cycle. UK research on, for example, minimal impact dairy systems (MIDAS) and nitrogen flows within complete grass/arable

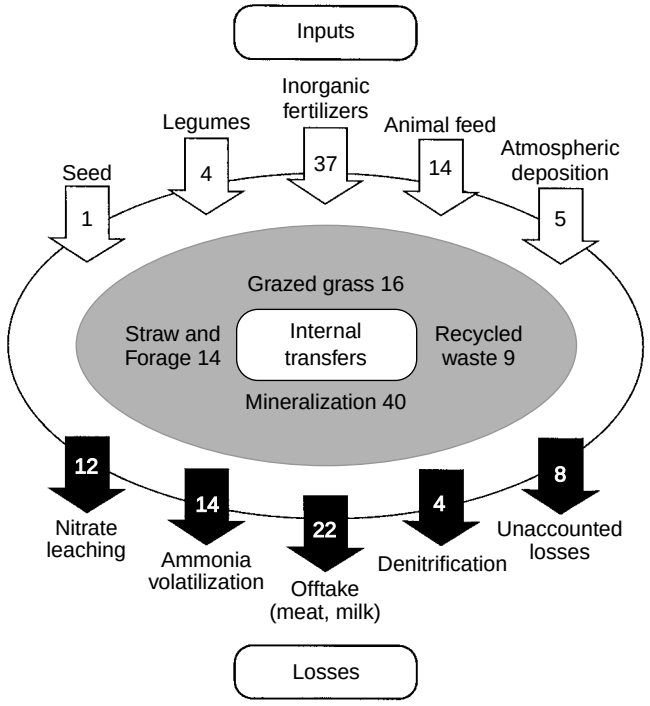

Figure 3 Measured nitrogen flows for a mixed grass/arable farm, southwest England. (Reproduced with permission from Jarvis (1999))

enterprises (Figure 3) has shown that improved management of nitrogen by, for example, adjusting fertilizer inputs together with manure management plus incorporation of maize silage, can reduce nitrate leaching whilst maintaining production. Such integrated studies demonstrate the way forward in achieving a balanced approach to nitrogen in agricultural systems.

Nuclear Waste: Geological Issues

Charles Curtis

University of Manchester Environment Center, Manchester, UK

For the last 40 years nuclear ssion has made a major contribution to global electric power generation. Currently 31 countries generate nuclear power and 17 rely on this source for more than 25% of their total demand. Looked at another way, had this power been generated by conventional combustion, current atmospheric carbon dioxide (CO_2) levels would have been substantially higher than they are and, presumably, we should be further down the uncertain path of global warming and climate change. Nuclear power generation probably represents the only current technology capable of substantial expansion that does not produce greenhouse gases.

The problem with nuclear power is that it generates radioactive wastes, which are hazardous to all life. Although the radiation, which generates the hazard, naturally declines in intensity with time, certain components within the waste remain active for thousands or even millions of years. The waste must therefore be isolated from the natural environment for time periods much longer than civilization as we know it has existed, therefore, for very much longer than our record of engineered structures. Most scientists and engineers who have worked with the waste problem argue for disposal of the waste in engineered structures deep underground. Earth scientists have two inputs to the debate: they are familiar with rock formations and also with geological and geochemical processes which take place over

time intervals of the same order as required for safe waste containment structures.

This article explores some of the technical issues which must be addressed by the nuclear industry if it is to demonstrate that radioactive waste can be managed safely and that, in consequence, nuclear power generation is a sensible choice for the future. It seems likely that any decision, whether it is to close down or to expand nuclear power generation, will have far-reaching social and economic consequences. On the one hand, there are those who see nuclear power as a threat to the long-term survival of the environment whereas others nd it dif cult to see how the legitimate aspirations of the developing world can be met without a huge increase in electric power generation. There are dif cult choices ahead.

THE NATURE OF THE PROBLEM AND WHY A GEOLOGICAL PERSPECTIVE IS NEEDED

Introduction

Rather more than 450 nuclear power plants (NPPs) are currently operational worldwide (see the section on nuclear power generation: different plants and products). Radioactive waste, mostly in the form of highly radioactive spent-fuel assemblies, continues to accumulate. To date, however, an insignificant fraction of the accumulated waste, both from power generation and military programs, has been disposed of (*disposal* is generally accepted to mean consignment to a facility that, once sealed, would require no further management: a final or permanent management solution): it is held in numerous temporary surface stores around the world. Most technologists working with national and international radioactive waste management programs have argued that deep geological disposal (hundreds of meters burial within stable rock formations) is a safe and the correct solution. There is much public concern, however, about the safety of such disposal. Special interest groups opposed to the nuclear industry have systematically reinforced this concern. The problem really is to decide which is the best management option for the planet: accepting that we have accumulated a very substantial inventory of hazardous radioactive waste which must be dealt with even if all nuclear power generation were to cease tomorrow. There is also the certainty that major global environmental changes will occur within the lengthy period during which the waste will pose a threat to health and the environment.

The Health Hazard, Real and Perceived

The threat to human health and the environment posed by radioactivity is straightforward: radioactive waste is one of many highly toxic materials generated by our society. The objective of radioactive waste management is simply to protect the public from this health threat (regulation and regulators are there to ensure the required level of protection).

Radioactivity is perceived widely to be uniquely dangerous. Perhaps this is because radiation is unseen, hence mysterious. Radioactivity and threat to life are also inevitably associated with the horrors of Hiroshima and Nagasaki.

Surprising to many, there are grounds for regarding radioactive wastes as far less of a threat than many other toxic wastes:

- Radioactive substances are easily detected and identified in minute concentrations (much more easily than most organic chemical toxins).
- The toxicity (dose risk relationships (see below)) of radioactive substances is very much better known than that of the vast majority of chemical compounds.
- Radioactive substances have always been regulated very much more closely than other toxic materials; their amounts and locations are much better known. The volumes of radioactive wastes are tiny compared with non-radioactive toxic wastes.
- Their amount, therefore threat, declines naturally with time, whereas elemental poisons like lead, cadmium, mercury and arsenic last for ever.

A geological perspective is needed because the half-lives of some radionuclides are very long: a small fraction of the radioactive threat lasts for hundreds of thousands or even millions of years. Only earth scientists work daily with processes that operate on such time scales. Long-term management solutions have thus tended to rely on designing repositories in geological settings where the mobility of radionuclides will be naturally constrained: in other words the radioactive elements and the hazard they represent will be contained. The existence of metalliferous ore deposits (including uranium ores) demonstrates that metals remain immobile over geological time periods in the natural subsurface environment. We can determine the age of such deposits and demonstrate them to be millions (or even hundreds of millions) of years old. Under the right geological conditions therefore, some radionuclides should be completely immobilized. Such natural occurrences, when studied in the context of waste disposal, are referred to as *natural analogs*.

Health-dose-risk and the Safety Case (over Geological Time!)

Radioactivity; Sources, Types and Damage Caused

Ionizing radiation is potentially harmful to all living organisms. Complex molecular structures, such as are found in all cells, can be damaged. Chemical bonds are ruptured or caused to rearrange such that molecular shape and

function are modified. Some of these modifications change the way cells grow or replicate, perhaps causing cancer or genetically transmittable mutations. Waste management aims to protect man and the biosphere from these harmful effects primarily by shielding (not allowing the radiation to come into contact with them).

Radiation is emitted when an unstable atomic nucleus disintegrates. This is now measured in units which correspond to single atom disintegrations, bequerels (Bq). Obviously these units are tiny since atoms are so numerous (1 g of hydrogen contains 6×10^{23} atoms). Every radioactive isotope (radionuclide) emits characteristic radiation as it disintegrates. It is useful to recognize a number of broad radiation categories. The most damaging, in health terms, is α-radiation. Table 1 summarizes the properties of the most common categories.

It should be remembered that since the Earth is naturally radioactive, there is an irreducible background radiation level and we are all subjected to significant radiation doses. To this natural background must be added man-made radiation, overwhelmingly medical in origin (especially X-rays). The source and dose of the principal contributors to background radiation are listed in Table 2.

Radioactivity, Dose and Risk

A dose is the amount of radioactivity absorbed by the body (or a part of the body). The different kinds of radiation are more or less harmful to living cells. Some parts of the body are more susceptible than others. An effective dose takes account of these variables and relates the radiation received to its harmful effect (units are sieverts rather than bequerels). These measurements are obviously very much more meaningful in health terms than simply documenting disintegrations of any kind (becquerels). The harm or hazard can be expressed in risk terms which allows the hazardous nature of radiation to be compared quantitatively with hazards from different sources: in turn permitting reasonable analysis of the costs and benefits of the nuclear industry and any remedial measures that may be contemplated.

Table 1 Types of radiation

alpha (α)	Helium nucleus (charged He^{2+}) massive	Ionizing
beta (β)	Electron: high speed, low mass, low momentum	Ionizing
gamma (γ)	Zero mass, charge, electromagnetic wavelength $<10^{-11}$ m^{-1}	Ionizing
Neutron	(Reactor product): creates radioactive isotopes in reactor body	

(unit = becquerel (Bq) = 1 disintegration per second)

Table 2 Typical background radiation levels as doses (units of sieverts – related directly to bequerels but taking account of the more damaging nature of some radiation)

Annual UK average: 2.50 mSv year^{-1}, 88% background, 12% man-made		
Air	1.30 mSv year^{-1}	Radon
Ground	0.35 mSv year^{-1}	^{40}K, Th, U
Food/drink	0.30 mSv year^{-1}	^{40}K
Medical	0.30 mSv year^{-1}	X-rays, irradiation
Cosmic rays	0.25 mSv year^{-1}	Air travel

Fundamental Protection Strategies

There are two basic approaches to managing the health risk posed by additional (over background) radiation from nuclear fission waste products. The first is to isolate (also immobilize or fix) the waste radionuclides within containers and store these within a shielded environment (the shielding to absorb all emitted radiation). The danger lies in some part of the radionuclide charge escaping the confines of the store and dispersing into the accessible environment hence, potentially, to living organisms via air, water or the food chain.

The shielding required is technically straightforward. Fortunately, α-radiation has very little penetration and a sheet of paper is sufficient shielding! The great danger from α-emitting radionuclides is only if they enter the body (as does naturally occurring radon gas). Containment is thus the problem, not shielding. β- and γ-radiation are much more penetrating, therefore, more comprehensive shielding is required. Relatively thin barriers of heavy metals (e.g., lead) or thicker barriers of steel or concrete can be constructed to provide completely effective shielding. The rocks of the earth also provide excellent shielding hence burial underground is wholly effective.

The alternative strategy is to allow discharges to the atmosphere (gases) and oceans (radionuclides dissolved in water) in such a way that the huge volumes of atmosphere and oceans dilute the discharged radionuclides to final concentrations which are radioactive at levels far lower than natural background. The additional risk is effectively zero, unless such huge discharges are allowed that background levels rise significantly. The calculations to evaluate these are simple and reliable. Current international conventions, however, are moving away from the discharge (dilute and disperse) strategy in favor of containment. One reason for this, perhaps, is the realization that dilution cannot be safely assumed for all radionuclides under all circumstances; mechanisms as yet undiscovered may afford reconcentration pathways to hazardous concentrations. Natural processes can and do concentrate elements to high

levels; without such mechanisms, there would be no ore bodies!

Regulation

Regulation aims to ensure that risks associated with radioactivity are quantified and then monitored against agreed limits. Internationally, imposed risks (of cancer or genetically transmittable mutation) of less than 1 in 10^6 are agreed as broadly acceptable. As can be seen from Table 3 this risk is extremely small when compared with risks we all take every day. It is also very small compared with that due to natural background radiation. By any standard, these regulatory risk standards, which apply not to the general public at large but to some small hypothetical group (the critical group) with maximum conceivable exposure, are conservative. Furthermore, many regulators have stipulated that the performance requirement for a waste repository is for an unlimited time. This literally means forever, with a fully quantitative safety case for 10^4 years, a semi-quantitative case for 10^6 years and reassurances that there will be no pulse at any time thereafter. It should be remembered that the hazard continuously decays: the radioactivity of spent fuel declines exponentially with time from the termination of the fission process.

The Fission Process and the Wastes Requiring Management

Nuclear Fission and the Products of the Fission Process

The release of thermal energy from nuclear fission arises because the nuclei of fissionable isotopes (notably ^{235}U and ^{239}Pu) are so destabilized by neutron capture that they split into fragments with release of radiation (α, β, γ, neutrons) and enormous amounts of energy. Nuclear power plants (NPPs) convert most of the energy into heat thence to electricity. One of the most unfortunate aspects of the fission process is that it is almost random in the fragments produced. Each single disintegration generates two or three specific isotopes of particular chemical elements. Within a fuel rod, numerous isotopes of very many different chemical elements are formed and, unlike the vast majority of isotopes in the natural environment, most derived from the fission process are unstable, themselves further decaying, sometimes in several steps with radiation emitted at each.

It is this very large array of different chemical elements and isotopes that poses the major management challenge. Each chemical element has unique properties that determine its solubility and migration properties within the geological subsurface, in the natural environment and food chains and also in any containment structure. For example, ^{127}I is a troublesome waste radionuclide in that it is very soluble in water as the anion I^- (iodide) and this interacts hardly at all with natural materials (see the later section on the ease with which different radionuclides move around in the natural environment). It is dangerous because the thyroid concentrates iodine: and radiation from ^{127}I may contribute to enhanced cancer risks. This mobility also means that iodine is difficult to remove from contaminated waters by a purification plant.

Predicting the performance of a deep geological repository (or any other management solution) thus must depend upon a knowledge of the geochemical cycles and environmental chemistry of a large proportion of the elements within the Periodic Table.

Table 3 Doses, risks illustrated by reference to background radiation levels[a]

Maximum individual regulatory risk to man (of developing terminal cancer or genetic defect)	$<10^{-6}$ year^{-1} or 1 in 1 000 000 year^{-1}
This compares with average risk of death per year	
Smoking 10 cigarettes a day	1 in 200 year^{-1}
Natural causes, age 40	1 in 850 year^{-1}
Road accident	1 in 9500 year^{-1}
Accident at home	1 in 26 000 year^{-1}
Accident at work	1 in 43 500 year^{-1}
Radiation exposure at 1 mSv year^{-1}	1 in 80 000 year^{-1}
Background radiation level, Table 1, is 2.5 mSv year^{-1}	1 in 32 000 year^{-1}

[a] Note, however, that there are different kinds of risks. Some are voluntarily accepted (smoking, car travel) whereas others are involuntary (fallout from a nuclear accident). The outcomes are also perceived in very different ways: some with dread, others as tolerable.

Nuclear Power Generation: Different Plants and Products

Rather more than 450 NPPs are currently operational worldwide. Most modern plants are pressurized water reactors (PWRs) or boiling water reactors (BWRs) which use ceramic uranium oxide fuel pellets encased within inert metal tubes (zirconium alloys, for example). Some older reactor designs, such as the UK Magnox reactors, use metallic uranium within magnesium cladding.

Once the energy has been extracted, the used or spent fuel assemblies contain the fission products trapped within the residual fuel. The assemblies also contain heavy radionuclides formed by neutron capture by uranium, including fissionable isotopes of plutonium (Pu). The oxide fuels, being not unlike naturally occurring uranium oxides, are chemically relatively stable. They are potentially less likely to react/dissolve and release trapped radionuclides into the natural environment than chemically much less stable metallic fuels.

Radionuclides are also generated by neutron bombardment (capture) of components of the fuel assembly and the reactor itself: ^{60}Co is one such.

Waste Forms and Categories

Obviously the bulk of the radioactivity generated by power generation lies within the spent fuel, but this is not all of the waste generated by NPPs. Throughout their working lifetime, relatively small amounts of waste are generated by maintenance. For example, ion exchange resins are continuously used to extract traces of radionuclides from primary and secondary cooling waters. The operations associated with refueling also create small volumes of waste. Both intermediate level wastes (ILW) and low level wastes (LLW) are generated and both pose health hazards hence storage and disposal is carefully regulated. A typical upper limit for LLW is 4 Gbq tonne^{-1} for α-emitters and 12 Gbq tonne^{-1} for β- and γ-emitters (1 GBq $= 10^9$ Bq). Higher radiation levels than these define ILW. High level waste (HLW) is so radioactive that significant heat is generated and cooling is required during storage. HLW includes both spent fuel and the bulk of reprocessing products (see below).

Another defining characteristic of waste is the half-life of the isotopes present. Short-lived wastes can be stored until activity has dropped to low levels making them much less hazardous. Many of the isotopes used in medicine and as tracers in experimental science, for example, have half-lives measured in hours or days. After ten or so half-lives, the residual activity is so low that they can be disposed of without special precautions. Many radioactive isotopes, however, remain dangerously active for thousands of years and some for many millions. In this context, of course, it is again worth remembering that non-radioactive toxic wastes such as cadmium (Cd), arsenic (As) and mercury (Hg) never decay!

A problem for long-term management is that many ILW and LLW waste forms contain organic matter (paper, cloth, ion-exchange resins). These materials are themselves unstable and will modify the chemical environment in which the radionuclides are stored or disposed of (see below). The nuclear industry understands these problems and separates all waste into streams with carefully documented compositions.

This was not necessarily true in the past, particularly in the early days of the industry. Then the principal and very urgent objective was Pu production for weapons. A consequence of the arms race is that all the major nuclear powers have major waste problems inherited from these early days. Furthermore, the amounts of waste generated in the past were much higher (per unit of energy generated) than arise from modern NPPs. We thus have two problems: management of waste arising from current activities and a much larger and more complex problem inherited from the past.

Conditioning, Reprocessing and the Once-Through Cycle

Some waste streams are more difficult to manage than others for reasons other than radiation levels. Liquids and gases are obviously more mobile than solids, therefore less easily contained. Many ILW and LLW waste streams contain organic matter (paper, cloth) and this is chemically unstable, breaking down to a range of more reactive and mobile substances. This is precisely similar to the degradation of organic matter to carbon dioxide, methane and organic acids (leachates) within landfill systems.

The first step in radioactive waste management (after good housekeeping in inventory description) is conditioning. This is the term used for treating and packaging waste to generate a more stable waste form, both physically and chemically. Much LLW and ILW is compacted. It is then placed in steel or concrete containers and grouted with cement-based filler.

There are two fuel cycles. The first is the once-through cycle which is designed to use fissionable fuel once only: extremely radioactive spent fuel assemblies are planned to be sealed within inert copper or stainless steel containers and these flasks can then be disposed of to a deep geological repository.

The alternative fuel cycle strategy involves reprocessing. Spent fuel is dissolved in acid, and fissionable uranium (U) and Pu are recovered for further use as fuel. All three products are at least potentially hazardous. The residual acid solutions are extremely radioactive, chemically reactive and potentially very mobile. Conditioning requires evaporative concentration and conversion to silicate glass (vitrification) which is then solidified within stainless steel flasks. These would be disposed of to a deep repository, much like spent fuel. Although valuable as fuel, U and Pu are potentially dangerous in the wrong hands and therefore demand strict security as an element of management. There is considerable debate about Pu management options; some argue for making it safe by mixing with HLW (the spent fuel standard), effectively reversing the reprocessing stage. It is technically very much more difficult to separate fissionable Pu from spent fuel than it is to manufacture a nuclear device from stolen Pu.

The relative merits of the two fuel cycles are the subject of intense debate. Ultimately, reprocessing can deliver much more energy from a given amount of U fuel than the once-through cycle. Whether or not reprocessing and the use of Pu for power generation become important as a global electrical power source will depend on developing energy demand worldwide, availability of raw materials and the environmental costs associated with different energy conversion technologies.

The Ease with which Different Radionuclides Move Around in the Natural Environment

The mobility of radionuclides obviously determines the likelihood (and rapidity) of their entering the food chain and significantly harming living organisms. Mobility equally dictates their behavior within engineered systems: how difficult they are to contain. This mobility depends not at all on their radioactivity nor on the health hazard they represent but entirely on their chemical properties. The design of containment systems depends primarily, therefore, on the chemical properties of the many different radionuclides generated by nuclear fission and the chemical form they have when produced as wastes.

The principal variables are solubility and degree of interaction with the solid constituents of the engineered barrier system or rocks in the subsurface. The most soluble radionuclides are those which form simple ionic species such as Na^+ and Cl^-. Negatively charged species tend to react least with rocks and minerals because most minerals have negatively charged surfaces. Radionuclides such as ^{36}Cl and ^{127}I are thus relatively mobile, being hardly retarded by these interactions.

The oxides/hydroxides of many metals are much less soluble in alkaline environments; hence concrete (highly alkaline) greatly reduces the mobility of such species in addition to physical containment when used as part of a barrier system. This is a further benefit conferred by the cementitious grout utilized in waste packaging. Another influence is the presence or absence of oxygen, which is generally present in soils and shallow groundwater but absent at depth. The solubility of metals such as uranium or technetium is much greater in oxidizing environments because different ionic species are formed (U^{4+} extremely insoluble, U^{6+} (as UO_2^{2+}) very soluble).

PRINCIPAL THREATS TO THE LONG-TERM INTEGRITY OF MANAGEMENT SOLUTIONS

Introduction

In looking to the longer term, beyond, say 10^3 years, it is important to assess the natural processes which could (and would) impair the containment properties of any store or repository. A good starting place is the performance of natural materials: the mineral constituents of soils, unconsolidated sediments and rocks. These should provide a good yardstick against which to judge the performance of synthetic materials such as cement and composites.

Chemical reactions, whether at the earth s surface (weathering) or deep in the subsurface (diagenesis) are relatively slow and continuous. Most other natural processes which would threaten a containment system, however, are physical, essentially discontinuous with most of the action taking place over very short time periods.

Chemical Degradation/Modification: Continuous Reactions

Chemistry of Rock Degradation Reactions

At the earth s surface, all rocks are broken down to unconsolidated soil products by chemical weathering. The chemistry is very simple with just two core reactions; dissolution and hydrolysis/hydration. For example, quartz dissolves readily (in contrast to some received wisdom) to produce dilute silicic acid:

$$SiO_2 + 2H_2O = Si(OH)_4 \quad (1)$$

All substances are soluble to some extent in pure water; hence rain (very low ionic strength) is a particularly aggressive reactant. The second important reaction type requires both hydrogen ions and water in order to generate charged solute species. Hydrogen ions are abundantly available in soils from organic matter breakdown products, including carbon dioxide (CO_2).

$$CO_2 + H_2O = H^+ + HCO_3^- \quad (2)$$

These reactions normally produce both solid and dissolved products: potassium feldspar under intense weathering breaks down to give soluble silicic acid and potassium with a residue of extremely insoluble aluminum hydroxide (a small proportion of that also inevitably dissolving too).

$$KAlSi_3O_8 + H^+ + 7H_2O = Al(OH)_3 + 3Si(OH)_4 + K^+ \quad (3)$$

Provided there is lots of rainwater available and the temperature is reasonably high (chemical reactions all speed up with increasing temperature), all rocks disintegrate to leave residues rich in hydrated oxides of aluminum and iron. In the humid tropics where both rocks and unconsolidated materials are commonly converted to duricrusts of which bauxites are aluminum rich and ferricretes the iron-rich equivalents.

Environmental Controls on Weathering Reactions

The rate (and completeness) of rock breakdown depends obviously on the availability of pure water capable of taking solute species into solution. Waters with dissolved salts already present are less aggressive because the rate of dissolution is a function of the degree of undersaturation. For both these reasons stone buildings survive longer in arid than humid climates, other things being equal. This applies also to extreme cold where no water is available for reaction; but then other forces may come into play! The basic observations of soil science thus tell us that high temperatures, high rainfall, topography (rapid movement of water away from the weathering site not allowing

the build up of solutes) and high organic productivity (high hydrogen ion input; itself promoted by rainfall and temperature) promote mineral dissolution and rock disintegration. Acid precipitation further accelerate surface weathering. It should also be noted that the salt content of pore waters increases with depth in soil profiles, accordingly they become chemically less aggressive. This pattern extends to depth within groundwater. Equally, rates of pore water movement decline sharply from the unsaturated to the saturated zone of soils and again this trend continues within groundwater. Chemical reactions which lead to mineral dissolution and rock disintegration are thus at their fastest at the Earth s surface and rates decline markedly into the subsurface.

Weathering rates have been quantified in numerous studies of building stones (and gravestones) dating back many hundreds of years. Equally, denudation studies offer quantitative estimates of the rate at which the land surface is being lowered in different climatic and topographic settings. Such studies generate data relevant to assessments of waste management strategies in different places, with various purposes and for the kinds of time interval needed for radioactive waste isolation.

Evaporative concentration of weathering solutions in arid environments can cause rock disintegration by a different mechanism; salt precipitation in pore space. Within the deeper subsurface, however, mineral precipitation leads to cementation rather than disintegration. In fact the norm when sediments are buried is diagenetic cementation. Were this not the case, of course, we would not have physically strong sedimentary rocks, notably sandstones and limestones; perhaps the most common of all building materials.

One other important environmental control on mineral stability and solute mobility is the presence or absence of excess oxidants (especially molecular oxygen) or reducing agents (notably organic matter). In water-saturated environments such as the geological subsurface, free oxygen is almost invariably absent whereas in drained soil systems, oxygen is present. Rocks with minerals stable only in reducing environments will be stable in the subsurface but not at the surface, and *vice versa*. Very energetic redox reactions ensure rapid degradation reactions when the environmental setting changes. The oxidation of sulfide minerals when brought to the surface as a result of mining operations is the most familiar example (with disastrous environmental consequences) (*see* Redox Potential, Volume 2; Contaminated Lands and Sediments: Chemical Time Bombs?, Volume 3).

Differential Stability of Solids

It takes only one mineral from an assemblage to break down and the rock will fall apart. The analogy of a chain and its weakest link is apt. From both observation and theory, the relative chemical stability of all common rock-forming minerals is known; hence it is possible to assess with confidence the geochemical stability of different rock types. A further obvious control is porosity and permeability since chemical reaction demands water access. Other things being equal, extremely tight rocks are most resistant to degradation.

Potential Host Rock Types For Deep Repositories

Three different rock types (lithologies) have been widely advocated by different agencies as suitable for deep radioactive waste disposal sites. These are crystalline rocks, shales and salt. Each has its advantages and disadvantages. Crystalline rocks have high mechanical strength and thermal stability (good engineering properties) but are often fractured. The resulting permeability may be high and is difficult to model (therefore to demonstrate safety). Shales and salt, by contrast, are low permeability rocks, which behave plastically: they are naturally self-sealing and also easy to excavate. Shale is a rather poorly defined term covering clay rich rocks, which vary from poorly consolidated, highly plastic muds and clays to less porous, more indurated and sometimes fissile rocks: mudstones or shales proper. This progression from mud through to shale records age and burial history; the older the formation, the more likely it is to be indurated. Salt is thermally stable and highly conducting, both positive attributes not shared by shales. On the other hand, salt is potentially very mobile were there to be a change in groundwater regime. All three lithologies presently host underground stores or laboratories: Sweden, Canada and Finland in crystalline basement, Belgium and Switzerland in shales and the USA in salt (Waste Isolation Pilot Plant (WIPP) site).

Theory and Demonstration: Building Confidence

This very brief review of a substantial and mature science leads us to rather surprisingly precise statements about settings and about materials that are likely to survive for long time periods: a blueprint both for containment (packaging, engineered containment) and for good geological settings. Natural analog studies allow these general observations and conclusions to be focused on specific issues in nuclear waste management. Studies of ancient uranium ore bodies, for example, prove that, in certain situations, solution and migration have not occurred over millions of years: natural containment has been complete. In this particular case, of course, it is the natural radioactivity that gives us precise dates for the original mineral formation. In a similar way, the stable isotope equivalents of key radionuclides can be studied in a range of geological environments and ages. Such studies should build confidence in management strategies for the necessary very long management terms required by regulation.

Climate and Climate Change (Arid/Humid Changes, Sea level change, Warm/Cool Transformation ± Glaciation)

From the previous discussion it follows that climate change (time scale 10 to 10^3 years) will influence the stability of rocks and synthetic materials at the surface and in the subsurface. Chemical degradation rates at the surface will decline markedly going from a humid to an arid climate, and *vice versa*. In desert environments the effects of physical disturbance last for decades whereas all traces of such disruption are quickly lost in the humid tropics where chemical and biological activity are both intense. As yet, the science of global climate modeling is insufficiently advanced for any kind of confident long-term (centuries) prediction. Historical rates of change are well documented in the geological and oceanographic literature and give some indications of stability and uncertainty.

Deep subsurface environments are very much less sensitive to climate and, obviously, to climate change. Within an arid basin of low topographic variation, groundwater will be saline and, almost certainly, stratified. The density difference between meteoric water and saline brines is sufficiently great to demand high pressure-heads for displacement. Consequently, a change to a more humid setting would simply establish strong salinity/density gradients in groundwater and effective isolation of deep from shallow water systems. So geological (and other) materials at depth are very much less susceptible to chemical modification than those at the surface and also less sensitive to climate change.

There are examples of deep penetration of fresh, aggressive water which apparently has caused significant dissolution (porosity and permeability enhancement: important in oil and gas reservoirs) but these seem invariably linked to high differential topography.

There is abundant evidence of sea level change throughout geological history clearly preserved in virtually all sedimentary rock successions. Such changes will modify groundwater regimes in the coastal zone, delineated by the extent of rise/fall. Seawater will easily displace freshwater but not the reverse so the overall effect is probably to promote the development of salinity stratified waters in sedimentary basins (the observed norm).

The glaciation end of the cycle lowers sea level to a minimum. Glaciers themselves, however, are in hydraulic continuity with groundwater and can generate high hydraulic heads which could lead to anomalous displacement of groundwater with glacier derived meteoric water. Zones of actual or potential glaciation therefore pose substantial questions about the nature of chemical reactions in deeper rock sequences: uncertainties not present in non-glacial settings.

Sea level change and, especially, glaciation lead also to physical erosion. In both cases the effects are more or less continuous with transgression of shorelines, down-cutting of river systems and deep glacial excavation.

Discontinuous Physical Erosion Processes

Unlike glaciation or sea level change, the essentially statistical nature of weather means that most erosion by storm or tidal surge (or other events) means that almost all the action takes place once every 10^2 or 10^3 years with really not much happening in between. Risks of this kind are easily identified and evaluated: it is surely rather surprising, even allowing for the benefits of hindsight, to note just how many NPPs and manufacturing facilities have been constructed so very close to the ocean in Europe and in North America. Like chemical degradation, the physical threat to materials and structures at the Earth s surface is very obviously much greater than that to similar materials and structures located in deep geological formations.

Earthquake, Volcanicity Tsunamis

There are also disruptive events generated by crustal processes. Stress releases cause fault displacements. Individual fractures are confined to very small, two-dimensional zones and the probability of one intercepting (and destroying) a structure is very low. Moreover, the distribution of fault zones on the Earth s surface is well characterized and those with high activities can be avoided without difficulty. A much bigger problem is the energy released by displacement events (earthquakes). This can destroy structures by shaking or secondary land deformation (foundation failure, landslips, etc.) over 10 s to 10^4 km^2. Submarine energy releases cause waves which can travel great distances and which have devastating consequences for coastal zones they intercept (tsunamis).

MANAGEMENT PRACTICE

Waste Management Principles and Practice

In spite of 50 years of radioactive waste generation, no nation has yet put into practice any long-term solution for spent fuel and high liquid wastes (HLW). The International Commission for Radiological Protection and the Earth Summit (1992 UN Conference on Sustainable Development) cite the principle of intra-generational equity: that management burdens should not be passed on to future generations. This argues clearly for disposal: there will be no future management requirement. For a variety of reasons the opponents of nuclear power argue against disposal in favor of temporary surface storage. One case made is that available scientific and technological knowledge on waste disposal is not good enough; that we will not hand on a worse problem (a failing repository: although no

systematic analysis of such failure and its consequences has, to my knowledge, been undertaken). It is also true, however, that a solution to the waste management problem would give the green light to the nuclear industry. These opposing views and values are not for debate here but the alternatives are clear. We either surface store (for some indeterminate period) or we attempt some more permanent solution, deep disposal being the apparently obvious choice. Where does the geological perspective lead us in this debate? As outlined above, shielding is easy but containment is not. The principal threat to health is contamination of surface and groundwater used for drinking and agriculture.

Surface Store

The least expensive form of management in the short term is surface storage. Dry stores take conditioned waste forms (see the section on monitored, retrievable deep store) and store them in a facility which:

- provides security (against terrorist acts and thefts of fissionable material);
- provides shielding (against worker/public irradiation);
- provides cooling (for HLW and spent fuel);
- allows continuous monitoring (for containment failure);
- is designed to contain leakages (since very accessible to the biosphere);
- provides a facility for repackaging when failure occurs.

The key element here is that continuous management is required (with finite doses for management staff). The design of the facility will be such as to minimize the effects of weathering (protection from the elements) and to minimize the effects of catastrophic natural events. The design life of store buildings is likely to be tens of years, certainly not hundreds or thousands.

Provided management is assumed, no long-term safety case is required. Delivery of such stores should be relatively straightforward and modern NPPs may install sufficient spent fuel storage capacity for their entire working lifetimes.

It is inconceivable that the regulatory requirements for disposal could be made for surface disposal. Exposure to both natural degradation processes (weathering, erosion, flooding) and man-induced failure (accidental damage, terrorism, economic breakdown with consequent failure of management regime) would all seem to be almost infinitely greater at the surface than deep beneath the ground in a reasonably well chosen location.

Deep Disposal

Although a simple comparison of surface and deep disposal suggests the latter to be very much safer in the long-term, possible failure mechanisms have been studied in great detail as part of the preparation of post-closure performance assessment: as required by regulators. The geosphere (i.e., the rocks above the repository) provide perfect shielding but must be evaluated for possible radionuclide escape pathways. In general, repository design concepts are based on the so-called multiple barrier approach. Conditioned waste is placed within sealed canisters which, in turn, are surrounded by engineered barriers (absorptive clay, concrete, etc.) which provide both physical and chemical containment. The geosphere itself acts as a barrier to radionuclide migration and provides physical protection for the engineered barriers. The properties of the geosphere (rock permeability, hydrodynamic regime, geochemical environment, tectonic stability, presence or absence of natural resources likely to be sought, sensitivity to climate change) are evaluated at the site selection stage, final choice obviously being guided by some form of multi-attribute analysis.

Monitored, Retrievable Deep Store

In recent years, consultation exercises have revealed that the general public doubt the safety case made for deep repositories (in one sense, of course, proof is unattainable: it is fundamentally impossible to prove the negative). Special interest groups aiming to end all nuclear power generation encourage and sustain this doubt. They see that a good, safe solution to the waste problem would offer a green light to expansion of the nuclear industry. This being the case, it follows that it is not in their interest to find good solutions to waste management problems.

The case for proving the very long-term safety of a repository is very difficult: harsh regulatory targets have to be met for times much longer that the history of the human race! The only way to demonstrate such safety cases is via risk analysis and mathematical modeling: neither is easy to explain nor is likely to give reassurance to the non-specialist. For this reason thought is now being given to designing deep repositories with some of the apparent benefits of surface stores. The integrity of the conditioned waste can be continuously monitored up until the time of closure (and for some time thereafter) and, up to that time, waste can also be retrieved easily.

It is also apparent that a fail-safe element can be designed into deep repositories. The failure of institutional control would remove management and immediately expose surface stores to terrorist threats or accidental damage in the short-term whereas deeply stored/disposed material would be much less vulnerable.

Very Deep Disposal

Various suggestions have been made for very deep disposal of HLW or Pu at great depths (several kilometers) by

drilling. In the most elegant designs, sufficient heat is generated by the waste just to melt surrounding crystalline rock. On subsequent dissipation of some of the heat so generated, the melt would fuse, encapsulating the waste in a large impermeable container. Retrieval would not be possible but once so entombed, it appears very unlikely that significant waste would ever escape within the decay period of almost all radionuclides.

THE GEOLOGICAL PERSPECTIVE IN SUMMARY

Geologists, and earth scientists more generally, work with natural materials and processes which take place on time scales comparable with those required for nuclear waste to be contained and stored (until its radioactivity has decayed to such low levels that they no longer pose an hazard to Man and the environment). These time intervals are many times longer than the totality of civilization such that conventional technology has absolutely no relevant record of performance.

The regulators, nevertheless, have stipulated that any repository designed for permanent disposal (i.e., a sustainable waste management solution) must meet safety standards extending far beyond the likely survival of *Homo sapiens*. The only way that future performance can be assessed is by mathematical modeling. The only reasonable validation is by analysis of processes spanning equivalent time periods historically: geological studies of natural analogs.

Geological studies demonstrate that natural circumstances have prevailed which, over millions of years, have isolated materials analogous to conditioned radioactive wastes. It therefore seems likely that repository designs, which maximize the benefits of natural geological containment are likely to meet the most stringent (and barely sensible?) regulatory requirements. Rock properties such as low permeability and high chemical retardation are not rare. Sites with very low groundwater flow tendency, which are tectonically stable, which are insensitive to the effects of weather and of climate change should not be too difficult to locate.

The geological perspective thus suggests that deep geological disposal is a safe option and certainly much safer than long-term surface storage where conditioned wastes are hugely more exposed to degradation (natural and man-induced) and eventual leakage directly to the accessible environment and biosphere. Deep geological disposal similarly reduces vulnerability to global environmental change, particularly to the suggested increasingly common extreme meteorological events.

The information upon which this perspective is based must be made available to the general public such that informed debate can take place and informed policy developed. The geological perspective is only one of several which must be brought to bear on this complex and pressing problem. As time passes, the problem gets more urgent as most of the world s economies are becoming less robust. How many will be able to meet the costs of management and, indeed, how many of the stronger economies have actually made real provision to meet the costs? Within this depressing scenario, those groups who regard delay as success may be celebrating pyrrhic victories.

Nuclear Winter

The enormous direct impact of nuclear explosions in warfare was dramatically demonstrated in the Japanese cities of Hiroshima and Nagasaki on August 6th and 9th, 1945, causing the death of 120 000 people from the heat and the shock waves of the explosions. The explosive power of the two weapons was equivalent to 15 and 21 ktons of trinitrotoluene (TNT), corresponding to energies of 6.3

and 8.8×10^{12} J, respectively. In the meanwhile, despite some reductions in nuclear arsenals in the US and the former Soviet Union, the total worldwide number of nuclear weapons is still more than 10 000, each with explosive powers averaging 20 30 times those of the Hiroshima and Nagasaki weapons. These weapons are mainly in the possession of Russia and the US. Although the impact of a nuclear war with the current arsenals can not be scaled up linearly from the experiences in Hiroshima and Nagasaki, the devastating direct impact of a nuclear war on the nations involved in such a nuclear conflict would still be enormous.

However, the potential impact on humanity resulting from the effects of a nuclear war was actually, for a long time, much underestimated. Following an article by Crutzen and Birks in the beginning of the 1980s, a large number of scientists drew attention to the large climatic and environmental consequences, which would result from the large amounts of highly sunlight-absorbing black smoke, which would be injected into the atmosphere by the many fires that would start burning after nuclear explosions in cities and in oil depots (Crutzen and Birks, 1982). As a consequence of the enormous loading of the atmosphere with the black smoke, and its transport over much of the Northern, and part of the Southern Hemisphere, sunlight at the Earth s surface would be much reduced over large tracts of the Earth. Also, as a consequence of the major reductions in sunlight, temperatures at the Earth s surface could become greatly reduced, possibly to below freezing even during the summer. Together, the nuclear war could upset crop production over much of the Earth, putting a large fraction of the Earth s population at risk of starvation and death, including people living in the attacking nation. The combination of darkness and freezing temperatures is known as *nuclear winter*, a name first coined by Richard Turco, now at the University of California, Los Angeles.

Oil and the Arctic Environment

David J Thomas
Axys Analytical Services Ltd., Sidney, Canada

Petroleum hydrocarbons have been detected in all abiotic and biotic compartments of the circumpolar arctic environment and have both local and regional sources. One of the greatest concerns for ecological impact in the arctic environment is related to oil spills because the severity and persistence of the impacts will be greater than those in temperate and tropical environments where biological recovery is faster due to higher growth rates, longer growing seasons, faster generation turnover times and lower ages at maturity. Moreover, physical characteristics of the Arctic such as permafrost, sea ice regime, severe temperature and remoteness could make clean up of oil spills exceedingly slow and in some cases impossible leading to long-term exposures and impacts.

The traditional de nition of the Arctic, namely that area of the earth north of the Arctic Circle, is generally inadequate for environmental applications because it fails to take into account physical, geographical and ecological characteristics. Instead, the Arctic Environment can be thought of as the area north of the tree line and the 10°C July isotherm; speci cally, the terrestrial and marine areas north of the Arctic Circle and north of 62°N in Asia, and 60°N in North America modi ed to include the marine areas north of the Aleutian chain, Hudson Bay and parts of the North Atlantic Ocean including the Labrador Sea.

Oil is a general term used to describe a wide variety of natural substances of plant, animal or mineral origin and a group of synthetic compounds. In this paper, oil is taken to mean crude oil or petroleum, a substance which consists primarily of a series of complex hydrocarbon compounds such as alkanes, naphthenes, aromatics and alkenes. Crude petroleum is a complex and variable mixture of hydrocarbons of different molecular weight and structure, and contains as many as 300 different petroleum hydrocarbon compounds.

SOURCES

Petroleum hydrocarbons in the arctic environment have both natural and anthropogenic sources. The primary natural source is seeps from geological formations. Smaller quantities of specific petroleum hydrocarbon compounds are produced naturally by bacteria, fungi, and higher plants and during the incomplete combustion of organic materials such as wood, coal and oil. Anthropogenic sources include chronic discharges from oil and gas exploration, development and production activities, accidental releases from oil spills, discharges from shipping and atmospheric deposition. A summary of possible sources is shown in Table 1.

Natural Oil Seeps

The presence of petroleum seeps has been documented in many areas of the Arctic including Canada (Mackenzie River Delta), the US (several locations along the Beaufort Sea Coast), the Barents Sea and near Spitzbergen (Figure 1). The largest seepages occur in north-flowing rivers (e.g., Mackenzie River and Ob River) which eventually discharge the petroleum hydrocarbons into the Arctic Ocean. The rate of natural seepage of oil into the arctic marine environment relative to total input is thought to be greater than the 15% estimated for the global marine environment (GESAMP, 1993).

Table 1 Sources of petroleum hydrocarbons to the Arctic environment

Natural	Oil seeps Biogenic synthesis Transport by ocean currents Transport by northward-flowing rivers Transport by air movements from subarctic and temperate regions
Anthropogenic	Transport by ocean currents Transport by northward-flowing rivers Transport by air movements from subarctic and temperate regions Oil and gas exploration, development, production (operational discharges, blow-outs) Transport of crude and refined oil (accidents from tankers at sea, tanker ballast washing, leakage/spillage from pipelines and tanker trucks on land) Transportation (discharges and spills from shipping, emissions and leakage from vehicles) Land-based discharges and run-off (municipal waste water, refineries, industrial waste water, combustion of wood and fossil fuels)

Oil and Gas Exploration, Development and Production

The Arctic may contain some of the world s largest oil and gas reserves. Current proven reserves are approximately 17 billion m^3 of oil and it is estimated that undiscovered, conventionally recoverable oil may exceed another 20 billion m^3.

Significant hydrocarbon exploration has taken place both offshore and on land in the Canadian Arctic during the past 30 years, but no permanent production facilities exist except for those at Norman Wells on the Mackenzie River. Production is approximately 2 million m^3 per year.

In the US Arctic, large-scale production of oil has occurred since 1977 when the Prudhoe Bay fields began shipping oil south via the Trans-Alaska Pipeline System. It is estimated that about 7 billion m^3 of oil are still recoverable from the Prudhoe Bay and adjacent fields (AMAP, 1998). In addition, expected production from undeveloped offshore areas will be about 0•08 0•43 $\times$ 10^9 m^3 and 0•05 0•24 $\times$ 10^9 m^3 for the Beaufort Sea and the combined Chukchi Sea Hope Basin region, respectively (MMS, 1996).

Oil and gas exploration and production activities in the Russian Arctic occur primarily (1) in the Nenets Antonymous District of the Arkhangelsk region, (2) in the Komi Republic within the Pechora River drainage basin, and (3) in the Yamal-Nenets Antonymous District of Western Siberia. Total annual production exceeds 100 million m^3 of crude oil, 740 trillion m^3 of natural gas and 2.2 million m^3 of gasoline (figures in tonnes have been converted to m^3 assuming a specific gravity of 0.9). Large oil and gas fields have been discovered along the continental shelf areas of the Barents, Kara and Pechora Seas.

The only remaining significant oil and gas activity in the Arctic occurs in the Norwegian portions of the Barents Sea and in the Norwegian Sea. Total proven reserves are approximately 400 million m^3 of oil and natural gas liquids, and 350 million m^3 of gas (NPD, 1995). Undiscovered reserves are estimated to be similar in size to proven reserves.

Chronic point source losses of petroleum hydrocarbons to the environment are associated with most oil and gas exploration, development and production activities. Primary sources of relatively minor petroleum hydrocarbons include discharge of oil-base drilling muds, oiled drill cuttings, rig wash, produced water and periodic accidental losses of refined petroleum products.

Blow-outs, tanker spills and leakage, however, pose the largest threat from oil pollution to terrestrial and aquatic ecosystems in the Arctic. To date two large-scale spills have occurred: (1) 1989: the EXXON Valdez tanker accident where 35 000 tonnes of crude oil entered the marine environment (*see* Exxon Valdez Oil Spill, Volume 5), and (2) 1994 1995: the pipeline rupture at Usinsk, Siberia where more than 100 000 tonnes of crude oil flooded rivers, lakes and tundra. In both cases, significant damage was done to the flora and fauna of the arctic environment, damage that will take decades to repair.

Shipping

Currently, inputs of petroleum hydrocarbons to the arctic environment related to routine marine transportation are limited by the small amount of ship traffic. The most common arctic shipping is associated with sealifts to isolated communities and industrial facilities, ice breaker support for sealift traffic, fishing, seismic and oceanographic research and supply of offshore drilling operations. The potential exists for large inputs, however, as a result of the likely expansion of traffic on the Northern Sea Route (NSR). The NSR is a system of sea lanes north of Asia joining the Kara and Barents Seas in the west with the Bering Sea in the east. It was officially opened by the former Soviet Union in 1987; annual inputs of petroleum hydrocarbons, largely from illegal dumping of bilge waters and accidental fuel spills, vary between

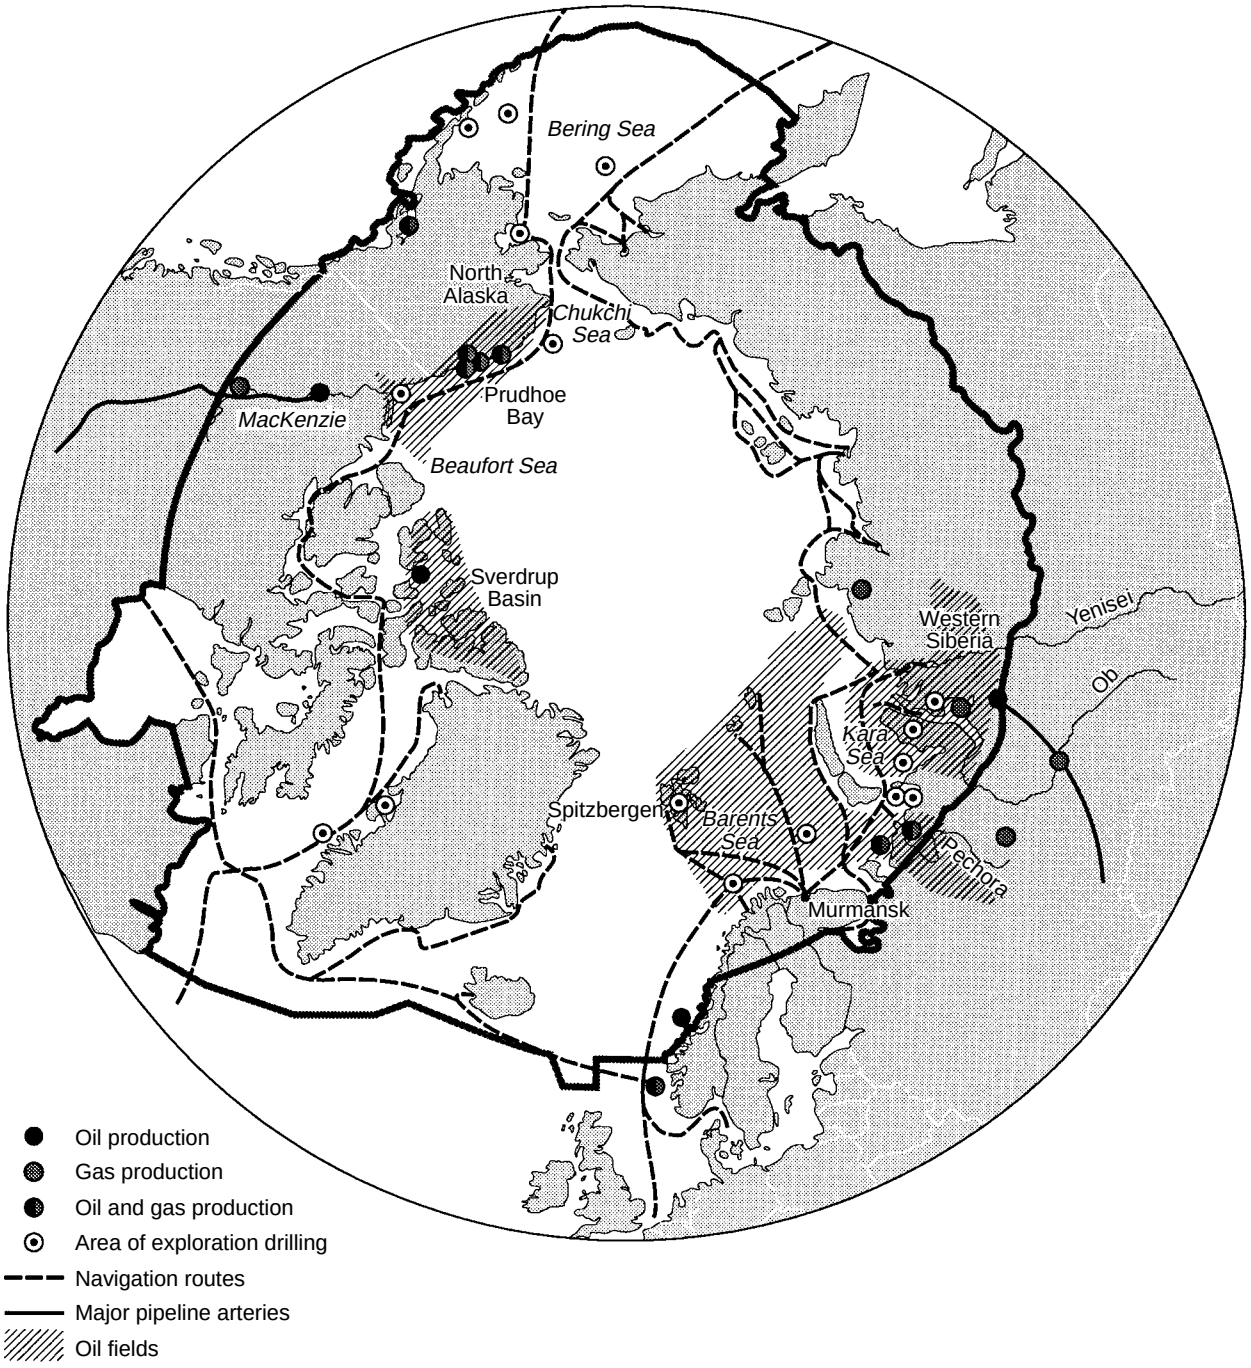

Figure 1 Main oilfields, production and exploration wells of the Arctic showing pipelines and navigation routes

15 and 1500 tonnes, depending on year (Melnikov *et al.*, 1996).

Local Municipal Sources

Most human settlements in the Arctic are low in population and generally constitute a limited source of petroleum hydrocarbons. Exceptions occur in the Russian Arctic where cities can be large, industrial activity significant, and only poor infrastructure development exists to deal with municipal and industrial wastes. For example, Murmansk (pop. 500 000) on the Kola Peninsula has no municipal waste treatment facilities at all. Annually, it discharges about 65 million m^3 of untreated waste water containing 56 tonnes of petroleum products directly into Kola Fjord. Total annual discharge of wastewater to the Siberian Shelf

coastal zone from coastal settlements is approximately $36 \times 10^6\,m^3$ and $21 \times 10^6\,m^3$, untreated and treated, respectively (AMAP, 1998).

CONCENTRATIONS OF PETROLEUM HYDROCARBONS IN THE ARCTIC ENVIRONMENT

The largest quantity of data for petroleum hydrocarbons in the Arctic pertains to Russia. The main reason for this is not that petroleum hydrocarbons are necessarily more problematic in Russia, but rather that Russia is the only circumpolar nation that has conducted systematic, long-term monitoring of petroleum hydrocarbons in the Arctic.

The geographical coverage of samples for petroleum hydrocarbon levels across the Arctic is generally poor because most sampling has been limited to relatively accessible locations close to sites of human activity. Samples are more commonly available from the aquatic environment (marine and freshwater) than from the terrestrial environment. There are especially few measurements of petroleum residues in biota as such measurements have not been emphasized in most sampling programs. This is largely because petroleum hydrocarbons are not generally persistent in the environment. Additionally, although many of the petroleum compounds, particularly aromatic hydrocarbons, are rapidly bioaccumulated, they are also readily metabolized by many organisms, particularly fish and other vertebrates.

Direct comparison of the values obtained by the various programs which have measured petroleum hydrocarbons in the Arctic are often impossible because of typically wide differences in the analytical methods, instrumentation, quantification, and reporting used to produce the results. Some values, particularly those produced by non-specific analytical techniques, tend to overstate the amount of petroleum hydrocarbons present in a sample. Other values, especially those which are based on the sum of individual compounds, tend to understate the total amount of petroleum hydrocarbons present. The lack of consistency among the data sets severely limits their usefulness for analyses of spatial and temporal trends.

It is also important to note that few of the petroleum hydrocarbon compounds, which comprise crude oil, are unique to crude oil. Many have terrestrial biogenic, marine biogenic, pyrolytic or diagenetic sources. Consequently, values reported as petroleum (or oil) residues often include components from non-petroleum sources.

Concentrations in the Arctic Marine Environment

In general, the concentrations of dissolved petroleum hydrocarbons (detected by infrared) for samples from the Russian Arctic are higher in river estuaries than at offshore locations. The concentrations are also generally higher in surface than in subsurface waters. Both trends strongly suggest anthropogenic sources.

In the shelf seas, dissolved petroleum hydrocarbon concentrations are usually highest just off of the river mouths, and tend to decrease with increasing distance from these areas. Reported concentrations of dissolved petroleum hydrocarbons in marine waters of the Russian Arctic are generally much higher than those found in North American areas.

The highest concentrations of petroleum hydrocarbons are observed in the vicinity of seaports, such as in Kola Fjord near the port of Murmansk. During winter, when the waters of the Kola Fjord are relatively stagnant, concentrations of total hydrocarbons in surface water and bottom water exceed the maximum permissible concentration (MPC) of $50\,mg\,l^{-1}$ set by the Russian Federation by factors of 150 and 36 126, respectively. The average concentrations of paraffin oil in surface water and bottom water are five times the MPC and 35 times the MPC, respectively. In contrast, during summer, when water movements throughout the fjord are greatly increased, concentrations of total hydrocarbons seldom exceed two times the MPC (ACOPS, 1995).

The concentrations of total petroleum hydrocarbons in marine sediments from the Russian Arctic are highly variable. The highest concentrations have been reported from the Ob and Yenisei estuaries, and the Baydaratskaya Gulf.

The few measurements of dissolved, low molecular weight hydrocarbons in the Canadian Beaufort Sea indicate that methane is relatively high for marine waters and highest in concentration near the seabed, suggesting that the sediments are a methane source. Concentrations of methane, ethane and ethylene in some samples from the Chukchi Sea, Bering Sea and Norton Sound also show a near-bottom enrichment, also indicating a sedimentary source for these compounds. As high ethane, propane and n-butane concentrations were not found in conjunction with the high methane concentrations in the American and Canadian Beaufort Sea samples, petrogenic activities can be ruled out as a source. Very few measurements have been made of alkanes in seawater because background concentrations are generally well below historical detection limits. The few data that do exist, however, indicate individual alkane concentrations are in the low part per billion range and are derived from terrestrial plants, not crude oil.

Taken as a whole, the reported concentrations for alkanes, aliphatics and petroleum hydrocarbons in arctic marine sediments are highly variable in part because few have been normalized against particle size. Interpretation of sedimentary hydrocarbon assemblages generally strengthens the conclusion that the hydrocarbon

content off most coastal and shelf sediments usually reflects multiple sources: specifically, there are marker compounds present which are characteristic of both crude oil and terrestrial plant materials (Thomas, 1988; Steinhauer and Boehm, 1992; Yunker *et al.*, 1993).

Low levels of petroleum hydrocarbon contamination have been detected in various biota samples (including flounder, sculpins and zooplankton) throughout the arctic marine environment.

Concentrations in the Arctic Freshwater Environment

It is well documented that the Russian Arctic rivers, especially in areas of oil and gas exploration and production such as the lower reaches of the Ob River, are heavily contaminated with petroleum hydrocarbons. Data from the Russian Federal monitoring network show that mean concentrations of hydrocarbons in water samples obtained from this river, in the areas of the most extensive oil extraction activities, and determined with IR-spectrophotometry, exceeded the established standards for freshwater (MPC $= 50\ \bullet \mathrm{mg\,l^{-1}}$) by 12 16 times, although it is generally accepted that for analytical reasons these values are over estimated (AMAP, 1998). By contrast, dissolved petroleum hydrocarbons in the Mackenzie River occur at sub-nanogram to low nanogram per liter concentrations, which are considered to represent background (Erickson and Fowler, 1987).

Mean concentrations of petroleum hydrocarbons in bottom sediments at the mouths of Russian Arctic rivers during the period 1991 1993 were in the range of about 30 60 $\mathrm{mg\,l^{-1}}$, and thus similar to data from the Mackenzie River, and rivers along the US Beaufort Sea Coast. The highest concentrations were found in the Pechora and Ob Rivers.

A survey of petroleum hydrocarbon contamination of the bottom sediments in the Pechora River Basin was made in 1994 1995, in connection with the Usinsk oil spill. In the immediate vicinity of the oil spill site, the concentration of oil was approximately 1.4%. In the mouth of the Kolva River, the hydrocarbon concentration decreased to 0.05%. Farther downstream, however, where the Usa River flows into the Pechora, the bottom sediments were strongly contaminated with hydrocarbons (1.6%), a result of particular hydrological conditions of the river at this site which are favorable for sediment accumulation. Farther downstream, the concentrations did not exceed 100 $\mathrm{mg\,l^{-1}}$. These observations emphasize the importance of factors such as particle composition and hydrological conditions in influencing the distribution of petroleum hydrocarbons in rivers and also proximity of sources; even relatively large volume oil inputs are primarily a local-scale environmental phenomenon.

Concentrations in the Arctic Terrestrial Environment

Data on the concentrations of petroleum hydrocarbons in soils are only available for Russia. Background levels appear to be approximately 10 40 parts per million. A great potential for pollution of the Russian Arctic terrestrial environment is associated with spills and leakage from oil pipelines. A recent example is the 1994 Komi spill in the drainage area of the Pechora River. A survey of the spill site made in the autumn of 1994 showed that the total area affected by accidental and operational releases was 1 320 000 $\mathrm{m^2}$, with a mean level of soil contamination of 0.3%. The concentration of oil in the soil 5 m from the main leakage site was 15%.

Further large volume losses of oil from pipelines in the Russian Arctic seem likely. Almost all of the oil and gas is transported from the extraction fields to processing plants by pipelines, most of which have exceeded their design life and have not been well maintained over the years.

BIOLOGICAL EFFECTS FROM OIL SPILLS

The potential effects of petroleum pollution on the various arctic ecosystems (terrestrial, freshwater and marine) depend on a number of factors including type of oil, size of spill, time of year (temperature, photoperiod, life cycle stage of biota), location (proximity to sensitive and vulnerable biota), etc. The duration and severity of the impacts will generally depend on how all the factors combine to influence oil spill countermeasures and to influence the many weathering processes, which begin to modify the oil immediately after it is spilled. These factors include evaporation, photochemical degradation, dissolution, bacterial mineralization, emulsification, adsorption and mixing. In general, biological effects of oil spills are similar in tropical, temperate and arctic ecosystems for related or similar types of biota. The important environmental differences are those, which affect the distribution, composition, and physical state of the petroleum hydrocarbons in space and time, i.e., their bioavailability. Typical biological effects can be lethal and sub-lethal. They are expressed in the ecosystem by loss of certain species; changes in species biomass, diversity, distribution and abundance; effects on reproduction and growth; and short-term and long-term toxic physiological effects. The severity of any effects is usually thought to be greater in arctic ecosystems than in more temperate ones because it will generally take arctic ones longer to recover from oil damage. This is because of typically slower growth rates, shorter productive season lengths, longer generation turnover times and longer ages to maturity.

An oil spill on land generally will be more confined than a spill in the aquatic ecosystem. However, the duration

of exposure and effects could be longer in the terrestrial setting if the oil migrates downward through the soil where degradation is inhibited.

A similar protracted spectrum of effects is also possible in the marine ecosystem if oil is spilled under multi-year ice. In this case, the oil remains practically unchanged until the ice thaws creating the possibility of extensive spreading and longer exposure periods to toxic components of the crude oil.

It is also important to note that due to the fragility of the arctic ecosystems (particularly the terrestrial and freshwater ecosystems) a quicker recovery could be achieved from a spill by not further damaging sensitive environmental components as a result of the countermeasures effort.

Significant oil spills can also have potentially serious social implications in the Arctic. Many of the indigenous peoples in the circumpolar countries have diets and social structures that rely heavily on the use of local flora and fauna. This traditional reliance on the land together with the related hunting and gathering activities provides a rich cultural heritage and folklore, strong social interactions and a strong sense of identity among indigenous peoples of the Arctic. Consequently, long- or even relatively short-term displacement or alteration of the access to traditional food items caused by oil spills or the resulting cleanup operations could have far reaching consequences.

POTENTIAL EFFECTS OF GLOBAL CLIMATE CHANGE

It is commonly accepted that the effects of global climate change will be considerably greater in Arctic regions than on a global average. Measurements over the past 40 years, for example, confirm that the rate of global warming has been greatest between 40 °N and 70 °N, thus overlapping the area between approximately 60 °N and 70 °N where most of the oil and gas activity occurs.

Climate warming will have a profound effect on the distribution and characteristics of sea ice, snow cover, tundra, surface water drainage, permafrost and vegetation, among others. This will lead to new spatial and temporal overlaps between Arctic biota and present and future oil and gas activities, thereby having a significant influence over how and when exploration, construction and production of oil and gas reserves occurs. It will probably also increase the impact of oil spills and the subsequent cleanup activities. Sound science-based decision making and the use of proven, appropriate engineering practices will be essential to ensure that development does not occur in a way that exceeds the ability of engineering and management to operate safely and in an environmentally friendly way in the Arctic.

Two other concerns and research priorities should be mentioned:

1. The arctic permafrost may weaken or even collapse in a warmer climate, releasing methane and creating problems for pipeline construction and overland transport (*see* Permafrost, Volume 1).
2. Methane clathrate deposits will need to be investigated (*see* Methane Clathrates, Volume 1).

Oil Fires: Kuwait

Tahir Husain
Memorial University of Newfoundland, St. John's, Canada

The Gulf War aftermath witnessed two historical environmental episodes, i.e., the largest oil spill on record and torching of more than 700 oil wells in the Kuwaiti oil fields. Other impacts were those associated with the damage to the terrestrial environment caused by massive troop movements, the release of ammunition during ground and air battles, potential release of toxic materials into the environment during the war, and the deployment of land and sea mines. The estimates of the volume of oil spilled into the marine environment as a result of the Gulf War ranged from 7 to 11 million barrels. Over 640 km of shoreline extending from Kuwait to Abu Ali Island in Saudi Arabia was impacted by the oil slick.

The problems arising from the torching of more than 700 oil wells in the Kuwaiti oil fields in February 1991 are discussed here. According to the estimates by the Kuwaiti Oil Company (1991), 605 oil wells were on fire, 108 wells were damaged and 46 wells were gushing oil on a continuous basis. Approximately 22 000 tons of sulfur dioxide (SO_2), 18 000 tons of soot, and thousands of tons of carbon monoxide and oxides of nitrogen (NO_x) were emitted by these wells as a result of 2.5 million barrels of oil lost initially on a daily basis (Husain, 1995). The unburned and partially oxidized oil was separated into: (a) heavy drops which fell to the ground within the vicinity of the fire and contributed to the formation of oil lakes, and (b) fine droplets of oil which behaved like a spray which traveled with the plume for some distance and then fell to the ground.

EFFECTS ON THE TERRESTRIAL ENVIRONMENT

The most obvious environmental problem during the Gulf War was due to the impact caused by the largest oil spill on record and torching of more than 700 oil wells in the Kuwaiti oil fields by the Iraqi troops before the conclusion of War in February 1991. The plume from the burning oil field as shown in Figure 1 was towards the south and southeast covering the eastern part of the Kingdom of Saudi Arabia. The environmental consequences of the Persian Gulf War on the terrestrial environment in the region can be summarized as follows (Husain, 1995; Husain and Amin, 1994; WMO, 1992):

1. The smoke plume was usually below 2 km and was never detected above 6 km from the base of the oil fires. The particulate counts within a few kilometers from the source were very high ($10^5\,cm^{-3}$) but decreased with distance. At about 300 km from the fire the particle counts were in the range of 5000 to 15 000 cm^{-3} while beyond 1000 km from the source, the counts decreased to the range of 300 500 cm^{-3}.
2. The plume was usually not photochemically active until it had traveled over 200 km. Within the plume at about 1000 km downwind, the ozone concentration was found to be relatively high but there was no indication of a regional oxidant episode.
3. The meteorological conditions in the area during March to October 1991 were such that materials in the plumes were largely confined to the horizontal cloud without much mixing down to the surface. Hence, pollution levels at population centers in the region, although higher than normal, were less than initially predicted.
4. The deposition of soot on the ground surface within 100 km from the source was more than 500 mg m^{-2}. Between 100 and 300 km downwind from the source, the deposition was estimated to be in the range of 100 to 500 mg m^{-2}. The soot deposition level between 300 and 500 km radius downwind was found to be in the range of 50 to 100 mg m^{-2}. The effect of soot from oil fires was observed even beyond 500 km from the source.

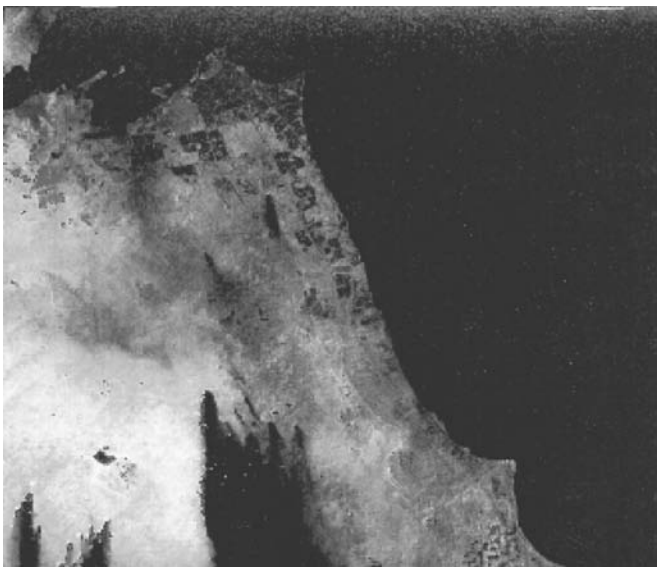

Figure 1 Plumes from Kuwaiti oil fields during oil fires in 1991

Soil samples were collected from different locations near the source of the oil fires and from other locations in Kuwait. The analysis of these samples showed that the concentration of organic constituents on the surface of the soil was much higher than in the deeper soil (Husain, 1995).

Table 1 Comparison of gaseous pollutants in post-war (1991) and pre-war conditions

Stations	SO_2 ($\mu g\,m^{-3}$)	NO ($\mu g\,m^{-3}$)	NO_x ($\mu g\,m^{-3}$)	Non-methane hydrocarbons ($mg\,m^{-3}$)	Methane ($mg\,m^{-3}$)
Mansoria (30 km north of Burgan oil field)					
Pre-war 1990	4.69	30.00	77.60	0.29	1.15
1991	5.99	16.40	43.20	1.33	1.74
Increase (as a %)	+28	−45	−44	+352	+50
Rega (about 15 km northeast from Burgan oil field)					
Pre-war 1990	3.65	35.20	83.60	0.27	1.13
1991	7.82	120.40	161.60	0.41	1.09
Increase (as a %)	+114	+242	+93	+48	−4
Average increase (as a %)	+71	+98	+25	+200	+23

The concentration of inhalable particulates was high and in many cases it was above the permissible limit of $340\,\mu gm^{-3}$. On the other hand, the level of gaseous pollutants was usually lower than the permissible limit but comparing the value in 1991 during oil fires with the prewar situation, it was found that the pollutants were elevated by 200% in some cases. Table 1 lists the concentration levels during the Gulf War and the prewar situation at two locations in Kuwait.

EFFECT ON WEATHER AND THE MARINE ENVIRONMENT

About 10% of the sun s radiation was transmitted through the thickest part of the super composite plume, 75 80% of the sun s radiation was absorbed, and the remainder was scattered by the smoke in the super composite plume (Hobbs and Radke, 1992). A temperature drop of up to 10 °C in Kuwait and in northern Saudi Arabia was recorded. Seawater temperature in the Gulf was considerably lower during 1991 as compared to previous years. The measurements at about 250 km from Dhahran towards Kuwait showed a decline of 2.5 °C in mean sea temperature in 1991 mainly because of the smoke plume covering the area. Total solar radiation in the Arabian Gulf coast near Dammam in 1991 was only 79% of the 1990 recorded value. Due to the reduction in mean temperature and solar radiation, fisheries in the Arabian Gulf were severely affected (McCain *et al.*, 1993). The shrimp catch by the Saudi Fisheries Company in 1992 was significantly reduced compared to the level before the Gulf War, with estimated loss to the prawn fisheries of US$55 millions. In 1992, the catch of adults and juveniles was only $1.5\,tons\,boat^{-1}\,year^{-1}$ compared to 195 205 $tons\,boat^{-1}\,year^{-1}$ in 1989 1990.

The spawning biomass index also fell to about 1.8% of its pre-war year level. The prawn landing fell to 2.5 tons in the first half of 1992 compared to 4000 tons in 1989 (Mathews *et al.*, 1993). A plankton survey showed that eggs/larval abundance declined significantly in 1992. One of the causes of such a decline in prawn population was the decrease in solar energy on the prawn spawning grounds, the deposition of soot on the water surface and the oiling of tidal and sub-tidal areas in the region.

CONCLUSIONS

The air pollutants from the Kuwaiti oil fires were complex mixtures of many organic and inorganic compounds. Some of these compounds were toxic to human health and their concentrations were elevated significantly compared to pre-war and post-war conditions. A detailed investigation should therefore be conducted on the long-term effects of these pollutants by a reliable quantitative risk assessment methodology incorporating emission estimate, assessment of exposure levels, dose-response relationships, and risk characterization.

Oil Industry: Cultural Impacts and Environmental Risk Tolerance

William R Stanley
University of South Carolina, Columbia, SC, USA

Petroleum is extracted in company-controlled concessions, obtained through marketing arrangements with national oil companies, especially in the important producing states, or purchased on the open or spot market from other producers. Pro t margins, however, generally are highest when the petroleum is corporate controlled, from producing eld to transport to re nery and eventually, to sales at the retail gas station or equivalent. Diversity in supply is standard for industrial operations and the oil industry is no exception. While it has long been an accepted facet of the petroleum industry that exploration for oil is worldwide in scope, some producing regions are more important than others. Provided there would be suf cient economic incentives, coupled with the absence of political constraints in the oil importing countries, the proven gigantic reserves and relatively low production costs would make it possible for the Gulf oil producing countries alone to provide for the needs of the entire world into the next several decades, possibly longer. Were this the case, one might legitimately ask why petroleum is sought and extracted in such physically hostile and monetarily expensive environments as the Arctic north of Alaska, the depths of the North Sea and the Grand Banks of Newfoundland or semi-impenetrable tropical forests of three continents? The answer is alarmingly simple. The day is past when oil is found seeping from easily tapped, above ground ssures. Petroleum companies have but one basic product to sell, and corporate nancial health is contingent upon a continuous ow of the raw material. Since production elds on the scale of the ones in eastern Saudi Arabia or in the Caspian Sea region are the exception and new ones of this magnitude are increasingly unlikely to be discovered, the industry seeks economic and political risk diversity in supply. In some cases, this means exploring for oil in physically remote or hostile environments. It is a given fact that the cost of nding oil in such locations and bringing it to market is certain to be high.

OPERATIONS IN THE ARCTIC AND TROPICS

Environmental degradation, possibly resulting from the extraction of oil in diverse climatic, topographic, vegetative, cultural and maritime zones, varies by site and sometimes by nationality or size of the oil company. Weak governments in search of economic development at almost any cost clearly are attractive situations for petroleum companies not overly concerned for pollution. That this once was the case cannot be disputed. Today, however, oil companies share a common bonding in that, if one is guilty of some infraction or has been careless to the extreme, then all are painted with the same ugly brush. There have been well-publicized occasions when the so-called ugly brush carried severe financial penalty. Therefore, it is in all of their interests that adequate concern be given to the environmental impacts of their operations and to the level of technical response on hand in case of emergencies. This is not to suggest that sloppiness has been vanquished or that accidents never will occur. Rather, it reinforces the notion that all petroleum operators have a financial and moral obligation to insure environmentally friendly operations to the maximum extent possible.

Frequently more severe in the magnitude of dislocation, and usually longer lasting, are the negative cultural impacts to the local community resulting from the exploration and production of hydrocarbons. These negative impacts also are found associated with the routes used to transport the petroleum or gas to the next stage in the production marketing continuum. This culturally disruptive face of the industry is relatively late in surfacing in the public s consciousness. Nevertheless, it is now being taken seriously, often more so than the better publicized environmental issues. One problem is to be able to identify the potential negative issues prior to the commencement of a project. This is not always easy. Indeed, some projects have been extolled in the first instance by the leadership at all levels of government as offering the local inhabitants an opportunity to share in the benefits of economic change. Only later did these same proponents discover that the financial costs associated with cultural disruption outweighed any possible combination of economic benefits! Some Canadian First Nations people have recently had land claims settled, and are sending out some encouraging signals about pipeline construction.

At least one major hydrocarbon transport scheme, the Mackenzie Valley pipeline project for evacuating natural gas from the Beaufort Sea in Canada s Northwest Territories for sale in the United States, was canceled because of this potentially negative cultural impact dimension. Proponents of the scheme, however, were critical of the reasoning for cancellation. This particular project has not been resurrected and other industry projects have been delayed.

To assess the environmental and social impacts of the oil industry, two widely separated projects in contrasting physical settings are examined. One is in Nigeria (West Africa) where oil has been extracted since the 1950s and where its presence (and who would control revenues) was an important consideration in events leading to Nigeria s tragic civil war in the 1960s. Today, oil revenue is not only the mainstay of this country s foreign exchange, but it has

also been responsible for substantial change and possibly even some economic development. Nevertheless, Nigeria is in a state of almost constant turmoil and the quest for oil and oil revenue has negatively impacted those living near production facilities. The second case study is Alaska s North Slope, astride the coastline facing the Arctic Sea. Here, the study focuses on the important issues behind exploration and production in a pristine but climatically harsh natural environment. Nigeria is densely populated and many people reside in close proximity to petroleum operations. In contrast, the indigenous population in this northernmost portion of Alaska is numerically small and, until recently, generally lacking in political influence. Fewer still reside in close juxtaposition to petroleum operations.

Case Study – Nigeria

Nigeria is a developing country where the great mass of the approximately 100 million population lives close to poverty. The oil industry has operations both in the rainforest and adjacent offshore areas. This country has suffered economic decay, political collapse, military dictatorship, religious antagonism resulting in serious loss of life, decline in agricultural production, urban crises and, ironically, persistent shortages of gasoline at the retail pump due to the large volumes of refined products shipped illegally to neighboring countries or otherwise entering the black market. Several major on-shore and off-shore oil spills have occurred and illegal tapping of a gas pipeline connecting a refinery near the southern city of Warri to northern markets has resulted in two recent fires that claimed the lives of scores, perhaps hundreds of people. Attempts to obtain precise casualty figures floundered on the unwillingness of survivors to report to hospitals for fear of arrest.

Oil revenue has fashioned a remarkable economic landscape. Four-lane highways crisscross the country and schools and hospitals are readily observable in most urban and in many rural places. Particular to this analysis is the impact of petroleum operations at the local level. A new administration building or road may mean less than the prospect of steady employment and attractive wages with an oil firm. Consider a villager living near a constantly burning oil flare. Environmental stress is all the more intense if that person or family has no direct link with the oil firm, such as employment. He assumes that the oil company is taking care of itself financially, for why is it here. He realizes that government may not support his village in practice, irrespective of what is said in the state capital or in Lagos. His children likely have less opportunity for obtaining any of the coveted school or university scholarships than do children in the city.

Whether government cannot deliver the desired level of services or whether the money for providing such services goes astray somewhere along the way is not the question. The villager knows what is being done, the means used to accomplish the task(s), and what is not being done. He is just as apt to listen to BBC s World Service radio broadcast as is someone in the city. To him, the manner in which the oil company is operating is nothing less than a marvel of efficiency. Wages are paid in full, and aside from mandatory and well-publicized deductions, the worker receives full accounting. For better or worse, life has been substantially changed. At the same time, he realizes that the village clinic is in the Dark Ages when compared to the nearby company clinic, and while he and his family may have access to the company health service, there are others here and elsewhere not so fortunate.

Set in motion is at first a trickle, then a stream of requests to the oil firm s management for improving the local setting: books and furniture for the school, an access road, drinking water from wells and more. Government is responsible for these but the villager knows only too well that government is slow to respond. He may even suspect that the oil company is not the responsible party for providing such basic services. He probably appreciates that some of his requests and those of others are an imposition upon the company. By the same token, he assumes that he is simply using the company as a proxy of government. It is better to get the task completed, and why not, for the company surely will charge government for the cost of any socio-economic or infra structural assistance. Government will be paying to have done what it is unable to do itself or has not accomplished because the necessary funds never reached their destination. The oil company is a means often the only means to gain the attention of Government!

The oil company manager emphasizes the fact that his company can help Nigeria best by doing an efficient job in the locating, extracting and marketing of oil. The better the performance, the more taxes and royalties are paid to government, and, as a result of these taxes, the more services can be provided by government. Nevertheless, there has been a tidal wave of raised expectations because of oil and, because of the weak existing infra structural base students lacking classrooms or books, unsanitary drinking water, unreliable utilities, abdominal communications and inadequate medical care development is seen to be lacking.

> We are operating in areas where need is everywhere; we have both a professional and humanitarian wish to be of assistance. Furthermore, being of assistance is good business practice and each of the companies in Nigeria budgets funds for good neighbor services. This we accept as the price of doing business, and no less important, because indeed we are good neighbors. Let s face it, if the village outside our compound contracts the plague, then our employees also are at risk. It is better to help out in the health and sanitation sectors from the outset. I employ the same logic for helping to furnish the local primary school or in assisting in providing electricity or in making available

> clean potable water. Frankly, I don t feel the same sense of urgency for a village 3 km distant.
>
> (Stanley, 1990)

Close observation of petroleum operations in Nigeria suggests that residents frequently tolerate relatively severe environmental degradation if economic opportunity is present. Unfortunately, the latter is available to only a relatively small component of the impacted population. Even so, oil spills, fish kills, destruction of vegetation or air pollution does not seem to generate the sometimes vitriolic responses experienced in more affluent parts of the world. Pollution generally is tolerated, if not accepted, due to lack of empowerment and questionable local concern for the environment. In 1985, an analysis of 1100 questionnaires offered to Nigerians residing in the oil impact area showed that nearly 77% of respondents answered in the negative when asked if they or their families had benefited personally from oil operations (Stanley, 1990). The tropical forest regions of the world too often are used to cover or hide man s littering of the landscape. Pollution can be significant but seldom so severe that payments to the most affected cannot resolve the problem locally. Littering and misuse of the landscape is no less severe in arctic regions, but here the effects are more difficult to hide and, in Alaska, the most affected populations often have vocal and influential spokespersons not to mention friends and supporters in and out of government.

Case Study – North Slope of Alaska

Alaskan oil (or its problems) is embellished in the minds of many as representing a special dimension of what is wrong with this industry. The reader is reminded that the Exxon Valdez disaster was maritime in origin. The knowledge that it could have occurred almost anywhere in the three-quarters of the earth s surface covered by water does not lessen its connection to Alaska, nor to the company and port whose names the oil tanker carried. That said, let us go back in time to 1969 when there was no pipeline connecting the Prudhoe Bay field to Alaska s ice free and year-round maritime accessible south coast and when the only hydrocarbon activity at Valdez was the occasional arrival of a small products tanker for local gas stations and the regular departure of liquefied natural gas vessels carrying Alaska s natural gas to Tokyo for electricity generation.

By the mid-1960s, it was clear in industry circles that the Alaska North Slope oil reservoir in the vicinity of Prudhoe Bay was substantial if not world class and, as such, well worth pursuing in economic terms. A major handicap was climate. The northern areas of Alaska are bitterly cold in winter and the offshore Beaufort Sea is frozen for much of the year. The issues, then, were two-fold. First would be the development of a townsite, extraction field, pumps and pipeline and storage capacity for the oil removed through drilling. Second was the problem of how to evacuate the oil once it was extracted. The first issue was daunting but something the petroleum industry could resolve once sufficient resources were directed to establishing a permanent facility at Prudhoe Bay. The second issue was more perplexing and, in retrospect, proved to be a genesis of the Exxon Valdez disaster.

In the summer of 1969, Humble (Exxon subsidiary) Oil s largest US Flag Tanker, the 119 000 dwt SS Manhattan had completed an unusual refit. The tanker s bow was reinforced with so much steel that the ship acquired icebreaker qualities. All other steel faces of the vessel were reinforced in order to withstand the punishing effects of ice. These decisions were made at least three years earlier and were predicated on the knowledge that proper development and steady oil extraction in Alaska s North Slope required a means of shipping the product on a scheduled basis. At the time, the Pacific Coast of the US, unlike its eastern seaboard, was not experiencing shortages of oil (gasoline). There was and still is not a trans-continental petroleum pipeline, one that would permit the shipping of oil from one coast to another, from surplus regions to areas lacking sufficient petroleum. Oil from Alaska was not meant to serve markets in the west. Thus, a maritime route through the Bering Strait and into the Beaufort Sea might have been technically feasible but impractical since the petroleum still would be on the Pacific Coast. There is, however, a maritime route to northern Alaska by way of the North Atlantic, from the east. This is by way of Newfoundland and the Labrador Sea, the Davis Strait separating Baffin Island and Greenland, Lancaster Sound to the south of Devon Island and, once through, the use of two possible routes into the Beaufort Sea. The difficulty is that these waters, painted blue on maps, are frozen solid for all but several weeks of the year. It was in preparation for such unusually severe physical conditions that the SS Manhattan was fitted-out and deployed for its epic journey.

The voyage was timed for late summer departure from Houston, which would bring the Manhattan into the deep Arctic at a time of maximum melting and ice movement away from shore (northward). Two icebreakers accompanied the Manhattan, one Canadian and one American. The voyage was a press extravaganza. The Manhattan carried scores of scientists to test practically everything, biologists to report on the fauna, oceanographers, climatologists and, not least, a constant presence of Canadian officials. The political consequences of this voyage have been long lasting, not least of which is the introduction of a permanent Canadian military force on Baffin Island. Not only were some officials in Ottawa concerned for their southern neighbor and how she might respond to a long term use of Canadian Arctic waters for a critical resource, there also was some concern for such a massive territory assigned to Canada on atlases but almost totally lacking in Canadians.

This large hunting and gathering culture realm, to which much of Alaska can be joined, contains few residents and they live in widely dispersed villages, government centers or mining camps.

The voyage northward was not uneventful and on several occasions the tanker was ice bound, dependent upon icebreaker assistance to break free. In spite of the reinforced steel plates, punctures from the ice were recorded. Eventually, but only after much travail, the SS Manhattan anchored offshore from Prudhoe Bay. This voyage was a technical success but served to convince oil company executives that an alternative route for evacuating oil would be necessary if ever production were to commence in the North Slope.

There were several reasons behind this decision and all revolved around the almost impossible task of guaranteeing ship arrivals at Prudhoe Bay. Scheduled tanker visits are necessary for the orderly removal of oil already extracted and stored in on-shore holding tanks. Drilling and storage in the Arctic requires heating, without which the oil would freeze once brought to the surface. Imagine the consequences if ice were to prevent tankers access to the region, and the holding tanks at Prudhoe bay no longer had storage capacity. Drilling operations would have to be halted with enormous costs associated with restarting the process. Pack ice deeper than usual or winter storms not only would hinter tanker operations; such conditions would enhance the probability of punctures or other types of maritime disaster. Envision a fully loaded tanker caught up in extreme winter weather conditions and suffering even a modest oil spill. A comparable spill in the Persian Gulf is bad, but at least the physical environment in that part of the world offers the prospects for recovery vessels and personnel to attempt a clean-up at sea. How would this be managed in a region with almost 24 hour winter darkness and in temperatures lower than minus 50 °C? Clean-up would be impossible. Imagine further the ecological consequences of an oil spill in waters with constantly low temperatures? These were the issues that caused the industry to explore alternative evacuation routes and eventually to construct a pipeline connecting the North Slope to the ice free port of Valdez.

At the time and prior to the Exxon Valdez, primary concern was for the multi-billion dollar pipeline and for the twin issues of interference with traditional animal migration routes and what heating the pipeline might mean for permafrost stability. In retrospect, the evacuation of oil by pipe has been relatively incident free, certainly nothing on the scale of the tanker grounding. Clearly, however, there have been cultural dislocation problems amongst the indigenous population and a powerful environmental lobby at this writing has succeeded in preventing further oil and natural gas developments in northern Alaska.

FUTURE PROSPECTS

Political turmoil is evitable and national energy security issues are bound to resurface. Automobile manufacturers undoubtedly will allocate increasing resources to developing marketable electric or electric hybrid vehicles. Electric utilities will endeavor to reduce their dependence on high sulfur coal and petroleum (which essentially guarantees greater use of nuclear generated electric power). Wind generated power will gain more adherents and increased spending; tidal, geothermal and solar power will have a greater role in future energy use. Nevertheless, fossil fuel consumption can only increase as greater numbers of people in developing countries seek and achieve the good life. Those residing in countries with high current levels of energy use give no indication of a collective willingness to tighten the belt and reduce energy consumption. An ever-increasing demand for petroleum and all forms of energy can only lead to a future scenario of supply disruptions, environmental degradation and outright military struggles for still existing oil reserves. The world is constantly stretching safe economic and environmental parameters while economic growth remains dependent upon increased petroleum use. New technologies could reduce the rate of future economic environmental collapse but this is problematic. Will future observers look back to the beginning this Millennium with envy or disdain?

POSTSCRIPT

Alaskan oil is shipped to markets in the eastern US, but by way of the Panama Canal. Tankers collecting oil in Valdez are too large to traverse the Canal so the oil is off loaded or reloaded into smaller tankers at both entrances.

Oil Shales and Tar Sands

Joe Macquaker
University of Manchester, Manchester, UK

Oil shales and tar sands are alternative sources of hydrocarbons to conventional oil, gas and coal deposits. Oil shales are any shallow buried, organic matter-rich rocks

that yield oil upon pyrolysis (i.e., heating in an inert atmosphere to approximately 500 °C). Oil shales are potential viable reserves if they generate more oil and gas than is used in the extraction process. This requirement, in practice, means that oil shales must contain at least 5% total organic carbon. Tar sands are sands and sandstones (sedimentary rocks with a grain size in the range 0.0625 - 2.0 mm) that contain abundant heavy viscous oil in their pore space. The oil in tar sands at near-surface temperatures and pressures is not mobile and, therefore, can only be extracted using specialist techniques that typically involve heating. In the past, oil shales have been extensively mined and processed as a source of oil. The first plant to extract oil from oil shale was established in Bathgate, Scotland in 1851 by James Young. This was followed by widespread shale oil industries developing in countries such as Australia (1865), Brazil (1881), New Zealand (1900), Switzerland (1915), Sweden (1921), Spain (1922) China (1929) and South Africa (1935). Despite much commercial interest, tar sands have not been commercially exploited on a large scale, although pilot plants have been developed in Canada to extract the Athabasca tar sands, and in the Orinoco region of Venezuela. In the early years of the 21st century, there are few commercial oil shale and tar sand reserves being exploited due to the high cost of production from these deposits. Worldwide, however, hydrocarbon reserves within these regions are significant, and governments and industry continuously review their potential as a resource. Plans are currently being developed to utilize oil shale resources in Queensland (Australia), Estonia and Jordan and also to expand tar sand extraction operations in Canada.

Inevitably as conventional sources of crude oil and gas run short in the mid to late 21st century, and the real cost of crude oil reaches more realistic levels, the economics of extracting hydrocarbons from oil shales and tar sands will become more favorable. It is likely, therefore, that increasing attention will be placed on these resources, in addition to coal, assuming that hydrocarbons continue to underpin the world-wide economy. The successful separation of hydrocarbons from these alternative resources without sustaining enormous ecological damage represents a real challenge.

OIL SHALES

Composition

Oil shales are most commonly siliciclastic-rich, organic matter-bearing mudstones (sedimentary rocks with a grain size • 0.0625 m, e.g., Dinantian oil shales in the Midland Valley of Scotland). A few, however, are carbonate-rich organic matter and clay-bearing mudstones (e.g., Cretaceous, Green River Formation in UT, CO and WY, US). Oil shales are characterized by having very low densities (0.95 to 1.05 g cm^{-3}) in comparison to other rock types. The organic matter component of oil shale is predominantly *kerogen* (defined as the organic fraction that is not soluble in common solvents) with minor *bitumen* (defined as the organic fraction that is soluble in common solvents). Kerogen is very variable, and comprises both material that is easily recognizable: for instance, cysts derived from green algae (e.g., *Botryococus* spp. and *Tasmanites* spp., which are particularly common in torbanite from the Dinantian of the Midland Valley of Scotland, boghead coal from the Permian of Autun, France and the Stuart Shale from the Tertiary of Queensland) and material that is amorphous, which is probably derived from bacteria. In addition to these organic components, oil shales also contain: (i) detritus derived from subaerial weathering (e.g., clay minerals such as illite, illite/smectite and quartz), (ii) productivity-derived components (e.g., shell debris), and (iii) diagenetic (cement) components (most commonly pyrite, and a variety of carbonate cements e.g., calcite, dolomite, ankerite and siderite).

The primary depositional fabrics in oil shales are rarely disrupted by burrowing organisms; thus in both field and hand specimens, they commonly appear thinly bedded and laminated (10^{-2} to 10^{-3} m scales). At an individual bed-scale, the grain-size within depositional units commonly either becomes finer upward from silt to clay, or exhibits thin alternating laminae composed of either couplets of clay and organic matter, or couplets of carbonate cement and organic matter. Compressed faecal pellets, derived from zooplankton, are commonly observed within some units.

Origin

All oil shales are deposited subaqueously in either lakes or shallow seas. The preservation of organic matter within these rocks requires a number of key prerequisites to be met. Firstly, it is important that there was high organic productivity in the water column to supply the primary organic material to the sediment water interface. Secondly, it is crucial that this organic material was not diluted by other components during deposition. Thirdly, a significant proportion of the primary organic matter must survive prior to being incorporated into the sediment. Finally, it is vital that following deposition, heating induced by burial was insufficient to drive off a large proportion of the key volatile hydrocarbons.

Primary productivity within the water column mainly occurs in the photic zone, and is controlled by the availability of nutrients (mainly phosphate and nitrate) and light. On continental shelves and in lakes, the key nutrients are supplied by rivers and, to a lesser extent, upwelling. This inevitably means that zones of highest productivity occur close to river mouths and beneath regions of local upwelling. In these settings, the proportion of organic matter that actually reaches the sediment is controlled by a

complex trade-off between absolute water depth, the depth of the photic zone, the concentration of nutrients in the surface layers, and the effects of dilution by non-organic components. These lead to most oil shale precursor sediments being deposited in regions bypassed by the main clastic supply, yet beneath zones that are nutrient enriched relative to surrounding areas.

Producing abundant organic matter is only part of the equation that leads to the formation of an oil shale. It is also vital that this primary organic material is not completely destroyed prior to being incorporated into the sediment. Organic matter is most commonly destroyed by organisms using it as a reducing agent, either in the water column or during the first few meters of burial. This degradation of organic matter is driven by a combination of organisms using aerobic (macro and microorganisms that use oxygen as an electron acceptor) and anaerobic (microbial organisms that use alternative oxidizing agents to oxygen, e.g., sulfate, nitrate, manganese) respiratory pathways. The simplest mechanism to reduce the proportion of organic matter destroyed prior to its incorporation into the sediment is to limit its exposure to prolonged microbial degradation. This is most simply accomplished by rapidly transporting it through the water column (i.e., depositing it in relatively shallow water) and then burying it quickly to a depth where it can no longer be extensively oxidized by bacteria (depths below which sulfate-reducing bacteria thrive, typically 0.2 0.5 m). In most depositional settings, rapid burial is accompanied by significant clastic dilution of the organic component, inevitably reducing the organic content of the sediment and so preventing the formation of oil shales. In oil shales, rapid burial without the organic matter being diluted by clay and silt components is most commonly caused by episodic sedimentation events (e.g., storms, floods or density currents). Organic matter preservation is also enhanced by the bottom waters containing no dissolved oxygen (i.e., being anoxic). The absence of oxygen in these settings restricts the time available for aerobic organisms to metabolize the organic matter, thus allowing a greater proportion of organic matter to reach the sediment and be buried. Deposition in depositional basins where the bottom waters are anoxic causes the sediment fabric to be undisrupted by burrowing organisms and primary lamination to be preserved.

Restricting the ability of aerobic organisms to colonize the bottom waters can also be accomplished in settings where either all or part of the water column is hypersaline. Here, faunal diversity is dramatically reduced, and the preservation potential of organic matter is commonly much greater. The positive effect of reduced benthic colonization of the water column is partially offset, however, by more sulfate being available than is present in either marine or lacustrine environments, acting as an oxidizing agent. This causes increased anaerobic microbial degradation in these hypersaline settings. Where oil shale deposition has occurred in hypersaline settings, organic matter is commonly intimately associated with evaporitic minerals. For instance, in the Green River Formation (a Cretaceous-aged oil shale from WY, CO and UT, US), organic matter is interspersed with trona deposits, suggesting that oil shale deposition here occurred at least partially in hypersaline environments.

Lacustrine (lake-dwelling) settings are particularly favorable places for the preservation of organic matter, as the concentration of dissolved sulfate is commonly lower than in normally marine settings. Anaerobic decay via sulfate reduction is, therefore, reduced and the potential for organic matter preservation is higher than in marine systems. Preservation in these locations is further enhanced because lakes are more prone to being stratified than continental shelves. This stratification causes the bottom water layers to be anoxic and to enhance the preservation potential of organic matter still further.

It is crucial that if an oil shale deposit is to be a viable resource, it must not have been heated much above 80 °C during its burial history. Above this temperature, the volatile hydrocarbon components are driven off, and the residual organic component becomes enriched in carbon relative to hydrogen, leaving it with a much lower calorific value.

Extraction

Prior to extracting oil from an oil shale, the rock has to be mined (using either opencast or sub-surface methods) and transported to the pyrolysis plant. Once at this plant, oil is typically extracted from the shale by placing crushed fragments in a retort and heating them in an inert atmosphere to approximately 500 °C. This process breaks down the kerogen into short chain liquid hydrocarbons and also liberates various gases e.g., methane, oxygen, nitrogen and sulfur compounds. In most early plants (19th century in Scotland, France) heat was supplied to the retort externally by burning coal, and thus the process was energy expensive. In later (20th century) plants, however, heat was supplied internally by either burning gas (France, Brazil), using spent hot shale (Russia) or by the insertion of hot ceramic spheres (US) into the unprocessed rock. These methods resulted in an increase in efficiency relative to the early externally heated retorts. Recently, recycling techniques have been employed that use both the surplus carbon produced after pyrolysis (coke) as a fuel, and the hot shale itself to provide the necessary heat to drive the pyrolysis reactions. Together these dramatically improve the efficiency of these most modern retorts. In spite of these advances, however, extracting oil from oil shales is still energy intensive, generates significant volumes of mineral waste (oil shale waste occupies a larger volume than the original oil shale, generates significant volumes of dust and

is depleted in many key plant-nutrients making it difficult to bioremediate), and conventional mining techniques cause significant ecological damage.

In Estonia, oil shale reserves, rather than being retorted, are first powdered and then burnt directly as fuel to provide energy for electricity generation. As oil shale is a dirty fuel, the combustion process generates large volumes of dust, and can cause atmospheric pollution because of the emission of sulfur compounds.

Reserves

Significant oil shale reserves exist in many parts of the globe. Estimates of the value of these reserves are highly variable and depend on geopolitical variables. Among the most important are those in Estonia and northwestern Russia (four billion tonnes, which are likely to be used for electricity generation), Brazil (800 billion barrels of oil), Australia (28.9 billion barrels), US (560 billion barrels), and Jordan (27 billion barrels).

TAR SANDS

Composition

Tar sands contain both hydrocarbon (15 20%) and mineral grains (80 85%). Hydrocarbons infill intergranular and grain dissolution porosity within tar sands. The hydrocarbons comprise heavy oils with a density range 0.93 g m^{-3} to 1.06 g m^{-3}, and are predominantly composed of asphaltenes and some resins, in addition to minor alkanes and alkenes. The proportion of alkanes and alkenes in the oil fraction of these rocks is significantly less than in conventional oil reserves. The mineral grains in tar sands most commonly comprise quartz, rock fragments and feldspar.

Origin

Tar sands were deposited in several environments, e.g., shallow marine, fluvial and lacustrine settings. Their original depositional setting, however, is not so important when it comes to their relative potential value as a tar sand resource. Their crucial attribute in this context is that they contain more than 15% porosity (either intergranular or grain dissolution). This prerequisite, in practice, means that they have not been subjected to extensive cementation, which usually implies that they have not been significantly buried. Once in place, the porous sandstones have the potential to become tar sands if they are charged with oil migrating from source rocks to the surface of the Earth. In the sub-surface, oil migration pathways are commonly horizontal, which causes tar sand deposits to mainly occur on the margins of petroleum-forming basins. Overall, tar sands may be considered as near-surface petroleum reservoirs.

Once established, bacteria, yeast and fungi degrade the hydrocarbons within the sands, as they are close to the surface of the Earth, in the zone affected by groundwater circulation patterns. In these environments, microorganisms are able to oxidize the volatile oil fraction, particularly the short chain (• C 20) unbranched molecules, to alcohols, ketones and a variety of acids. This biodegradation process leaves the longer chain, more complex, heavier-oil fractions concentrated in the pore space where these form the characteristic heavy oils that fill the pore spaces. This fractionation process is commonly facilitated by evaporation.

Extraction

The hydrocarbons in tar sands are extracted either by mining followed by transport to a plant and then steam extraction (Canada), or by *in situ* steam extraction (Canada and Venezuela). In the former process the tar sands are mined in large open cast pits, the raw material is then transported to a plant where the hydrocarbons are separated from the mineral component of the rock. This process utilizes a combination of treatments that involve steam and hot water injection, addition of caustic soda, followed by diluting the resulting heavy oil with naphtha prior to separating the light oil fractions with a centrifuge. In contrast, the *in situ* techniques involve drilling a pattern of wells, injecting steam at the periphery of the pattern and driving the volatile hydrocarbons towards a central drainage well. The latter process produces an emulsion composed of oil and water termed *Orimulsion*, which can be used as a low-grade fuel. Future use of horizontal drilling technology will inevitably lead to more efficient extraction operations.

Reserves

The potential oil reserves in Athabasca, Canada and the Orinoco region of Venezuela are enormous, with estimates being as high as 1.7 and 1.5 trillion barrels of oil, respectively. Additional reserves are also present in Russia. Unfortunately, the economics associated with extracting oil and the environmental damage that results from mining operations are such that in the early years of the 21st century, tar sands are not yet economic reserves of hydrocarbons.

Organic Farming and the Environment

Carol Morris and Michael Winter
Cheltenham and Gloucester College of Higher Education, Cheltenham, UK

As a major land user across the globe, the impact of agriculture on the environment is of unquestionable signi cance. Agriculture necessarily involves a modi cation of natural ecosystems in order to enhance their potential for food production. However, the profound extent to which the natural environment has been adversely affected by agricultural activity has recently become a matter of scienti c, public and political concern. Examples of these extensively documented, but spatially variable, effects include biodiversity loss through the damage, removal and neglect of habitat and landscape features, the pollution of surface and ground waters by livestock ef uents and agrochemicals, and soil erosion. The environmental problems within agriculture are widely attributed to a conventional or productivist farming system. This is based upon a high input- high output logic, particularly with regard to the use of chemical inputs, and has provided the model for agricultural development throughout most of the 20th century. In response to these problems, there is a recognized need to develop more environmentally sustainable systems of agriculture, of which organic farming represents one variant. Others include integrated farming systems (Morris and Winter, 1999), and environmentally friendly farm management practices which emphasize the production of environmental goods such as hedgerows, woodlands and ponds. Within many of the developed market economies, organic farming is currently generating considerable interest and support. A range of environmental bene ts is believed to accrue from organic farming, but only some are presented here: the impact of organic farming on landscape quality; biodiversity; and soils and natural resources. The disbene ts of the approach are also given brief consideration. Stolze et al. *(2000) provide a more comprehensive review of the environmental impacts of organic farming in Europe.*

BACKGROUND

Driven by mounting evidence of the environmental impacts of conventional production systems, and consumer concerns about the safety of food produced using chemical inputs, organic farming was given official recognition in Europe and North America in the 1980s. However, the origins of present day organic farming lie in a number of alternative agriculture movements during the early 20th century, inspired by a variety of philosophical currents. This dimension remains important within the contemporary organic farming movement. For many organic practitioners, organic farming is an agricultural philosophy as well as a farm management system. The ideological aspect extends beyond production methods. The organic movement also challenges conventional food processing and marketing arrangements and the distance these have created between producers and consumers. In their place, the organic movement advocates a decentralized system of marketing and a more intimate relationship between consumers and producers. However, the recent growth in interest in organic food, exemplified through its presence in the major supermarket chains, has led some commentators to argue that organic farming has become commoditized and divorced from its philosophical foundations (Tovey, 1997).

Organic farming has been defined as an approach to agriculture where the aim is to create integrated, humane, environmentally and economically sustainable agricultural production systems, which maximize reliance on farm-derived renewable resources and the management of ecological and biological processes and interactions, so as to provide acceptable levels of crop, livestock and human nutrition, protection from pests and diseases, and an appropriate return to the human and other resources employed (Lampkin, 1994: 4 5). Rather than thinking of organic as the type of inputs used, Lampkin argues that it should be thought of as referring to the concept of the farm as an organism, in which all component parts the soil minerals, organic matter, microorganisms, insects, plants, animals and humans interact to create a coherent whole (Lampkin, 1994: 5). Lampkin principal features of organic farming are:

- protection of the long-term fertility of soils by, e.g., maintenance of organic matter levels;
- provision of crop nutrients indirectly by the use of relatively insoluble nutrient sources made available by soil microorganisms;
- nitrogen (N) self-sufficiency, e.g., through the use of legumes and recycling of livestock wastes;
- weed, disease and pest control through a variety of physical and cultural methods, e.g., crop rotations and use of resistant varieties, and limited (preferably minimal) chemical intervention;
- extensive, welfare-friendly management of livestock;
- consideration to the wider impact of farming on the environment (e.g., avoidance of pollution) and the positive management of wildlife and natural habitats.

Organic farming is readily distinguished from other types of farming systems by the application of legislated and voluntary standards and certification procedures.

The area of land farmed organically has witnessed a significant expansion in recent years. In Europe, e.g., the area under organic production increased from 100 000 to 600 000 hectare (ha) between 1985 and 1993 (Lampkin, 1994), and to over one million ha in 1997 (UK Agriculture Departments, 1998). However, in the European Union as a whole, less than 5% of the agricultural area is in organic production, which is just over 1% of holdings. Moreover, the rate and extent of conversion varies greatly between nation states. The highest concentrations are in Sweden (12% of all farms), Austria (9%) and Finland (4%), but conversion is also now taking place rapidly in southern countries, particularly in Italy and Spain. A recent European-wide study revealed that organic farms have the following characteristics (Offermann and Nieberg, 2000):

- larger on average than comparable conventional farms (although average organic farm size varies considerably in relation to national averages) and like their conventional counterparts are increasing in size over time;
- natural conditions are worse and soil quality is lower than the national average and relatively more organic farms are located in less favored areas;
- labor use per ha of utilizable agricultural area (UAA) is on average 10 20% higher than conventional equivalents, although labor use is very much dependent on farm type. As in conventional systems, labor use in organic farming is falling.
- a greater diversity in land use, largely because of the importance of integration between enterprises in these systems;
- stocking rates are consistently lower than on conventional farms, although significant variation occurs with farm type.

ORGANIC FARMING AND LANDSCAPE QUALITY

A European-wide research project recently set out to evaluate the relative contributions of organic and conventional farms to landscape quality, encompassing the concept of cultural environment (Kuiper, 2000). Findings varied between the case study countries, with the differences between compared organic and conventional holdings sometimes negligible, particularly where the organic holdings were small and isolated. However, the aggregated observations suggest that organic farms are more likely to make a superior contribution to landscape quality arising from, e.g., their more positive approach to the management of landscape features, greater biodiversity and less soil erosion.

ORGANIC FARMING AND BIODIVERSITY

Organic farm management practices seek to encourage biological diversity, e.g., through the use of crop rotations, maintenance of ground cover, protection and management of natural habitats and avoidance of practices such as use of artificial pesticides likely to disturb species and habitats. Organic standards typically specify a minimum area on a farm (e.g., 5%) that should be devoted to natural habitats. This reflects the recognition of the relationship between habitat features and biological control of pests as well as a commitment to the positive management of these features for nature conservation objectives. Evidence from a variety of European research projects has demonstrated higher levels of abundance of butterflies and spiders in organic than conventional farming systems (Feber *et al.*, 1997; Cobb *et al.*, 1999). The cropping patterns within organic farming (notably the use of grass leys, complex rotations and the structural complexity of the organic cropped habitat), rather than management practices, are believed to account for this pattern. Greater floral diversity, in field margins, arable fields and grassland has also been observed on organic farms within Europe (van Elsen, 2000). In this case, organic farm management practices are important, particularly the absence of agrochemicals which prevents defoliation, allows more flowers to set seed and allows a greater variety of nectar sources for insects (Cobb *et al.*, 1999).

ORGANIC FARMING, SOILS AND NATURAL RESOURCES

Soil is a key agricultural resource and soil structure one of the most important soil properties influencing crop production. A well-developed soil structure enables effective drainage and nutrient supply to the crop and assists the soil s ability to resist erosion. The impact of conventional and organic systems on soil structure in two farms in the US corn-belt have been compared (Gerhardt, 1997). The management methods associated with the organic system, i.e., organic inputs and crop rotations, contributed to an improved soil structure evidenced by the increase in organic matter content, soil biota presence and activity. Conventional management methods were found to degrade soil structure as a result of a lack of organic inputs, conventional tillage, monoculture and use of chemical inputs. While conceding that good management practices in both organic and conventional systems can reduce soil erosion problems, Conacher and Conacher (1998) suggest that the build-up of soil organic matter, maintenance of a protective surface cover and minimum tillage in organic farming favor a reduction in soil loss and its associated problems.

Loss of nitrogen from a farming system can lead to water pollution and human health problems. Organic farming potentially reduces these losses due to lower nitrogen

inputs because mineral fertilizers are not permitted, and livestock densities tend to be lower than in conventional operations. Stolze *et al.* (2000) show that the soil nitrate content on organic farms is lower than on conventional farms during the critical autumn period. They also point to improvements in organic husbandry designed to deal with the high nitrate run-off that can occur when grass and clover leys are ploughed. Likewise, comparing nitrogen surpluses on a limited number of Danish conventional and organic pig and dairy farms, Dalgaard *et al.* (1998) demonstrate that a reduction in nitrogen surplus is possible by converting from conventional to organic dairy farming. However, nitrogen surpluses are greater in organic than conventional pig farming and are attributed to differences in production methods. Scenarios for widespread conversion to organic dairy farming were predicted to require a significant increase in the total dairy farm area, undermining production levels from other farm types.

Using a slightly different approach based on secondary information from a collection of representative data, Cobb *et al.* (1999) attempted to compare the relative environmental burdens of organic and conventional farming. A range of significant impacts on the resource base were examined and calculated in £/ha: nitrous oxide (HNO_2), methane (CH_4) and ammonia (NH_4) emissions to the atmosphere, nitrogen leaching to ground water, carbon dioxide (CO_2) emissions and energy use on the farm and from the manufacture of nitrogen fertilizer, and total pesticide footprint. The total range for organic farming was calculated at £10 15, compared to £25 40 for conventional. These researchers argue that their calculations provide robust evidence of a higher natural resource cost arising from conventional than organic systems.

THE DISBENEFITS OF ORGANIC FARMING

Organic farming undoubtedly is a more environmentally friendly approach, particularly when compared with conventional, high input specialist arable or livestock operations. However, the environmental advantages are less clear when compared to sensitively managed, conventional mixed farms, extensive livestock systems and arable systems employing an integrated management system (Clark *et al.*, 1998). Furthermore, organic farming may be associated with some environmental disbenefits. For example, in the UK, nature conservationists have expressed concern where species rich, extensively farmed grassland has been ploughed out for incorporation into an organic rotation. In Australia, some natural (e.g., farm yard manure) or alternative (e.g., sewage sludge) soil amendments used to promote fertility in organic systems can present a pollution threat, and particular types of natural/alternative pesticides carry a health risk (Conacher and Conacher, 1998). Similar concerns have been raised elsewhere. A recent illustration was the temporary removal from sale of organic mushrooms by one of the UK s largest supermarket chains, prompted by food poisoning fears arising from contamination of the organic growing medium. Thus, it cannot be unequivocally assumed that the organic option is always environmentally benign and can be guaranteed to produce the safest and healthiest food.

In addition, conventional producers are discouraged from converting to organic farming due to some economic disbenefits, notably lower yields. For example, in Europe, yields of cereals are 60 70% and pulses 80% of those from comparable conventional farms. Data on livestock performance is more limited, but studies demonstrate that the yield difference is smaller in organic animal production than it is for crops. Lower yields can be largely attributed to the prohibition of input use and restrictions on stocking rates in organic systems. Although this may discourage some farmers, attuned to a high-input high output mentality, reduced yields may be offset by reduced costs and higher prices received for organic products. Again, European-wide research on the economics of organic farming suggests that the profits of organic farms are quite similar to, and in many cases higher than, those of comparable conventional farms (Offermann and Nieberg, 2000).

CONCLUSIONS

Further scientific research is required to provide precise quantification of many of the environmental, health and economic benefits and disbenefits of organic farming. Available data on the environmental impacts display a number of problems. For example, research tends to focus upon one element such as soil structure, butterfly populations or landscape quality, within an organic system and compares this with its conventional equivalent, rather than comparing the systems as a whole. Even when whole system analyses are undertaken, there is potential for considerable variation in management practices within both organic and conventional systems, making the collection of comparable data between systems undergoing organic transition very difficult. Additionally, research is frequently conducted at the plot or field scale, although whole farm analyses are becoming more common.

These caveats aside, the potential of organic farming to make a positive contribution to a more environmentally friendly agriculture is now widely accepted (Stolze *et al.*, 2000). However, it will only be realized if sufficient land area is converted to this system of production. Achieving higher levels of organic conversion is contingent upon public, and policy support, research and development programs, a well-developed advisory system, adequate processing, distribution and marketing structures, willing and able farmers, and sufficient economic returns. Although predictions of the future extent of organic farming, both in

terms of the UAA and market share, are constantly being revised upwards, in the final analysis it seems unlikely that this approach will be universally adopted. This reinforces the point that organic farming is just one possible option in the development of more environmentally sustainable agriculture.

Phosphorus: Global Transfers

Vaclav Smil

Winnipeg, Canada

Although relatively rare in the biosphere, phosphorus (P) plays several key roles in the chemistry of life, above all due to its presence in nucleic acids (deoxyribonucleic acid, DNA and ribonucleic acid, RNA) and in adenosine triphosphate, the life's carrier of energy. Phosphorus – unlike carbon, C, nitrogen, N and sulfur, S – does not form any long-lived atmospheric compounds and hence its global cycle is just a part of the grand, and slow, process of denudation and geotectonic uplift. But on a small scale the element is rapidly recycled between organic and inorganic forms in soils and water bodies. Human activities now annually move more than four times as much phosphorus as did the natural processes during the preagricultural era.

Together with nitrogen and potassium, phosphorus is one of the three macronutrients needed by all plants, and its applications in inorganic fertilizers have been essential for raising crop yields during the 20th century. The nutrient is also frequently the limiting factor of aquatic productivity, and even its relatively low concentrations present in the runoff from fertilized fields can cause eutrophication (excessive nutritional enrichment) of both fresh and ocean waters, an environmental change with numerous undesirable consequences. Fortunately, appropriate agronomic practices and wastewater treatment can moderate the environmental impact of anthropogenic phosphorus.

IMPORTANCE OF THE ELEMENT

Phosphorus is one of the three macronutrients required by plants. It is particularly important for the growth of young tissues, flowering and seed formation (cereal grains contain 0.25–0.45% phosphorus (P), more than is contained in any other plant tissues). The element is also an essential micronutrient in humans: its daily intakes are usually around 1.5 mg capita^{-1}, well above the recommended daily minima of about 1.2 mg (National Research Council, 1989).

P is absent in cellulose, hemicellulose and lignin, the three polymers that make up the bulk of the plant mass, as well as in proteins that compose the metabolic tissues of heterotrophs. However, the element is abundant in bones and teeth: hydroxyapatite, a calcium phosphate, makes up 60–70% of their mass. The element is indispensable in phosphodiester bonds linking mononucleotide units of RNA and DNA, and all life processes are energized by transformations of adenosine triphosphate.

NATURAL STORES AND FLOWS OF PHOSPHORUS

Comprehensive assessments of the global P cycle have been much rarer than the studies of carbon or nitrogen flows (Smil, 1990; Jahnke, 1992; Mackenzie *et al.*, 1993; Tiessen, 1995; Smil, 2000; Figure 1; Table 1). The Earth's crust is the largest reservoir of the element, nearly all of it bound in apatites, calcium phosphates containing also iron, chlorine or the OH group. Soluble phosphates are released by weathering, but they are rapidly transformed to insoluble

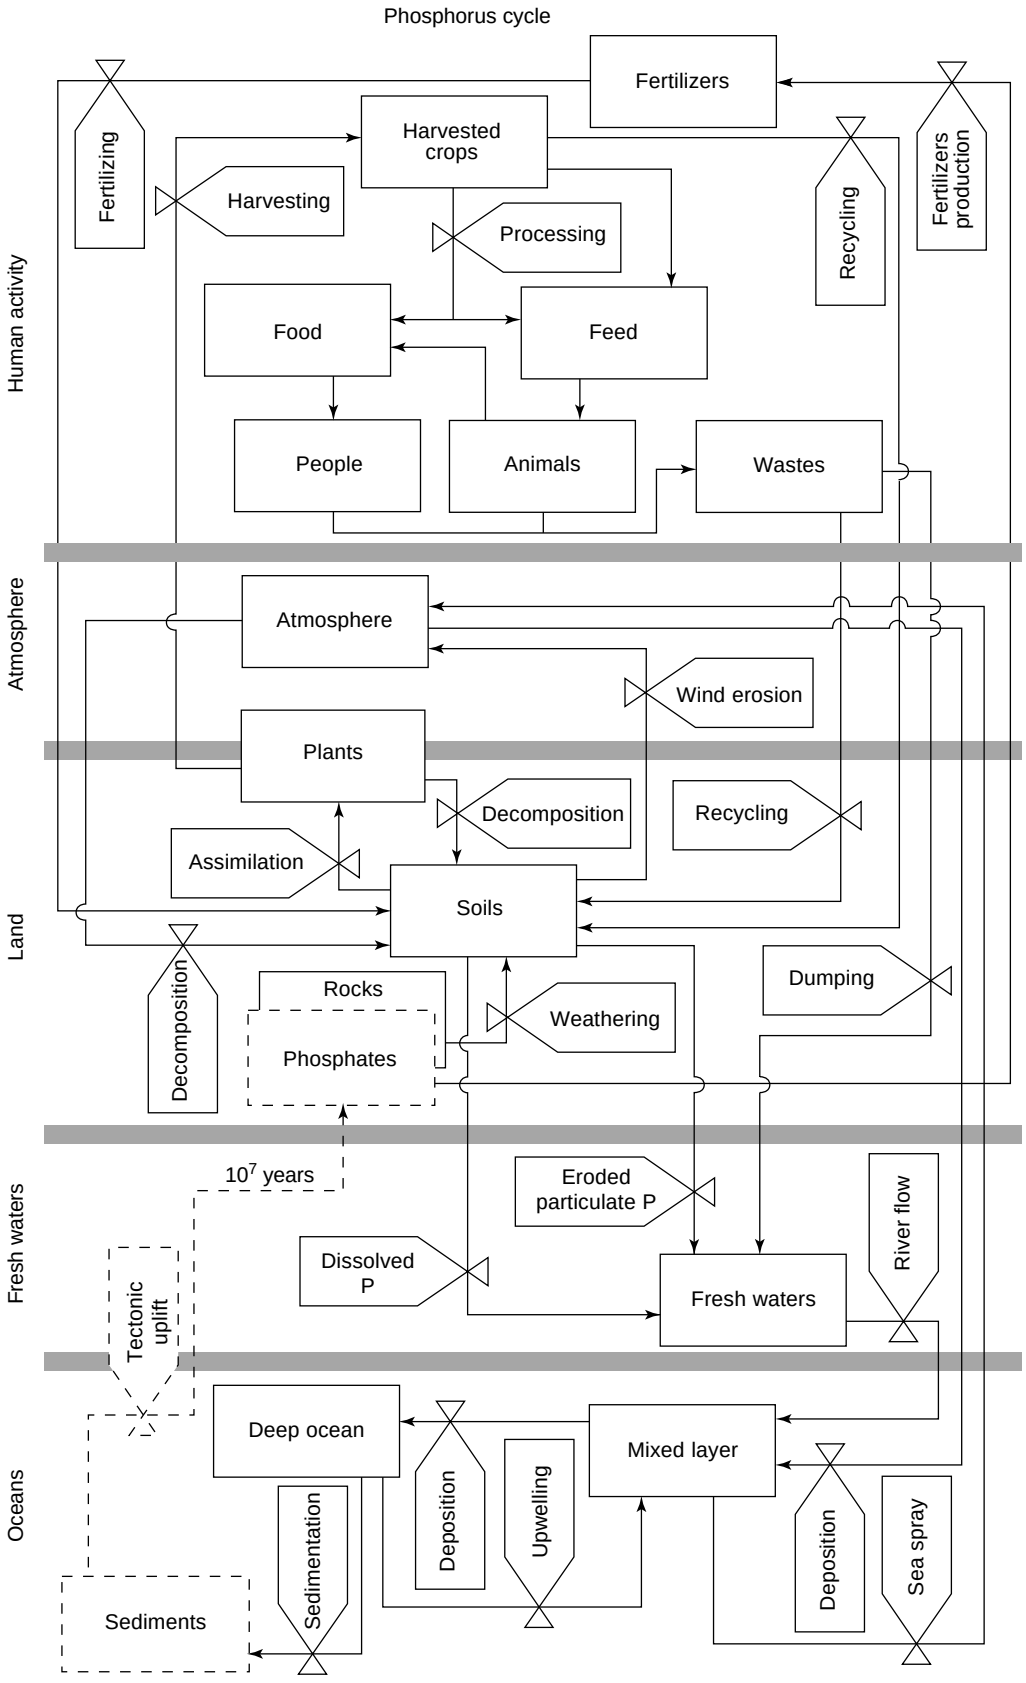

Figure 1 Global phosphorus cycle

Table 1 Major biospheric reservoirs and fluxes of phosphorus

Phosphorus reservoirs	Total storage (Mt P)
Ocean	93 000
Surface	8000
Deep	85 000
Soils	40–50
Inorganic phosphorus	35–40
Organic phosphorus	5–10
Phytomass	570–625
Terrestrial	500–550
Marine	70–75
Zoomass	30–50

compounds in soils. Consequently, plants must be able to absorb P from very dilute solutions and concentrate it 100 1000 fold in order to meet their needs, and P released by decomposition of biomass is rapidly reused.

The element is even less available in fresh waters and in the oceans where its particulate forms sink into sediments and where soluble phosphates are rapidly recycled in order to support phytoplanktonic photosynthesis in surface waters. Only in the areas of upwelling are surface layers enriched by the influx from deeper waters. Phosphorus in marine sediments can become available to terrestrial biota only after the tectonic uplift re-exposes the minerals to denudation. The element s global cycle thus closes only after tens to hundreds of millions of years. However, the temporary interruptions of the element s oceanward journey are indispensable for the Earth s life.

The terrestrial phytomass stores about 500 Mt of the element, plant growth assimilating up to 100 Mt P year^{-1}. Phosphates dissolved in rain and dry-deposited in particles amount to only about 3 Mt a year. Soils store about 40 Gt P, with no more than 15% of this total bound in organic matter. Natural denudation and precipitation transfer annually about 10 Mt of particulate and dissolved phosphorus from land to the ocean. The marine phytomass stores only some 75 Mt phosphorus but because of its rapid turnover, it absorbs annually about 1 Gt P from surface water. Mixing between sediments and the surface layer is effective only in very shallow waters, and high near-surface concentrations of the nutrient only occur in coastal areas receiving phosphorus-rich runoff. Coastal seas contain only some 0.2% phosphorus in the ocean but they support a disproportionately large share of marine productivity, and the top 300 m of the open ocean contain less than one tenth of all marine phosphorus.

ANTHROPOGENIC MOBILIZATION OF PHOSPHORUS

Human activity intensifies biospheric phosphorus flows in five main ways:

1. accelerated erosion and runoff caused by large-scale conversion of natural ecosystems (mainly forests and grasslands) to arable land;
2. settlements and transportation links;
3. recycling of organic wastes crop residues, animal manures and human urine and faeces to fields;
4. releases of untreated, or insufficiently treated, urban and industrial wastes to streams and water bodies;
5. applications of inorganic fertilizers; and combustion of biomass and fossil fuels (Smil, 2000; Table 2).

Although the last process is the least important source of phosphorus, it is the largest anthropogenic source of carbon and a large source of fixed nitrogen (*see* Phosphorus Water Quality Objectives, Volume 3) Trace amounts of phosphorus present in wood and coal remain overwhelmingly in the ash and less than 0.3 Mt P are released annually in airborne particulate matter.

Recycling of organic wastes has always been a mainstay of traditional farming and it remains an important

Table 2 Human intensification of the global phosphorus cycle (all values are in Mt P year^{-1})

ingredient of well-balanced modern agriculture. Progressing urbanization and diffusion of sewers have gradually reduced the often intensive recycling of human wastes, once characteristic of many regions of Asia and Europe. Nevertheless, the recycling of crop residues remains highly desirable, not only because of the return of plant nutrients but also because of its contributions to better tilth, higher water absorption capacity and reduced soil erosion. During the 1990s, global crop harvests produced about 3.75 Gt (dry matter) of residues (mostly cereal straws). About half this phytomass was recycled, returning (with average content of 0.05 0.1% phosphorus) 1 2 Mt P to arable soils.

Animal wastes are potentially a very large source of recyclable phosphorus. Every year, over four billion large mammals and some 10 billion domestic birds produce together about 2 Gt of dry waste containing up to 20 Mt P. Only the wastes produced in confinement are recyclable but, because of their bulk, uneven distribution and excessive cost of application beyond a limited radius from the source, not all of this manure is actually applied to fields. The best estimates indicate annual return of up to 8 Mt P, with the highest applications (exceeding 50 kg P ha^{-1}) in such regions of high animal density as the US Corn Belt, Northwestern Europe and East Asia.

The global population of six billion people now discharges every year about 3 Mt P in its wastes. Nationwide production densities of human waste are as high as 9 kg P ha^{-1} of cultivated and settled land in densely populated countries (Egypt, Japan), and more than 100 kg P ha^{-1} in large cities. A large share of human waste produced in rural areas of the low-income countries is deposited on land, but progressing urbanization puts a growing share of human waste into sewers and then, treated or untreated, into streams or water bodies. Since the 1940s phosphorus-containing detergents have added another major source of waterborne phosphorus. Neither the primary sedimentation of urban sewage (which removes only 5 10% of the initial phosphorus in the sludge), nor the use of trickling filters during the secondary treatment (removing 10 20% phosphorus) withhold enough of the nutrient to prevent eutrophication, undesirable enrichment of waters with the nutrient that most often limits the growth of phytoplankton.

Conversion of forests and grasslands removes the canopies and litter layer that protect the soil and opens the way for accelerated soil erosion which increases typically by one or two orders of magnitude, from 0.1 2 t ha^{-1} to 10 20 t ha^{-1} a year; overgrazing of permanent pastures has a similar effect. The additional phosphorus lost due to these changes is difficult to quantify with any degree of confidence. I have estimated that over 20 Mt more phosphorus are lost annually from farmland and pastures than erosion would have removed from the same area of land if it were covered by undisturbed natural ecosystems. Enhanced anthropogenic loss of dissolved phosphorus adds another 1 Mt P $year^{-1}$.

Production of inorganic fertilizers began during the 1840s with the treatment of P-containing rocks with dilute sulphuric acid. The resulting ordinary superphosphate (OSP) contains 7 10% phosphorus, ten times as much as recycled phosphorus-rich manures. Discovery of huge phosphate deposits in Florida (1870s), Morocco (1910s) and Russia (1930s) laid the foundation for the rapid post-World War II expansion of the fertilizer industry. Consumption of phosphatic fertilizers reached 5 Mt P in 1960 and it peaked at more than 16 Mt P in 1988. After a 25% decline by 1993 the global use began rising once again (International Fertilizer Industry Association, 1999; Figure 2). The top three producers (USA, China and Morocco) now account for about 2/3 of the global output. Major fertilizers besides OSP include triple superphosphate (TSP, containing about 20% P) produced by treating phosphate rock with phosphoric acid, and combinations with nitrogen (mono- and diammonium phosphate), calcium and potassium (UNIDO and IFDC, 1998).

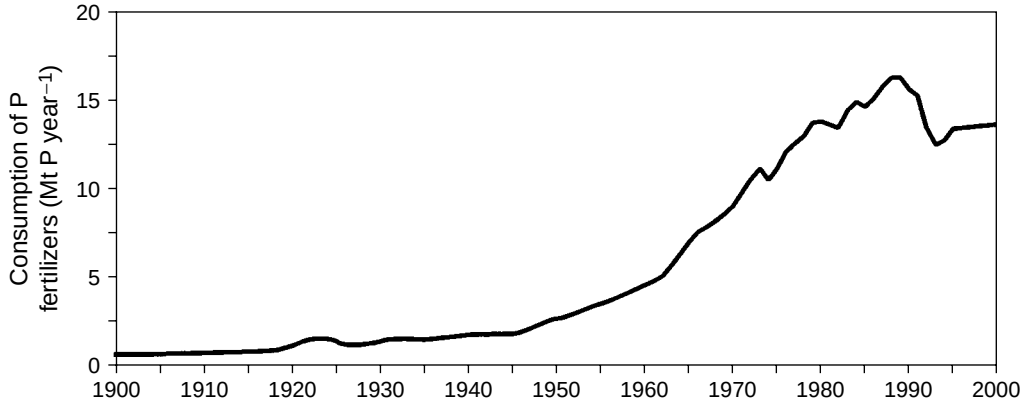

Figure 2 Consumption of inorganic phosphatic fertilizers, 1900–2000

DEPENDENCE ON INORGANIC FERTILIZERS

Modern cultivars whose harvests now dominate the production of food and feed remove annually between 15 35 kg P ha^{-1} of cereals, 15 25 kg P ha^{-1} of leguminous and root crops and 5 15 kg P ha^{-1} of vegetables and fruit (Pierzynski and Loan, 1993). Global food harvests now assimilate about 12 Mt P in crops and in their residues while no more than 4 Mt P are supplied annually by weathering of P-bearing rocks and by atmospheric deposition (Smil, 2000). Applications of phosphatic fertilizers have thus become indispensable for producing today s harvests and this dependence will only increase.

Combination of an early stabilization of human population at less than 10 billion people, less meaty diets in affluent countries (where about 60% of all cereals are now used as animal feed), and relatively modest increases in animal food consumption in low income countries would significantly lower the growth rate of global food demand during the first half of the 21st century but they would still result in a substantial rise of overall phosphorus requirements.

During the 1990s global applications of inorganic fertilizers averaged just over 10 kg P ha^{-1} of arable land, with continental means ranging from a mere 3 kg P ha^{-1} in Africa to over 25 kg P ha^{-1} in Europe (International Fertilizer Industry Association, 1999). These means hide enormous inter- and intra-national differences, as well as uneven use on different crops. For example, in Africa applications are adequate on some plantation crops while tens of millions of the continent s subsistence peasants have never applied any phosphorus at all. International surveys indicate that nearly 2/3 of all applied phosphorus is used on cereals, 10% on oilseeds and about 5% on vegetables (Harris, 1998). Crops receiving the highest applications are corn in the US Corn Belt (around 60 kg P ha^{-1}), Japanese rice (over 40 kg P ha^{-1}) and Chinese and West European winter wheat (about 35 kg P ha^{-1}).

PHOSPHORUS IN AGRICULTURAL SOILS

Phosphorus applied in both organic and inorganic fertilizers is involved in complex reactions that transform a large part of soluble phosphates into much less soluble compounds (Figure 3). Particularly important in this regard are reactions between superphosphates and Al, Fe, K and Mg. The resulting compounds are relatively insoluble and hence immobile in soil. This process of P fixation has been known since 1850 and it has received an enormous amount of research attention (Khasawneh *et al.*, 1980; Morgan, 1997). The traditional argument is that the fixation is rapid, dominant and irreversible. Accordingly, phosphate applications were seen as overwhelmingly futile albeit laborious and costly exercises of moving the element from extracted rocks to insoluble soil compounds (Tinker, 1977).

This misconception resulted in decades of excessive use of phosphorus in agriculture: global N : P ratio of applied fertilizers was just around 1.5 by the late 1940s. Mounting evidence of relatively high efficiency with which crops use the nutrient has finally changed that wasteful practice (Karlovsky, 1981; Isermann, 1990). By the late 1990s the global fertilizer N : P ratio stood around 6 : 1. Recovery rates of 50 60% of applied phosphorus are not uncommon, and maxima are above 70%. Even the global mean appears to be close to 50%, virtually the same as the rate for inorganic nitrogen. Decades of relatively high P applications and the gradual release of a part of the initially fixed nutrient have resulted in many fertilized agro ecosystems have considerable surpluses of available phosphorus (Edwards *et al.*, 1997). Present annual accumulations commonly amount to several kg P ha^{-1}, surpassing 30 kg P ha^{-1} in the most intensively cultivated regions.

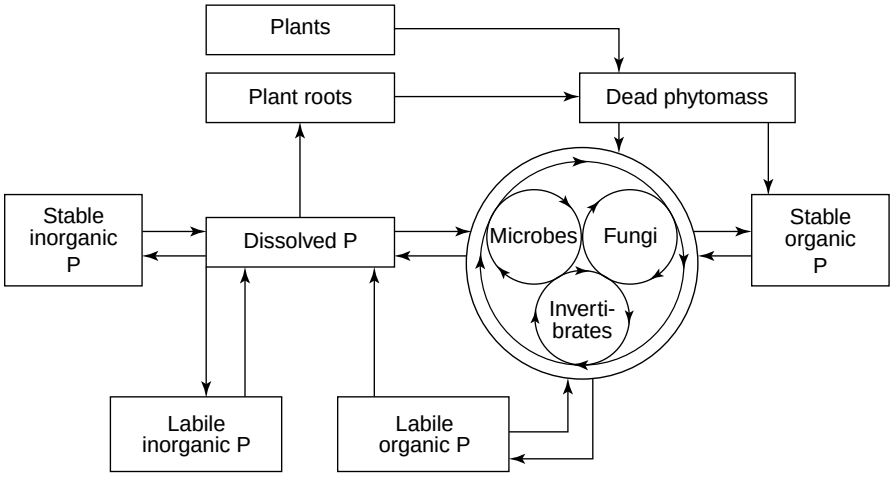

Figure 3 Phosphorus cycle in soil

PHOSPHORUS IN WATERS

The low solubility and high sorption rates of phosphorus compounds limit their leaching into ground waters, leaving diffuse runoff from fertilizers and manures and direct, point discharges of urban and industrial wastes as the two principal ways of enriching surface waters with phosphorus. Because a single atom of phosphorus supports the production of as much phytomass as 16 atoms of nitrogen and 106 atoms of carbon, even relatively low additions of the nutrient can cause eutrophication (*see* Eutrophication, Volume 2), excessive nutritional enrichment of waters (Harper, 1992; McComb, 1995; Tunney *et al.*, 1997). Mere 10 μg P l^{-1} will support algal growth that will greatly reduce the clarity of water. As total phosphorus in water increases, the standing phytomass goes up linearly. It may include unsightly scum-forming algal blooms and filamentous cyanobacteria, as well as thick coats of algae on any submerged surfaces.

Concentrations above 50 μg P l^{-1} will result in deoxygenation of bottom waters during the decomposition of the accumulated biomass; this can cause extensive summer fish kills and reduce or eliminate many aquatic species: pike may disappear while bream and roach, species adapted to turbid waters, become dominant. Offensive taste and odor of water filled with algae requires expensive treatment before drinking, and neuro- and hepatotoxins released by decomposition of some of these blooms may be a serious health hazard to livestock and people. Studies of polluted lakes and estuaries have shown that excessive eutrophication can be generally prevented if annual loadings are lower than 1 g P/m^2 (10 kg P ha^{-1}) of water surface but much higher loadings may not cause serious problems as long as the average retention time of imported nutrients is short.

Eutrophication also seriously disrupts coastal ecosystems in regions receiving high P inputs. For example, it has affected the growth of corals in parts of the Australian Great Barrier Reef (Bell and Elmetri, 1995). In the North Sea it repeatedly creates anoxic conditions and toxic algal blooms while a third of the sea bottom of the Baltic Sea proper (its southern part) is now intermittently deprived of oxygen, the condition which also results in formation of toxic H_2S by S-reducing bacteria and precludes the survival of previously very common mussels and bottom fish (Jansson and Dahlberg, 1999) (*see* Water Resources: Baltic, Volume 3; Baltic Sea, Volume 4).

MODERATING THE HUMAN IMPACT

There is no shortage of ways to lower the anthropogenic loss of phosphorus. By far the most effective measure would be to reduce the intake of animal foods in affluent countries where *per capita* consumption is now commonly above 60 kg $year^{-1}$ of meat and that of dairy products above 100 kg $year^{-1}$. Lowering these intakes by 15 35% would still allow the enjoyment of diets with plenty of animal foods. In addition, since 2/3 of all phosphatic fertilizers are used on cereals and 3/5 of all grains in rich countries are used as animal feed the need for phosphatic fertilizers would decline by 5 15% without any investment.

An approach that is much more likely to be successful relates to best management practices aimed at reducing phosphorus applications or limiting the post-application losses (Sharpley and Withers, 1994). Indirect measures include reduced tillage, crop rotations and recycling of crop residues; direct ways include applications of phosphatic fertilizers derived from repeated soil testing, balanced amounts of the three macronutrients, maintenance of appropriate soil pH, and incorporation, rather than broadcasting, of phosphorus compounds.

Phosphorus in sewage can be effectively controlled either by the use of coagulating agents or by microbial processes (Imperial College of Science, 1997). Addition of flocculating reagents (most commonly salts of iron or aluminum) can remove 70 95% of all phosphorus initially present but the increased bulk of the resulting sludge and high cost of reagents favor microbial treatment of waste water. This treatment relies first on anaerobic conditions for phosphorus release and then during the aerobic stage on a rapid uptake of soluble P by phosphate-accumulating microorganisms. While conventional sludge has 1.5 3% phosphorus, activated sludge contains up to 7% phosphorus and the effluent has less than 1 mg P l^{-1}. Phosphorus-rich sludge can be either recycled or it can be dried and incinerated and the nutrient recovered from ash.

The best way to deal with waste phosphorus is to precipitate it in discrete crystalline products of reasonable purity that can be used either directly as fertilizers or as raw materials. Nearly a dozen of these processes are now commercially available or in an advanced research stage; they produce magnesium ammonium phosphate or calcium phosphate (which is ideal for further processing as it is indistinguishable from phosphate rock), and they release effluent with less than 0.5 mg P l^{-1}. Naturally, the eventual mass deployment of these efficient controls will depend on their cost and on the standards set by national environmental regulations.

In many cases, perhaps most notably in the Great Lakes, eutrophication has been greatly reduced due to the elimination or restricted use of phosphorus-based detergents and increased phosphorus removal from sewage. In other cases it remains a serious problem: although total Dutch phosphorus inputs were cut by about 50% by 1995 compared to the year 1985, phosphorus-saturated soils remain a large source of excessive runoff and many surface waters have phosphorus concentrations an order of magnitude above the natural levels (Uunk, 1991). And while phosphorus loadings may have stabilized, or even substantially declined in

many lakes in North America, Europe and Japan, they are rising in China and India, and eventually they will increase also in Africa.

Yet another long-term environmental problem associated with applications of phosphatic fertilizers and recycling of manures and sewage sludges is the presence of cadmium (Van Kauwenbergh, 1997). Cadmium is the most enriched element in phosphate rocks, occurring in concentrations almost 70 times higher than in average shale. Maximum daily intake should not exceed 50 70 μg Cd day^{-1} for most adults while the recent European intakes are already as high as 40 μg Cd day^{-1}. Consequently, about a dozen countries (including Australia, Denmark, Germany, Japan and the Netherlands) have already set Cd limits for fertilizers.

Phosphorus Water Quality Objectives

Ilija Vukadin

Institute for Oceanography and Fisheries, Split, Croatia

During the last three decades, there has been a several-fold growth in use of nitrogen (N) and phosphorus (P), particularly in agricultural and chemical production, such as in detergents and in food additives. Many factors are important in controlling levels of plant biomass in aquatic ecosystems, but phosphorus is generally considered the key element that controls or limits productivity. The enrichment by nutrients and suspended matter causes accelerated growth of algae

and higher forms of plant life and produces an undesirable disturbance to the balance of organisms present in the waters. Excess phosphorus inputs into surface waters are a major determining factor in eutrophication phenomena associated with the impairment of commercial and recreational fishing, local water quality problems and aesthetic damage.

Viewed in terms of water quantity, it is agriculture that uses the most water, followed by industry and cities, leaving barely enough for the natural environment to exist. From the standpoint of water quality, the greatest polluter of water is industry, followed by municipalities and agriculture.

The aim of this paper is to briefly discuss the main feature of the present flux of nutrients through agro-urban and aquatic ecosystems, and the measures available to reduce or stop the great losses of nitrogen and phosphorus. Special attention will be paid to phosphorus, because this element is looked upon as a limited natural resource.

During the last three decades there has been a several-fold growth in use of nitrogen and phosphorus, for example, agriculture production, in chemical production such as in detergents and as food additives. Cola drinks, for example, contain 180 mg P dm^{-3}, a concentration about 350 times higher than that of the effluent (0.5 mg P dm^{-3}) from modern sewage treatment plants operating with dephosphatation. Feeding a growing population means increased human nutrient excretion (Forsberg, 1994).

The mobility of nitrogen differs from that of phosphorus. Compared to the easily mobile nitrate ion, phosphorus is fixed in different systems, at least temporarily. The modern agro-ecosystem accumulates about 60% of the annual input of phosphorus.

Since the amount of phosphates from municipal sewage contributes about 40% of total P-loading in European countries, of which about 40-50% is due to detergent phosphates, the reduction of detergent phosphates could have a beneficial effect in reducing the total load.

PHOSPHORUS WATER QUALITY OBJECTIVES

Many factors are important in controlling the levels of plant biomass in aquatic ecosystems, but phosphorus is generally considered to be the key element that controls or limits productivity (*see* Soil Amelioration, Volume 3). Nitrogen plays a secondary role, although it can sometimes become important (*see* Nitrate Leaching, Volume 3). Another reason why emphasis is given to phosphorus in eutrophication studies is that phosphorus is often derived primarily from sources related to human activities. The main sources of phosphorus loading are well recognized and could be sufficiently quantified, although there are some uncertainties particularly in evaluating loading from non-point sources of agricultural origin. The contribution of agricultural diffuse sources results in a mean value of 17% of the total P load, although values as high as 30% are attained, and even higher (see Figure 1).

Our estimates of point and non-point source nutrient loads to the Bay indicate that they contribute near to equal amounts of phosphorus to the loading of the Bay.

Continuous monitoring of seawater along the eastern Adriatic coast has been carried out for the past decade. The goal of this research is to observe the influence of urban and industrial effluents on the quality of the receiving seawater. The nutrient balance has been calculated (Vukadin, 1992) for the whole Adriatic Sea (see Table 1). River runoff and domestic wastes are very probably the

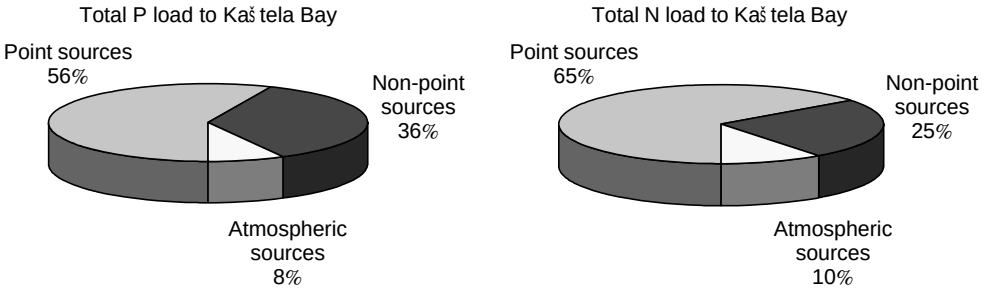

Figure 1 Source of nutrients in Kaštela Bay, Croatia

Table 1 Annual pollution input into the Adriatic Sea (• 10^3 t year^{-1})

Pollutants	Rivers	Domestic effluents	Industrial effluents	Agricultural	Total
Phosphorus (P)	79	2.5	0.5	3	85
AD	14 000	2200	–	–	16 200

AD, anionic detergent.

causes of eutrophication and phytoplankton blooms in the northern and middle Adriatic (Vollenweider *et al.*, 1992).

The values of anionic detergents (AD) and phosphorus found in the Adriatic coastal waters can be classified as sufficiently safe (values AD lower than 1 10 mg dm^{-3}, i.e., the acute values of toxicity of linear alkylbenzene sulfonates for aquatic life). These values are still far beyond these levels and are in compliance with proposal quality standards, (Vukadin *et al.*, 1997).

Two different approaches for obtaining water quality criteria have been followed in different countries:

- without considering the type and use of the water body receiving the contaminant;
- adapting the quality of the pollutant to the natural characteristics of the receptors (rivers, lakes, coastal waters) and taking into account the characteristics of the pollutants (toxicity, persistence, bioaccumulation).

The well-known Organization for Economic Cooperation and Development (OECD) models provide a method of interpreting and using nutrient load estimates in water management effort (Table 2). The model attempts to relate the classical limnologic trophic terminology of oligotrophic, mesotrophic, eutrophic and hyper trophic to specific in-lake levels of several water quality parameters.

Table 2 OECD boundary values for trophic categories

Category	Total P concentration (mg dm^{-3})
Oligotrophic	• 10
Oligo–mesotrophic	10–20
Mesotrophic	20–50
Eutrophic	50–100
Hypertrophic	• 100

Recognition of the probabilistic nature of the responses of lakes to given P-loadings is an important aspect in assessing the trophic response of a lake. Some probability distributions, based on the OECD database, are presented in Figure 2 (Chiaudani *et al.*, 1988). A lake with an average phosphorous concentration of 10 mg m^{-3} would have a 10% probability of being ultraoligotrophic, 26% of being mesotrophic, only 1% of being eutrophic and no probability of being hypertrophic.

As already mentioned, phosphorus inputs into surface waters are a major factor in eutrophication phenomena associated with the impairment of commercial and recreational fishing, local water quality problems and aesthetic damage. Phosphates from a number of different sources enrich surface waters, but restriction or a ban on their use in detergent alone would significantly reduce (30% 50% of the total phosphorous content comes from raw sewage) the nutrient loading, and would significantly reduce the rate of eutrophication.

The effective and long-term control of eutrophication can only be achieved by reducing nutrient loads by adequate preventive measures, supported by appropriate administration and legal powers. Basic options are:

- chemical phosphorous removal in treatment plants and the development and improvement of enhanced biological phosphorous removal;
- ban or reduction of phosphates in detergents;
- pollution control measures relating to agricultural practices; and
- regional planning including land use control.

THE ROLE OF PHOSPHATES IN DETERGENTS

About 50 years ago, it was discovered that a particular phosphate salt, sodium triphosphate (STP)-$Na_5P_3O_{10}$, has outstanding properties as a detergent. This compound

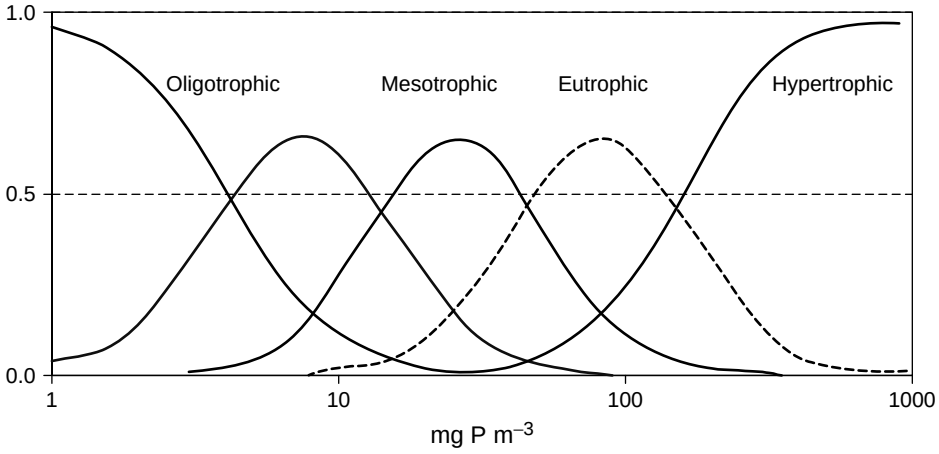

Figure 2 Probability distribution of trophic categories, based on total phosphorus

reduces water hardness (by sequestering magnesium and calcium ions) and detaches certain stains from fabrics.

STP is an excellent compatible with other ingredients used in detergent manufacture; in particular, it is stable to oxidizing agents (i.e., sodium perborate) during storage and washing. Technically, STP is easy to manufacture as a convenient powder, and does not produce any significant health hazards during its manufacture and use. Of course, the higher the level of STP in detergents, the better its performance. This is why, in the late 1960s and early 1970s, North American and European laundry detergents contained up to 60% STP. According to the nature of the material to be washed, several categories of detergents are available:

- light-duty detergents for delicate materials (30 40 °C);
- detergent for colored and synthetic fabrics (60 °C);
- detergents for pre-washing;
- heavy-duty detergents for high temperature washing (up to 90 95 °C).

In liquid detergents, STP is usually replaced by sodium (or potassium) pyrophosphates which play a role similar to that of STP (See Table 3).

As a result of recent political and environmental pressure, STP levels in laundry detergents have decreased to the 20 30% range. Detergent manufacturers have reformulated their products, trying to achieve a balance between consumer demands for clean laundry and the public demand for less phosphate in detergents. Below approximately 25% STP, the precipitation of Ca_3 $(PO_4)_2$ starts to occur in detergents. This damages fabric fibers and washing machine heaters. The search continues for an alternative to the triphosphates in detergents, hoping to find a more effective or cheaper substance. From the late 1960s, environmental concerns about the use of phosphate in detergents strongly intensified this research. Of the many organic and inorganic materials proposed as a substitute, there are only two options: the sodium salt of nitrilotriacetic acid and synthetic sodium aluminum silicates (zeolites).

Table 3 Composition of typical European detergents (%)

Constituent and function	Light-duty powders	Heavy-duty powders
STP, builder	2–15	20–25
Surfactants	25–32	10–15
Sodium perborate, bleaching agent	–	15–25
Sodium Sulphate, filler	10–40	0–30
Sodium silicate	–	5–10
Minor ingredients and water	Up to 100	Up to 100

Prehistoric People and Forest Soils

Ian Simmons
University of Durham, Durham, UK

During the 19th century, a great deal was learned about the nature of soils in pre-industrial agriculture, since the 'improvement' of cropping in the European nations' empires was actively sought. That knowledge has often been the basis of the interpretation of relationships between prehistoric people and soils. One nding is the idea of a tension between the forest as a land bank, convertible to farming, and its use as a resource of many kinds: wild food and wood products most notably. During the 20th century it was realised that the forest-farming connection was also the site of traditional ecological knowledge and this has informed a view of prehistory that the farming systems were usually not 'primitive' but sensitively tuned to the capacities of the environment and the cultural desires of the people.

Forest soils have never been globally homogeneous but they do share some ecological characteristics. In their natural state they generally exhibit tight nutrient cycles, for instance. The mineral nutrients in the ecosystem circulate between the tissues of the tree and the soil so that while they are in the living vegetation they are bound into complex molecules. They then fall as litter and are decomposed into simpler forms and enter the soil. The root system of the tree, possibly aided by mycorrhizal fungi, then takes up the mineral ions in solution and incorporates them once more into living tissues. The times and states when the ions might be lost to runoff or downwash are few. The soils under such vegetation tend to be deeply penetrated by humic material whose concentration attenuates gradually down the profile so that visible separation of the horizons in the soil profile is absent and the organisms which perform the task of decomposition are adapted to shady conditions. The water relations of the system are also dominated by the trees: a canopy in leaf intercepts a proportion of the incident precipitation and allows it to evaporate back into the atmosphere. The water which reaches the soil is partitioned: some runs through the soil and into runoff, but another proportion (the relationship between the two components is very variable according to climate, forest type and topography) is taken up by the tree roots and transpired back to the atmosphere via the stomata in the tree s leaves. In the wet climates of Northwestern Europe, acid brown earth soils under deciduous forest were transformed into podsols during the mid-Holocene period (Dimbleby, 1962).

If by prehistoric, we mean pre-literate or before European contact (rather than simply pre-industrial), then the human impact upon these types of flows and cycles may be seen as either obviously temporary (on a time-scale of a decade or less) or apparently permanent on a time-scale of centuries. In the first case, *shifting cultivation* has been common in many biomes (Nye and Greenland, 1960) (*see* Shifting Cultivation and Land Degradation, Volume 3). While it is most commonly associated with the tropics (sometimes called *slash-and-burn agriculture*), shifting cultivation was probably also used by prehistoric populations in Northern Europe when they first replaced hunter-gatherer groups. It was practised in the coniferous forests of Finland until the 19th century. The second instance records the quasi-permanent removal of forests for grassland management (for the production of domesticated or wild animals) or for tillage. In some places, permanence was probably not intended but became necessary to support growing human populations: in others, the forest reclaimed the land if the population decreased after, e.g., famine or epidemic disease.

In ecological terms, clearance of forest carries certain quite fundamental consequences for the dynamics summarised above. The removal of trees, for example, takes away the dominant plant of the ecosystem. Thus, those elements of flora and fauna which depend upon the tree s products for their life cycles and nutrition (and especially the soil flora and fauna) are deprived of their niches. The absence of trees usually allows daytime temperatures at ground level to rise and thus exceed the tolerances of some of the litter-layer organisms, so that the rapid processing of plant litter no longer occurs. But human activity often involves burning the accumulated litter and the debris from felling, so that the cleared area to some extent mimics the pre-existing conditions and indeed pH may rise initially (Sillitoe, 1995). Fire may however bake the top of the soil and kill the remaining flora, fauna and components of the seed bank. Nitrogen is lost in smoke and from rapidly decomposing organic matter at the soil surface (Lal *et al.*, 1986). In any case, the replacement vegetation under agriculture is likely to produce less litter (since most of the plant material will be harvested by humans) and so the humus content of the soil becomes lower. This in turn makes for a less tightly bound crumb structure and so the soil is more prone to erosion, especially on steep slopes. Since the trees have gone, the soils are more open to the impact of the intensive rainfall often found in, e.g., the tropics. Vulnerability to erosion and downwash is therefore increased: bare soil may yield 100 times as much silt as forest. The absence of tree rooting systems also means that the water-pump effect of the trees is lost. Neither canopy evaporation nor root-trunk-leaf transpiration systems is present to remove water and so the soil may either shed the water quickly (which it may do if it is baked by fire, for instance) thus enhancing its erosive power, or it may stay in the upper

horizons of the soil and waterlog them. Hence removing only some trees to form a clearing may result in the death or retarded growth of others. In very wet environments, such as that of upland Britain in the mid-Holocene, the plants able to tolerate the wet and acid conditions fail to break down completely when dead and accumulate to form considerable depths of peat, even on water-shedding slopes. Just as such peat may act as a sponge and hold water, as did the root layers of the original forest, so downwashed soil may accumulate at the foot of a slope and be of considerable agricultural value in its new setting. In a similar fashion, upland forests in the Rocky Mountains of North America hold the snowpack until well into the spring, making for a steady release of water.

So the magnitude of environmental impact upon forest soils of clearance by prehistoric people has been quite high and not always covered over by later changes: the peats of upland Britain are still there, for instance. But later periods of human occupation, with advanced technology, have often produced even greater changes. It is worth noting that one of humankind s major alterations of the face of the earth is the agricultural terrace, which acts as a check on the downward movement of soil and water (padi rice is an extreme case) which have often been mobilised or released by forest removal. Also on the positive side, shifting agriculture seems to have been a reasonably productive system provided that the exhaustion of the cleared plot could be followed by a period in which the nutrient and water cycles were reconstructed by colonising woody vegetation which ended in the re-establishment of closed-canopy forest. Traditional shifting agriculture, for example, loses very little soil down slope. Colonial administrators in the tropics often thought of shifting cultivation as primitive and wasteful without recognising that fallow under forest was an exact analogy of fallow periods in temperate agricultural systems. As in the management of most biological resources, however, too heavy a cropping regime (i.e., too short a fallowing cycle) produces poorer crops and less resilient agro-ecosystems.

Red Tide

Red tide is a common name for an algal bloom accumulating as a dense visible patch with reddish tinges in the surface of the water in seas in coastal areas. Under such conditions, the water appears to be red. The term red tide is thus a misnomer because they are not associated with tides and they are not usually harmful. On the other hand, algal species that are harmful may never reach the densities required to discolor the water. Thus, the term *harmful algal blooms* is now preferred and used by scientists to refer to marine algal bloom phenomena containing toxins that cause negative impacts (*see* Harmful Algal Blooms (HABs), Volume 3).

Refugees and Human Conflict

Phil O'Keefe and John Kirkby
University of Northumbria at Newcastle, Newcastle, UK

Throughout the world, 50 million people are displaced from their homes - a population almost as great as that of the UK. Put in stark terms, one person in every 120 has been driven from home. Some 13 million of them are legally recognized as refugees: they have left their country to escape persecution, violence or armed con ict. The remainder, a mixture of stateless people, asylum seekers, the internally displaced and returnees, are sometimes recognized. They all need humanitarian assistance. They urgently need help with food, shelter, water and medical care. Just over half of that 50 million receive help, largely through the United Nations (UN) and international non-governmental organizations (NGOs). The remainder must survive as best they can.

The 1990s were dominated not only by complex, protracted emergencies, but also, in the former Soviet Union, former Yugoslavia and Africa, by protracted local wars that frequently gave birth to new states or challenged national sovereignty. Early on in the decade, the Gulf War (1991), a politico-military intervention, colored all subsequent humanitarian assistance.

The Gulf War heralded a new era of cooperative measures in defense of international security. It also posed a humanitarian problem because the Western Alliance was unwilling further to protect the Iraqi population, especially the Kurds. Subsequent episodes, in Bosnia and Somalia, showed an increasing willingness to intervene in the internal affairs of a sovereign nation state but at a cost. In

Bosnia, the cost was the realization that peacekeeping to allow the delivery of humanitarian aid was dangerous when there was no peace to keep; humanitarian agencies were also conscious that negotiating access with the combatants frequently involved rewarding them with humanitarian supplies as the price for access to the needy. The cost in Somalia was a flawed intervention that rendered an international community increasingly reluctant to engage in other complex emergencies, particularly when it meant a military involvement. The cost of this reluctance was the withdrawal of the UN Assistance Mission from Rwanda and the subsequent genocide. The position was only reversed in Kosovo.

The Gulf War, the North Atlantic Treaty Organization s action in former Yugoslavia and the UN intervention in East Timor raise, in their different ways, difficult questions for humanitarian assistance. Can military intervention legitimately be used without a UN mandate to protect refugees? Can systematic violations of human rights go unchecked? Could active peacekeeping in support of humanitarian assistance take place without military intervention? Can the UN respond to its charter and rise to the defense of a shared humanity? Will the international community respond to peace with the commitment to consistency that it sometimes gives to war?

A complicating factor is that not only are refugees victims of war, but also of natural disasters (earthquakes, floods, droughts, etc.). In this latter case, climate change and sea level rise over the next 100 years must also be considered (not discussed in this paper).

HUMAN IMPACT OF EMERGENCIES

One of the most challenging humanitarian tasks is the relocation of people usually called *repatriation*. According to the US Committee for Refugees, the number of people in need of emergency assistance, in January 1998, was around 36 million. The single largest group was internally displaced persons estimated at over 18 million. Repatriation is an inappropriate term for relocating internally displaced persons.

The United Nations High Commission for Refugees (UNHCR) presents other data. On the 1st of January, 1999, the total number of people of concern was 21 459 620, of whom 11 491 710 were refugees. The agency estimates that, worldwide, there are a total of 30 million internally displaced persons, of whom five million receive UNHCR assistance. It suggests that the total number of people forced to flee their homes is about 50 million.

Although there are common characteristics, relocation in each emergency is always unique, not least because of different histories of architecture and settlement patterns. Relocation now often takes place in conflict or at least in unstable or insecure peace processes. Refugee and internally displaced person camps may themselves become targets of war. Most relocation is voluntary repatriation, that is spontaneous relocation without external supervision. Voluntary relocation raises a dilemma for humanitarian agencies. Their duty to protect does not allow them to encourage return to unsafe areas, but if refugees and internally displaced persons exercise their right to return, what responsibility for assistance and protection can the humanitarian agencies offer? Even with successful relocation, is there is a gap between resources available for humanitarian assistance and longer-term development needs? If relocation is not linked to the rehabilitation of productive capacity, a cycle of displacement is likely to emerge.

The increase in complex disasters has produced an expansion in humanitarian and agency aid and in the amounts of food allocated for emergency relief. Bilateral donor expenditure (excluding food aid) rose to US$3.5 billion in 1994. If emergency food aid and contributions to multilateral institutions from the member countries of the Organization for Economic Cooperation and Development/Development Assistance Committee are included, the total for 1994 would exceed US$6 billion, some 12% of official development assistance expenditure. From the late 1980s to the early 1990s, the volume of bilateral emergency assistance and food aid doubled. In the same period, aid monies and monies channeled through multilateral organizations declined.

Until recently, emergency aid seemed to be relatively well protected, despite declining official development assistance. It was a popular cause, but was always attached to specific events, frequently those in which politicians and pop-stars could present their humanitarian credentials on television (other catastrophes often went unreported and under aided). Nevertheless, the most recent available figures show that distress relief expenditure fell marginally as a proportion of total official development assistance from 5.86% in 1994 to 5.19% in 1995 (excluding food aid). For some agencies, the fall has been even more pronounced, forcing them to retrench (IFRC, 1997).

The European Union (EU), largely through the European Community Humanitarian Office, has become the single largest humanitarian donor; together with the US it provides almost half of the global humanitarian funds. Their distribution is markedly skewed however; for example, three disasters in the Northern Hemisphere (Iraq, Yugoslavia and Haiti) took almost 60% of total bilateral emergency spending in 1995, which resulted in a *per capita* expenditure twice that for African emergencies in the same year. Much of that disparity arises, of course, from differences in local costs.

CHANGING CONTEXT OF HUMANITARIAN ISSUES

In humanitarian interventions, less attention is now paid to the sovereignty of individual nation states and more to human rights. Peacekeeping, conflict resolution and preventive diplomacy are increasingly deployed. Expenditure is difficult to classify since relief, rehabilitation, reconstruction, development or prevention cannot easily be separated in protracted emergencies. The scope of expenditure is widening to include local capacity building, restoring democracy and civic institutions and promoting good governance.

Gender and environment are crosscutting issues in humanitarian assistance. Much of the diplomacy underlying this changing political landscape is out of sight in regional bodies such as the EU, or in dialogue between donor governments and the UN. Humanitarian assistance is marked not so much by donor fatigue as by donor frustration. Political activity to prevent emergencies is becoming more commonplace, including early warning systems for emerging conflicts, and a drive to ensure, in the aftermath of Rwanda, that humanitarian assistance should not be used as a substitute for political intervention.

Debate about the civil and political rights that must underpin the delivery of humanitarian assistance is increasing. The distinctive feature of a rights-based approach is its legal foundation. If it is to be effective, a legal apparatus must be created to monitor the respect, promotion, protection and fulfillment of human rights.

Military interventions, partly based on experience in Bosnia and Somalia, have moved from small vehicles and lightly armed peacekeeping forces, to heavy artillery and battle troops to ensure access to beneficiaries for humanitarian agencies. Armed forces are willing, where necessary, to work alongside humanitarian agencies, although some agencies find this a difficult relationship. Security for humanitarian personnel is increasingly a problem, as they and the assistance they bring become targets for protagonists in complex emergencies.

INSTITUTIONAL TRENDS

Institutional trends in the delivery of humanitarian assistance are clear. Donor pressure, and the internal drive for change, have made responses to complex and protracted emergencies a major issue for the UN. Control is increasingly moving from individual agencies to the secretary general s office and there is a drive to set the complex emergency agenda before both the UN General Assembly and the UN Security Council. Coordination is being strengthened by concentrating overall responsibility for it with the UN Office for the Coordination of Humanitarian Affairs. These moves have been paralleled by efforts to unify fund raising into consolidated appeals.

Individual UN agencies have been undergoing similar change, for example, UNHCR s responsibilities have widened; it has an increasing caseload of refugees and internally displaced persons to support, to repatriate and to resettle. It now has direct responsibility for beneficiaries and so frequently takes the operational lead in the field.

The International Committee of the Red Cross (ICRC) and the International Federation of the Red Cross and Red Crescent (IFRC) have also experienced change over the last decade. Both have expanded their roles, particularly in addressing the needs of internally displaced persons where a UN response is sometimes inappropriate. Donor agencies respect the leverage that ICRC and IFRC can generate because of their neutrality, although concern has been expressed about mandate drift between the two.

Institutional change has also influenced the NGOs. Their involvement in humanitarian assistance has grown very quickly over the last decade, new international and local organizations have emerged and global NGO families have been strengthened. UN agencies are increasingly selecting leading NGO families, rather than individual organizations, as their partners for particular disasters. NGOs compete amongst themselves, and amongst themselves and UN agencies for humanitarian funds and, more generally, for access to development funds. Their mandates have also drifted; partly as a consequence of increased competition, relief organizations have moved towards development, and *vice versa*. Donor agencies, including the UN, are increasingly attempting to evaluate their comparative capacity and performance. As donor pressure increasingly demands low cost, high quality, integrated assistance, many NGOs seek to reclaim a measure of independence, especially in matters of neutrality and impartiality, by reaffirming that their prime responsibility is to pursue justice for the beneficiaries.

These institutional changes have produced calls for legal and technical criteria by which institutions can be judged. This includes the establishment of a code of conduct for the *International Red Cross and Red Crescent Movement and NGOs in Disaster Response*, the *SPHERE Project* that establishes objective standards for the delivery of all humanitarian assistance and the *Active Learning Network on Accountability and Performance in Humanitarian Aid*. Parallel changes have taken place in the academic discussion of protracted emergencies. Key concepts are vulnerability, entitlement and livelihood systems and a demand-side approach, even if such concepts are difficult to capture in the improved early warning systems.

CHANGING APPROACHES

The number and quality of early warning systems for protracted emergencies, e.g., sea level rise, drought, have improved. However, predictions about future political events and social change are inherently difficult and

uncertain and there are limits to formalized models as well as to political risk analysis.

Conflict prevention is a problematic venture in which humanitarian agencies, by themselves, have little or no influence. Thus, they are expected to respond effectively and efficiently to developments that are difficult to predict, and over which they have little control.

Humanitarian actors do not sufficiently recognize that a pervasive humanitarian presence will distort local coping mechanisms and livelihood systems and may additionally fuel, rather than prevent, the conflict in a protracted emergency.

Obtaining access for the provision of food and medical assistance is crucial for saving lives, and humanitarian agencies are increasingly concerned to resolve access problems caused by reluctant governments, rebels and by anarchic violence. However, sometimes the affected population needs security more urgently than it needs material supplies.

Security is also an issue for humanitarian workers and, in many places, has been violated and goods looted and misused in violation of the principles of humanitarian aid. These situations tend to occur when there is a serious imbalance between assistance and protection and where the humanitarian agencies have been unable to protect civil victims of the conflict. Nevertheless, the right of humanitarian access is strongly affirmed, even where it contradicts the principle of national sovereignty.

There has been much discussion on creating effective links between relief and development. However, dealing with protracted emergencies and countries in-between conflict and peace is difficult, and thought will be required about the role of government, especially about its responsibility for reintegrating returning refugees and internally displaced persons. As the volume of assistance for victims of conflict cannot be sustained by development budgets, humanitarian agencies will have to improve the quality and sustainability of their rehabilitation activities. This will require the increased use of local resources, human and material, to strengthen the local economy and to build capacity for local governance.

River Regulation

Geoff Petts
The University of Birmingham, Edgbaston, UK

Human societies depend upon water for household use, for industrial processes and for irrigation. Viewed from space, the Earth is a green and wet planet, but water scarcity is a major global problem and in 1990, 40% of the world's population of 5.3 billion suffered water shortage. Agriculture is the largest water user, accounting for nearly 80% of consumption. In many areas, dry climate, intermittent drought, and population growth imply an increasing need for water security in agriculture as well as increasing water needs for domestic and industrial supply.

River regulation is the control of river ow for human use. Traditionally, these uses include water supply, ood control, wastewater disposal, and navigation. Large dams and water storage reservoirs are key components of river regulation schemes as are networks of embankments, weirs and locks.

Throughout history, water-dependent civilizations have experienced drought and drought-related pollution, poverty

*and war. Civilizations dependent upon rain-fed agriculture have been less powerful than those that achieved control of the variations of river ows to sustain irrigation agriculture. Over the past century, and increasingly, river regulation has been closely linked to major transfers of water from one basin to another (*see *Inter-basin Transfer (IBT) for Water Supplies, Volume 3).*

Dams and their associated river regulation schemes are often the single largest infrastructure investment undertaken by a country. Until the 1970s, they were seen as engineering challenges offering enormous opportunities for harnessing a seemingly under utilized and renewable resource. During the 1970s and 1980s, the damaging impacts of these schemes upon the environment and social systems were forcefully demonstrated.

Strains on water supply systems in this century will relate not only to continuing population growth but also to rapid urban development in many arid and semi-arid regions, requiring even more intensive development of river regulation and inter basin transfers. River regulation, especially for agricultural and urban water supplies, and for hydroelectric power production, is still a key component of development programs. Scienti c research over the past 20 years has now established the basis for evaluating the sustainability of new river regulation proposals and for planning for the sustainable development of river corridors.

A HISTORY OF RIVER REGULATION

The control and appropriation of water has been fundamental to the building of human civilizations for more than 2500 years. Most of the early civilizations were dependent upon the management of floodwaters to irrigate agricultural lands. The rise of civilizations in the Middle East, Northern India, Southeast Asia, China and Meso-America reflected the sophistication of technology and the power of the centralized state authority, which emerged out of water control. In some cases, the fall of these civilizations related to natural drought or soils becoming infertile because of salt accumulation resulting from mismanagement of the irrigation systems. The combination of hydraulic agriculture, a hydraulic government, and a single-centered society constituted what Wittfogel (1956) referred to as a hydraulic civilization.

The earliest dams for the purpose of river regulation were constructed over 5000 years ago and they were widespread throughout the Mediterranean area by Roman times. By 2000 BC, irrigation agriculture, the development and distribution of potable water supplies to urban centers, and elementary flood control were widespread. However, the first 3000 years of river regulation were dominated by the desire to control river flows in order to increase food production and to generate food surpluses. River regulation was also to provide the foundation for industrial growth using waterpower and urban centers based upon water-borne trade. In England about 3000 BP, early towns, such as Egham on the River Thames, developed as focal points for trade along inland waterways and the Domesday records of 1086 indicate that there were already more than 5000 water mills. Pound locks, the catalyst for a rapid expansion of inland waterway trade, a product of the Italian Renaissance, were widespread across Europe by the mid-16th century. The Industrial Revolution saw water assuming an ever-widening role, for power, navigation, water supply, and waste disposal. With urban and economic growth came wetland drainage, canalization of natural channels for boat traffic, embanking and dredging of rivers for flood control, and the construction of ever-larger water storage reservoirs.

The basis for the modern era of river regulation was established between the 16th and 19th centuries through advances made by surveyors, cartographers, architects, and military engineers. Progressively, the art of river regulation was replaced by a scientific method based upon mathematical calculations and physical laws. The control of major rivers was seen not only as a practical necessity, but also as a way to capture the public imagination, enhance the status of the engineer, and become symbols of national prowess (Cosgrove and Petts, 1990). Gigantic works of water engineering came to signify, especially to the French and British, the natural dominion of imperialist powers over the environments and peoples of other lands. By the end of the 19th century all the major rivers of Western Europe had been regulated. In 1817, the training of the braided Alsatian section of the Rhine had been initiated to establish a fixed, single channel with benefits for navigation, flood control and land drainage. The latter was not only required to create more agricultural land but also to combat malaria by eliminating mosquito habitat. One of the greatest works of the 19th century was the regulation of the River Tisza, which drains the southern and western Carpathians; the works shortened the river by 340 km!

Faith in the power of technology to control the natural environment spread with colonial expansion to the New World and then to the Third World. Led by the popular pioneering vision of Man s struggle to tame nature and entrepreneurs motivated by the desire for economic growth, river regulation was to form the core of plans to develop entire river basins.

Grand water projects were politically and socially acceptable, and they had a major role in generating employment, especially during the inter-war years, including the Great Depression of the 1930 s when, in the US:

> In the interests of the national welfare there must be national control of all running waters of the United States, from the desert trickle that might make an acre or two productive to the rushing flood waters of the Mississippi (US National Resources Planning Board 1934, cited in National Research Council 1992, 42).

The 221 m high Hoover Dam on the Colorado River, USA and its 37 • 10^9 m^3 reservoir Lake Mead, constructed in 1935, provided one model for water development: the creation of massive impoundments. A second model was provided by the Tennessee Valley Authority (TVA) in the US, formed in 1933. Total control of the river was sought by using many, large multi-purpose dams to exploit the full potential of the catchment s water resources (water supply and hydroelectricity) and of the river for navigation, whilst at the same time achieving control over flooding. Today, the TVA has 32 large dams and there are 20 other dams in the basin.

Throughout the US there followed 30 years of construction of integrated systems within large river basins (the Columbia, Colorado, and Mississippi Missouri rivers), consisting of new large, multi-purpose storage reservoirs and expansion and improvement of the inland navigation systems.

By 1965 virtually every river in Europe and North America had been regulated and even small streams had been incorporated into water resource plans. On other continents progress towards river regulation moved rapidly, such that few rivers remain that are not affected by regulation in some way.

Globally, the construction of dams over 15 m high (large dams, as defined by the International Commission on Large Dams) accelerated from less than 100 per year in the 1950s to a peak of global dam building activity, during the 1970s of more than 500 per year (World Commission on Dams, 2000). Today there are more than 45 000 dams over 15 m high. However, one estimate suggests that including small dams, approximately 800 000 dams have been constructed worldwide.

Today, a mega-project can be defined as one that meets one or more of the following criteria: the dam is higher than 150 m, the dam volume is more than 15 000 • 10^3 m^3 or the reservoir storage capacity is greater than 25 000 • 10^6 m^3. Currently, there are 410 mega-projects constructed, under construction or planned. The largest dams are higher than 275 m or impound reservoirs with capacities of over 150 • 10^9 m^3 (Table 1). The largest schemes, such as that proposed for the Caroni tributary of the Orinoco river in Venezuela (Figures 1 and 2), would convert entire river systems into chains of lakes impounded by large dams.

Dams account for 18% of the electricity generated worldwide, provide reliable water supplies in many of the world s expanding urban centers, vital flood control in some areas, and played a key role in expanding irrigated land from 95 220 million hectares between 1950 1975.

ENVIRONMENTAL IMPACTS

In the past, the need to conserve flora and fauna, let alone entire ecosystems, was not simply viewed as a constraint on progress, as it is in many developing economies today; it was irrelevant. The legacy of progress in river regulation over the past 200 years, has been pollution, dried-up rivers, widespread destruction of wetland and aquatic habitat and

species extinctions. Three indicators of unsustainable water use at the end of the 20th century were:

- the mighty Huang He (Yellow River) (China) and Colorado (US) rivers no longer flowed to the sea in the dry season (*see* Yellow River, China: a Case Study in Water Resources, Volume 3);
- the surface area of the Aral Sea (Kazakhstan) shrunk by 25 000 km^2 because of water abstractions from the Syr Darya and Amu Darya rivers (*see* Aral Sea, Volume 4);
- salinization caused severe loss of fertility in 20% of irrigated lands: (*see* Salinity and Agriculture, Volume 3).

Studies of the environmental impacts of dams (e.g., Petts, 1984) are important for the development of predictive models for the dual purposes of sustaining natural ecosystems and meeting human needs for water resource development and hazard control. Particular attention has been given to the fate of fisheries. Atlantic Salmon (*Salmo salar*) disappeared from many rivers of Western Europe following river impoundment; in Eastern Europe the Sturgeon (*Acipenseridae*) have been similarly affected, whilst in Northwest US the numbers of Pacific Salmon (*Oncorhynchus* spp.) declined dramatically subsequent to dam construction. Along tropical rivers, fisheries are a particularly important component of indigenous cultures; flood regulation by dams can cause a dramatic decline in river fish stocks.

The development of new fisheries in reservoirs is often seen as a benefit of dams. In Africa, for example, reservoir fisheries are important both by virtue of the area they occupy (40 000 km^2 for reservoirs exceeding 10 km^2) and because they contribute 150 000 t of fish; 10% of the overall inland fishery yield (Kapetsky and Petr, 1984). However, in many cases the fish production in the reservoir only replaces that lost from the river downstream, whilst in many other cases the amount of fish lost downstream of the dam surpasses the potential of the dam itself. Thus, below the Kainji dam in Africa, 6000 t of fish have been lost and the reservoir behind the dam yields only 5400 t. Reservoirs that support fish populations and fisheries where yields are higher than the rivers they submerge can be found only where the productivity of the natural river is low (Welcomme, 1985).

Most ecological changes resulting from river regulation can be related to one of four situations:

1. The introduction of dams creates barriers especially to the migration of anadromous fish. Fish passage facilities have been introduced on many dams, including ladders, locks, lifts, and collection and trucking, but with varying degrees of success. The primary problem appears to be the ability of the fish collection system to intercept or to attract migrants by providing entrances at proper locations and with suitable hydraulic conditions. The design and efficiency of fishways is dependent upon a detailed knowledge of the swimming capabilities and behavior of migrating fish; for many species this knowledge is not yet available. Irrespective of the height of the dam, delayed migrations (upstream and downstream) related to fish movement through a reservoir can adversely affect the survival and reproduction of migratory species.
2. All dams change the distribution of flows downstream, they trap sediments being transported along the river, and the retention of water in reservoirs can alter the water quality of the river downstream. In most cases, the flow variability is reduced, the average flow is reduced and sediment loads are dramatically reduced. Nutrient levels and temperatures of water released from the reservoir depend on the depth of withdrawal; deep-water releases from the hypolimnion of the reservoir can cause particular problems, discharging cold anoxic water.

   Such limnological impacts affect the river ecosystem for a long distance downstream of the dam. For example, for 400 km below Glen Canyon Dam on the Colorado, the water is now too cold for most native fish (Holden and Stalnaker, 1975). In other cases, production of algae and plants within regulated rivers can be enhanced by reduced turbidity, flood regulation, and increased water temperatures. The cumulative influence of runoff from non-regulated tributaries and inputs from riparian sources causes the effects of a reservoir to decrease downstream, such that the linear effect of regulation is partly dependent upon the structure of the drainage network. Nevertheless, a down river variation in organic life, with the most dramatic change occurring within the first 2 km below the impoundment, often

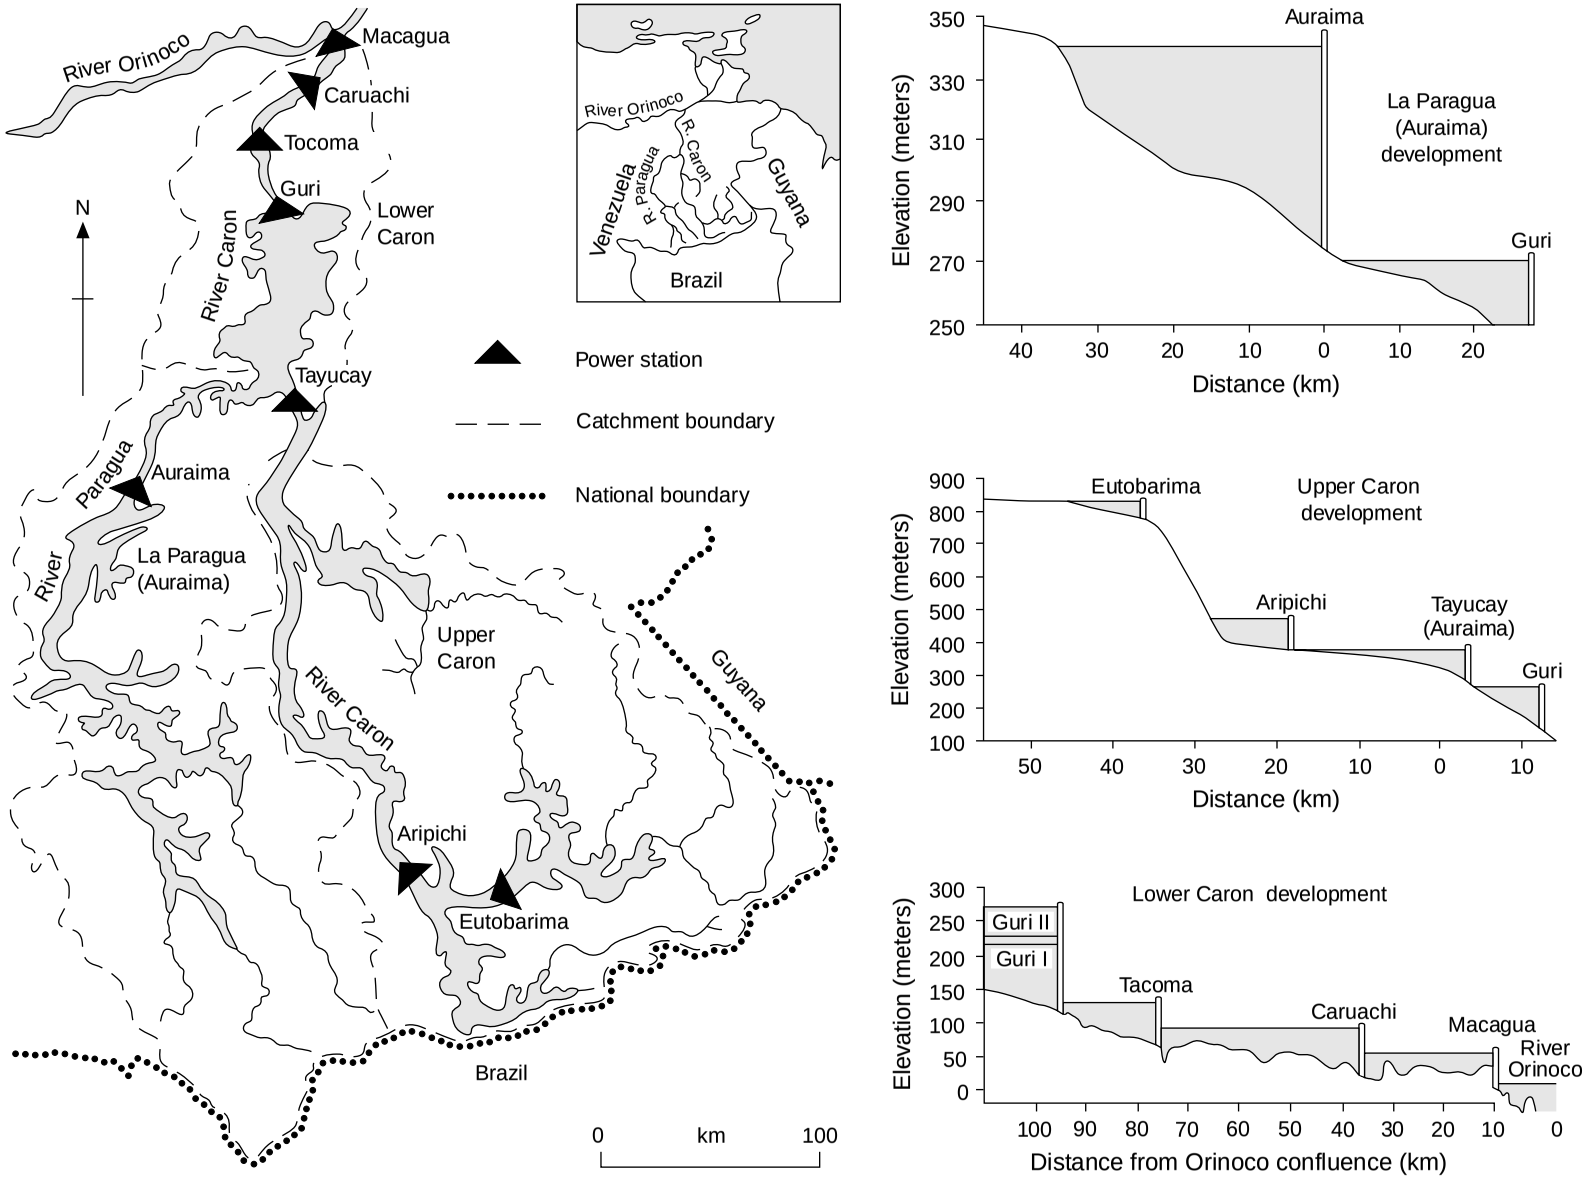

Figure 2 A proposal to regulate the Caroni River Venezuela. The scheme would convert a fast flowing river into a series of slow flowing lakes impounded by large dams

occurs below dams. Such changes are characterised by a lower diversity and higher density of invertebrates. The cumulative effects of river regulation may be even more marked producing major changes in the chemistry of coastal seas and having marked effects on the chemistry of nearly enclosed seas. For example, long term data on the discharge of water and nutrients by the Danube into the Black Sea show a reduction of more than 60% in the dissolved silicate concentration of water in the central Black Sea. The consequent changes in the ratio of silicon to nitrogen in the sea appear to be larger than that caused by eutrophication alone and is thought to be responsible for a dramatic change in phytoplankton species composition from diatoms (siliceous) to coccolithophores and flagellates (non-siliceous). The upstream damming of the Danube at the Iron Gates appears to have been a key factor in causing these changes (Humborg *et al.*, 1997). River regulation has contributed to changes in the biogeochemistry of the entire Black Sea and probably to alterations to food web structures and biogeochemical cycling in coastal seas in many parts of the world.

3. Geomorphological changes are induced by changes of the hydrological and sediment transport regimes. Changes of channel morphology are associated with changes of the instream hydraulics (depth, velocity and shear stress distribution) and substrate characteristics, as well as space and shelter availability. The dimensions of river channels adjust to the hydrological and sediment transport regimes, and a range of channel changes have occurred below dams (Petts, 1984; Williams and Wolman, 1984). Changes in flow and sediment transport have had dramatic impacts on habitats for wildlife (Figure 3).
4. Biodiversity is reduced by the isolation of the river channel from its alluvial plain and by the loss of primary habitats. Separation of the major bed of the river (its floodplain) from its minor bed (the main channel) has had a considerable effect on the ecological diversity of the highly productive alluvial corridor and riverine fish populations. Natural river corridors are biologically diverse and highly productive (Naiman and Decamps, 1990). Floodplain forests, sustained by flooding and periodic rejuvenation by channel erosion, contain a diversity of habitat patches of different types and ages. In turn, the range of habitat types and ages sustains a rich diversity of biota. The elimination of access to backwaters, floodplain lakes, and marshes has severely impacted fish stocks (Welcomme, 1979) by eliminating spawning habitats and refuges during periods of lethal and/or critical water quality.

A fundamental problem in the development of a general model of ecosystem response to river regulation is the failure of many studies to consider observed changes within an appropriate time scale. Most studies of the impacts of dams have focussed on impacts at a single point in time, often within five years of dam closure (Petts, 1987). A wide range of physical, chemical, and biological factors interact to determine the character of a river and to maintain the river system in a state of quasi-equilibrium. The ecosystem recovery process cannot proceed in advance of the physical recovery process. Whilst new regulated hydrological and water quality regimes will stabilize relatively rapidly, over 5 10 years, the physical adjustment of channel morphology can require a time scale measured in tens or even hundreds of years.

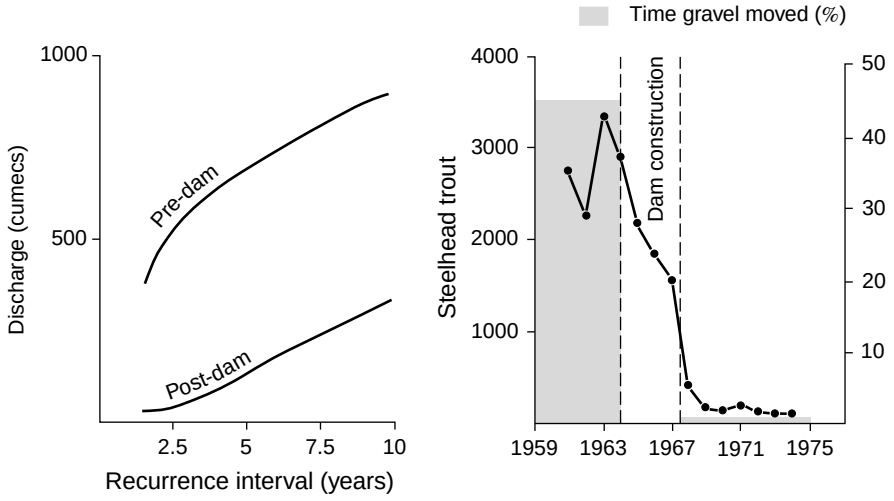

Figure 3 Impact of the Lewiston dam and reservoir on the Trinity River in Northern California, US. Reduced flood magnitudes have dramatically reduced the frequency of sediment movement, causing channel change, and a marked decline in fish numbers

LESSONS FOR THE FUTURE

Despite the growth in environmental awareness, for many, water running to the sea is perceived as a lost resource; floods are viewed as major hazards; and wetlands are seen as wastelands. Yet the nature conservation value of river corridors and the ecological services they provide are dependent on the natural hydrological regime, and its related biochemical and geomorphological dynamics.

The real question is not whether rivers should be regulated but what steps should be taken to reduce the adverse environmental impacts to a minimum. There are two important lessons for the future. First, all dams will cause environmental changes. Any change in the hydrological regime will cause ecological change. However, research on ecological dynamics within regulated systems is beginning to define the sensitivity of species, communities and environmental processes to hydrological change; approaches are being developed to enable selection of sites for development that are least sensitive to change; and options are being developed to mitigate unacceptable ecological changes.

Secondly, in many cases the most dramatic impacts have been shown to result from poor planning, ineffective administration, and bad management of the water resources scheme. A dam and reservoir may have been the catalyst for change but often the major impacts resulted from the lack of appropriate planning, administration, and operational management. The failure to consider the secondary and tertiary impacts of water development schemes on the environment and on people during the early stages of project assessment. One of the most serious of such secondary impacts of dam construction is degradation of soil fertility by waterlogging, salinization and alkalization caused by irrigation without adequate drainage facilities or controls on rates of water application. Many of the health problems associated with water development projects are also linked to secondary impacts including irrigation and the immigration of people with either new strains of endemic diseases or new diseases not normally found in the project area. For example, schistosomiasis and river fluke infections are often high in areas of perennial irrigation.

Sustainable socioeconomic development needs dams; it also requires water engineering projects that are environmentally sound. A strategy for sustainable river regulation to conserve biological diversity and important ecosystem functions along river corridors requires:

1. the allocation of water and land to meet ecosystem needs;
2. comprehensive catchment and national planning and coordination and in some cases international plans that incorporate both development and conservation objectives;
3. community participation in the decision-making process and project management;
4. long-term monitoring.

However, despite dialogue to formulate environmental guidelines for water projects, such guidelines are often difficult to implement, have seldom been taken seriously by governments and are commonly ignored by project officers of development agencies.

River regulation works are built with a prospective lifetime of around 100 years. Reservoirs are usually managed with a defined flood storage capacity. Such planning usually assumes no long-term change in climatic or river regime. Many existing projects have seen severe consequences of upstream land use and land cover change, particularly through increased runoff and siltation. Global climate change will add to these impacts and exacerbate problems of decision making in relation to storage of water for downstream users and flood detention capacity. As changes in storm intensity and frequency may aggravate both upstream soil erosion and downstream channel stability, the designed pattern of river regulation may become inadequate to cope with future events. Stresses on aquatic and riparian ecosystems may increase. Reservoir managers and river regulators need to consider all these possible impacts of climate change when formulating their sustainable catchment management and river regulation plans. For information on the science and management of regulated rivers there is a dedicated international journal: *Regulated Rivers: Research and Management*, published by John Wiley. For an interesting example on water management in a river basin.

Salinity and Agriculture

Arthur Conacher
University of Western Australia, Crawley, Australia

Extensive coastal and inland areas in arid and semi-arid environments, worldwide, are characterized by the natural accumulation of soluble salts in soils, groundwater and ephemeral streams and lakes. Such areas are referred to as areas of primary salinity. In contrast, regions where salt concentrations in soils and water have increased (salinization) as a result of human actions are referred to as being affected by secondary salinity. These are the areas of increasing concern which are the subject of this article.

Agriculture has long been known to cause salinity problems; whether by irrigation, cultivation under natural, rainfed regimes (dryland agriculture), intensive or even extensive pastoralism. The problem, very simply, is related to excessive concentrations of soluble salts in water or soils. Discussions of the salinity problem are usually couched in terms of the adverse effects of high salt concentrations on agriculture and downstream water users - human consumption, industry and infrastructure - with relatively less emphasis on natural ecosystems. Even fewer writers comment on the collapse of civilizations because of salinization. Direct causes of the problem involve changes to landscape hydrology and are reasonably well understood. Solutions, usually involving political, social and economic responses, human attitudes and perceptions, as well as technical measures, are much more complex.

SALINITY CAUSED BY IRRIGATION AGRICULTURE

Irrigation in arid and semi-arid environments inevitably, it seems, results in *waterlogging* (*see* Waterlogging, Volume 3) and *salinization* of the land and water. The best known early example is Mesopotamia, where the development of early civilizations and settlements was dependent on irrigated farming in the valleys of the Tigris and Euphrates. Gradually, changes in environmental conditions were reflected in the agricultural crops. The increase of salinity in ancient Southern Mesopotamia (now Iraq) affected the growth of wheat, which is salt-sensitive, which was gradually replaced by the more salt-tolerant barley. From grain impressions in pottery dated 5500 years BP (before the present), the proportions of wheat and barley were equal. One thousand years later wheat comprised only 20% of the crop and 1500 years later only 2%, being abandoned by 3700 BP (Goudie, 2000). Eventually, in the kingdoms of Sumer and Akkad, even the substitute barley could not grow and people were forced to abandon the area (Ghassemi *et al.*, 1995).

Historic evidence from other parts of the world, including China, the Indus River basin, South America and Arizona, indicates that the problem of human-induced salinization permeates history. Now-desertified parts of Roman North Africa, the bread basket of ancient Rome, are another example. Remnants of historic irrigation channels can be identified from aerial photographs, and salinization of this previously productive region was yet another factor contributing to the fall of the Roman Empire. The persistence of some springs and remnants of forests in the Tell and the Atlas indicate that the North African climate has been relatively stable for the last 4000 years. Land degradation, therefore, was primarily a consequence of human actions (Conacher and Sala, 1998). Here as elsewhere, people were forced to move on, often causing salinization in the newly settled areas.

More recently, in the later part of the 19th century, British engineers constructed large-scale irrigation projects in India and Pakistan to increase food production and reduce the risk of famine. Of some 17 million hectares (Mha) of irrigated agricultural land in Pakistan, in the Indus Plain, at least 25% of the land had become salt-affected by the late 1970s, with the electrical conductivity (EC) of soils exceeding 4000 micro Siemens per centimeter (and 8% with $EC > 15\,000\,\mu S\,cm^{-1}$). A decade later, surveys showed that groundwater tables below 8.8 Mha of the irrigated lands were within 3 m of the soil surface at the end of the monsoon season (Ghassemi *et al.*, 1995). As discussed below, soil salinity problems are closely associated with the proximity of groundwater to the soil surface. Goudie

(2000) reported estimates that salt-affected and waterlogged soils comprised 50% of the irrigated area in Iraq, 23% of all Pakistan, 50% in the Euphrates valley of Syria, 30% in Egypt and over 15% in Iran. The irrigated San Joaquin Valley in Southern California is another recent example. Of more than 2.26 million irrigated hectares, 900 000 ha experience high salinity and at least 600 000 ha are characterized by high water tables (Conacher and Sala, 1998).

Salinity problems in irrigated agricultural areas affect not only the irrigated crops but also the quality of the water beneath the soil (the groundwater) and in the streams or rivers, which are usually associated with these areas. Downstream uses of water for irrigation, to water stock, to maintain wetland ecosystems, or for industry or even human consumption may be affected adversely. The Murray-Darling Basin, which drains one-seventh the area of the Australian continent, is an example of all the above aspects. River water salinity increases progressively down the Darling and Murray rivers as a result of return flows of irrigation water and concentration by evaporation. River discharges are being manipulated to provide environmental flows to preserve important wetland ecosystems under the international Ramsar convention. The one million inhabitants of the city of Adelaide near the mouth of the Murray River rely on the river for about 40% of their water supply. Yet the State of South Australia, of which Adelaide is the capital, has no control over most of the Murray-Darling Basin, which is largely under the jurisdiction of other states Victoria, New South Wales and, to a lesser extent, Queensland. This provides a nice case study of realpolitik, with the Murray-Darling Commission being given the responsibility of dealing with the problem (Murray-Darling Basin Commission, 1993; Conacher and Conacher, 2000).

The most common salts which affect water users include sodium, calcium and magnesium combined with chloride and sulfate. But in some areas other toxic elements are also present. Concentrations of selenium, e.g., exceed 4000 parts per billion (ppb) in parts of the San Joaquin Valley in California, in contrast to naturally occurring amounts of 0.2 and 0.1 ppb in fresh and marine water, respectively. Selenium can be transmitted through the food chain, with toxic effects on humans and animals. At one location in the Valley, some 20% of waterfowl nests in wetlands were found to contain deformed embryos and 40% had at least one dead embryo (Tanji *et al.*, 1986; reported in Conacher and Sala, 1998).

Causes of the Problem

The fundamental problem concerns the manipulation of water and all water contains some salts. In irrigation agriculture, the problem occurs when more water is added to the soil (by irrigation practices or from leaking irrigation channels) than is drained from the subsoil and used by plants. As a result, water accumulates in the soil and evaporates from the surface recalling that irrigation is generally practiced in hot and relatively dry environments leaving the salts behind. Over time, the concentrations of the salts in both soils and water increase, eventually reaching toxic levels (with the concentration of concern varying according to the land use). Waterlogging and problems relating to poor soil structure are commonly associated with salinization. Theoretically, many crops can be irrigated with water containing relatively high concentrations of soluble salts provided that the soils are thoroughly drained or flushed (Hollaender *et al.*, 1979). This requires larger quantities of water than are usually available to irrigators and well-drained, coarse-textured soils and groundwater tables many meters below the soil surface. Since irrigation areas are often located in low-lying, generally flat, alluvial flood plains of river systems in relatively arid areas where the rivers have ephemeral or seasonal flow regimes, these requirements are rarely, if ever, met. Moreover, irrigation can raise water tables from quite considerable depths to within 1 2 m of the surface within only a few years, especially if drainage is poor.

Depths to groundwater tables are a key variable. If the soil surface is within the capillary fringe of the groundwater table, then water can be drawn to the surface and evaporated, leaving the soluble salts behind. Theoretically, capillary heights are almost infinite. They are greatest with silt-textured materials (particle sizes between 0.002 and 0.02 mm in diameter) and least in coarse sand. Most soils or sedimentary (alluvial) materials are heterogeneous, with capillary tubes being interrupted by the presence of coarse layers. A practical rule of thumb of about 2 m is often used; but the real possibility of capillarity (and hence salinity) developing over significantly greater depths to groundwater must be recognized (Peck, 1978). Problems of waterlogging and salinization can also arise from the development of perched water tables, if subsoil layers are relatively impermeable. Water infiltrating into the soil can be held up (perched) close to the surface, above these relatively impermeable layers, and prevented from reaching the deeper groundwater aquifers. Such layers often develop as a consequence of repeated cultivation and in response to waterlogging and deterioration of soil structure. Thus it is not always necessary for the water table of the permanently saturated zone to rise close to the surface for salinity problems to develop.

Salts are present naturally in varying concentrations in underlying rocks and sediments, and in rain and dustfall. Salts released from rocks by chemical weathering eventually reach the sea (an interesting question is whether the salinity of our seas is increasing, and if not, why not), with some released into the atmosphere as salt spray, returned to the land in rain and eventually to the sea (so-called cyclic salts). Coastal areas with onshore winds receive

considerable quantities of salt in this way from 10 to as much as 50 kg ha^{-1} for each 100 mm of rainfall each year. In more arid areas, even at some distance from the sea, or where underlying lithologies or groundwaters contain soluble salts in appreciable quantities, salts tend to accumulate over time as there is insufficient rain to flush them from the system. Increased salt concentrations in soil water in the root zone of plants affect osmotic pressure potentials across the root/soil interface. Normally, plant roots take up water (and nutrients) by a positive pressure differential across the root/soil interface. But where salt concentrations are sufficiently high, the osmotic pressure differential is reversed. Water movement then is (potentially) from the plant to the soil. Even though the plant may be standing in water, it dies of thirst.

SALINITY CAUSED BY DRYLAND AGRICULTURE

The development of secondary salinity problems in non-irrigated agricultural areas seems to be a much more recent problem or at least, one which has been recognized only recently. Australia provides a good case study. The first accounts of the development of salinity problems were recorded from Western Australia and Victoria late in the 19th century, soon after the natural woodland vegetation was cleared for agriculture by the European settlers. By 1996, more than 2.4 Mha of agricultural land in Australia had been rendered unproductive due to increased concentrations of soluble salts in the soils, up from only 0.4 Mha as recently as 1982 (Conacher and Conacher, 2000). All States have areas of secondary, dryland soil salinity. Western Australia is the worst affected, with more than 1.8 Mha in 1996. This is predicted to increase to over 6 Mha by equilibrium (i.e., when groundwater tables have stopped rising): the equivalent national prediction exceeds 12 Mha. Increased salinity of water in streams, rivers, lakes and dams is an associated and possibly more serious problem. In the southwest of Western Australia, all rivers which have their headwaters in the agricultural areas are unfit for human consumption, even though they were fresh before the development of agriculture. This has had serious ecological as well as economic consequences, particularly as numerous stream and other wetland habitats for aquatic fauna have been destroyed.

Similar problems of secondary soil salinization occur in the North American Great Plains, from Alberta, Manitoba and Saskatchewan in Canada down through Montana and the Dakotas in the US. More than 600 000 ha have been rendered unproductive in that region. Dryland salinity also occurs in parts of South Africa, Turkey, Thailand, India and Argentina.

Ghassemi *et al.* (1995) cite a 1991 source in providing data for the global extent of human-induced salinization (Table 1). It is not clear whether the data refer to salinity in dryland as well as irrigated agricultural areas, although the Australian data imply that they do, or what the proportions of the two forms of salinity are. Moreover, as a result of improved survey techniques, the situation in Australia, at least, is now known to be much more serious than the 0.9 Mha indicated in their Table.

Table 1 Global extent of human-induced salinization

Continent	Millions of hectares
Asia	52.7
Africa	14.8
Europe	3.8
North and Central America	2.3
South America	2.1
Australia	2.4
Total	78.1

Source: Ghassemi *et al.* (1995: 19); (Australian data from Conacher and Conacher, 2000, 57).

Causes of the Problem

As in irrigated areas, secondary salinity in dryland agricultural areas is caused by too much water in the wrong places. And again there is the striking irony of this situation in semi-arid environments, where the single most important limiting factor for crop growth is insufficient water. However, the mechanisms leading to the accumulation of excess water are quite different.

Fundamentally, the problem in dryland agricultural areas is caused by the replacement of indigenous vegetation with introduced crops and pastures. In Australia, the native vegetation is usually a woodland association. The plants have deep root systems, which enable them to draw on subsoil moisture for the entire year, sometimes from considerable depths ($>$20 m). In contrast, the introduced agricultural species have shallow root systems and they grow only during spring and early summer. Thus, less water is transpired by the agricultural plants than by the native vegetation, resulting in the accumulation of water in the soil.

There have been various studies into the extent of this imbalance, particularly in the south west of Western Australia. In general terms, in areas with mean annual rainfalls of around 300 400 mm, the amount of excess water in the landscape is only of the order of 6 15 mm yr^{-1}, which infiltrates to groundwater and also forms perched soil-water systems. Because valley floor gradients in the ancient landscape of the semi-arid, Western Australian wheat-belt are very gentle, and hydraulic conductivities of the deep, intensely weathered (kaolinized) lateritic soil materials are very low (as little as 0.009 m day^{-1}), the rate at which groundwater drains from catchments is as little as 0.05 0.3 mm yr^{-1}. Thus, since clearing of the native vegetation, more water is entering the groundwater systems

than is able to drain from them. As a result, groundwater tables in the Western Australian wheatbelt are rising at rates of between 0.02 and 0.3 m yr^{-1} in areas receiving less than 350 mm of rain a year, to 0.15 1.5 m yr^{-1} in areas with more than 500 mm of rainfall annually. Mixing of these deeper, saline groundwaters with near-surface, relatively fresh aquifers is common (Conacher and Conacher, 2000).

As in irrigated areas, saline water accumulates to within the capillary fringe of the soil surface, water is evaporated and soluble salts are left behind, to concentrate in the soil and at the surface. In many situations salty groundwater also emerges at the surface as saline seeps, which then contribute salty water to adjacent streams.

The consequences are similar to those in irrigated areas loss of soil structure and fertility, increased erosion by water and wind on the bare, salt-affected surfaces, waterlogging, reduced agricultural productivity, salinization of streams, rivers and lakes, and severe degradation of habitats with the loss of several species. Additionally, many farm houses and towns in Australia were built adjacent to (then) fresh streams and rivers. The water was used for human consumption, for steam locomotive boilers, to irrigate vegetables and fruit trees, for recreation, and for a range of other purposes. Unfortunately, these low-lying areas have been amongst the first to be affected by waterlogging and increased salinity. As a result, many farm houses and their adjacent building complexes have had to be abandoned, and some 80 rural towns in Australia are being affected by rising, saline groundwater tables or the development of perched water tables. Mortar and bricks fret and crumble, playing fields and home gardens become dust(mud)bowls, and the basements of hotels and other large buildings are filling with salty water.

In North America, the original tall prairie grasses were also replaced by agricultural crops and pastures. Here the hydrological disruption is more finely balanced than in Australia, as the differences in transpiration of water between introduced and indigenous plants, and therefore the amount of excess water infiltrating into the soil, are much less. The nature of the soils and underlying materials, and the composition of the salts, also differ from those in Australia. But whilst the consequential saline seeps are very similar, it has been easier for land managers in North America to rectify the hydrological imbalance.

TWO SPECIFIC SITUATIONS

There are instances where neither of the above situations accounts for the development of secondary salinization. One occurs worldwide, and not only in semi-arid or arid environments. In coastal (including estuarine) areas, overpumping of fresh groundwater (sometimes for irrigation, often for urban water supply) results in seawater incursions into the groundwater aquifer (Goudie, 2000). The problem has been reported from Israel, California, Bahrain, the United Arab Emirates, the Nile Delta (due to the Aswan Dam rather than direct pumping of groundwater) and in more humid environments, from London and Liverpool in England, Germany, the Netherlands, Japan, the eastern seaboard of the US, and Perth (Western Australia).

A second situation concerns the Aral Sea in the Commonwealth of Independent States (CIS), previously the USSR (Ghassemi *et al.*, 1995) (*see* Aral Sea, Volume 4). In the 1950s, the Amu Darya and Syr Darya (rivers) were diverted from the Aral Sea to develop irrigated lands. Those irrigation areas produced 90% of the former USSR s cotton output and 40% of its rice. But the result was to cause severe shrinking of the Aral Sea. Between 1960 and 1989 its level dropped 12.9 m and its area decreased by 40%, and the problem has continued since then. The effects on the ecology of the Sea and on the fishing communities which depended on it have been disastrous. In terms of salinity, the exposed lakebed has been stripped by strong winds and the highly saline sediments deposited over an extensive area. The chemistry of the salts (and probably other toxic ingredients) appears to be such as to have caused a range of serious illnesses in people living in the affected area, a problem which is still the subject of research.

FAILURE TO IMPLEMENT SOLUTIONS

The situation of the Aral Sea in particular, but also the many other extensive problems of secondary salinity around the world, raise the obvious question: why do they persist? The problems have been known for a long time especially in the case of irrigation agriculture and the causes are well understood. Why, then, have apparently obvious preventative measures, let alone effective solutions, not been implemented, and why do the problems not only continue but become more severe?

There is an increasing feeling in certain quarters that there may not be solutions. In some instances, such as the Aral Sea, the areas irrigated by the Amu Darya and Syr Darya could be closed and the river flows redirected to the Sea. Social, economic and political factors work against this solution. In other instances, clearing of natural vegetation in areas potentially subject to secondary, dryland salinity could be prevented. Legislation to control clearing in parts of Australia has been introduced, but its enforcement leaves much to be desired again for social, economic and political reasons.

In other cases there may well not be a practicable, long-term solution. Irrigation needs relatively large amounts of fresh water to flush salts from the system. But water is in short supply in arid and semi-arid environments, the soils progressively lose their structure and become

increasingly impermeable, and the problems of waterlogging and salinization inevitably increase until the land has to be abandoned. Lining irrigation channels with impermeable materials and using drip rather than flood irrigation systems can slow the rate of salinization but will not prevent it.

Research in the Western Australian wheatbelt indicates that, in the catchments of saline areas, it is very difficult to plant crops or trees which will both transpire sufficient water and earn an income for the farmer. Nevertheless, extensive tree planting schemes are being undertaken which are the thrust of the state s salinity strategy (Government of WA, 1996) but the schemes are unlikely to solve the salinity problem and they will not return the land to its previous agricultural productivity. Relatively small saline seeps can and do respond to management, but the extensive, salinized valley floors which characterize much of the wheatbelt are a much more difficult proposition. It is being suggested that up to 30% of the wheatbelt may have to be abandoned. Agronomic and environmental efforts can be concentrated on the remaining 70% which may eventually provide greater total yields than are currently being obtained from the entire wheatbelt, and alternative commercial (or other) uses can be found for the (predicted) saline 30%. Unfortunately this still begs the question of the salinized water systems and the socio-economic consequences of the loss of infrastructure.

Deep drainage is another alternative which has been touted from time to time. But this is technically not a feasible proposition in most cases (due to the low gradients of the valleys and low hydraulic conductivities of the soil materials), it is very costly, and it would only exacerbate the problem of water salinity downstream.

A major problem now and in the past has been the lack of political will to take effective preventative or remedial actions. In Western Australia, reputable scientific, government researchers had demonstrated the nature and causes of the secondary salinity problem, and warned against further clearing for agriculture, in the 1920s and again in the 1930s. The warnings were not heeded, just as they are being paid insufficient attention in 2000 in Queensland especially, where clearing continues at breakneck speed. Decades of boards, committees and agreements in the Murray-Darling Basin (mainly involving New South Wales and Victoria), clearing bans in South Australia, and the more recent state salinity strategy in Western Australia, have failed to halt the inexorable spread of soil and water salinity problems across the nation. Unfortunately the farming electorate to which the politicians pay heed either do not understand or do not wish to understand the scientific messages.

Pannell (2000) considers that lack of awareness is not the main factor responsible for the slow or non-adoption of remedial measures. Rather, he argues, the major factors are related to the economic costs and benefits of current treatment options, the difficulties of testing the options, long time scales, externalities and social issues. A specific study by Kington and Smettem (2000) in one Western Australian wheatbelt catchment takes the argument further. They found that tree planting of 37% of lower slopes would need to be comprehensively adopted by all farmers; or that 60% or more of the upper catchment would need to be revegetated. However, existing catchment management policies (regulatory, cooperative and market-driven) were found to have inherent implementation problems and are inadequate for the purpose. The authors further suggest that perhaps no policy approach, even if fully implemented, would abate the salinity problem. They ask, therefore, whether it would not be more appropriate to develop policy strategies aimed at minimizing the inevitable social and environmental impacts and therefore extend current policy beyond its almost exclusive focus on dryland salinity management.

In contrast, in parts of North America the more tractable problem of secondary dryland salinity (in comparison to the Australian situation) has been treated successfully by judicious planting and management of *lucerne* (alfalfa). These plants are relatively deep rooted and high transpiring, and are therefore able to return the hydrological system back to its previous equilibrium. The main difficulties were to involve the farmers in the saline seep catchments in a cohesive and coordinated approach to the problem (Black *et al.*, 1981).

IMPLICATIONS OF CLIMATE CHANGE

There are two aspects of climate change which are relevant to the problem of secondary salinization; global warming, and changes in precipitation.

While global mean surface temperatures have increased in recent decades, the changes have not occurred uniformly around the world. In some parts of the globe the increase was as much as 4 °C whereas in a few areas temperatures actually declined (see map reproduced in Kerr, 2000). Continued warming of currently cold regions may make cropping possible in areas now unsuitable or marginal for agriculture, notably in the northern parts of the North American and the Eurasian continents, leading to the hydrological changes and resulting salinization which have been discussed here. On the other hand continued temperature increases in hotter areas, in parts of South America, Africa, Eastern Europe, South and Southeast Asia and Australia, may encourage efforts to increase irrigation, again with adverse consequences with regard to salinity.

Predicted changes in precipitation are even more uncertain and spatially and seasonally variable. With reference to Australia, e.g., winters in the southwest of the continent

are likely to be drier and summers wetter, as synoptic systems shift to the south. Increased summer rainfall in this Mediterranean climate type region will not benefit agriculture, but drier winters may conceivably result in less water accumulating in groundwaters with potentially beneficial consequences as far as the secondary salinity problem is concerned. On the other hand, increased summer rains in the agricultural areas of eastern Australia may well lead to expanded areas being cropped, with adverse implications for salinization.

A FINAL COMMENT

This article has discussed largely intractable problem of secondary salinity. It occurs throughout the world, usually in association with irrigation or dryland agriculture. But it needs to be recognized that salinity (and waterlogging) is only one, highly visible, manifestation of severely disrupted ecosystems. Other manifestations include loss of soil fertility, reduced soil structure, increasing soil acidity, increased erosion by water and wind, accumulation of chemical residues in soils and water, and loss of biodiversity and wildlife habitat. These problems result in decreased agricultural production and offsite environmental problems such as eutrophication of water bodies, the accumulation of chemical residues in food and species extinctions.

The ecosystems have been disrupted by agricultural practices. In a world with a burgeoning population and therefore increasing demands on increasingly scarce good land to produce more food and fiber, this is not good news. Yet in many places (e.g., around the Mediterranean Basin), agricultural and pastoral land has been abandoned. We have to learn to farm much more cleverly and more intensively on the small areas of good land, and maintain the world s biodiversity on the remaining, extensive areas with low actual and potential agricultural productivity. And we have to learn how to distribute food much more efficiently and equitably from those regions with surpluses (Europe, North America, Australasia) to those experiencing widespread famines and starvation, notably in Africa.

Shifting Cultivation and Land Degradation

Bryant Allen
The Australian National University, Canberra, Australia

Shifting cultivation is a form of agriculture where fields are rotated from place to place instead of crops being rotated around fields. During the rotation the majority of fields are not cultivated, but are left in fallow. During the fallow, natural plant successions develop on the field. In the archetypal shifting cultivation system, the fallow successions reach tall forest stages, before the trees are again felled and burned. However, shifting cultivation takes many forms. Although it is a very old form of agriculture, it is neither primitive, backward nor wasteful of resources. But because increasing pressure on shifting cultivation systems, by population growth and economic development, inevitably leads to the destruction of forests, shifting cultivators have been blamed for deforestation since Roman times. It is still routine to blame so-called slash and burn agriculture for contemporary deforestation, when the real causes lie deep in the competitive political and economic behavior that typifies all human societies.

SHIFTING CULTIVATION AS A SYSTEM OF AGRICULTURE

Shifting cultivation is a form of agriculture in which the cultivated or cropped area is shifted regularly to allow soil properties to recover under conditions of natural successional re-growth. In a shifting cultivation system, at any particular point in time, a minority of fields will be in cultivation and a majority will be in various stages of natural re-growth. Over time, fields are cultivated for a relatively short time, and allowed to recover, or are fallowed, for a relatively long time. Eventually, a previously cultivated field will be cleared of the natural vegetation and planted in crops again. Thus, fields in established and stable shifting cultivation systems are cultivated and fallowed cyclically.

Although fallow fields are not cropped, they are not unproductive. During the fallow period, shifting cultivators use the successional vegetation species for fencing and construction, firewood, thatching, ropes, clothing, tools, carrying devices and medicines. It is common for fruit and nut trees to be planted in fallow fields to such an extent that many are in fact orchards. Commonly, fallow re-growth species attract birds and animals and so indirectly increase the amount of food provided through hunting. Fallow tree species also draw nutrients to the surface from deeper in the soil profile. Particular species that have been shown to improve soil conditions are deliberately planted or protected from slashing or burning in fallows. Fallow shrubs and tree species protect the soil surface from direct sunshine and from the impacts of heavy tropical rainfall, either directly, or through the deep layers of leaf litter that build up over time. This litter and the fallow shrubs and trees themselves provide ecological niches for a myriad of parasitic plants, worms, insects, arachnids and small animals. Stable shifting cultivation systems significantly enhance and sustain biodiversity. This is in direct contradiction of popular views of shifting cultivation as destructive of forest resources.

Shifting cultivation becomes destructive only when systems become unstable. A critical relationship that governs the stability of shifting cultivation systems exists between the time for which the land is cultivated and the time for which it is fallowed. These parameters determine whether or not the shifting cultivation system as a whole suffers a net loss of nutrients over time. A system in which there is a net loss of nutrients with each cycle will eventually become unstable. Resources will be degraded unless actions are taken to arrest the losses.

The longer a field is cropped, the greater is the loss of soil organic matter, the reduction in the cation-exchange capacity and in nitrogen and phosphorus, and the greater the increase in acidity. Continued cropping leads to reductions in soil porosity and infiltration capacity and the loss of seeds of naturally occurring plant species from soil seed banks. In a stable shifting cultivation system, the fallow is long enough for the natural vegetation to recover to the state that it was in before it was cleared, and for the soil to recover to its pre-cropping condition. During fallow periods soil temperatures are lower, wind and water erosion is much reduced, nutrient cycling becomes closed again, nutrients are extracted from the subsoil, soil fauna increases, acidity is reduced, soil structure, texture and moisture characteristics improve and seed banks are replenished.

No optimum relationship exists between the length of the cropping period and the length of the fallow period. In

favorable agricultural environments, cropping periods can be longer and fallow periods shorter, than in less favorable agricultural environments. In favorable environments, soil conditions at the beginning of a cropping cycle will be better and fallow successional stages will proceed faster, than in less favorable environments. Nevertheless, even in the most favorable environments, it is likely that if the cropping period is extended beyond a certain point, the fallow conditions required for an adequate recovery of soils and vegetation will be jeopardized.

If the fallow period is shortened, there will be less time in which the soil recovery processes and vegetation successions can take place. The length of fallow period required to prevent net loss of nutrients will again depend on the quality of the environment, which will in turn, determine the rate at which recovery occurs. But sooner or later, if the fallow period continues to be reduced, an observable change will occur in the fallow vegetation. Secondary forest may be reduced to shorter, thinner stemmed, fewer, woody bush or jungle species, bush may be reduced to scrub and tall grasses which may be in turn reduced to short grasses. Less directly observable, but nevertheless critical, changes will also occur in the soil.

Changes in environmental conditions that happen subsequent to either a lengthening of the cropping period or a shortening of the fallow period often result in a fall in crop yields. It is not difficult to perceive how a shifting cultivation system, once destabilized, can proceed into a vicious circle of declining yields and in order to maintain overall production, a further shortening of fallows or lengthening of cropping periods, which in turn leads to further degradation of environmental conditions. This process, its causes and possible solutions are discussed further below.

Shifting cultivation is also known as *swidden agriculture* (*see* Swidden, Volume 3), an old European term, and, in some cases, is wrongly termed bush fallowing, or slash and burn. Stable shifting cultivation systems can exist where the fallow successions do not proceed beyond grasses. There are shifting cultivation systems where the slashed vegetation is never burned. In some systems, planting occurs beneath the standing trees and as the crops mature, the trees are felled on top of the crops to let in more sunlight. Shifting cultivation systems can be irrigated. Shifting cultivators may mulch the soil surface of fields or create mounds in which green manure is placed as compost. On slopes it is common for barriers to be constructed along the contour to reduce soil erosion. Crops may be mixed together or planted separately in different parts of the same field or in completely separate fields. A complex cycle of shorter and longer fallows may follow the cultivation of different crops. It is not uncommon for farmers to employ shifting cultivation systems in conjunction with sedentary (or non-shifting) systems, often using one system in one environment and the other in another.

The secondary forests created by shifting cultivation are commonly much richer in plant and animal resources useful to humans than primary forests, even though they may be less biodiverse. Shifting cultivators view the forest as an agricultural landscape of fields at various stages in a regular cycle. People not accustomed to living in forests cannot see the fields for the trees. Rather they perceive an apparently chaotic landscape in which trees are cut and burned randomly and so they characterize shifting cultivation as ephemeral, pre-agricultural, or as primitive and as a stage to be progressed beyond. Shifting agriculture is none of these things.

Stable shifting cultivation systems are highly variable, closely adapted to micro-environments and are carefully managed by farmers during both the cropping and fallow stages. Shifting cultivators possess a highly developed knowledge and understanding of their local environments and of the crops and wild plant species that they exploit. Complex and highly adaptive land tenure systems exist under shifting cultivation. Furthermore, introduced crops for food and for sale have been skillfully integrated into shifting cultivation systems.

PRIMITIVE, BACKWARD, WASTEFUL, UNPRODUCTIVE?

Shifting cultivation is negatively stereotyped. Shifting cultivation systems are perceived both by the supposedly well informed as well as the general public, as primitive, backward, wasteful, unproductive, exploitative and the cause of widespread environmental degradation. Shifting cultivators are blamed for the destruction of much of the world s tropical forests, and thus for land degradation, atmospheric pollution and global climatic change.

Contemporary manifestations of these attitudes towards shifting cultivators are often political and reflect competition between land-occupying farmers, migrant settlers, loggers and international capital for unfettered access to tropical forests (see next section). However, the attitudes can be traced back to the late 19th and early 20th century, to European colonial administrations in tropical and subtropical South Asia, Southeast Asia and South America. Colonizers characterized the indigenous occupants of the colonies and their cultures as primitive and hence viewed their agricultural systems, which were commonly a form of shifting cultivation, also as primitive. In addition, there developed a fundamental misunderstanding that shifting cultivators were nomadic wanderers who selected sites for cropping at random in previously unused forest and that they destroyed the forest by slashing and burning.

These attitudes prevented otherwise astute observers of tropical environments from understanding the social and economic conditions that explain why shifting cultivation systems become unstable and hence destructive of

environments. It is ironic that a major pioneering work published in the 1950s and renowned for its demonstration of the extent of human impacts upon the Earth contains a chapter on agriculture in the tropics that states No matter where we go we find primitive agriculture was carried on at the expense of forest and makes a distinction between primitive tropical horticulture and agriculture as practiced by higher cultures (Bartlett, 1956). This chapter implies all shifting cultivation systems are destructive of resources. Yet in the same book another chapter describes the massive loss of the forests in Europe prior to the beginning of the 20th century and details the social and economic conditions, other than shifting cultivation, which brought about their destruction (Darby, 1956). Many of the conditions responsible for the deforestation of Europe are similar to those causing deforestation today. It is worthwhile therefore commenting upon what happened in Europe.

SHIFTING CULTIVATION IN EUROPE

Shifting cultivation was still practiced as a viable and stable form of agriculture in many parts of Europe and west into Siberia at the end of the 19th century and in some places well into the 20th century. In the Ruhr in the late 1860s a forest-field rotation system, known as *Reutbergwirtschaft*, was using a 16-year cycle of clearing, cropping and fallowing with trees to produce bark for tanneries, wood for charcoal and rye for flour (Darby, 1956, 200). Swidden farming was practiced in Siberia at least until the 1930s, using specially selected varieties of swidden-rye (Steensberg, 1993, 98). In Eastern Europe and Northern Russia the main swidden crops were turnips, barley, flax, rye, wheat, oats, radishes and millet. Cropping periods were usually one year, but were extended to two or three years on very favorable soils. Fallow periods were between 20 and 40 years. In Finland in 1949, Steensberg (1993, 111) observed the clearing and burning of a 6 ha swidden 400 km north of Helsinki. Birch and pine trees had been cleared over a period of a year and the logs sold for cash. A fallow of alder (*Alnus*) was encouraged to improve soil conditions. After the burn, turnip was sown for sale and for cattle feed. Shifting cultivation was disappearing in this part of Finland because of a loss of agricultural labor to the industries of the towns. Steensberg (1993, 110 152) provides eye-witness descriptions of shifting cultivation being practiced in Sweden in the 1900s, and in Estonia, Poland, the Caucasus, Serbia, Bosnia, Hungary, Switzerland, Austria and Germany in the 1930s to the 1950s.

That these agricultural practices survived from the Neolithic into the middle of the 20th century amidst the sweeping changes that occurred in Europe over that period, suggests they were adaptive and in themselves, were not massively destructive of the environments in which they were practiced. This raises the question: if it was not shifting cultivation that led to the disappearance of European forests, what was it?

The earliest written accounts of forest destruction in Europe begin around 1000 BC in the histories of Homer, Thucydides and Plato and in Strabo s *Geography*. Forests in Southern Europe were exploited for ship building, and urban development, the manufacture of casks, pitch and charcoal, as well as being cleared for agriculture. An increased demand for ships, which were manufactured completely from forest products, followed upon an intensification of trade and warfare. Although goat herding is singled out as an important cause of environmental degradation, a more important cause of forest destruction was the practice in some places of granting ownership rights to those who clear-felled forests and brought the land into permanent cultivation. Evidence that circumstances other than agriculture were the major causes for forest destruction was the recovery of tree cover in many parts of the Roman empire from 400 BC to around 500 AD following the collapse of the Roman economy and industry. Darby observes that by 400 AD land that had once been tilled became derelict and overgrown and quotes Lactantius who wrote that in many places cultivated land became forest (Darby, 1956, 186). The other major causes of forest destruction in the hot dry summer Mediterranean environment were wild fires that became more common following human disturbance of the forests.

In Central and Northern Europe the use of stone tools and fire in agriculture is well established in the palynological and archaeological record from the Neolithic. Here, just as in Southern Europe, the destruction of the forest was not through shifting cultivation but the result of more intensive agriculture, following the invention of the plough and of the growth of trade, mining, smelting, tanning, building and urban construction. Nearly constant warfare, including the demands of naval shipbuilding, also contributed more to the destruction of the forests than shifting cultivation.

By the Middle Ages in Europe, large areas of forest were being cleared and converted into arable land in association with the development of feudal tenurial practices. From the 1500s to the 1700s the demands of iron smelters for charcoal, increasing industrial developments and the discovery and expansion of colonial empires as well as incessant warfare that increased the demand for shipping to levels never previously reached, all combined to deforest Europe. With the loss of the forest, shifting cultivation became restricted to the periphery of Europe, where permanent agriculture was uneconomic, transport costs constrained logging or terrain prevented the use of draught animals or tractors. It has disappeared from even these refuges since 1945, as agriculture has become increasingly capital intensive, rural areas have become depopulated and the remnant European forests themselves

have been revalued ecologically, economically and socially as watershed protection and places of recreation and tourism.

SIMPLE SOCIETIES, SHIFTING CULTIVATION AND ENVIRONMENTAL CHANGE

The forests of Europe were destroyed by the seemingly inexorable advances of civilization, industrialization and warfare, the sort of advances that many of those who criticized shifting cultivators in the 19th century thought were desirable and indicative of higher cultures. The same kinds of processes have continued to lead to the destruction of tropical forests in the last decade of the 20th century. So advances in civilization, now known as *development*, have not resolved these problems. The problems are located not in the practice of a particular form of agriculture, but within the fundamental relationships that human societies have with their environments. In complex developed economies, these relationships become very elaborate and are difficult to comprehend. However, in simple economies, where agriculture is the major source of wealth creation, they can be easier to understand.

A growing body of archaeological and palynological evidence indicates that simple human societies also brought about extensive changes to their environments before the establishment of any sort of state, feudal or capitalist, and before the development of large-scale mining, smelting or shipbuilding industries. In these societies, agriculture was the driving force in the economy and shifting cultivation was the most common type of agriculture practiced. By examining the relationships between social and economic change and the agricultural change in these societies, insights can be gained on contemporary social and economic change and global environmental change, and the place of shifting cultivation in these relationships.

Questions about relationships between the rise and fall of the Mayan civilization of the Yucatan Peninsula in equatorial America and shifting cultivation were raised as early as 1930 and continue to be debated today. Archaeological evidence suggests the development of Mayan society and economy began around 250 AD. A mere 700 years later it reached its apogee, by which time the population may have reached two million people. There followed a precipitous decline that left the great cities and ceremonial centers vacant and overgrown with jungle vegetation. The causes of this decline are uncertain; but warfare and the exhaustion of agricultural land are commonly cited (Meggers, 1954; Dumond, 1961; Turner, 1974).

Polynesian settlers appear to have followed similar paths in New Zealand and the Pacific Islands. Within 500 years of their arrival around 1100 AD, the Maori turned substantial areas of coastal New Zealand from forest into scrub and fern, in the process causing the elimination of many bird and animal species (Kirch and Hunt, 1997). In the restricted environments of the Pacific islands, including Fiji and Hawaii, clear evidence of early extensive erosion and change of vegetation is presumed to have been caused by shifting cultivation on slopes. Soils washed from slopes were deposited in valley bottoms as a rich, swampy alluvium. The newly created environments were then exploited to develop intensive, irrigated fields for taro (*Colocasia*). The change from shifting cultivation to intensive irrigated fields occurred in association with a rapid growth in population and the development of elaborate and highly socially stratified chiefdoms (Kirch, 1984). In the larger, temperate latitude islands of New Zealand, the presumed course of events took a different path. There the stimulus for population growth was the hunting of large birds to extinction, during which time forests in drier areas were destroyed by burning. This was followed by the development of intensive agriculture in favorable environments, based mainly on sweet potato (*Ipomoea batatas*) and a reliance on the gathering of two main wild plant species (bracken fern and *Cordyline*) in less favorable environments. These changes, as in the smaller islands, were accompanied by population growth, the competition for the occupation of the best environments, increasing complexity in social organization and endemic warfare (Anderson, 1997).

The record of human-induced changes in environments is longer in New Guinea than in most places, agricultural activities probably beginning 5000 years ago, and possibly as long ago as 9000 years. However, the most spectacular changes, in both societies and environments, are believed to have occurred in the central highlands of the island within the last 1000 years, in association with the introduction of a crop new to New Guinea, the sweet potato (Golson, 1982a,b). One of the most striking signals of the relatively recent intensification of agriculture is the sudden increase in sedimentation rates in small lakes.

The question posed by these and the numerous other examples that could be cited of simple societies that have intensified their agricultural systems in association with increases in population, social complexity and warfare is not whether or how shifting cultivation was responsible for the extensive changes to landscapes and environments. Rather it is why simple societies of shifting cultivators in the tropical forest of Yucatan, or the highlands of New Guinea, began to grow in numbers, to develop stratified and sometimes complex social hierarchies and to fight each other with increased frequency and ferocity.

At first sight, the greatest stimulus to the intensification of a shifting cultivation system is a growth in population. If no other changes occur within the system, for each extra person to be fed from agriculture, a small extra amount of land must be cultivated. The total amount of land available is the land being presently cropped and all of the land in fallow. If the area occupied by the system

is not expanded into previously unused land, or cannot be expanded because it is already occupied by neighbors, then either the cropping period must be extended or the fallow period shortened. The environmental consequences of changing these relationships have been explored above.

At least two problems exist with the population growth hypothesis. First, population growth rate in most preindustrial shifting cultivator societies has been shown to be very low over the long term. Second, no human societies are known where people work only to eat. People engage in social relations with each other; and agricultural produce, together with other commodities, is used in the conduct of these relationships. Studies of these relationships are the focus of two attempts to understand the nexus between human societies and their environments, one an explanation of a particular situation and the other a general exploration of the problem.

In a study of the Duna in the Southern Highlands of Papua New Guinea, a group in the process of moving from shifting cultivation into permanent field agriculture postsweet potato, Modjeska (1982) argued for the development of two self-amplifying feedback loops of ecological and social causation. The trigger was very slow population growth and the slow expansion of agriculture to meet the demands of this growth. This set in motion the first feedback loop, the use-value loop. As more forest was cleared, there was a decline in wild food resources and protein produced from hunting, which was substituted for by an increase in domestic pig raising. An increase in domestic pigs required a further expansion in agriculture. The greater protein available from the larger number of pigs increased human fertility and survival rates and resulted in faster population growth.

Increasing numbers of people also set in motion the second or exchange-value loop of social causalities. More people meant greater numbers of human interactions, including increased opportunities for conflict. There arose the need for a means to mediate these relationships. The Duna (and other highlanders in New Guinea), says Modjeska, substituted pigs for humans and began to exchange pigs to compensate for losses of humans killed in warfare, or in marriage or from deaths from natural causes. The demand for pigs thus increased and the production of pigs increased to meet the demand, with all of the consequences observed in the use-value loop. This is what Brookfield (1972) calls social production in his distinction of the importance of production for social reasons over production for human nutritional requirements alone. Increased pig production and the exchange of pigs to mediate relations between individuals and groups created opportunities for leadership and management of resources and some men gained authority over other men and all women. As groups became more complex, competition between men and between groups increased, increasing the opportunities for conflict.

The outcome of the operation of the two loops, one bringing about ecological change and the other social and economic change, is an expanding and intensifying agricultural system. Forest is converted to grassland, the population grows at an increasing rate and expands geographically and the society increases in complexity and stratification.

Another explanation of the relationships between simple agricultural societies and their environments is that of Ellen (1982, 252 270). Ellen does not attempt to separate use-values from social production. He argues that almost all of the materials required by humans to live (with perhaps the exception of air) are obtained through social relations of production and that these relations proliferate and are modified in numerous ways. The values that humans attribute to items produced from the environment arise out of cultural arrangements and not from the objects themselves, a restatement of Karl Sauer s dictum that resources are cultural appraisals . Humans frequently translate actual objects into culturally conceived forms, an example being the translation by the Duna of the pig into an item of compensation and redemption. As a result, two fundamental processes underlie the ecology of human social systems. The first is that of obtaining material items from the environment with subsequent alteration and circulation through social relations, and the second is the giving of material values to the items which will affect how important it is to obtain, circulate or alter them. Environmental pressures are thus mediated through social relations.

Transitions in ecological systems and in social systems do not proceed at the same rate. The rate of evolution of new varieties of plants and animals proceeds slowly and is determined mainly by natural selection but also partly by human interference and adaptation, as in the domestication of a wild species. Social evolution however, proceeds rapidly because humans have the ability to learn and to communicate their knowledge to each other and to future generations. Most social systems have the tendency to increase in complexity and sooner or later they come into conflict with, or into contradiction (Friedman, 1979, 1982) with their environments. What happens around the point of contradiction will determine the extent of the environmental degradation that will occur. Of particular importance is the ability of a society to change, to invent or to innovate technologically and sociologically, in order to overcome the contradiction without incurring continuing environmental degradation, or social disintegration.

An economic study of what occurs at the points of conflict with specific reference to shifting cultivation is that of Ester Boserup (1965). Boserup argues that low intensity farming, extensive shifting cultivation for example, has lower labor costs than more intensive farming systems. She argues that given a choice, a human group will always choose the technique which has the lowest absolute labor cost rather than the highest yield. This assertion is

questionable, but Boserup s model nevertheless retains its interest. At the point of conflict, yields will have become unsatisfactory. Boserup argues, contra Malthus, that rather than population always overwhelming resources, humans will invent a new agricultural technique or adopt an existing innovation that will boost yields. The new or adopted technology is adapted to the new environmental conditions created by the degradation that has occurred already, even though the society will pay for the increases in the form of higher labor costs. Examples of such changes are the adoption of new higher yielding crops, the exchanging of a digging stick for a hoe, or a hoe for a plough, or the development of irrigation systems. The controversy over Boserup s proposal is in part over whether intensive systems are more costly in labor terms, and whether humans bring about change in their agricultural systems before environmental degradation forces them to do so (*see* Technological Society and its Relation to Global Environmental Change, Volume 5).

A number of very important things happen in the passage from simple to more complex societies and agricultural systems (Ellen, 1982, 272 273). External demands for cash crops on a local production system may destabilize the local ability to regulate human environment relations. Parts of the agricultural system may become more specialized, species diversity may be reduced or lost, wild plant and animal resources reduced or lost and ecosystems become more fragile. Improved communications result in a higher rate of innovation and hence a greater rate of change. Higher rates of change and increased differentiation in the society give rise to increased conflict. Increased differentiation also leads to larger numbers of individuals not producing anything, and more being produced by fewer, such that the system as a whole becomes less efficient. Greater organization and specialization results in greater complexity, technical division of labor and a greater codification of cultural responses with more extensive social control. All of these things increasingly isolate large parts of society from the environment on which their consumptive demands are impacting. Hence responses to changes in environments that have a direct and immediate impact on humans in simple societies, become indirect, heavily mediated and muted in complex societies.

SHIFTING CULTIVATION IN THE CONTEMPORARY WORLD AND GLOBAL ENVIRONMENTAL CHANGE

No human societies remain isolated from the world economy and the forces of globalization. All humans are to a lesser or greater extent, part of one enormous and highly complex society. It is to be expected, that shifting cultivation systems will be influenced by global economic and social forces and that the responses of shifting cultivators to changes in their agricultural systems will be similarly influenced. Yet shifting cultivators continue to be blamed for environmental outcomes as if they were isolated in time and space from the rest of the world.

The estimated rate of deforestation in Southeast Asia in 1990 was 3.4 million ha year^{-1} (FAO, 1990, quoted in Potter, 1993). In Indonesia alone it was estimated that 1.31 million ha year^{-1} were being lost, 368 thousand ha year^{-1} from Sumatra and 377 thousand from Kalimantan, of which 144 thousand ha were due to the fires of 1982 1983. Since those estimates were made, huge fires ravaged Indonesian forests during the 1997 98 El Nino-associated drought.

Shifting cultivation was assessed by the Food and Agriculture Organization (FAO) to be one of the causes of this deforestation while logging was not. The apparent discrimination against shifting cultivators caused a confrontation between FAO and environmental groups, who saw the FAO supporting commercial logging interests against the rights of indigenous people (Potter, 1993, 108). Other independent studies of the problem note that despite lack of government control over forests and the dominance of a political elite in the logging industry, the causes of deforestation are highly complex. It is true that the logging industry has driven roads into the forests, built logging camps and caused severe environmental damage with heavy machinery. The industry is replete with instances of corruption at the highest level that results in an almost complete lack of control over where logging is practiced and how it is practiced. The loggers have also provided paid employment to former subsistence farmers. One of the outcomes of cash incomes and better access to the outside world has been rapid population growth among indigenous groups of former shifting cultivators placing pressure on their traditional long fallow farming systems.

Many farmers have taken advantage of the improved road access to urban markets by planting cash crops, such as rubber or pepper. Increased cash incomes have been spent on chain saws, which have enabled larger areas to be cleared for cultivation faster. Fallow periods have been radically reduced and cropping periods extended. Serious poverty elsewhere in the country has brought thousands of land-hungry settlers into the cut-over forests along the logging roads. The settlers practice what appears to be shifting cultivation but which is in fact a one-cycle slash, burn, continuous cropping, with no intention to fallow for a long time. Clearing of trees and the permanent cultivation of fragile soils in a tropical environment with little attempt to replace lost nutrients causes rapid degradation of the environment on a large scale. The loss of forest in Indonesia, Thailand and the Philippines during the 1990s was preceded by major ecosystem disruptions in Vietnam, Laos and Cambodia in the 1970s and 1980s as a result of warfare. Forests were sprayed with defoliants, thousands of

rural forest-dwelling people uprooted from their homes and roads driven into previously isolated areas.

The loss of the tropical forests of Southeast Asia is the particular outcome of the general possible outcomes described by Ellen (see previous) when small local ecological and social systems become part of a larger system. When the previous relatively stable ecological relationships are destabilized, degradation can occur rapidly. Similar forest losses and fragile ecosystem destruction are occurring in the Amazon Basin, by large-scale state-sponsored colonization of forest land (Becker, 1995, 61) and in Central Africa where endemic armed conflict is destabilizing rural settlement and farming communities on a massive scale.

CONCLUSION

In the tropical developing world, shifting cultivation in its many diverse forms remains an important practice. Shifting cultivation was one of the very first forms of agriculture practiced by humans and its survival into the modern world suggests that it is a flexible and highly adaptive means of production. However, it is also a seriously misunderstood practice. Many casual observers cannot see past the clearing and burning of standing forest and do not perceive often ecologically stable cycles of cropping and fallowing. Nevertheless, shifting cultivation systems are particularly susceptible to rapid increases in population and to economic and social change in the larger world around them. The blame for the destruction of forest resources is often laid on shifting cultivators. However, the forces causing the rapid tropical forest loss at the end of the 20th century are those that led to the destruction of the forests of Europe at the beginning of the millenium. They are essentially related to urbanization and industrialization but are all too often driven by the application of the latest technology to extract ever more resources from the environment in pursuit of political and military power by competing groups. Shifting cultivators then, as now, are swept along in changes that are largely not of their own making.

Studies of small, isolated and pre-capitalist groups and their relationships with their environments suggest that the roots of the contemporary problem lie deep in human behavior. However, it has been shown that simple societies can adapt to the changes that come from within, population increase, competition and conflict, and which impact on the environment. But they are less able to adapt to external economic, political and social forces beyond their control. Globalization is pushing shifting cultivators all over the world into direct contact with world economic, social and political forces. The outcome is often severe environmental degradation. Global climatic changes may further increase stresses upon shifting cultivation systems.

Shifting cultivation systems are extremely diverse. Wide variations are found in land use, animal husbandry, crop germplasm and successional re-growth species, as well as in the societies themselves. Continued exploitation of shifting cultivators and their forest resources will result in continued rapid degradation of the environment, loss of species and loss of human knowledge. If the biodiversity, agrodiversity and the knowledge of local environments that is held within shifting cultivation societies is to be conserved, the people who practice shifting cultivation must be the subject of political and economic equity at national and international levels.

Shipping: Harbors and Ports

Brian Hoyle
University of Southampton, Southampton, UK

The global maritime transport system and the world cityport system that it serves both re ect and in uence the physical environments within which they are set. Transport is a central dimension of the national and global production systems that are reshaping the world. Global economic integration relies upon ef cient maritime transport, and interlinkages between global environmental change, ports and shipping re ect policy and technology as well as socio-economic conditions.

Harbors, ports and the cities with which they are associated provide essential mechanisms and contexts for economic and social development and change. The evolving world cityport system depends upon many factors, including the biophysical environment. Relationships between port systems and environmental circumstances are never static, but change as a consequence of multidirectional in uences and effects. In both advanced and developing countries, technological skills increasingly facilitate ef - cient port operation but the development of port-industrial systems is often accompanied by adverse effects on the environment. Global environmental factors affect port systems everywhere. Speci c events such as oil spillages can have serious consequences on the local environment of affected ports and harbors.

Ports and shipping perform critical roles in the development process. While expanding port systems generally bene t regional and national economies, they can have negative effects on local or regional environments. Urban redevelopment in older port areas no longer used by shipping presents challenges and opportunities that can yield substantial environmental improvements. Any global sea-level rise induced by climatic change will adversely affect low-lying coastal zones worldwide and many port-city systems will face substantial problems.

TRANSPORT AND THE ENVIRONMENT

Relationships between transport and the environment are extremely complex, whether considered from scientific perspectives or in political terms. Concern about the environmental consequences of transport development and operation is not new, and transport takes a central position in environmental debates. The development of land-based transport modes roads, railways, canals and airports involves many potentially damaging impacts on land and landscapes as well as many forms of noise, water and air pollution (Hunter *et al.*, 1998; Hayashi *et al.*, 1999). Throughout the world, maritime transport and port development produce environmental problems, effects and controversies. The changing technology of maritime transport, the scale and character of modern port operation and development, the increasing globalization of world trade, and their associated patterns of economic development and urban growth all produce planning debates in which environmental issues loom large. In both advanced and less-developed countries, debates linking policy, technology, ecosystem resilience and rates of environmental and economic change influence decision-making processes.

Maritime and coastal conditions currents, tides, winds, water depths, natural harbors provide permissive or restrictive environmental frameworks which facilitate or constrain the operation of the global maritime transport system. Widespread concern for the possible impacts of the system upon the environment, in terms of land and water use (involving consumption, congestion, pollution and competition) affects the functioning and development of the ships, ports and trade relations which make up this transport system (Goudie, 1993). Maritime disasters involving oil spillage, the fouling of beaches and coasts, and the loss of wildlife and habitats, often highlighted in the media, sometimes reflect inappropriate juxtaposition of oil terminals and conservation areas (as at Milford Haven, UK). Port development, promoted in the context of changing socio-economic structures, invariably affects delicate coastal ecosystems; the instability of both ecosystems and local human society is influenced by changes in maritime technology. While modern technology means that environmental constraints on maritime transport development are less than in past times, concern for the environment has increasingly influenced the operation and expansion of maritime transport systems. Nevertheless, contrary to what is often supposed, the development of modern ports can have significant beneficial effects on local environments.

PORTS, HARBORS AND THE CITY/PORT INTERFACE

Every port needs a good harbor a sheltered area of water within which the port can develop. Natural or artificial, the harbor is the environmental and engineering context within which the economic, trade and transport roles of the port occur. Relationships between the harbor, in its natural or improved state, and the development of port facilities, are very variable. Within its harbor, a port is fundamentally a central place of economic and cultural interchange, and specifically a place where the mode of transportation changes from land to water-borne systems. Ports function as transfer points in the flow of ideas, goods, services and biological elements of change. Ports are also points through which exotic species may spread: the role of shipping in the ecology of the black rat, for example, is significant.

Ports originate, grow or decline in response to demands from their customers; they serve as nodes in multimodal transport systems (Hayuth, 1985; Slack, 1998), and may become important industrial centers, sources of employment and major urban complexes. The term *cityport* is sometimes used to describe multifunctional settlements of this kind. Not all ports are located on the shore of seas and

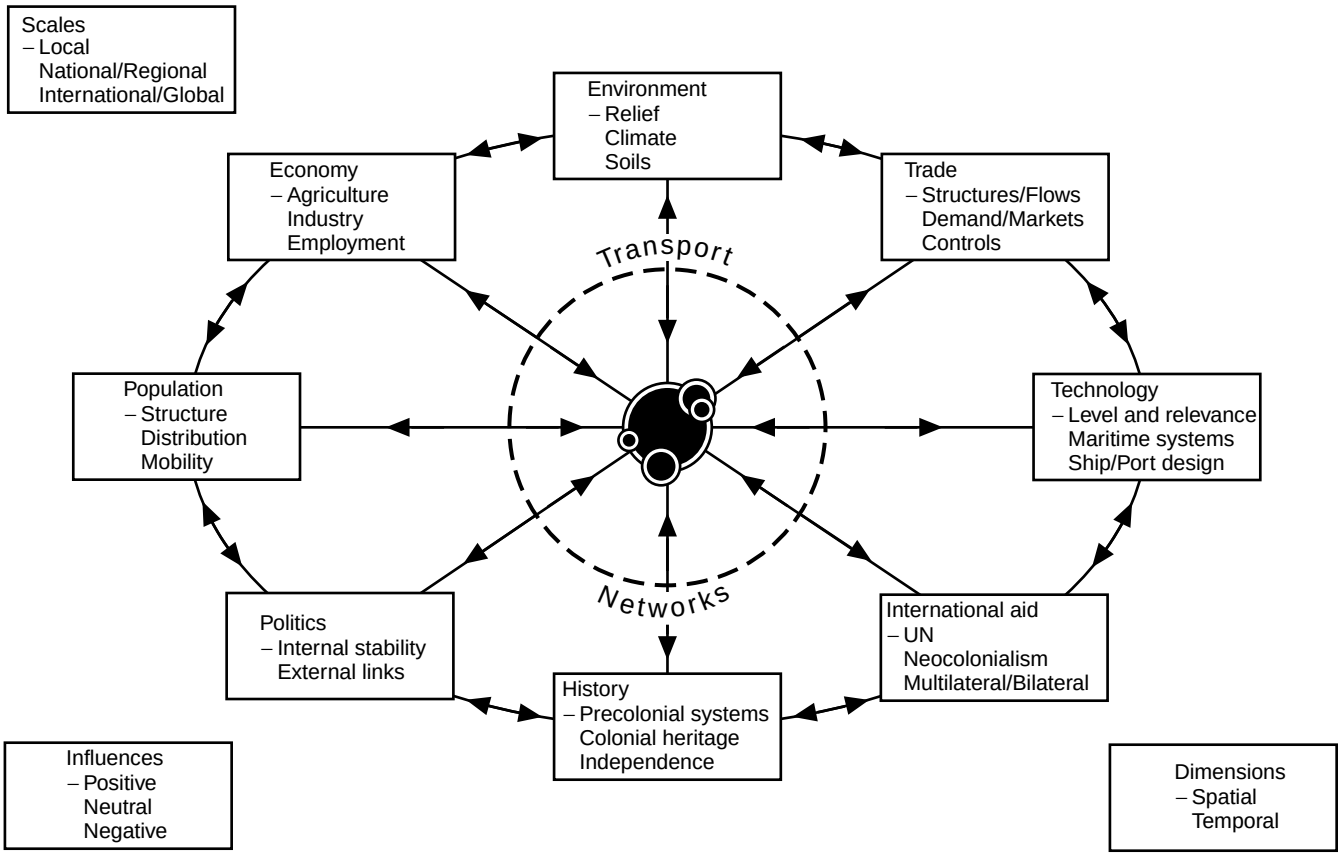

Figure 1 The world cityport system. (The first version of this diagram was published in Hoyle and Pinder, 1981)

oceans: inland ports on rivers (Montreal, Canada; Manaus, Brazil) and lakes (Chicago, USA; Kisumu, Kenya), sometimes a very long way from the open sea, are major elements in national and global maritime transport networks.

Throughout human history the essential problems of port development have been: how to adapt port activity and growth to the physical environment; how to respond to technological innovation, especially to changes in ship design; how to survive inter-port competition; and how to serve local needs, on the waterfront and in the city, as well as to reflect national and global conditions. At various scales and in both spatial and temporal terms, a wide range of interdependent factors is involved in the growth of transport networks and cityport systems (Figure 1). Whether the viewpoint is local or global, each factor (including the environment) may influence others, or the system as a whole, in positive, neutral or negative ways.

Shipping and maritime trade normally underpin the origins and early growth of coastal cities, although links between port functions and urban activities are often less intimate today than in the past. The growth of ports is basically affected by four factors: the land situation, the water situation, the land site and the water site. The water site (i.e., the physical conditions of the harbor) often provides the initial stimulus to development, but unless conditions in the other three categories are favorable, the settlement is unlikely to prosper. The level of port development, measured in terms of cargo-handling capacity or the volume and value of commodity flow, is chiefly a reflection of the land situation the extent and pattern of economic development including transport infrastructures in the hinterland and the demand for port services thus produced. The land site provides a more direct control over urban growth patterns and the operation of landside port functions; and the water situation affects relationships with major trans-oceanic shipping routes. The prosperity of a port ultimately depends, however, upon the efficiency with which it is able to respond to demand from its customers and on the degree to which it is able to maintain and enhance its competitive position. Adaptability to environmental, technological, socio-political and economic change is clearly a critical dimension of port policy.

Within these four inter-related contexts, environmental influences are critical directly and indirectly, and port development ultimately depends on the assessment of situation and site factors in an environmental context. In changing port-city interrelationships, environmental controls may be seen as a filter (Figure 2), intended to reduce pollution and harmonize development. In this port-city interface model, which expresses the inability of cityport sites to absorb not only rapidly-changing and expanding port development but also successive phases of urban

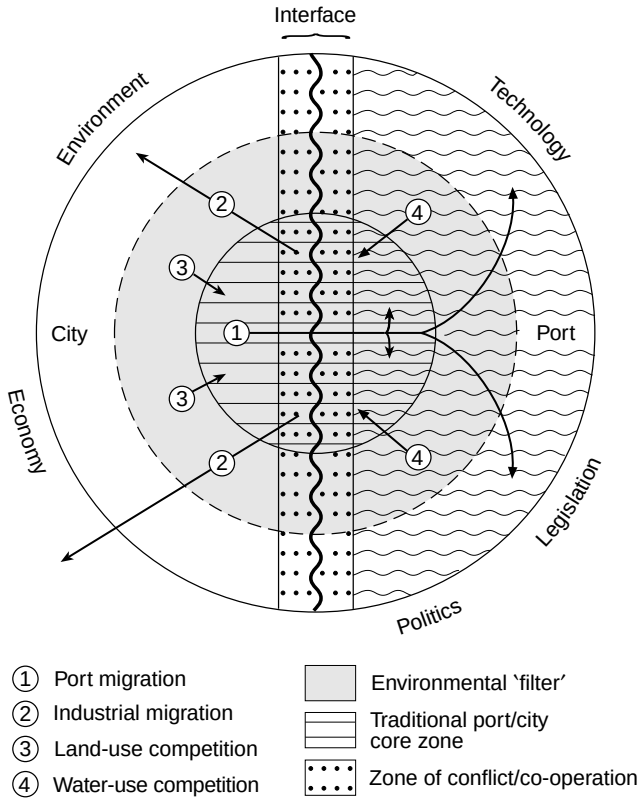

Figure 2 The port-city interface model. (Reproduced from Hoyle *et al.*, 1988)

growth, urban land uses are separated from maritime activities by a zone of conflict or cooperation characterized by decay or by regeneration. Port development migrates downstream in search of bluecoast sites with deeper water and more land/water space, while port-based industries migrate to greenfield sites. Competition for the use of the most attractive available waterfront locations comes from developments such as housing, offices and marinas. These processes involve negative and positive changes to nearby ecosystems and the built environment (AIVP, 1994). They are affected by and also influence the way local people and non-governmental organizations (NGOs) perceive environmental conditions and changes (Cau, 1996).

PORT DEVELOPMENT IN ADVANCED COUNTRIES

Faced with finding the most efficient and cost-effective response to customers demands, port authorities see themselves as driven by inter-port competition and constrained by acknowledged environmental issues and responsibilities. In advanced countries, port-city industrialization has developed in a transport-dependent context that has involved complex relationships with, and

impacts on, the environment. Cityport industrialization, with all its risks and opportunities, has been traditionally based on the juxtaposition of maritime transport the cheapest form of transport for bulk goods and the opportunity to develop processing or manufacturing activities at the break-of-bulk point where the mode of transportation changes. Such transformation activities based on flows of import or export goods have long provided port-city employment, encouraged urbanization and created or exacerbated environmental problems including land, water and air pollution.

This system changed radically after 1960 as growth in demand, production and transport led to a revolution in maritime technology. The widespread use of standard-sized containers for rapidly increasing transport of goods by sea and land led to multimodal and intermodal transport systems involving origin-to-destination movements from an interior location point in one continent via two or more ports and a sea voyage to an inland destination in another continent that reduce or obliterate the traditional port s break-bulk processing and transformation function. However, the evolution of the global economy has also involved vastly increased flows of oil, ores and other bulk commodities, and many of these shipments originate in developing countries and terminate in advanced industrialized countries (e.g., crude oil from the Middle East and West Africa to Europe, and iron ores from West Africa to Japan and the USA). Links between suppliers and customers in such cases are made technically possible by the development of very large crude carriers (VLCCs) for oil and very large ore carriers, and by the simultaneous development of very large port facilities where such carriers can be received and where it often makes sense to process goods before onward movement.

As ships get larger, the differentiation between large hub ports and smaller feeder ports increases (*see* Transport: Global Freight and Passenger Flows, Volume 3). Demand for oil and steel in the 1960s and 1970s meant that previously unexploited crude oil reserves (e.g., in Indonesia, Nigeria and the North Sea) and iron ore resources (e.g., in Quebec, Western Australia and West Africa) were developed. The invention of ULCCs (ultra-large crude carriers) for oil in the 1970s and 1980s facilitated flows but created problems for ports, thus accelerating port concentration. The global pattern of trade and transport in oil and oil products produces a pattern of oil slicks within which there are long-term abuses which can be reduced by good practice of the diluting capacity of the oceans. Accidents involving vessels of these types, pollution emergencies, can have devastating environmental impacts on coasts, beaches and wildlife. The loss of the *Torrey Canyon* off Cornwall in 1967 (*see* Torrey Canyon, Volume 5) led to agreement by international oil companies to pay compensation for massive coastal pollution. The true long-term impacts of maritime and coastal oil spills are unknown. Some oiled birds may recover, but oiled mangroves and coral may never do so (Newson, 1995). The restructuring of global oil production, refining and transport industries from the 1980s has, however, yielded some beneficial effects in certain coastal zones (Harcombe and Pinder, 1996).

From the 1960s, the response of some port authorities, and of many regional and national governments, to the increasing scale of maritime goods transport and associated port facilities was to develop maritime industrial development areas (MlDAs) which capitalized on economies of scale arising from bulk handling and from the geographical juxtaposition of heavy industry (oil refining, steelworks) and the maritime transport system used to import the raw materials for these industries. Traditional ports cannot cope with this scale of activity, because MIDAs require vast amounts of land and water space for storage and transforming industries as well as for the reception of vessels and the loading and unloading of their cargoes.

Today the basic economic and logistic arguments for MIDA-style developments in coastal zones are no longer accepted at face value (they never were in the UK). There is a much stronger awareness of coastal environments and the threats posed to them by industrialization. Planning controls have been greatly strengthened in European countries. In Japan it is now increasingly difficult to develop new port-industrial areas (except on artificial land, as at Kobe); and Japan invests in heavy industry in the countries producing required raw materials. MIDAs now incorporate the importation of semi-finished goods, the conservation of coastal zones, the diversification of industrial activity, and residential and other non-industrial urban functions. The MIDA idea has led over several decades to less purely economic, more socially acceptable and more environmentally aware views and policies concerning how port cities should grow, how coastal zones should be conserved, and how the relationships between ports, cities and industries should be managed.

Venice, Italy

Two European examples, Venice (Italy) and Southampton (UK), illustrate the environmental issues associated with port-industrial growth and the substantial increases in scale involved. Venice (Figure 3) exemplifies Italy s concentration of industrial development in coastal zones, with the expansion of port facilities from the Marittima zone opened in the western part of the city in the 1880s and the creation of the industrial zone of Porto Marghera on the mainland during the early decades of the 20th century (Soriani, 1996).

Port-industrial development in the Venice area, especially during the post-World War II period, has involved environmental impacts of great significance. Industrial waste

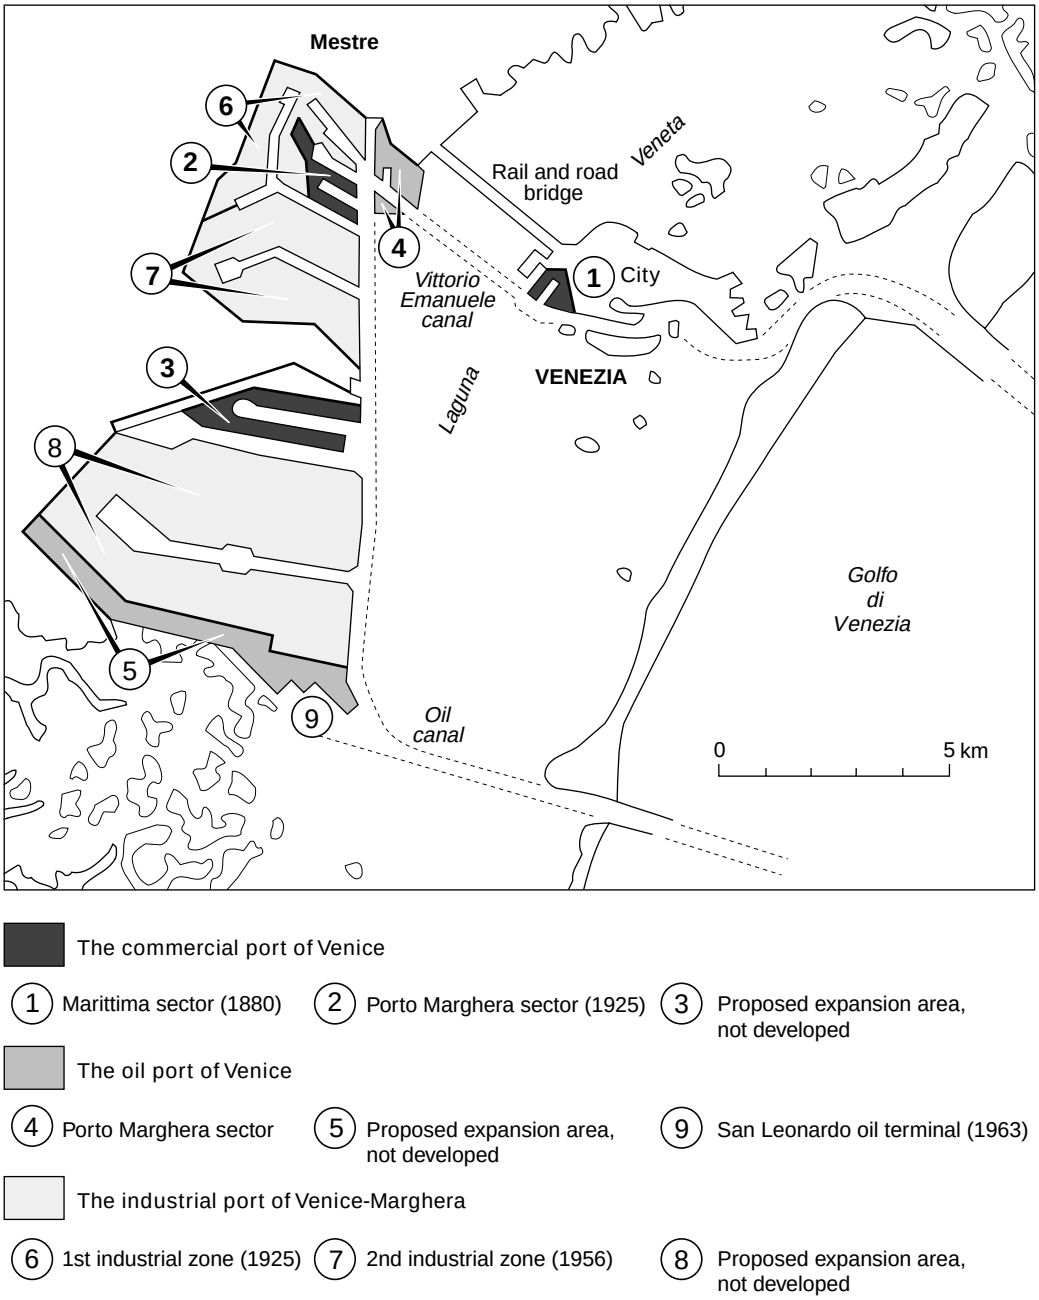

Figure 3 Port and industrial development in the Venice lagoon, Italy. (Reproduced from Hoyle, 1996)

has strongly contributed to the modification of the lagoon s ecosystem. Rapid industrial growth at Porto Marghera after 1950 involved chemical, steel and oil-refining plants, which discharged wastes directly into the lagoon, inducing deterioration of water and sediment quality. Although strictly regulated from the 1980s, serious damage is still caused by the release of pollutants of industrial origin. Dredging operations, especially those designed in the 1960s to facilitate the access of increasingly large vessels, seriously affected the morphology of the lagoon and its hydrological regimes. The introduction of coastal barriers to protect the entrances to the lagoon, and the excavation in the 1960s of an oil canal designed to allow large tankers to enter the port without passing the city s historic core, also increased the influence of marine forces on the dynamics of the lagoon. In addition, the abstraction of ground water for industrial purposes appears to have contributed to the slight but significant gradual reduction in the height of Venice above sea level.

On 4th November 1966 Venice was flooded as a consequence of exceptionally high tides, a strong southeasterly gale and inadequate coastal protection. This dramatic

event may have marked the end of port-industrial expansion within the Venice commune. Public concern led to widespread action aimed at the protection and conservation of the traditional historic core of the city. A United Nations Educational, Scientific and Cultural Organization (UNESCO) report published in 1969 stressed the demographic characteristics of the city, inhabited by an increasingly ageing population and by the accelerating migration to the mainland, and questioned the continuing integrity of Venice in the context of the Porto Marghera developments. New research centres were established during the early 1970s to study the environmental problems of the area. Private, mostly foreign, organisations took steps to finance the restoration of fabric of the historic city. The Italian Government promulgated a 6th Special Law for Venice in 1973 outlining policies for the lagoon area as a whole. The idea of the third industrial zone was abandoned, and part of the already reclaimed land was flooded again.

The question of the protection of Venice has not yet been solved. Many investments have been made to reduce polluting emissions and waste in recent times. Nevertheless, the relationships between the environment and port-industrial development is still a thorny problem, both in the context of navigation and in relation to industrial accidents. Venice continues to be flooded by high tides far more often than previously. Issues related to the protection of Venice, in socio-political and environmental terms, now fundamentally condition the future of the Porto Marghera port-industrial complex. The 1973 special law for Venice provided, *inter alia*, for the diversion of oil traffic away from the lagoon. By the late-1990s this law had not been put into effect. Oil traffic represents about 45% of total port traffic; revenues from oil movements underpin the financial viability of the port and provide the raw material for the refining and petrochemical industries in the port-industrial area. Projects aimed at connecting Porto Marghera industries by pipelines with other oil terminals on the northern Adriatic coast have been proposed. However, a lack of clear signals from the national government and the expectation of further job losses have combined to postpone a solution to this problem. The result is that the underlying controversy arising from conflicting factors involved in coastal zone management in this area is often rekindled, thus preventing continuity in the planning process.

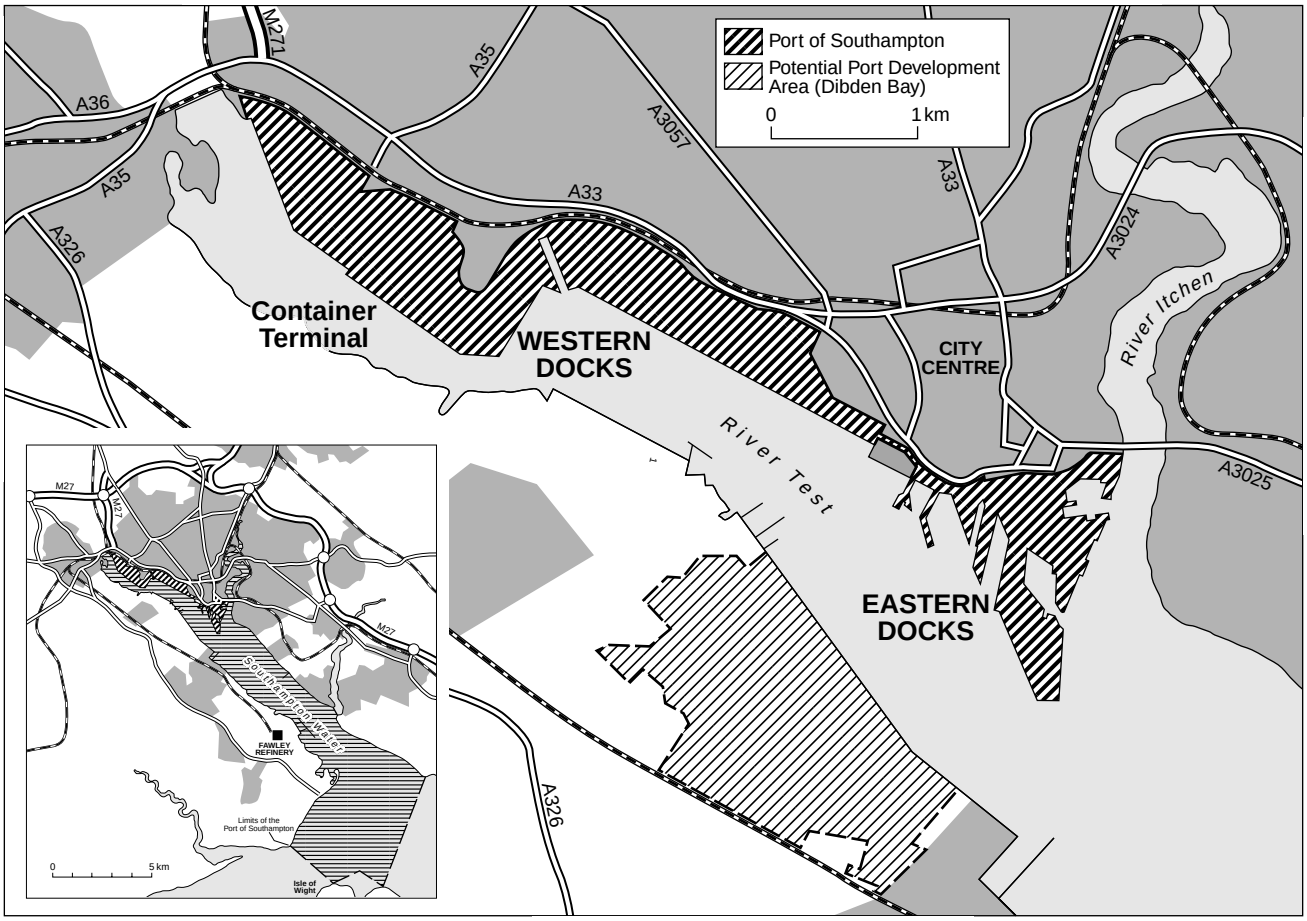

Figure 4 The port of Southampton, UK. (This map is an updated version of one published in Hoyle, 1986)

Southampton, UK

Located on a peninsula at the confluence of two small rivers, the port of Southampton (Figure 4) was in the early 20th century a major transatlantic passenger port and gateway to the British overseas empire. Today it is an important commercial gateway orientated towards the European continent and the Far East, with worldwide container trades. The environmental advantages of the site include extensive, sheltered deep water and, in earlier times, a reasonably secure defensive location. As a result of complex tidal conditions in the English Channel, there is high water for long periods, important for ship maneuvers.

Disadvantages include the distance from the open waters of the Channel (in comparison with Portsmouth), restrictions on modern urban transport circulation imposed by the shape of the peninsula, and a lack of natural land sites suitable for modern port facilities. All Southampton s 20th-century port facilities have been developed on artificial reclaimed land (*see* Land Reclamation from Seas, Volume 3). The Eastern Docks, which extended the natural peninsula, have been partly redeveloped for recreational, commercial and residential functions, and for the University of Southampton s research center for deep-sea oceanography and marine geology. Further development upstream, beyond the modern container port, is very unlikely; but reclaimed land nearby was set aside in 1967 at Dibden Bay, a brownfield site created from port dredging between the 1940s and the 1970s. Pressure on existing facilities means that the development of new container berths on this site is being promoted. Preliminary consultations and studies have addressed, in particular, the environmental and ecological implications of creating new berths (with associated road/rail links and river channel deepening) in a development zone close to residential areas and to the New Forest. The needs of wildlife and plants as well as people are central to the port authority s proposals, submitted to the UK government as a basis for a planning enquiry and for eventual landscaping and construction. The port authority and the government are anxious to balance the needs of the port, the local communities and the environment. Despite some local opposition, port expansion is widely recognized as essential if Southampton is to maintain and enhance its global competitive position as a maritime transport hub.

PORTS AND PORT CITIES IN LESS-DEVELOPED COUNTRIES

Ports and port cities have played a large part in the development of the less-developed countries of the modern world, often as gateway settlements from the standpoint of a colonizing power and as windows on a wider world for the societies and economies of coastal and interior zones (Hilling, 1996). Imperial port cities, in Australia and North America as well as, for example, in India and Africa, were critical nodes in the establishment of both transport networks and urban systems, helping to develop dependent territories within a globalizing economy. These key elements normally provided foundation stones of continuing importance in the context of present-day urban and transport systems.

Environmental conditions in less-developed countries are often inimical to transport network development as a whole and to port growth in particular. Good natural harbors are infrequent and often inconveniently located whereas modern ports are often needed where site conditions are unpropitious. While this is generally the case, it is especially so in tropical Africa. Dangerous surf on the Atlantic coasts of West Africa, and coral growth along the Indian Ocean shores of East Africa, are not only problems for navigators and travelers but also for port engineers, and they increase the costs of port development. Good natural harbors such as the drowned river valleys at Mombasa (Kenya), the lagoons at Lagos (Nigeria) and the sheltered bay at Dakar (Sénégal) have encouraged port and urban development on a large scale; but the land sites of some good harbors such as Freetown (Sierra Leone) are unsuited to large-scale city growth and the land situation of others such as Mtwara (Tanzania) are badly located in relation to the economic and transport geography of their hinterlands. Numerous artificial harbors have been created, as at Tema (Ghana) and Cotonou (Benin), to provide sheltered deep-water accommodation for shipping in association with economic development where the coastal environment does not provide adequate shelter for shipping.

Ports provide one set of dynamic instruments through which the external relations of developing countries are conducted and through which their environments are continually threatened, modified or enhanced. Examples from West and East Africa illustrate these principles.

Abidjan, Côte d'Ivoire

The Atlantic shores of the West African republic of Cote d Ivoire are generally low and sandy, completely lacking in shelter, but backed by a series of deep-water lagoons. The capital port city of Abidjan has been shaped both by its lagoon-based physical environment and by liberal economic policies that have led towards active participation in international maritime trade. Created in 1950 by the opening of the artificial Vridi Canal linking the Gulf of Guinea with the Ebrié Lagoon, and aligned to avoid siltation from the sea the port experienced rapid growth in traffic and facilities until the early 1980s, and the city has added numerous industrial and service functions to its commercial role. Modern Abidjan is a remarkable example of adaptation to a very difficult physical site and of African port-city growth within an economy responding to local, national and regional needs.

The environmental cost of these economic and social achievements has been the severe pollution of the waters of the lagoons on which cityport development has occurred. To the east of the cityport, the Ebrié lagoon was formerly linked directly to the estuary of the Comoé River and the open sea, and tides contributed to the regular renewal of the lagoon waters. This link has been closed as the urban road network has intensified, and the Vridi Canal is inadequate to ensure a normal circulation of the lagoon waters. Pollution has resulted from natural causes and from urban waste. The proliferation of parasitic water plants (notably the water hyacinth) reached serious, and seemingly uncontrollable, levels in many parts of the lagoon by the mid-1990s. The treatment of urban waste is limited, bacteriological pollution is high, and the port-industrial zones of the cityport complex contribute substantial quantities of hydrocarbons to the water bodies. Solutions to these problems require the reopening of the Comoé estuary, stricter control on port-industrial effluents and more efficient urban waste management. Rapid cityport development has produced increasing environmental pollution, and a more socially responsible policy of waste management and environmental control is required as urban populations and port-industrial activities continue to increase.

Mombasa, Kenya

A different kind of adaptation to problematical physical site conditions is illustrated by the Indian Ocean port of Mombasa (Kenya) (Figure 5). A series of drowned river valleys or *rias* resulting from Pleistocene changes in relative sea level provide the essential geomorphological

and geographical context for port development at Mombasa, as elsewhere along the East African coast for example at Dar es Salaam (Tanzania). Mombasa is unusual in that the port has two harbors: the island on which the town center and many of the port facilities are located lies between two arms of a complex double ria, and each of these two harbors has been developed for commercial purposes in quite different ways. Mombasa Old Harbor, rather narrow and relatively shallow, was well suited to medieval navigation and now provides shelter for smaller craft, while Kilindini Harbor (the place of deep water) provides modern facilities. The significance of Mombasa as a seaport in both medieval and modern times is largely due to the geographical juxtaposition on this site of these two harbors contrasted in area, depth and capacity.

These conditions have enabled Mombasa, unlike many other ports, to adapt successfully to functional and navigational changes over a long period of time, and this cityport is now overwhelmingly the dominant port, urban and industrial complex on the Kenya coast. Environmental conditions have generally favored the growth of the port and town and have rarely proved a constraint. The development of Mombasa as a port over the centuries has been conditioned not by environmental change but by the perceptions of successive generations concerning the opportunities provided by the specific environmental characteristics of the island and its harbors for the development of trade and settlement.

Today, although urban pollution (especially on the coastal fringes of the Old Town) is a growing problem, water pollution is not a serious issue as the harbors are open to tidal fluctuations and the movements of vessels (especially oil tankers) are carefully controlled. Improvements in operational efficiency, management restructuring and the revitalization of the port in the competitive context of the East African port system as a whole are critically important current policy objectives. Environmental conditions in terms of land and water sites do not present any insuperable obstacles to physical port expansion in the foreseeable future. Additional deep-water berths and container terminals could be developed at Kipevu or on the southern shore of Port Reitz where a maritime industrial development zone has been proposed (Hoyle, 1999).

WATERFRONT REDEVELOPMENT: THE TRANSFORMATION OF THE PORT–CITY INTERFACE

An aspect of port-city change that has received much attention in recent years around the world is the phenomenon of urban waterfront redevelopment. While this is not, directly, a result of global environmental change in a physical sense, it nevertheless expresses a worldwide trend in the reshaping of cities on water and in the refashioning of the human environments that ultimately depend on the conservation and use of water bodies. Although waterfront redevelopment has spread to innumerable cities of many kinds, it is nevertheless particularly associated with port cities (Hoyle *et al.*, 1988).

The main reason for recent changes and problems in the port/city interface zone, and ultimately for the global waterfront redevelopment movement, is that traditional cityport sites cannot absorb rapidly changing and expanding port development and successive phases of urban growth. Cities and ports which once were intimately connected and finely balanced have grown apart, and both ports and cities have found ways of adjusting to their new relationship. In many instances this process stems essentially from the fact that many cityport land and water sites were environmentally ideally suited to the relatively limited forms of urban development and port activity which characterized, for example, ancient or medieval times the examples of Venice and Southampton illustrate this point but such sites are totally unsuitable for modern ports and cities which require far more extensive sites for their development where factors affecting ports and those affecting cities are less closely associated.

In Europe, waterfront redevelopment is regarded as essentially maritime in character, linked to port cities, while in North America it is seen more as a process of urban renewal, as many settlements with a waterfront introduce redevelopment in a context that has little or nothing to do with port activity. Often a major issue is how to get rid of the railways and highways that skirt the shoreline, replacing them with accessible green spaces. The spatial diffusion of waterfront redevelopment started in North America in the 1960s (in Boston, Baltimore and San Francisco) and spread to European port cities such as London in the 1970s and 1980s and then to Australia and Japan (Figure 6). In the 1990s it became important in newly industrializing and developing countries too for example in SE Asia, in the Caribbean, and in South and East Africa. Diversity is obviously a keynote of this diffusion, but common elements include the maintenance or provision of public access to the water s edge; opposition to (and prevention of) insensitive and inappropriate development in waterfront zones; enhanced rapprochement rather than continuing or increased separation between waterfront zones and urban cores; the conservation and sensitive development of open green space; the cultivation of difference and of a sense of community; and the maintenance of links with the past.

An emphasis on greening the port-city waterfront environment is often a key to successful integrated redevelopment in this context. As the movement spreads to less-developed countries in a context of modernization, urbanization and globalization, clear links are perceived between port-city urban renewal and other socio-economic sectors: water supply, housing, employment, tourism. Costs

are high, progress is slow and socio-economic progress is often associated with environmental deterioration.

IMPACTS OF RISING SEA LEVEL

An aspect of global environmental change that directly affects harbors and ports in the longer run is the prospect of substantial sea-level rises as a result of continued global warming. If the global warming now being detected were eventually to involve substantial sea-level rise, all the world s harbors and ports would be affected. Some ports might find deeper water alongside existing facilities an advantage; others would find their operation restricted and their functions curtailed. It is more likely, however, that low-lying coastal zones, including some urban areas in port cities, would experience serious flooding. If, however, some lowering of sea levels were eventually to occur (unlikely in the next million years), the consequences for ports would be far more serious, as many would find themselves with insufficient deep water and, *in extremis*, at some distance from the sea. The examples of Rye (UK) and Bruges (Belgium) show how coastal evolution can effectively reduce a port s traffic over a relatively short time period, although in such cases soil erosion and local sedimentation may explain more than will global sea-level change.

CONCLUSION

Links between global environmental change and global maritime transport systems are expressed at one level very specifically in terms of water quality, sea-level change, and the impact of port-industrial and urban development on air, land and water pollution. In a much wider sense, however, the changing global environment is clearly a major factor in the dynamic evolution and operation of international maritime transport systems and port-city development. Environmental changes, and world shipping, are two interdependent dynamic systems that influence one another over longer or shorter time periods, at many different levels of socio-economic development, and in association with a wide variety of other factors and systems.

The redevelopment of port-city waterfronts is a feature of late 20th-century urban environments. As the new millennium unfolds, and as new centers of global innovation and change emerge and strengthen in the Pacific rim, the forces of globalization, intermodal transport systems and the communications revolution mean that ports and port cities may lose some of their traditional significance as the need to adapt and transform intensifies. The relative success of port-city change and development will depend in part on integration between communities and localities, so that appropriate development based on environmental conservation and social objectives can at least gain ground against (if not ultimately supersede) commercial development driven only by the profit motive. This demands politico-economic restructuring, a sense of scale, an appreciation of interdependence, and a reassessment of environmental priorities.

Soft Energy Path

Soft energy path is an energy future that combines significant increases in energy efficiency with the development of relatively environmentally benign, and renewable, energy sources, including solar power, wind power, geothermal energy, biomass and small-scale hydroelectric generation (*see* Biomass Burning, Volume 3; Wave Power Development, Volume 3; Wind Power Development, Volume 3; Environmental Politics, Volume 5).

Soil Amelioration

J Keith Syers
Naresuan University, Phitsanulok, Thailand

To ameliorate a soil means to enhance its productive capacity by improving soil properties, which may be inherently poor or have been degraded by Man's activities.

Improving the productive capacity of soils by soil amelioration has a long history. For example, practices such as drainage (to remove excess surface and subsurface water), marling (to improve the mechanical composition and nutrient status of sandy soils), and the addition of animal manure and human excreta (to provide soil organic matter and nutrients) have been used widely.

Soil degradation, accelerated by Man's activities, has increased the need for ameliorative practices. These include nutrient input from a range of sources, but particularly from chemical fertilizers, to combat nutrient depletion; the addition of lime to correct soil acidity, which has increased in many countries because of industrial emissions and the use of legumes, which acidify the soil; and drainage to combat salinity in conjunction with the use of by-product gypsum ($CaSO_4$) (when available and affordable) to reverse sodication. Our fundamental understanding of nutrient depletion, acidi cation, and salinization (salinity and sodication) is good, but in the case of sodication (process whereby exchangeable sodium is increased) and to some extent nutrient depletion, there is a need to develop effective ameliorative management practices which can be used at the farm level.

Bioremediation of soils contaminated with toxic organic pollutants (e.g., hydrocarbons and halocarbons) involves biodegradation brought about by enzymes. Bioavailability, including the physical accessibility of the organic molecules to the microorganism producing the enzyme, is critical. Molecular techniques are being used with a view to accelerating the biodegradation of more resistant organic molecules.

HISTORICAL CONTEXT

Soil amelioration has a long history, with a wide range of practices being used over the centuries to increase crop productivity.

Probably one of the oldest and the simplest practices of soil amelioration is that of land drainage whereby the water table is lowered, thus improving the oxygen status of the soil. This is vitally important for the growth and development of most plant species. Drainage systems range in complexity from simple ditches, to ridges and furrows that remove surface water, to clay tiles placed at depth to transport excess sub-surface water away, to the currently-used perforated plastic pipe, again placed at depth, often about 75 cm below the surface. Wet, heavy-textured soils are cold and difficult to cultivate. Only by installing field drainage systems can such soils be made productive.

Soil ameliorants, traditionally added to soils in historic time, include clay, lime and chalk, seaweed, animal manure, and human excreta. Initial use of these materials predated the development and use of chemical fertilizers. These materials are not fertilizers because they contain insufficient quantities of the three major plant nutrients nitrogen (N), phosphorus (P), and potassium (K). However, some of them contain useful quantities of plant nutrients and they were essentially the only source of nutrients up until the beginning of the 20th century.

Until around the middle of the 19th century in the UK, the amelioration of low-fertility, coarse-textured (sandy) soils was achieved by the practice of marling (for an account of the early practices of marling and chalking, see Hall, 1945). Marl contains calcium carbonate in association with clay, and when added to sandy soils, it substantially increases soil fertility and productive capacity. For example, in Norfolk (UK), the usual practice was to excavate pits down to the marl or clay underlying the surface sands, remove the marl, and spread it at the rate of 100 to 300 loads per hectare on the surface of sandy soils. Not only did the marl improve the texture but it added calcium carbonate (a liming material) and some plant nutrients (e.g., P and K). Chalking involved the addition of very large quantities of chalk (almost pure calcium carbonate). At Rothamsted Experimental Station (UK) up to 250 tons of chalk per hectare were added to experimental sites in the 18th and early 19th century (Johnston, 1991). The practices of marling and chalking were at their height during the early 19th century, but the rise in labor costs and the development of chemical fertilizers in the early 20th century resulted in their demise.

Before the advent of chemical fertilizers, the large quantities of animal manure returned to the soil were the major source of plant nutrients, in Europe and Asia in particular. Soil physical properties, such as soil structure and water-holding capacity, were improved through the addition of large quantities of decomposable organic material, which produced humus in the soil.

The addition of human excreta to the land is often regarded as being a Chinese technology, and it is sometimes forgotten that the transport of night soil from urban areas to rural areas for disposal on land was an important way of reversing the flow of nutrients and reclaiming areas of low-land peats, as in northern England. Public health regulations in many countries now restrict the use that can be made of human wastes in agriculture to sewage sludge, which has been digested to remove pathogens (Evans, 1998). Restrictions on the dumping of human wastes at sea and of uncontrolled incineration have increased the need for land disposal. This has led to legislation in several countries, particularly in Europe, to limit any adverse effects of the heavy metals present in sewage sludge. However, it seems likely that there will be further restrictions on the disposal of sewage sludge on land and controlled incineration may become a much more important outlet for disposal.

PRESENT SITUATION

At the present time, there is increasing recognition of the importance and impact of soil degradation on crop productivity and environmental quality, and thus the need for soil amelioration. This is particularly the case in the ecologically-fragile semiarid tropics, where the need for increased food production is great (Syers *et al.*, 1996). Soil degradation may be defined as a temporary or permanent lowering of a soil s productive capacity. It is an insidious process which results in a reduction in soil fertility and crop productivity. Although widely recognized as a global problem, the geographical distribution of soil degradation is not well understood.

The major types of soil degradation include wind and water erosion, which displaces soil material, and several *in situ* chemical degradation processes (including nutrient depletion and loss of organic matter, acidification, salinization, and pollution) and physical degradation processes (including compaction, crusting and sealing, and waterlogging) (*see* Waterlogging, Volume 3). It is in the context of soil degradation that soil amelioration has its greatest impact, with the technologies ranging from low-technology liming to high-technology bioremediation. Examples of some of these follow.

NUTRIENT INPUT

Nutrient depletion is a characteristic feature of agriculture in most developing countries. This occurs primarily through crop removal in harvested products, and crop residues that are not returned, and by leaching and soil erosion. Nutrients, in inorganic or organic forms, are added to soils to improve the nutrient-supplying power of low-fertility soils or to balance losses from productive farming systems, which are essentially restricted to the developed world. Resource-poor farmers are usually unable to provide the required nutrient inputs in the form of fertilizers and further productivity declines are inevitable. Recycling of low nutrient-containing crop residues in subsistence agriculture can only promote continuing poverty. Organic agriculture, without the input of essential nutrients from external sources, will not solve the problems of world hunger and poverty.

Chemical fertilizers have had an enormous impact on crop production in developed countries, to the point that surpluses of several agricultural commodities now exist, although several commentators consider that such agricultural surpluses are insufficient to protect the world in years of bad harvests. In lesser-developed countries, where the need for external nutrients is invariably greater, the supply of chemical fertilizers is sometimes erratic. Even where chemical fertilizers are in adequate supply, their price frequently restricts use to rates that are less than those required for optimum crop production. This situation is particularly serious in Sub-Saharan Africa where mining of soil nutrients is occurring because removals and losses are exceeding inputs. It is for this reason that the World Bank and its partners are interested in implementing a program of soil fertility recapitalization.

Phosphorus is now a limiting nutrient in many acid, weathered soils of the sub-humid and humid tropic (*see* Phosphorus Cycle, Volume 2; Phosphorus Water Quality Objectives, Volume 3). Amelioration of phosphorous deficiency can be achieved gradually with moderate, seasonal applications of phosphorous at rates which are sufficient to increase the available soil phosphorous levels. Alternatively, this can be achieved almost immediately with a large one-time application of P. An excellent example of amelioration of degraded soils is provided by the work in Southeast Asia of the Potash and Phosphate Institute (located in Singapore). In Southeast Asia, approximately 40 60 million hectares of natural forest have been removed by recent human activity, and following short-term cropping have reverted to shrub and grass savannah. The soils are acid and their productivity is limited by P deficiency. In Indonesia, a large ameliorative application of reactive phosphate rock of about 1000 kg ha^{-1} is sufficient to supply enough available P for annual and plantation crops for up to eight cropping seasons. The economics of this practice are very favorable (von Uexkull and Mutert, 1995), but the most critical issue is the financial outlay for the initial heavy application of phosphate rock. Because reactive phosphate rock materials have liming value (equivalent to about 30% by weight of the phosphate rock material), an added benefit from this strategy is the partial amelioration of soil acidity.

CORRECTION OF SOIL ACIDITY

Acidification is a natural process, which is enhanced by Man s activities. The continuous movement of weakly acidic rainwater through the soil leaches soluble basic cations, particularly calcium (Ca) and magnesium (Mg). Natural acidification has been accelerated by the use of legumes, which fix nitrogen and which generate ammonium-nitrogen; the heavy use of ammonium-containing fertilizers (and manure and slurry), the nitrogen from which can cause eutrophication of surface waters; and emissions of acidic sulfur dioxide and nitrogen oxides into the atmosphere and their return to the soil. It is only when the ammonia and ammonium salts are converted to nitrate (nitrified) by soil microorganisms and the nitrate leached that acidity (H^+) is developed. This may be shown as follows:

$$NH_4^+ + 2O_2 = NO_3^- + 2H^+ + H_2O \qquad (1)$$

The H^+ thus generated further accelerates the loss of basic cations.

Because Ca is the dominant cation in many agricultural soils, where soil pH is maintained in the range of 5.5 7.0, calcium or lime loss is usually given emphasis in the acidification process. Thus, the lime requirement to maintain soil pH, or return it to a desired level, has considerable practical significance. The value depends on soil pH and the capacity of the soil to buffer changes in soil pH, in addition to the amount and acidity of the rain. Work at Rothamsted Experimental Station (UK) indicates that basing the lime requirement on the need to neutralize soil acidity, rather than balancing Ca loss, appears to be a more correct approach (Goulding and Annis, 1998). Recent work in the UK indicates that lime requirements for agricultural land have doubled between the late 1960s and early 1970s, and the late 1980s and early 1990s, a fact attributed to increased fertilizer nitrogen use and atmospheric deposition.

As mentioned herein, in the section on the historical context, the use of lime and chalk has a long history in much of Western Europe. The benefits of lime are well established and include positive effects on the availability of certain plant nutrients (for example, phosphorus, potassium, sulfur and molybdenum). However, increasing soil pH by liming will decrease the availability of manganese and boron. Lime addition can also improve the physical properties of soils. Acid, degraded soils often have a poor structure, which restricts air and water movement, and frequently develop surface crusts (discussed herein), which reduce water infiltration and restrict germination. Liming can assist in preventing crusting in coarser-textured soils and can improve the friability of heavy-textured soils.

Whereas liming materials are usually accessible to farmers in the developed world, resource-poor farmers in less-developed countries invariably find the cost of lime prohibitive, even when it is available locally. The result is that very large areas of acid soils remain unproductive, for example in Southeast Asia (*see* Acid Sulfate Soils, Volume 3).

REVERSING SALINIZATION

The changes to soils involving the increase in salts is usually referred to as salinization (*see* Salinity and Agriculture, Volume 3). Salt-affected soils are often separated into saline soils, which contain excess salts (usually the chlorides (Cl) and sulfates (SO_4) of sodium (Na), Mg, and Ca in the soil solution, and sodic (or alkali) soils, which have elevated levels of Na on the exchange complex. Saline and sodic soils occur naturally and also as a result of irrigation, which redistributes salinity within the soil, and transport salts and or Na to new locations. Unlike the more extensive saline soils, sodic soils have been studied less intensively (Sumner, 1993). Salinization through the intrusion of sea water often occurs in coastal areas.

Swelling and dispersion are associated with the highly hydrated Na ion in sodic soils and are the primary reasons for the degradation of soil physical properties, including

low infiltration and poor conductivity of water through the soil, and crusting of the surface (discussed herein). Also, the high salt concentration in the soil solution of a saline soil makes it more difficult for plants to abstract water through their roots, resulting in moisture stress which can adversely affect crop growth and development.

Definitions of *salinity* and *sodicity* are comparatively easy but in reality it is impossible to separate the effects of salts (salinity) from those of sodicity (Na), as they often go together. Furthermore, the level of salt in a sodic soil is important in determining physical properties. This has implications for the development of management practices to reverse salinization.

In theory, removing salinity should be easy and should only require supplying sufficient water, over crop requirements, to leach out the soluble salts. This requires that the soil is permeable and that the water table, into which the salts are leached, is below the rooting zone of the crop or can be brought below the rooting zone by installing a suitable drainage system. Because a high water table is often also a cause of salinity, drainage is a prerequisite for ameliorating saline soils. Where groundwater is naturally high and the soil profile permeable, it may be necessary to install a pumping system, thus adding to the cost of reversing salinization. However, the recovered groundwater can be pumped into irrigation ditches and diluted with irrigation water, if the quality (i.e., salinity) permits.

In arid and semi-arid areas, rarely does the luxury of surplus water exist for the flushing out of salts and frequently farmers have to contend with salinity or even abandon the land.

The amelioration and management of sodic soils is less well understood. Salt-transport models provide valuable information on the chemistry and physics of sodicity amelioration. However, this has not been translated into validated management practices for application at the farm level. As with salinity, ensuring adequate drainage is the primary consideration during the reclamation of sodic soils. Replacement by calcium of some of the Na on the exchange complex is the secondary consideration. For soils containing gypsum, flooding a well-drained soil is usually sufficient but when the amount of gypsum is low or absent, soils containing appreciable amounts of exchangeable Na, or free sodium carbonate, will disperse and become impermeable if wetted by high-quality irrigation water or by rain. Maintaining a sufficiently high salt concentration during the removal of exchangeable Na is essential. The slow release of calcium from gypsum is sufficient to progressively remove exchangeable Na down the profile, provided drainage is adequate. By-product gypsum, as phosphogypsum from the phosphate fertilizer industry or flue gas desulphurization gypsum, produced in coal-fired power stations, is the most suitable because mined gypsum is too slowly soluble. Thus, gypsum has found fairly extensive use for the amelioration of sodic soil in several countries, including Australia, Israel, and the US.

PREVENTING CRUST FORMATION

Although dispersive soils usually contain high levels of Na, it is known that highly-weathered, acid soils disperse under conditions of low electrolyte (salt) concentration in the soil solution and with mechanical energy inputs, such as raindrop impact. Disintegration of aggregates at the surface, under raindrop impact and dispersion of the clay at low electrolyte concentrations is followed by movement of clay particles into the pore spaces, which become blocked, thus lowering the infiltration of water and increasing runoff and erosion. This is referred to as surface crusting (Sumner and Stewart, 1992). Movement of clay sometimes leaves loose sand on the surface. The surface crust usually consists of a compacted layer, approximately 1 mm in thickness, underlain by a clay-enriched layer.

The formation of a surface crust can be alleviated by reducing raindrop impact, by using a mulch; adding manure to stimulate biological activity; and/or by adding by-product gypsum to supply electrolyte at the soil surface.

BIOREMEDIATION OF CONTAMINATED SOILS

Soil pollution is a form of soil chemical degradation resulting from the addition of contaminants (or pollutants) to the soil. It is usually a feature of specific industrial sites and industrial regions. Examples include contamination from hydrocarbons (e.g., oil), halocarbons (e.g., chlorobiphenols), and heavy metals (e.g., lead) and radionuclides.

Bioremediation uses biological systems to accelerate the breakdown or transformation of chemical pollutants to less harmful forms. Although plants are increasingly being used to extract heavy metals and radionuclides from contaminated soils, by the process of phytoremediation, it is with microorganisms and organic pollutants that bioremediation finds its greatest potential application (Head, 1998). Here, the ability of microorganisms to biodegrade organic pollutants to non-toxic end-products determines the applicability of bioremediation. In some cases the end products are water and carbon dioxide.

The natural process of biodegradation is the underlying basis of bioremediation. This involves the action of specific enzymes, produced by particular groups of microorganisms, on specific pollutants or groups of pollutants. Not all compounds can be degraded in this way. For example, whereas low- to mid-molecular weight alcohols and hydrocarbons are readily biodegradable, many of the halocarbons tend to be resistant.

Several microorganisms produce dehalogenase enzymes which are effective in the process of dehalogenation, for

example, in the removal of chlorine. Similarly, certain microorganisms can degrade chlorophenols by the action of monooxygenase, which produces phenol and eliminates chlorine. The physical access of microorganisms to pollutants in situ is also important in influencing biodegradation. Bioavailability to microorganisms can be reduced by interaction of the pollutant with organic and inorganic components in the soil, sometimes referred to as pollutant aging.

In the application of soil bioremediation it is essential to identify the target chemical to be degraded. Bioremediation, involving the natural microflora and natural environmental conditions, is often the first choice. However, biostimulation through nutrient addition (particularly with nitrogen and phosphorus) and bioaugmentation or seeding with specific biodegrading organisms to increase the rate and extent of biodegradation, is thought to be worthwhile.

There are exciting, new developments in molecular microbiology that are starting to impact on bioremediation. For example, new biochemical pathways are being developed using plasmid-mediated genetic information exchange between strains of microorganisms. This is being done with a view to accelerating the biodegradation of more resistant molecules.

Bioremediation is a very interesting and potentially cost-effective way of cleaning-up environmental contamination by toxic organic materials. However, much more work is needed before it is accepted as a routine treatment technology.

Soil Deterioration and Loss of Topsoil

Robert Evans
Anglia Polytechnic University, Cambridge, UK

Soil deterioration arises in a number of ways, one of which is the loss of topsoil. The impacts caused by soil deterioration can be seen over the short and long-term, onsite and, in the case of erosion of the topsoil, offsite. Indeed the offsite impacts of soil erosion may, over the short term, be much more important than the impacts on the land, and its users, which are directly affected by erosion.

Onsite soil deterioration can reduce the quality of the soil through a decline of fertility, acidi cation, salinization, or the loss of soil depth, all of which have corresponding impacts on crop and animal yields and soil and landscape biodiversity. In some instances there can be a total loss of the soil resource in terms of food, ber and timber production, for instance, when land is built on. Offsite impacts are related to the transport of soil particles from the land into water courses, reservoirs and ultimately the oceans.

The deterioration of soil is often closely bound up with social and economic factors, and can be further exacerbated by population pressure. Without a thorough understanding of the causes of soil deterioration and loss of topsoil and how these are often related to the use of the land, which in turn is frequently linked to social, economic and political factors, it is unlikely that the problem of soil deterioration will be resolved and the land used in a more sustainable way.

PROCESSES OF SOIL DETERIORATION

Most soil deterioration processes are related to how the land is used, but two, acidification and pollution, are also related to humankind s impacts on the atmosphere. Acidification can be induced both by application of fertilizers to the land or by airborne pollutants from industrial processes.

Loss of Topsoil by Erosion

Soil erosion, especially by water and wind, is the prime and most obvious cause of soil deterioration. Its manifestation can often be seen, as a dust storm or large gullies dissecting the landscape. For example, erosion came to the fore as a problem in the USA in the 1930s (the Dirty Thirties), as a result of the dust storms over the Great Plains and widespread water erosion of arable land (Bennett, 1939)

due to poor land management by farmers striving to make a living under dire economic circumstances. It is noteworthy, however, two decades before that Iceland had established a soil conservation department to combat wind erosion initiated by overgrazing and exposure of vulnerable soils on volcanic rocks or sandy glacial outwash. Concern about soil conservation was carried around the world from the USA, especially to countries which were then colonies of European states. Conservation techniques were often imposed in these countries, as they still are, with little understanding of the social, economic and political problems associated with erosion.

Much research in the USA focussed on intense rainfall as the major driver of erosion, and it was considered by many researchers that countries with generally low intensity rainfalls, such as those in Western Europe, did not have an erosion problem. That was a fallacy (Evans, 1996). Much erosion research in the USA and elsewhere has been based on plot experiments, often the plots were little more than 20 m in length and a few meters wide. Such experiments may have allowed replication of treatments and may have been good science, but they did not lead to a full understanding of the processes of water erosion. Only over the last two decades has the importance of landform been fully appreciated, for it is in depressions and valley floors that much erosion occurs. Plots cannot simulate such situations. Since field, rather than plot, assessments of erosion became more widespread, especially in Europe, there has been a better understanding of water erosion, its processes and the social and economic factors which drive it.

Agriculturists and many soil conservationists have written that soil erosion is a natural phenomenon, with the implication that because of this, erosion is less of a problem than it really is. Indeed, erosion of topsoil (and subsoil) is a natural phenomenon, but without the activities of humankind it would be much less widespread than it is now. High rates of erosion can occur in little altered landscapes not settled by large numbers of people, for they are usually inhospitable places. Glaciated mountains, especially those receiving high precipitation and still undergoing uplift and subject to earthquakes, such as the New Zealand Alps, the Himalayas and Andes, all suffer high natural rates of erosion. For example, the mean annual rate of erosion of the New Zealand Alps is estimated to be $100\,m^3\,ha^{-1}$, a surface lowering of $10\,mm\,year^{-1}$. Semiarid regions with sparse vegetation cover can erode severely when rare intense storms occur, *badlands* are the most severe example of this. Wind erosion can also be effective in deserts. However, elsewhere, and that is most of the world s land surface, where vegetation protects some 30% or more of the soil surface, erosion is rare.

Most landscapes were wooded, even many present day savannas, until humankind settled them in appreciable numbers and cleared the trees. In steeply sloping localities, tree clearance can destabilize slopes so that rapid mass movements such as landslides and landslips occur much more frequently and extensively, as in New Zealand. Triggering of mass movements is widespread in the mountainous tropics as slopes are deforested or, more commonly, settled for agriculture as population pressure increases. Even in temperate Britain there is much evidence that in the past, in periods of tree clearance, mass movements and gullying occurred.

Clearing trees from land changes its hydrology. More water becomes available for runoff, but erosion need not occur if the vegetation cover remains intact. However, it is likely that gullying will take place in valley floors and that stream heads will retreat upvalley, especially if animals track valley floors. The initiation of gullying and valley floor incision was widespread, for example, in the USA and South Eastern Australia when range lands were opened up for grazing in the late 19th century, and is widely seen now in much of tropical Africa. The increase in grazing pressures could sometimes be accompanied by climate change, as in the USA, which exacerbated erosion. Grazing pressures in the past could have initiated erosion which still continues today, for example, the Loess Plateau in China. However, some Chinese scientists consider that the erosion and desertification was triggered by the opening of the Silk Road trade route across the prairie grassland by creating a linear source of dust and sand which spread downwind over the centuries.

When land is cleared for agriculture, wind and, especially, water erosion can become widespread and sometimes severe. Compared to natural rates of erosion, rates can increase by orders of magnitude and in the case of water erosion will be associated with increased runoff and flooding. The impacts of erosion induced by agriculture (infilled valleys, thinned valleyside soils) can be seen not just in countries where intense rainfalls can cause severe present day erosion, but also in countries characterized by gentle rains. There is much evidence for widespread erosion since the Europeans settled North America. Similar evidence is found on the chalk, limestone and sandstone outcrops of Britain, much of it dating from clearance of woodlands up to 4000 years ago, but also due to cultivation in times of population and economic pressures in Romano-British and Medieval times and the present day. What happened in European and European-settled countries in the past is now happening widely in developing countries as their populations expand.

Peat Wastage

Peat soils when drained shrink and oxidize. Not only do topsoils disappear, so do subsoils. In Britain, for example, the East Anglian peat Fenlands have largely disappeared

since they were first drained in the mid-17th century and up to 4 m of peat has wasted away. The subsoil exposed is mostly of inferior quality to the peat and the lowered land surface has to be protected from flooding. In many parts of the world, especially South East Asia, new areas of peat land are presently being drained to add to the large coastal and deltaic areas already converted to agriculture.

LOSS OF NUTRIENTS FROM THE SOIL

Cereal and timber crops and animals remove from the soil, via harvest or slaughter, the nutrients they have taken from the soil which are stored in the seed, wood, meat, bone or hide. In a sustainable farming system the nutrients removed from the soil have to be replaced. Soils on grazed ranges will slowly deteriorate as rarely is any effort made to replace nutrients. In arable systems some effort must be made to replace the nitrogen, phosphorus, potassium and micro-nutrients needed by the crops otherwise yields will decline to a point which makes it not worthwhile farming the land. In the tropics where *slash and burn* agriculture is practiced, (*see* Prehistoric People and Forest Soils, Volume 3; Shifting Cultivation and Land Degradation, Volume 3) the arable land is left for grasses, shrubs and trees to recolonize so that when cleared and burnt in the future their ashes will return nutrients to the soil. A similar system was used by Mesolithic settlers in Britain.

As population increases, agriculture can become more intensive. To replace nutrients the land can be left fallow for a season to allow inputs from the atmosphere, especially nitrogen, to accumulate in the topsoil. Weeds can be cultivated into the topsoil to return organic matter and nutrients. If animal manure is available this too can be added to the land. Animals can be grazed on common land and then herded onto the arable land, or they can graze the vegetation that is left after crop harvest which comprises the crop stubble, unharvested plants or seedheads and weeds, and their dung returned to the soil to fertilize it. Such systems are widespread in many developing countries and were extensive in Britain until the 18th century.

In Europe, and earliest in the Netherlands, fallow land was gradually replaced by an arable rotation. In Britain this formed the basis for a four course rotation which became widespread in the late 18th century. In such a system, root crops or grass replaced the fallow and these were fed to cattle and sheep and their dung returned to the land. Yields increased greatly. However, for this system to work well, land had to be enclosed and farmers had to have secure tenure and markets for their products. This system offered a sustainable route for European farmers to take as populations grew. Such a route does not seem easily available in the present day, for climatic and social reasons, in many tropical countries of the world.

In the middle and late 19th century farmyard manure was in turn replaced in Europe and North America by manufactured fertilizers. Modern agriculture in the developed world and in those parts of the tropics where the *green revolution* came into being in the 1960s and 1970s, now depends on high inputs of artificial fertilizers (*see* Green Revolution, Volume 3). Ironically, in Britain, for example, because gases emitted to the atmosphere from industry and power stations are now much cleaner, insufficient sulfur is being returned to the soil and crop yields suffer unless fertilizers containing sulfur are added to the land.

Loss of Organic Matter from the Topsoil

Organic matter is a crucial component of the topsoil, for it not only holds and releases nutrients and water to the crop in disproportionate amounts to those released from mineral soil, but it also makes the soil better structured and resistant to erosion. The exposure of organic matter to the atmosphere by cultivation leads to its oxidation. After many decades an equilibrium is reached, but this may be below the level needed to maintain soil structural stability. Organic carbon is a surrogate for organic matter and a level of 2% is considered by some authorities to be needed to give a topsoil structural stability and so be resistant to erosion. The amount of organic carbon in a topsoil is positively related to its clay content. However, even in Britain with its temperate climate, many soils do not contain sufficient clay to retain 2% organic carbon. In hotter and drier climates less organic matter is held in soils in proportion to their clay content.

Salinization

Salinization of the soil comes about in two main ways. The first occurs on land irrigated by water containing salts, and such land is widespread in the semi-arid parts of the world. If the salts, especially sodium chloride, are not flushed through the soil they are brought to the surface by evaporation and are deposited on the surface. Such salinity inhibits growth and can be toxic to plants. The second way is due to the removal of trees which changes the hydrology and causes the groundwater table to rise to the surface, where salts contained in the water are deposited. As a result, in many localities in Australia, for example, plants in valley floors die, exposing bare soil which is then susceptible to water erosion. Soil salinity can also occur when adjacent seawater or fossil saline water intrudes into groundwater because of overabstraction, as occurs in many deltaic regions such as the Nile and Mekong deltas (*see* Salinization, Volume 2; Irrigation: Environmental Impacts, Volume 3; Salinity and Agriculture, Volume 3; Waterlogging, Volume 3).

Acidification of the Topsoil

When organic matter in topsoils breaks down, it releases weak acids. Over time, most topsoils will acidify unless they remain under (native) woodland where leaf fall recycles nutrients including calcium to maintain the soil s nutrient and acidity profile. However, if the air becomes polluted with acidifying gases such as sulfur dioxide, from burning fossil fuels in homes and industry, this may be *scavenged* from the air by plants. The acid water can then seep from the vegetation into the soil. An increase in acidity (decline in pH) will have to be rectified because many crops will not grow and yield well on acid soils (pH < 6.0). For natural or semi-natural vegetation, more acid tolerant plants will replace those which prefer higher pHs. When soils become very acid (pH < 4.0) aluminum may be released and in solution this is toxic to both plants and animals.

Acidification can also take place when nitrogenous fertilizers are applied to land year after year if the resulting weak acid released, and leached into the soil, is not neutralized by liming. The draining of soils, often developed in former estuarine deposits which contain iron pyrites, as in East Anglia, England or in South East Asia will lead to oxidization of the pyrites to form sulfuric acid and so result in extremely acid soils.

Other Soil Deterioration Mechanisms

Pollution

Pollution of soils and vegetation by emissions of heavy metals from smelting works can lead to the deterioration of the vegetation cover and ultimately to the exposure of soil to erosion.

Compaction

Compacted soils hold and release less water to the plant and dense and capped soils inhibit seedling germination. Topsoil structure is partly related to organic matter content (see above) but soils are also liable to be compacted by machinery or by animals. Land cleared of tropical forest by bulldozers is compacted more than that cleared by hand or by using light equipment drawn by animals. Using larger agricultural machinery increases the risk of soil compaction, especially if the land is cultivated or harvested when it is too wet. Animals can compact the soil if they congregate in large numbers, for instance, around a watering hole.

Waterlogging and Construction

Waterlogging of the soil can happen when surface drainage is obstructed by humankind s actions and land *built over* for homes, industry, commerce, and transport is removed from agriculture. In many parts of the world it is often the better agricultural land which is being swallowed up in cities.

EVIDENCE FOR SOIL DETERIORATION

There is a massive literature on the deterioration or degradation of the world s soils and the loss of topsoil by erosion. Unfortunately, much of the literature is of low quality, and there is little useful quantitative information. For example, much of the world s information on rates of soil erosion is based on plot experiments which have little relevance to what is actually happening in farmers fields or common grazing lands and which may overstate the rates of erosion by a factor of 10 (Evans, 1995).

Oldeman *et al.* (1991) have produced a world map of the status of human induced soil degradation. This is based on expert opinion. Although there have to be many reservations about the quality of this information, it is at present the best there is. Four degrees of soil degradation are classified, *light*, somewhat reduced productivity of the terrain; *moderate*, greatly reduced productivity; *strong*, soils are not reclaimable at farm level, but may be restored by major effort; and *extreme*, unreclaimable and beyond restoration.

North America is least affected by degradation (Table 1), Europe most, but it is Africa and Central America which contain the highest proportions of most degraded land. The areas of land affected by degradation seem small until they are compared with the areas of land suitable for agriculture (Table 2). Except for North America, between one fifth

Table 1 Impacts of human-induced soil degradation

	Light (%)[a]	Moderate (%)[a]	Strong (%)[a]	Extreme (%)[a]	Total (%)

and one third of the land of the continents suitable for agriculture has been affected by soil degradation.

Erosion by water and wind account for by far the largest proportion of the world s soil degradation (Table 3). Loss of nutrients is most important in South America, salinization in Asia, compaction in Europe and water logging in Central America. The types of degradation defined by (Oldeman *et al.*, 1991) relate well in the main to those described above. However, they attribute the loss of topsoil by water erosion just to *sheet erosion*, and their category *terrain deformation* includes rills, gullies and landslides. They claim the loss of topsoil by sheet erosion is the most important type of soil degradation but that appears unlikely if, as (Evans, 1995) argues, sheet erosion is generally an ineffective process in comparison to riling and gullying. It seems more likely that, as must be the case in North America, sheet erosion must include (small) rills. Estimates of degradation attributed to loss of topsoil by sheet erosion must be treated with circumspection therefore. In many localities, but probably not in North America, the loss of soil and crop productivity attributed to sheet erosion is probably related to loss of soil nutrients (see below).

Deforestation has triggered most degradation in South America, Asia and Europe (Table 4), overgrazing in Africa

Table 3 Type of soil degradation

	Percent of total degraded land

and Australasia, and cultivation in North and Central America. Industrial pollution as a cause of degradation is most widespread in Europe.

In most parts of the world water erosion, comprising interill (rainsplash and sheetwash) and especially channel (rill and gully) erosion (ISSS, 1996), is the major process degrading topsoils. The tentative map of the global pattern of suspended sediment yield shows where erosion rates are highest (Figure 1). However, the yield includes sediment derived from erosion both of the land surface by water and mass movements and from river channels, and identifies areas of high natural erosion rates as well as areas of high accelerated erosion rates. In some regions, for example, South East Asia, both high rates of natural and accelerated erosion occur, whereas elsewhere, mountainous regions especially if glaciated will also have high rates of natural erosion. High rates of erosion attributable to agriculture and grazing are found in the USA, the Mediterranean and Eastern Africa. The amount of sediment which reaches stream and river channels and the oceans is only a fraction of that eroded from the land, for much of the eroded soil is deposited before it reaches channels (Walling, 1983). However, much of the silt, clay and organic fractions, which are eroded from the land, will reach river channels. Thus, Figure 1 gives an indication of where accelerated erosion is occurring but is not helpful with regard to rates of erosion of the topsoil.

Rates of water erosion measured on experimental plots are frequently reported (Pimental, 1993), but unfortunately little of this information can be translated into *reality* (Evans, 1993). Rates of topsoil loss occurring in farmers fields or eroding rangelands are not widely reported but often the data implies that actual rates of erosion are much less than those recorded in plot experiments (Evans, 1995). Estimates of amounts of soil eroded often can not explain the losses in crop productivity of the soil, for losses are often less than a few millimeters in depth a year. In many parts of the world the decline in productivity is probably related not to the mass of the soil lost but to the loss of nutrients attached to silt, clay and organic particles which are transported from the soil by erosion and, especially, by the removal from the soil by the crop of nutrients which are not then replaced by the farmer. The loss of organic matter by oxidation when exposed to the atmosphere and the diminution of the role of organic matter in recycling nutrients, especially phosphorus, may be crucial, particularly in the tropics (Webster and Wilson, 1998).

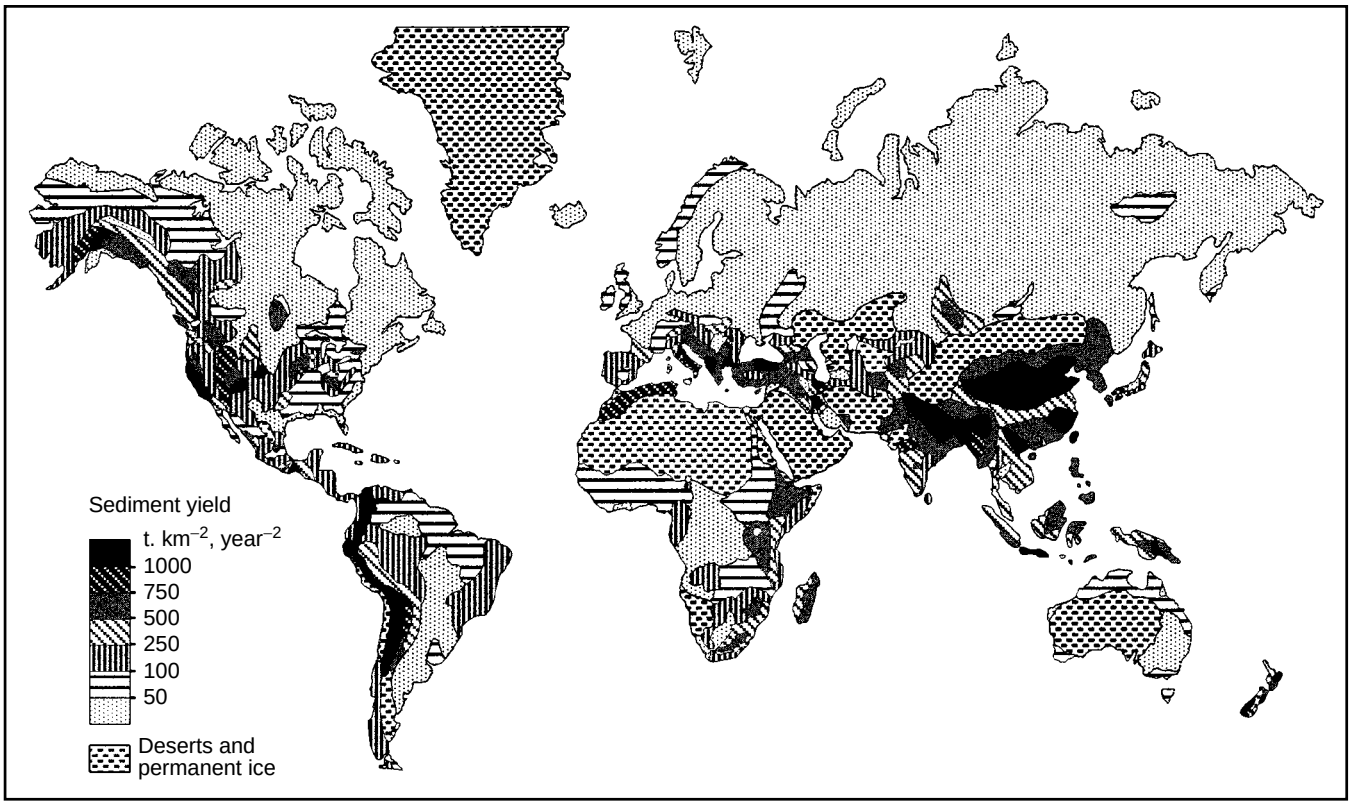

Figure 1 A tentative map of the global pattern of suspended sediment yield (Reproduced with permission from the Soil and Water Conservation Society in Walling, 1988) – includes all sediment from both disturbed and undisturbed areas of the Earth

SOIL DETERIORATION IN THE FUTURE

The outlook for soils in the next few decades is at best unsure, and is most likely to be bad. Soils will continue to deteriorate if land use continues as now. Also, as more forests are cut down and converted to pasture or arable land, wider areas will be affected by mass movements, runoff and erosion, and more peatlands will be at risk of wastage. Erosion of topsoil by water and wind will continue if large scale intensive agriculture continues and especially if these techniques expand into areas of less intensive agriculture. Cultivation techniques are available to alleviate erosion, such as conservation tillage which leaves a good protective cover of vegetation and stubble on the ground into which the crop is drilled. However, for large scale agriculture this technique relies on the use of a herbicide to kill weeds which compete with the crop. The herbicide could have an adverse impact on the environment s biodiversity and also pollute water courses. Grazing induced erosion will continue unless less intensive grazing regimes are introduced in many parts of the world.

Unless nutrients removed by grazing animals and crops are replaced by fertilizers soils will continue to deteriorate. However, before they can be used, for many in the world fertilizers will have to be made easily available and affordable. Moreover, over-application of fertilizers may lead to pollution and enrichment of drinking waters. Soils under continuous cultivation will loose organic matter and soil structure will deteriorate unless ways of recycling organic matter can be devised, such as the application to the land of compost made from urban household waste (*see* Soil Amelioration, Volume 3).

The use of nitrogenous fertilizers and emissions from industry could continue to cause acidification and pollution of topsoils. However, in developed countries laws to curb industrial pollution, such as the European Union s Integrated Pollution and Prevention Control regulations, may alleviate the problems of acidification and pollution. Judicious liming of the soil could keep acidification at bay, but that is only feasible where lime is easily available and cheap to buy. Salinization will continue unless more care is taken in the future when land is irrigated and unless techniques for alleviating salinity are brought into use more widely. The use of low pressure tyres on farm machinery, and varying of the depth of cultivation, could help in the future to alleviate soil compaction. Presently, it seems most unlikely that the building over of topsoils will cease in the future and hence good quality agricultural land will continue to be lost.

What appears a bleak picture could be made worse in those localities most affected by global warming. However, predicting where those localities will be is not easy at the present time, because of the coarseness of the resolution of the general climate circulation models. Increases in precipitation and in the occurrence of large storms could trigger mass movements on slopes and increase runoff and erosion. Increasing dryness could lower erosional thresholds on grazed land because vegetation could become sparser and recover from grazing more slowly. It will be where land use changes with climate change that impacts on the soil are likely to be most severe. Thus, forest clearance coinciding with increased rainfall or an increase in the area of land under cultivation as temperatures warm up at higher altitudes and latitudes will increase the chances of erosion happening.

CONCLUSIONS

There is much evidence worldwide, from experiments and observation, for the deterioration of soil and for the loss of topsoil. But there is little good quantitative evidence for the extent and size of the deterioration, even for the most studied aspect, accelerated soil erosion.

There is little apparent acceptance by farmers that soil erosion is a problem. This is because in developing countries subsistence farmers cannot afford to conserve their soils. And, like their colleagues in the developed world, generally they are not affected enough by erosion (and deposition) for them to want to do anything about it. Interrill erosion does not remove plants, nor do rills which run between rows of crops, and deposits rarely bury much crop. Only gullies and their deposits seriously interfere with the task of growing crops, and often these are of infrequent occurrence in a soil landscape.

Declines in crop yields can probably most often be attributed to declines in soil fertility. In those localities in the developed world where declines could be attributed to erosion thinning the soil they will be hidden by the application of fertilizers. In many localities it will likely take two or more generations for high rates of rill erosion to strip sufficient depths of soil to affect yields.

The short term impacts of accelerated erosion are most apparent off the farm; flooding, damage to property, siltation of water courses and damage to fisheries, pollution of water bodies and the oceans. These damages are costly to remedy and are often borne by that part of society which does not farm the land.

This is not to say the long-term impacts of erosion are unimportant; they are. In England and Wales for instance, it is estimated (Evans, 1996) that since the land was cleared of forest for agriculture the loss of crop production resulting from the thinning of topsoils and the exposure of impoverished subsoils is of the order of 10%. At present day prices this can be valued at £700 million a year.

Few countries have good quality information on the extent of erosion and the risk of erosion. There is a need to monitor erosion and other processes which lead to the deterioration of soils, but the monitoring needs to be done in farmers fields and on rangeland. We need to know what is actually happening, not what is considered to be happening based on anecdotal, local, experimental plot or modeled evidence. This information is especially needed so that good predictions of risk of deterioration based on reality can help us alleviate the probable adverse impacts of future global warming.

The rapid concreting over of land for houses, industry and roads may well at the present time be the world s most severe problem of soil deterioration. Although there is awareness of the problem in some countries, notably the UK and USA, there is a dearth of evidence on its impacts.

In the future, unless humankind makes a determined effort to use its soils wisely, soils will continue to deteriorate and disappear. The implications for long-term food, fiber and timber production could be severe. Over the short term, in many less developed parts of the world soil fertility needs to be maintained or, even better, improved, whilst in many localities accelerated soil erosion needs to be stopped to curtail such off-farm impacts as flooding, pollution and sedimentation. Planning regulations are needed to protect soils from being built on.

Swidden

Swidden, in modern usage, means shifting cultivation. Swidden is frequently said to be an old English term but it is not found in dictionaries of old English, or in a thesaurus of old English with extensive references to agricultural practices. The *Oxford English Dictionary (OED)* describes swidden as a northern dialect word to describe an area of land that has been cleared by slashing and burning. Swidden, also spelt as swizzen (to burn or singe), was first used in published English in 1788 by W H Marshall in his *Rural Economy of East Yorkshire* to describe the burning off of heath.

There is also a long published history of the use of a single word to describe shifting cultivation in Scandinavia. The Swedish word *svdjebruk* and the Finnish word *kaskeaminen*, are translated as swidden by Raumolin (1987). Raumolin finds the first papers on swidden agriculture were published in Swedish in 1750 and in Finnish in 1753.

The OED implies that the modern use of the term began in 1951, when K G Izikowitz in *Etnologiska Studier* wrote In English it is sometimes called shifting cultivation or slash and burn. There is no single word in English which covers the meaning .... In searching for an English word I have taken ... a dialect word, *swidden* . A number of similar terms for shifting cultivation are encountered in the literature. They include *ladang* (Malaysia and Java), *juma* (Sumatra), *kaingin* (Philippines), *jhum* (Assam), *taungya* (Burma), *milpa* (Guatemala), and *chitimene* (Uganda).

The association amongst swidden, burning and primitiveness is both unfortunate and wrong. Shifting cultivation is not a primitive form of agriculture, nor does it always involve burning. It was a very early form of agriculture. That it survives today suggests that it is highly adaptive.

BRYANT ALLEN *Australia*

Tidal Power Development

David Elliott

The Open University, Milton Keynes, UK

Tidal flows in rivers have been used since medieval times in tidal mills for corn grinding. However, it is only recently that tidal power has been seen as a potentially large source of energy.

Some very ambitious schemes have been considered for electricity production from barrages across major estuaries in the UK, Canada and elsewhere, but so far the only significant scheme is the 240 megawatt (MW) Tidal Barrage on the Rance estuary in Brittany in France, which was commissioned in 1968. There are some smaller barrages elsewhere, in Canada and China, for example, but although the global tidal resource is put at around 100 000 MWs (capable of generating perhaps 300 TWh per annum – which is equivalent to the UK's overall electricity requirements) this major renewable source of pollution free-power has not yet been taken up significantly.

Looking at the basic physics and engineering of tidal power can identify the main reasons for this. The rise and fall of the tides is caused primarily by the gravitational pull of the moon on the seas, which, modified by the smaller influence of the sun, produces a complex but highly predictable pattern of tides around the world. At any one point, there are two tides (approximately) every 24-h period, as the earth turns on its axis, but at most sites the tidal rise is small, whereas in others, like the Severn estuary in the UK, it can be enhanced by complex geographical funneling and resonance effects.

The construction of barrages or dams across estuaries allows water to be trapped at high tide, and this head of water can be used to power turbines, as with hydro electric power plants. The main difference is that the head of water is much lower than with hydro dams, as is therefore the power output – which is proportional to the square of the head. In addition, the continually shifting twice daily tidal pattern means that power can only be generated at certain times, and these may not coincide with periods of consumer demand. The end result is that expensive plant is not used fully, and although two-way operation and energy storage options exist, they are expensive.

In the longer term, when they have paid off their large initial capital costs, barrages, like hydro plants, can generate power relatively cheaply: after all, their fuel is free. They can also pay back their energy costs quite quickly – the energy used in construction and materials is only around 7% of the energy likely to be generated in a plant's lifetime, and relatively minor upgrades to turbines can extend the lifetime to a hundred years or more. However, given the short-term perspective adopted by most investors at present, barrages are not seen as economically attractive.

This economic problem can be exemplified by looking at one of the most developed proposals. The Severn estuary offers one of the best sites in the world given its large 11-m tidal range. The scheme proposed by the Severn Tidal Power Group, a consortium of leading UK construction firms, would involve the construction of an 18-km long barrage from Weston super Mare in Somerset across the Bristol Channel to the Welsh coast. It would have some 8600 MWs of generating capacity in the form of turbines embedded in the barrage structure and could generate around 6% of the UK's annual electricity requirements. However, it would cost around £10 000 million to build. So far, no private investor has emerged willing to take on this project; and large-scale publicly funded projects are currently not politically popular.

While the economic problem is probably the central issue, there are also potential environmental problems. Put simply, if you block up an estuary you are likely to have impacts on the local eco-system. Of course, some of the effects may be positive and the precise balance will be site specific. For example, given the lowered tidal range upstream, the decrease in the area of regularly exposed mud flats on the Severn might reduce the attractiveness of the site to some species. However, given the reduction in tidal flow, suspended silt would drop out, so that light would penetrate deeper, and the biological productivity of the water would increase, making it more attractive to

other species. Nevertheless, several environmental groups, fearing net adverse effects on migratory birds in particular, have come out against barrages.

With barrages in effect stalled as an option, attention has turned in the UK and elsewhere to another approach the use of tidal streams. Whereas barrages make use of the vertical tidal rise, use can also be made of the horizontal flow of tides the so-called tidal currents. A number of tidal current turbines have been developed: they are effectively like undersea wind turbines.

Although, as with barrages, the technology can only be deployed in specific sites, the technical potentials look good one study suggested that the UK could obtain nearly 20% of its electricity from such sources. The economic potential is less clear. In principle, tidal current turbines should be much cheaper than barrages since there is no need to build expensive (and environmentally invasive) dams across estuaries: tidal turbines can be free standing, mounted on the sea bed, or suspended from pontoons, out to sea. However, the power has to be brought back to land by expensive marine power cables and, as with offshore wave energy devices, tidal turbine systems would have to be designed to survive storms. As a result, at present, the technology is seen as only likely to be marginally competitive.

Tidal power offers a significant source of pollution-free energy, but so far only a few small to medium scale projects exist or are planned, perhaps the most promising being the 30 MW tidal current turbine system planned for installation on a causeway in the Philippines. With concerns about climate change growing, it could be that, if projects like this are successful, then the tidal option will be taken up seriously.

Tourism and Ecosystems

Joanna Burger
Rutgers University, Piscataway, NJ, USA

One aspect of global change that is often overlooked is the increase in movement of people on a temporary basis; people y within and among continents for business and pleasure. Travelling for pleasure, or tourism, is increasing worldwide as western economies boom and developing economies allow their citizens to attract tourists from abroad, and to travel themselves.

Tourism includes visiting friends and relatives, visiting archaeological or cultural features, basking in unique or pleasurable ecosystems (beaches, mountains, deserts), seeking exciting or challenging hunting or shing opportunities, enhancing other recreational activities, and visiting natural and ecological attractions. Ecotourism, aimed at providing the visitor with opportunities to view plants and animals within their natural ecosystems, is growing at an incredible pace. Ecotourists travel to the world's parks and nature reserves, and are attuned to the ideal of sustainable development. Ecotourism is a partnership among the travel industry, tourists and the conservation community to enhance environmental sensitivity (Ehrenfeld, 1992). People travelling on their own or on tours are visiting a wide array of habitats, and merely mentioning East Africa conjures up images of vast herds of zebra, wildebeest and gazelles, stalked by cheetahs during the day, and lions and leopards by night. Other world-renowned attractions include the Galapagos Islands made famous by Charles Darwin, the Antarctic with its colonies of penguins and nesting seals, Madagascar with its unusual primates, and the Great Barrier Reef with its spectacular sh diversity, colonial seabirds, and nesting sea turtles. Tourism, however, can also involve exploring towns, cities, and natural areas around home, with short trips of a few days.

Whenever people move about they leave their footprint on plant and animal communities, as well as on the ecosystem itself. In some cases, the imprint is short-lived: plants are trampled for only a brief period and then recover, or animals move temporarily, but return once the intrusion has passed. In others, the effects of tourism are longer-lasting; soil is compacted, plants die out, sea turtles abandon their nesting sites for less optimal places, iguanas are forced into other habitats or exposed to predators, birds abandon colony sites or foraging areas, and mammals leave suitable habitats to move farther into cover. Sometimes the effect of tourism is to reduce the time that animals can forage effectively in optimal habitat, increase the time they devote to vigilance for people and predators, increase their risk of predation, or expose themselves or their young to thermal stress.

While plants and animals, and ecosystems themselves, are resilient and have mechanisms to adapt to pressures from people, the problems faced by many species, communities and ecosystems are a direct result of increasing numbers of people, in different habitats, in more remote areas, for a longer period of time. While the effects of global changes in habitat, and habitat loss itself (Reaka-Kudla et al.*, 1997) are well known, the effects of tourism on naturally functioning ecosystems are less well studied. Such effects are often subtle, involving minor shifts in habitat, slight changes in species composition, or small declines in reproductive success, growth rates and survival. Small effects are cumulative, changing the overall health of plant and animal communities, and ultimately the ecosystems themselves. For*

species that are threatened or endangered, the effects of tourism can be catastrophic. As tourism increases globally, the effects on ecosystems will increase disproportionately, requiring careful environmental planning and management to sustain natural ecosystems.

In this article global changes in tourism, particularly ecotourism, are explored as they relate to Man's effect on individuals, populations, species, communities, ecosystems, and the landscape. Ecotourism is both a cause of concern for conservation, and a possible avenue of support for conservation. For example, the vast numbers of tourists that visit the Galapagos Islands contribute directly to their preservation through monetary rewards to the Ecuadorian government and through support of local guides, hotels, restaurants, boats, and other facilities (DeGroot, 1983). Similarly, many islands in Australia's Great Barrier Reef depend on ecotourism, yet are partially degraded by decades of resource use (Walker, 1991). Too many tourists strain fragile ecosystems, leading to declines of sensitive species, and reductions in the quality of the experience for the tourists themselves. Environmental degradation due to tourism is in many ways a common issue (Ostrom et al., *1999): each tourist who visits a place derives the full pleasure, while incurring only a small cost of the damage caused by that visit.*

TOURISM IS ON THE RISE

Tourism of all kinds is on the rise worldwide, as well as in countries such as the US, and is the largest business in the world (Miller, 1993). Tourism itself is difficult to define, since people can travel for the day, the weekend, or for extended periods of time, and can travel far from home, or tour around nearby. In this article I refer to tourism as travel by people, away from home, to see and observe natural, cultural, and political sights. By any measure, global tourism is not evenly divided among regions. Europe receives the greatest number of tourists, followed by the Americas and East Asia (Table 1, Figure 1, after World Tourism Organization, 1998, 1999).

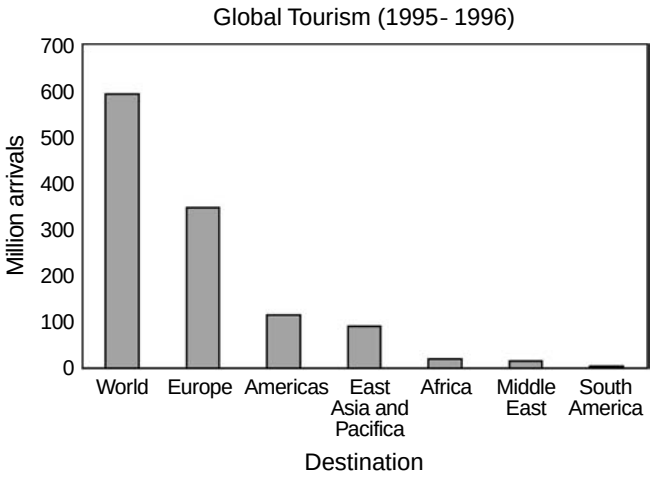

Figure 1 Tourism arrivals by region (after World Tourism Organization, 1999)

Ecotourism, as well as recreational activity, is also on the rise. For the US as a whole, based on a national survey, walking is the most popular recreational activity, followed by sightseeing, picnicking, swimming, fishing, bicycling, and bird watching (Cordell *et al.*, 1999). Some types of tourism and recreation are increasing more than others (Figure 2). Bird watching, hiking, backpacking, downhill skiing, and primitive camping are the five fastest growing activities in the US. For example, 21.2 million Americans (12%) were at least casual birdwatchers in 1982, while in 1995 the number had grown to 54.1 million (27% of Americans, Cordell *et al.*, 1999). Although some of these activities can be accomplished very near to home, most involve tourism.

Another measure of ecotourism is the number of people visiting National Parks or other reserves. In the US, the number of people visiting all sites under the National Park Service (including historic sites, battle fields, military parks, national monuments, national parks, preserves, seashores, and scenic rivers) has been increasing for many years, as has the number of people visiting the National Parks (Figure 3, after National Park Service, 1999). Despite the

Table 1 Ten most visited sites of the US National Park System (after Wiesenfeld, 1999)

Site	State	Hectares	Visitors in 1997
Blue Ridge Parkway	North Carolina, Virginia	35 802	18 373 279
Golden Gate National Recreation Area	California	30 146	13 803 382
Great Smoky Mountains National Park	Tennessee, North Carolina	211 280	9 965 075
Lake Mead National Recreation Area	Arizona, Nevada	605 328	8 528 422
Gateway National Recreation Area	New York, New Jersey	10 770	6 807 945
Natchez Trace National Parkway	Alabama, Tennessee	20 952	5 995 978
George Washington Memorial Parkway	Virginia, Maryland, D.C.	2934	5 844 204
Grand Canyon National Park	Arizona	492 876	4 791 668
Delaware Water Gap National Recreation Area	New Jersey, Pennsylvania	27 210	4 752 100
Statue of Liberty National Monument	New York, New Jersey	23	4 738 388

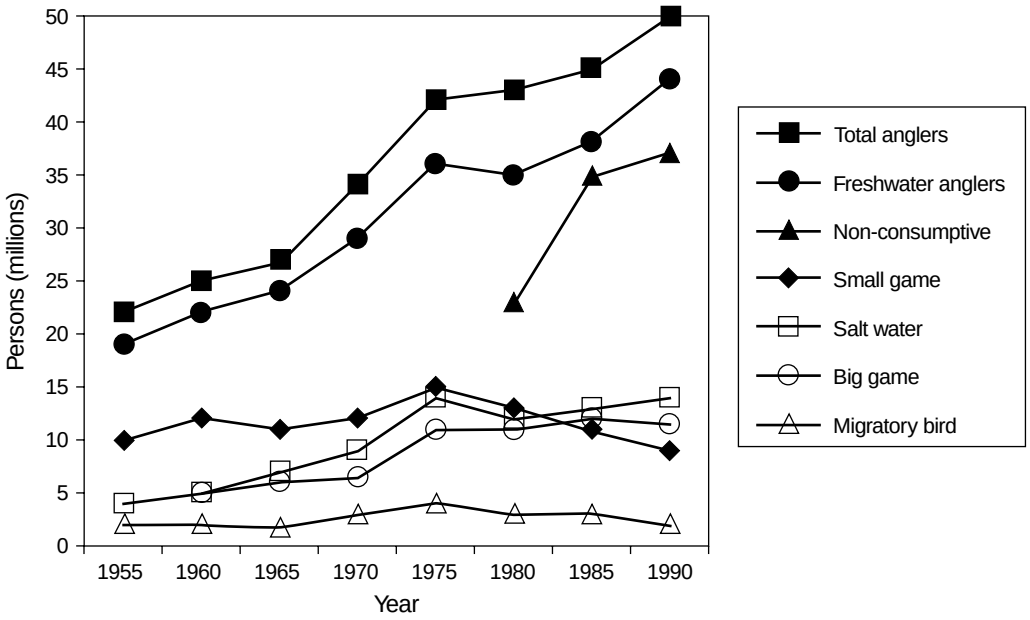

Figure 2 Growth in some forms of tourism and recreation in the US (after Knight and Gutzwiller, 1995)

wide variety of sites under the National Park Service, nine of the ten most frequently visited sites are parks and recreational areas (including parkways, Table 1); ecotourism is on the rise.

Marine and coastal tourism deserves special attention because of the fragility of these systems, because of a rapid increase in interest in the coastal landscapes, and because of the concentrations of people along coasts (Miller, 1993; Agardy, 1993). As human populations increase, these trends will continue, placing additional pressures on the plants and animals in these ecosystems. The pressures are two-fold: (1) an increase in human disturbance because increasing numbers of people will visit the parks, reserves, preserves, and other wild ecosystems; (2) increasing human populations and development will reduce available habitat elsewhere, leaving the protected ecosystems as islands.

TOURISM AND ECOSYSTEMS

There are many effects caused by tourists, whether they be ecotourists or otherwise, ranging from compaction of soil and increasing erosion, to destroying vegetation, altering the kinds and number of plants, displacing plants and animals, disturbing animals so that they abandon breeding or foraging habitats, increasing predation or piracy rates, and lowering survival and reproductive success. The kinds of disturbances caused by tourists vary by proximity, by species and the complexity of the ecosystem (Liddle and Scorgie, 1980; Knight and Gutzwiller, 1995; Liddle, 1997), as well as the type of tourists, and their locations (Mathieson and Wall, 1982; McNeely *et al.*, 1992; Ceballos-Lascurain, 1996).

The effects of tourists on ecosystems are multiple and complex (see summary in Table 2). Many of these effects are compounded by the great increases in the number of tourists visiting natural environments (McNeely *et al.*, 1992). There are effects for all major groups of species, and at all levels of organization. Whether people are walking over woodland trails, abandoned fields, sand dunes, or alpine tundra, soil is compacted, dramatically changing the soil microfauna and the ability of plants to germinate and flourish. Even walking over rocky outcroppings disturbs rock structure and lichens. Changes in soil compaction affect erosion, which in turn affects water dynamics, and ultimately stream flow, nutrient loss, and pollutant movement.

When soil is compacted, plants are affected as well, both by changes in their growing environment and by direct trampling by people, who also disperse a variety of native and exotic seeds among ecosystems. Changes in abundance and species composition of plants in turn alters all the animal communities dependent upon them. Thus, for all groups of organisms there are two types of tourist effects: direct affects that affect the organism itself (i.e., killing it, retarding its growth, and exposing it to predation, competition, or piracy), and indirect effects that include changing its microclimate, the plants or animals it depends upon, and its predators and competitors.

In turn, populations, community structure and function, and eventually ecosystems, are affected because of the cumulative effect of small-scale changes on soil and individual plants and animals (Figure 4). Some particularly

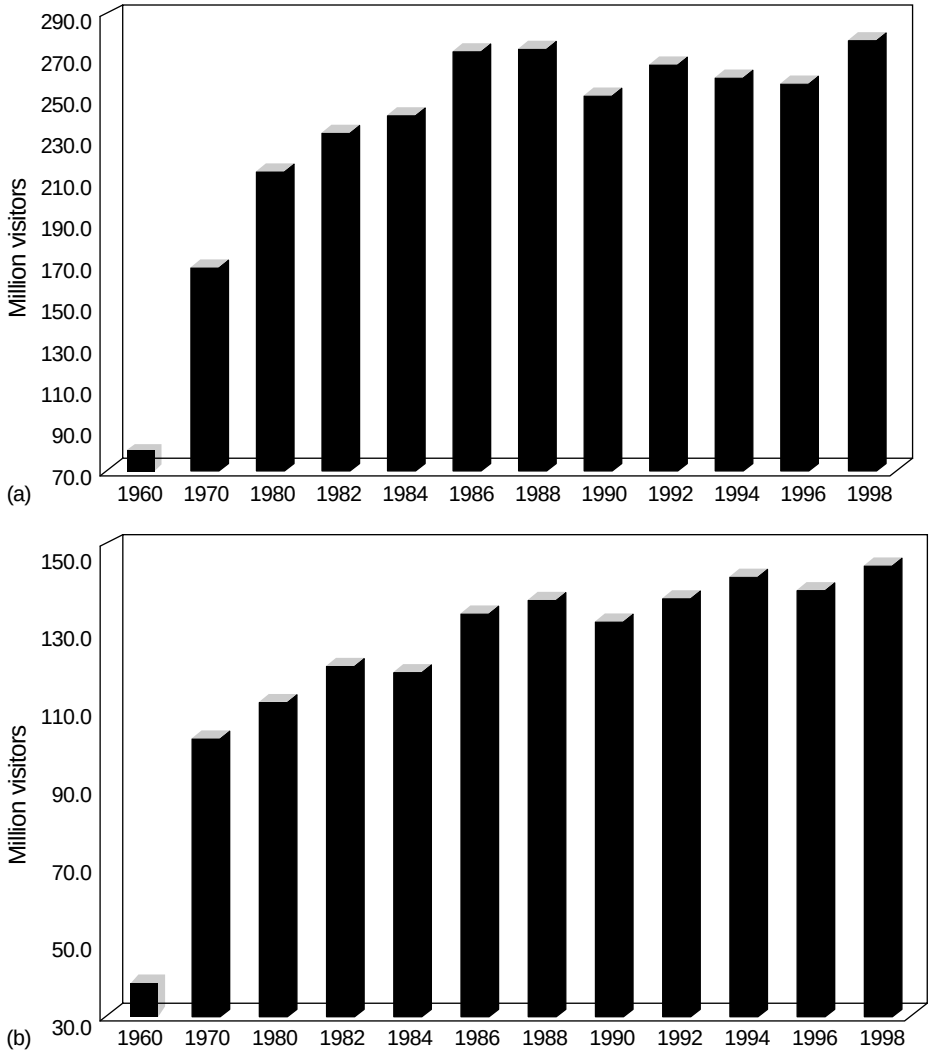

Figure 3 Number of visitors to all parks under the US National Park Service, including battlefields, historic parks, monuments, reserves and national parks (a), and number visiting the National Park sites (b)

sensitive species are affected merely by the presence of people, even though they are trying to be inconspicuous. For example, when predators, such as the big cats (lions and cheetahs), are surrounded by people, they hunt less frequently and have lower hunting success (McNeely *et al.*, 1992). Small or isolated ecosystems are particularly at risk, such as coral reefs, small islands and other delicate ecosystems (Mathieson and Wall, 1982). The feeding, breeding, and resting behavior of a wide diversity of animals are affected by increasing numbers of tourists (Mathieson and Wall, 1982).

There are also global effects, such as decreases in air quality because of air pollution from increased car exhausts, the destruction of coastlines, and the pollution of rivers (Mathieson and Wall, 1982). Waste materials generated by tourists can adversely affect water quality, and thereby ecosystems, in many different aquatic systems, including lakes, rivers and coasts; pathogens may also be introduced. Further, local geological features are often adversely affected by tourists who cause disruptions by merely walking there, or who remove materials (Mathieson and Wall, 1982). All of these changes affect both local and regional ecosystems.

For managers, the question then becomes how to reduce the effect of tourists, while still allowing ecotourists to have exciting and meaningful experiences. Reducing effects, however, requires detailed knowledge of how tourists affect a wide range of species, communities, and ecosystems.

ECOTOURISM, RECREATION AND BIRDS: A CASE STUDY

There are many types of ecotourists that affect and are affected by ecosystems and their component parts, but

Table 2 Possible effects on ecosystems by tourists moving through ecosystems

Area affected	Affects
Physical environment	Soil compaction Shifts in drainage erosion Increased addition of nutrients (from human waste and garbage) Shifts in depth of organic matter Changes in hydration
Litter, organic matter and soil invertebrates	Disruption of soil microfauna Changes in particle size Changes in earthworm population because of soil compaction Reduced soil anthropod numbers
Vegetation	Trampling, pruning, abrasion Shifts in species, biomass Damage to plant root Reduced root depth due to compaction
Reptiles	Direct killing of snakes to protect tourists Disturbances during egg-laying that lead to predation or sub-optimal selection of nest sites Lowered reproductive success due to compaction of soil over nests or hatchlings Inadvertent running over hatchlings Lights disorienting hatchlings/sea turtles and preventing them from reaching the sea Vehicles inadvertently running over reptiles
Birds	Decreases in time available for foraging Shifts in habitat Decreases in nesting Changes in nesting locations Shifts in time at the nest Leaving eggs exposed to thermal stress and predators Early abandonment of nest site by brood Changes in heart rate Frequent flushing from preferred resting sites Too rapid nest departure leaving eggs exposed to thermal stress or predators Increases in human predation of eggs and chicks Increased time away from colony site Lowered hatchling or fledgling rates Difficulties with hunters, prey
Mammals	Decreased foraging time Increased defense of young Disturbances during hibernation forcing relocation Withdrawing into sub-optimal habitat Running to exhaustion (from off-road vehicles or snow-mobiles) Changes in migration patterns Changes in escape routes Changes in heart rate Accidents while fleeing from people over rocky terrain
Community	Population declines Changes in predator population Lowered reproductive success and shifts among species
Ecosystem	Increased erosion of topsoil and destruction of soil and litter organisms Shifts in species composition Declines in species diversity Increases in invasive species

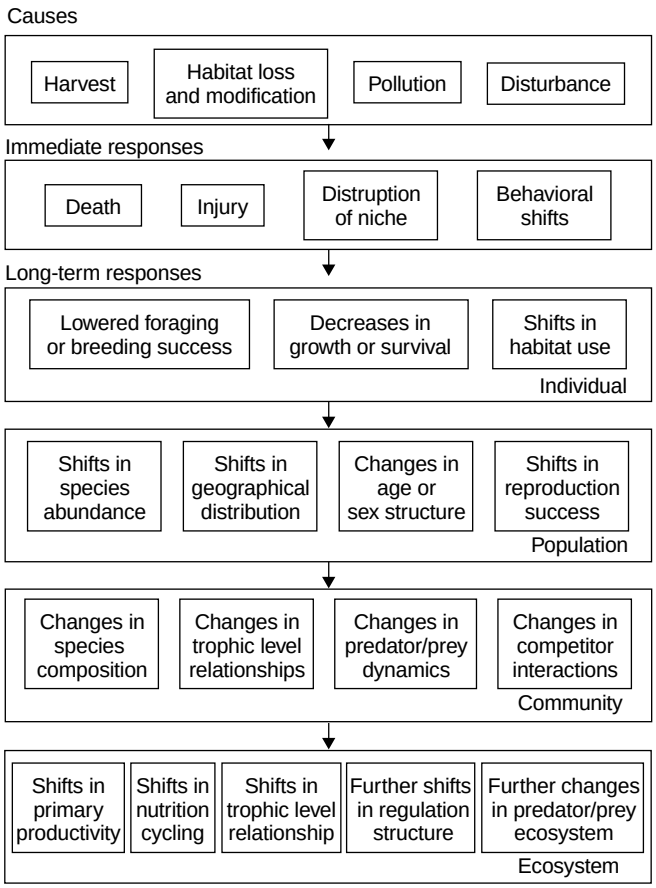

Figure 4 Model for the effects of tourism on organisms and ecosystems

basically they fall into two categories: people who specifically travel to observe or experience animals and plants in their natural habitats, and people who enter natural environments as part of some other pursuit, but who can affect ecosystems. The latter include a wide range of recreationists, such as walkers, joggers, hikers, campers, off-road vehicle users, and boaters. People who travel to see or experience natural habitats, and their plants and animals, include people who come to watch, photograph or study birds, butterflies, mammals or other natural spectacles. For ecotourists to receive maximum pleasure from their experience, the plants and animals must be in excellent condition. This includes high species diversity, unwary and visible animals, untrampled plants, and high numbers (massive herds of ungulates on the African plains, large numbers of nesting seabirds and basking iguanas on the Galapagos).

While the intent of people may differ between the two major classes of ecotourists, the overall effect on ecosystems does not. Twenty people walking through a fragile sand dune, whether to search for rare birds or to reach the beach, disrupt delicate dune vegetation and sand placement. Twenty people walking over the rocks of the Galapagos disrupt nesting seabirds or basking iguanas, regardless of whether they are photographing them, watching them, or merely walking to a fishing or swimming spot. Twenty people swimming over a coral reef, whether they are photographers, scientists, or merely divers watching fish, disrupt the normal rhythm of the sea creatures they are watching.

Because birds are generally diurnal, medium to large (that is, not microscopic), and live mostly in the same terrestrial space as people, they are enticing to ecotourists, and excellent subjects for scientific study. There is considerably more research on the effects of a wide range of human activities on birds than on all other groups of plants and animals. In this section the effects of people on birds are examined as a case study.

There are three major types of studies: (1) investigator effects; (2) experiments aimed at simulating ecotourists; and (3) observations of ecotourists around birds. Each will be discussed briefly because they illustrate how tourists and others affect birds.

Investigator Effects

Investigator disturbances were first noted for birds, such as seabirds and wading birds, that nest in large colonies, where a large proportion of the birds leave their nests when an investigator enters the colony. While scientists were interested in understanding how they affect birds so that they could reduce these effects, such information provided a basis for management programs.

The effects of investigators have been examined both experimentally and retrospectively, where the number of observers in a colony over a number of years is compared to some measure of effect (reproductive effect, colony size). For example, 21 years of data on Northern Fulmars (*Fulmarus glacialis*) indicated that hatching and breeding success was lower in years when 12 or more observers were present, compared to years with fewer investigators (Ollason and Dunnet, 1980). Other scientists have noted that birds will not establish territories and breeding colonies if people are present, some species desert nesting colonies if too many scientists walk through a colony (particularly during the early phases of nesting), and in some species, nesting density is lower in sections of the colony that are heavily visited (see Burger and Gochfeld, 1994).

During incubating and chick care, birds often take flight when there is an intrusion, exposing eggs or chicks to thermal stress and predation (Kury and Gochfeld, 1975; Roberts and Ralph, 1975; DesGranges and Reed, 1981), resulting in lowered hatching or fledging success (Hunt, 1972; Nettleship, 1975). Chicks can get lost and perish (Veen, 1977). Neighbors or marauders sometimes kill and eat chicks that wander from their territories as a result of human intrusion (Burger and Gochfeld, 1990, 1994). Some

parents and their brood abandon the nest site early when exposed to human disturbance, and move to other places farther away or where there is cover.

Many species of birds habituate (become accustomed) to the presence of investigators, who then cause little effect (Burger and Gochfeld, 1994; Brown and Morris, 1994), and disturbances can be reduced by providing cover for chicks (Quinn, 1984). Investigators also protect nesting colonies by their very presence, reducing vandalism, egging, and hunting (Haynes-Sutton, 1987).

This work demonstrated that investigators can have a negative effect, but that experience and knowledge can minimize the disturbances so that reproductive success is not reduced. Further, the factors affecting human disturbance for nesting birds were determined from this work, species (or reproductive stages) that were particularly vulnerable were identified, and methods of reducing human disturbance were described (reduced time in the colony, use of the same pathways where possible, walking slowly through any colony or nesting area, wearing dull clothing, and not looking directly at birds).

Experimental Studies

It soon became apparent that investigators could simulate the behavior of tourists and others approaching birds while they foraged or bred, which provided a paradigm for understanding how people affect birds, and a methodology for risk reduction and management. Experimental studies usually take the form of approaching birds to determine the distances at which they change behavior or fly; this has the advantage that the technique can be used on foraging and resting birds, as well as on nesting ones. Birds that are habituated learn to quickly distinguish whether a person is walking directly toward them or will pass a few meters away (Burger and Gochfeld, 1981).

For wading birds (herons, egrets) and seabirds that nest along coasts, distances that birds flush from their nests varies by species, but data suggest that nesting wading birds require people to stay at least 100 m away, and some seabirds require people to stay 200 m away to avoid undue disturbance to established colonies (Erwin, 1989). Greater distances are required to allow birds to establish new colonies. In a similar study in Florida, the distances that birds flushed from their nests when approached by people were used to derive management guidelines for pedestrian tourists and motor boats (Rodgers and Smith, 1994). Remarkably, the disturbance distances for wading birds were all about the same and for tern and skimmer colonies the distances (100 m) clustered at about 180 m. These data suggest that even with increasing human use of coastal ecosystems, preserving nesting colonies of birds will require maintaining these 180 m distances even in the face of increasing human density.

Even seabirds that nest on remote islands and apparently seem undisturbed by the presence of tourists respond physiologically by increasing their heart rate, by moving slightly away from advancing tourists, and by nesting farther from established paths. Boobies nesting on the Galapagos Islands, move away from tourists that pass as close as a meter from their nests, while birds that are over 6 m away seldom respond; albatross chicks on Midway Atoll in the northern Pacific Ocean likewise move back from approaching tourists (Burger and Gochfeld, 1999).

For songbirds nesting solitarily in shrubs and trees in forests, intrusions reduce singing (Gutzwiller *et al.*, 1994), which could affect their ability to acquire mates and defend territories. Response time even depends upon how many birds of the same species are nearby (Gutzwiller *et al.*, 1998). Such intrusions can result in nest abandonment and decreased nest attentiveness, leading to decreased reproductive success.

Birds that forage close to the ground are particularly vulnerable to predators, and can be easily disturbed by tourists or other people. When disturbed, birds either lose valuable foraging time, or fly away, where they are often forced to other habitats where food may be less plentiful and predators more abundant. Birds that forage alone or in flocks are equally vulnerable to human intrusions from walkers, joggers, birdwatchers or others moving toward them.

Many factors influence how close foraging or resting birds allow approach before altering their behavior or flying away. Birds in suburban areas where they have become habituated to people are less wary than those in rural areas (Cooke, 1980). Small birds often allow a closer approach by humans than do larger birds. Other factors that affect how birds respond include the number of people in a group, number of birds in the flock, time of day, and whether birds are migratory or not. In India, for example, where birds are not persecuted for religious reasons, resident birds allow far closer approach than do migrants from farther north where they are persecuted and hunted (Burger and Gochfeld, 1991).

Observational Studies of Tourists and Birds

Another way to assess the effects of tourists on birds is to design studies to specifically record how birds respond whenever tourists come by. The methodology is to quantify the amount of human disturbance in terms of type, frequency, proximity, and duration, and to document the response of birds to each type of disturbance. Such studies include understanding the effects on nesting and foraging birds. Tourist and recreational intrusions into forests can alter the abundance and distribution of songbirds, as well as changing species composition.

Intrusions into bird colonies in heavily populated coastal areas are difficult to document because most states protect

colonial species; many states post such colonies, and some fence them or employ wardens. However, observational studies have demonstrated that when picnickers disturb nesting herring gulls (*Larus argentatus*), hatching success declines by half (Hunt, 1972). Similarly, intrusions by tourists and others into Heerman s gull (*Larus heermanni*) colonies reduced fledging success by up to 75% (Anderson and Keith, 1980). Similar declines due to human intrusions have been documented for several other species. Colonial species disperse outward from the colony to forage, usually in coastal bays and estuaries or in the nearby ocean, rendering them less vulnerable to people at this time.

As more and more tourists visit beaches and other coastal regions throughout the world, the space available for nesting and foraging birds decreases and their exposure to human activities and noise increases. Shorebirds nesting solitarily on beaches are highly vulnerable to tourists because it is not easy to protect one nest here, another one 200 m away, and still another 500 m away. While fences can be placed around nests, it is far more difficult to protect these species while they and their chicks forage on beaches (Burger, 1994). For example, piping plovers (*Charadrius melodus*), a US endangered species that nest along the Atlantic Coast and along the Mississippi River in the US, nest on sandy beaches and forage at the water s edge, just where tourists want to walk, jog, swim, and sunbathe. Part of the plover s recent decline seems directly due to increases in the number of tourists along beaches, which restricts foraging time (Burger, 1994). The number of seconds that plovers are alert during foraging increases directly with the number of people on beaches (Figure 5). While adults can partially compensate for the lost foraging time by feeding at night, this is more difficult for chicks that have not mastered difficult tactile foraging skills. Further, continued disturbance while foraging scatters broods, and parents lose chicks that have run too far (Burger, 1991). Since the number of people is continuing to increase on these beaches, plovers will continue to lose foraging time, overall survival will decrease, and populations will continue to decline, unless managers exclude visitors during critical nesting periods.

With increasing numbers of people concentrating along coastal margins, birds nesting on estuarine islands are more exposed to tourists as well. Many types of recreational boats are being produced worldwide, especially personal watercraft (PWC) (Figure 6). PWC can drive into areas that are too shallow for other craft, destroying delicate submerged vegetation, disrupting bottom sediments, harming fish and crayfish nurseries, and disturbing nesting and foraging birds (Burger, 1998). Partly it is the noise that disrupts nesting birds, forcing them from their nests again and again, until they finally desert the colony site. As more and more people use PWCs, the pressure on ecosystems will increase, unless legislation restricts their use.

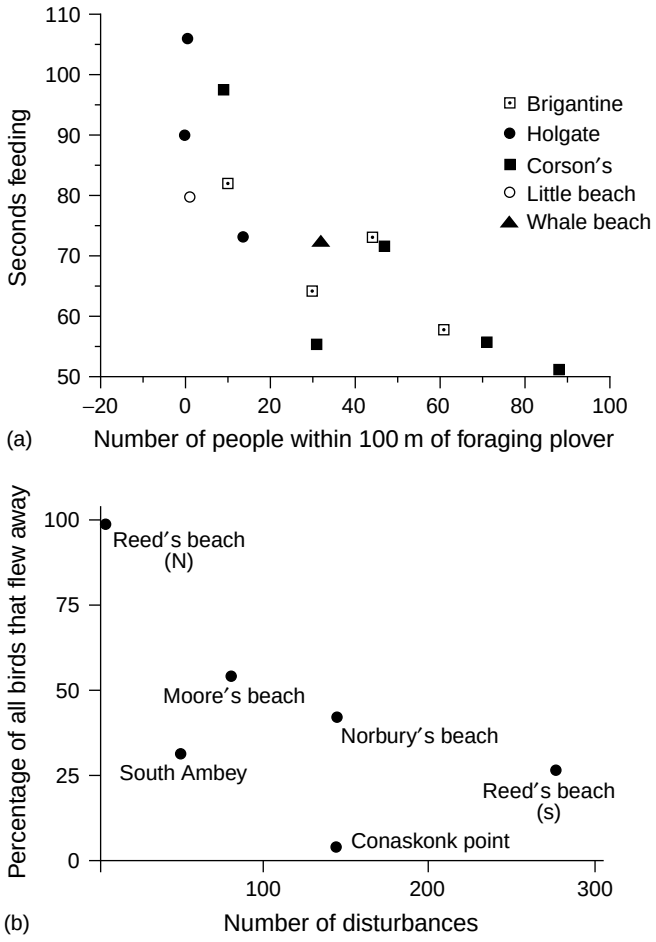

Figure 5 Dose–response relationship of the number of tourists and foraging behavior of (a) breeding piping plover (after Burger, 1994) and (b) migrant shorebirds (after Burger, 1986) (Cape May, NJ)

Migrant shorebirds are particularly vulnerable because they have very little time to lay down sufficient fat reserves to fly long distances, northward to breeding habitats or southward to overwintering grounds. Flocks of birds foraging along the shore are affected by the presence of tourists on the beaches by avoiding beaches with people, by moving from people (and their associated dogs) whenever they pass, of by ceasing to feed or guard their young when people pass by. The number of foraging shorebirds that fly away is directly related to the number of disturbances at Cape May, New Jersey (Figure 5, Burger, 1986; Burger *et al.*, 1995), a world famous birding spot where the number of tourists increases yearly. Further, when some members of the foraging flock take flight, other do as well, even though they are much farther away (Roberts and Evans, 1993). Tourists and others on migration staging areas can impact shorebird movements by moving shorebirds from preferred resting sites, and by displacing them from optimal foraging areas (Pfister *et al.*, 1992).

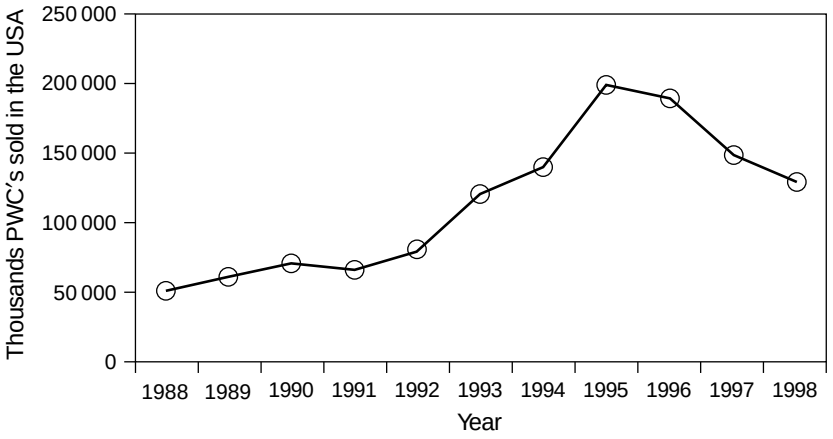

Figure 6 Sales of PWCs (personal water craft) in the US from 1987 to 1997 (after Burger, 1998)

Shorebirds and other species feeding on coastal beaches are particularly vulnerable to tourists because they are forced to move when people come by. However, even birds foraging in the water respond to tourists moving along dikes to watch them (Burger and Gochfeld, 1998). Gallinules (*Gallinula chloropus*), rails (*Porzana carolina*), ibises (*Plegadis falcinellus*) and herons (*Egretta caerulea*, *Egretta tricolor*) all spend less time foraging when people are near, and obtain less food than when there are no intrusions. Variations in the time they devote to foraging are a function of the number of people present, and the amount of noise made by people. Birds that are close to dikes when people pass usually swim away or fly a short distance before returning to foraging, while those that are farther from the tourists simply paddle away while continuing to feed. Such information is critical to managing tourists and birds because it means that where possible there should be a buffer between foraging birds and tourists, and decreasing noise levels is central to reducing the effects on foraging birds. It also suggests, however, that as the number of tourists increases, the problem will be exacerbated by the increasing noise that additional people, even those who are relatively quiet, will make.

Other birds that are vulnerable to disturbances by tourists are exotic, rare, or charismatic birds, such as birds of prey. Tourists frighten eagles off their nests, exposing developing eggs to cold stress, and human disturbance accounts for nearly all nest losses in some areas (Bocker and Ray, 1971). Ospreys (*Pandion haliaetus*) have abandoned nests after frequent disturbances by boaters, bird watchers, and photographers (Dunstan, 1968).

OTHER SPECIES

While the effects of tourism on birds have been extensively studied, there are fewer studies with other animals. Conservation of fish may largely reside in the hands of fisheries management, but many marine resources are affected by ecotourists. Marine sanctuaries are being developed in many places in the world, and direct concern for the effect of ecotourists on fish, sea turtles, seabirds, and marine mammals is being expressed. Yet there are few quantitative studies of effects.

Currently there is widespread concern about the effect of ecotourists on marine mammals, such as gray whales (*Eschrichiius glaucus*) in Southern California, humpbacks (*Megaptera* spp.) in Alaska and Hawaii, and Belugas (*Delphinapterus leucas*) in Alaska and the St. Lawrence River in Canada (Blane and Jackson, 1994). In many cases tourism boats get as close as possible, for as long as possible, and there is little information on the short- or long-term effects of these boats. Increasing pressures to visit species such as the northern elephant seal (*Mirounga angustirostris*) are resulting in management strategies such as limiting the number of visits, limiting the number of trails, limiting the time on trails, and enforcing non-disturbance policies (Magoon *et al.*, 1998).

There is almost no work on the effect of tourism on reptiles, except for the interest in sea turtles and Galapagos iguanas (Johnson *et al.*, 1996). Although watching sea turtles nest is an exciting experience, female sea turtles accompanied by a group of 15 people spend less time camouflaging their nests and return to the sea over a less direct route than unwatched turtles (Johnson *et al.*, 1996). Although reproductive success does not differ, ecotourism must be accompanied by protection of nests. The number of tourists interested in watching sea turtles nest is likely to increase. In the past decade there has been a 24-fold increase in visitations to Costa Rica s Tortuguero National Park. The park has responded with extensive tour guide training programs to ensure the protection of endangered sea turtles (Jacobson and Robles, 1992), but few data are available on the effects of ecotourists. Turtle watching in SE Asia has often been unregulated with adverse effects on turtle populations through overexploitation.

Experimental work in Costa Rica indicated that basking black iguanas (*Ctenosaura similis*) evaluate the risk from approaching people, discriminate whether they are walking directly toward them or will pass by, and respond accordingly (Burger *et al.*, 1991, 1992). A tourist approaching directly and looking at an iguana is the most threatening; partly the iguana response is due to eye size.

Population declines in wood turtles (*Clemmys insculpta*) in Connecticut over a 20 year period were directly correlated with increases in people in the surrounding communities, and in the number of recreational/tourist permits issued for turtle habitat (Garber and Burger, 1995). Remarkably, the recreational/tourist pressures were not great, but the increases in human presence nonetheless led to declines and shifts in the age distribution; there were no new recruits into the population. Such studies indicate that, for some species, even small numbers of recreationists and tourists can have devastating effects.

As with birds, land mammals suffer some of the same effects because of tourists (Liddle, 1997). Bears can be disturbed during their winter hibernation by skiers or others (Goodrich and Berger, 1994). Many mammals respond to increasing interactions with people by becoming wary and withdrawing. For example, the number of white-tailed deer (*Odocoilus virginianus*) observed from snowmobiles was lower on Saturdays and Sundays and was negatively correlated with the number of snowmobiles in St. Croix State Park, although the deer merely hid (Dorrance *et al.*, 1975). In contrast, caribou (*Rangifer tarandus*) change their migration route, avoiding areas where they were hunted by snowmobiles (Calef, 1976).

Like birds, some mammals habituate to the presence of tourists, and then can cause problems: when bears habituate they become dangerous, whereas when deer habituate they become nuisances, moving among habitation to consume garden and foundation plantings and spread Lyme disease. Some animals, such as foxes (*Vulpes vulpes*), habituate sufficiently to tourists and other people that they begin to live near human habitation although they still run from groups of noisy people. Habituation of some mammals, such as the large cats, can be deadly, as has happened in Africa when careless staff of lodges put out bait for large cats so that people can see them at close range.

While there are far fewer studies of the effects of ecotourists on groups of vertebrates other than birds, they indicate a full range of effects that are similar to those demonstrated for birds. They illustrate that there is much still to learn about the nature, magnitude, and permanence of tourist effects. These studies indicate that environmental management and planning are required to reduce the effects of tourists on the well-being, survival and reproduction of wild populations.

TOURISM AND ENVIRONMENTAL PLANNING

In 1980 the World Tourism Organization (WTO) recognized that there should be a close relationship between environmental planning and tourism, and that both natural and cultural resources must be conserved and protected (Inskeep, 1987). Such planning requires comprehensive environmental analysis of carrying capacity, development and application of local and regional strategies, planning for tourist facilities, maintaining the quality of these facilities and the ecosystems that attract the tourists, and monitoring the health of these ecosystems, as well as the tourist facilities. Planning and development of ecotourism should also include economic analyses of both direct and indirect effects of that tourism. What are the appropriate multipliers for the economic costs and benefits of tourism, on both the local culture and the local ecosystems?

Tourism may represent a significant threat to the environmental health of the very places that tourists want to visit. While many planners believe that ecotourism may provide an economic incentive to preserve habitats, more attention is devoted to planning for ecotourists than assessing the effects of those tourists on the ecosystems themselves. Many regions fail to take into account the fundamental issues surrounding tourism, particularly ecotourism (Table 4, Butler, 1991). While scientists may be determining the effects of ecotourists on plants and animals, this information may not be accessible to managers and planners.

Table 3 Arrivals (thousands) of tourists from abroad by region (after World Tourism Organization, 1998)

	1980	1993	1994	1995	1996
Africa	7329	18 605	19 009	20 117	21 553
Asia/Pacific	21 480	71 094	76 788	81 356	89 186
Europe	185 442	309 758	330 630	333 855	348 999
Middle East	7467	71 348	12 747	13 465	14 084
Central America/Caribbean	8238	15 184	16 092	16 641	16 885
North America	47 321	77 324	77 906	80 491	85 223
South America	5809	11 250	12 573	13 480	14 565
South Asia	2242	3511	3866	4200	4332

Table 4 Issues surrounding environmental planning, tourism, and ecosystem protection

Knowledge gaps	Dimension of tourism
	Potential growth of ecotourism
	Economic value of ecotourism
	Methods for containing ecotourists
	Data on effects of ecotourism[a]
	Data on carrying capacity for ecotourists
	Dose–response data[b]
	Role of education in reducing effects
	Methods of involving local peoples
	Methods of working in interdisciplinary teams
Technology gaps	Tools to determine sustainability
	Tools for maintaining restricted populations
	Methods for determining effects of tourism
	Methods for valuating ecotourism and biota
Philosophy gaps (agreement gaps)	Over desired level of ecotourism
	Over which types of tourism to encourage
	Over amount of wilderness to protect
	Over desired level of tourist development
	Over type of ecotourism[c]
	Over balancing industry/tourism[d]

[a] Effects of ecotourists on most groups of animals and plants have not been examined in detail.
[b] The relationship between the number of tourists and degree of effect has not been determined for many types of ecotourists or groups of organisms.
[c] For example, woods might be preserved for ecotourists interested in migrating birds, but old fields might be preserved for butterfly watchers.
[d] Is it better to cut down the Asian forests for timber, or preserve them for the tourist value of high species diversity.

Ecotourism has largely advanced on a piecemeal basis, but this will not be possible in the future because of increasing numbers of tourists, and increasing pressure on natural resources. Ecosystems and their component plant and animal communities must be protected or the stimulus for ecotourism will disappear. Studies of the type described above for birds are essential for a wide range of animals to assess the factors that allow tourists and animal populations to flourish side by side, even with increasing pressure from increasing numbers of tourists. Thus, both monitoring and research will play a more critical role as human populations and tourism increases. To plan for tourism within a healthy environment, interdisciplinary teams will be required (Grenier *et al.*, 1993, Table 4).

INCREASING GLOBAL TOURISM AND FUNCTIONING ECOSYSTEMS

The data presented above suggest that birds, as well as other animals, are vulnerable to increasing numbers of tourists during their breeding, foraging, and migrating phases. They respond both to features of the disturbance, as well as to their own constraints. Disturbance features that are important include the number of people, their activities, their noise levels, their location, and past behavior of humans (i.e., degree of hunting or persecution). Animal life history parameters that are important are flock, herd or colony size, activity (foraging, stage of breeding), location (on land, in trees, or in the water), location in the flock or herd, available cover, predators that are present, and physical stresses (e.g., thermal). While animals can habituate, there are some human activities that are not amenable to habituation (such as the noise of PWCs), and there are minimal distances that cannot be violated or the animals will cease their activities, losing valuable time when they could be feeding, engaged in breeding, or other equally important behaviors.

If the past is any indication of the future, tourism will continue to increase. Further, ecotourism, the form that has a direct effect on ecosystems, will also increase. Another complexity is the probability of significant climate change and rising sea level before the end of this century. This would modify, or even destroy some habitats, particularly along low-lying sea coasts. See for example, various articles in volume 1, and the overview paper: Intergovernmental Panel on Climate Change (IPCC): an Historical Review, Volume 4.

While direct habitat loss is clearly the greatest global threat to ecosystems, we also need to be concerned for the preservation of the plants and animals within the ecosystems that we choose to protect. There are a number of different types of protection available, ranging from national parks and reserves, where recreation and other human activities are often encouraged, to preserves and wilderness areas where human uses are severely restricted.

The feedback mechanisms between tourism and ecosystems are also extremely important. Tourists have the potential to affect the plants and animals within ecosystems in profound ways, as illustrated above. The tourists can affect the landscape itself. However, as tourists affect these animals and plants, they also can render the ecosystem less attractive to other tourists. This will in turn decrease the number of tourists that come to see that ecosystem, which may allow the system to recover. Thus, there is a very delicate balance between tourism and healthy ecosystems.

As more and more private land is developed, the pressures on public lands will increase, making the preservation of fragile and exciting ecosystems paramount. Understanding the relationships between the behavior of tourists and the survival and reproduction of plants and animals,

their communities and ecosystems, is critical to preserving functioning ecosystems for the future.

ACKNOWLEDGMENTS

Tourism as a Global Driving Force for Environmental Change

Poh Poh Wong
National University of Singapore, Singapore

In the last 50 years, the movement of people within and between nations in pursuit of leisure has been on an unprecedented scale. Restricted in the past to only the wealthy, tourism is now enjoyed by the masses, made possible by a decrease in the real cost of travel, a higher standard of living and available leisure time. The business of providing and marketing services and facilities for pleasure travelers is now the world's largest and most diverse industry. Tourism, itself, consists of diverse groups of industries covering the scale from multinational corporations to individually run enterprises. A wide range of tourist activities can be identi ed - visiting friends, beach holidays, coach tours, country walks, museum visits. Despite its growing complexity and scale, it represents an activity certainly well recognized, and has distinct impacts on the environment and society.

Tourism has become one of the most significant forces in environmental change in the latter half of the 20th century. It causes environmental changes affecting air, land and

water, particularly through its tendency to concentrate on certain areas such as coasts, mountains, wilderness areas, urban areas and small islands. The environmental impacts can be positive, e.g., the enhancement of local beautiful vistas, but often the impacts are negative, e.g., the inability of beach resorts to cope with the high demand by tourists during the summer months.

Tourism s response to an increasing awareness of environment and the need to reduce the environmental degradation has taken several directions. One response is *ecotourism* or nature-based tourism, which has become an important instrument for nature conservation. Another approach is to ensure that tourism development adopts proper environmental measures, for example, carrying out environmental impact assessment before implementation of a project. All the measures taken are towards making tourism a less negative force on environmental change and achieving sustainable tourism development.

However, measures to protect the environment have not become widespread, and the future scenario of environmental change by tourism is far from positive. Travel is expected to increase rapidly, leading to more greenhouse gas emissions by cars and aircraft. As more land is used for tourism development, additional degradation is to be expected. Plants and animals continue to be under threat. Fragile ecosystems such as sandy beaches, coral reefs and mangroves will come under increasing pressure. Tourism s constant search for new areas, for example, the Antarctic, and the rise of *adventure tourism* will put the environment on the defensive.

GLOBAL TOURISM

As defined by the World Tourism Organization (WTO), a tourist is a temporary visitor staying at least 24 hours in another country for pleasure or business. Tourism is now the largest industry in the world, constituting the largest item in world trade and the largest number employed. It is also one of the fastest growing industries in the world, averaging nearly 10% per annum from 1950 1970, although it has slowed down since then (Figure 1). For 1997, the

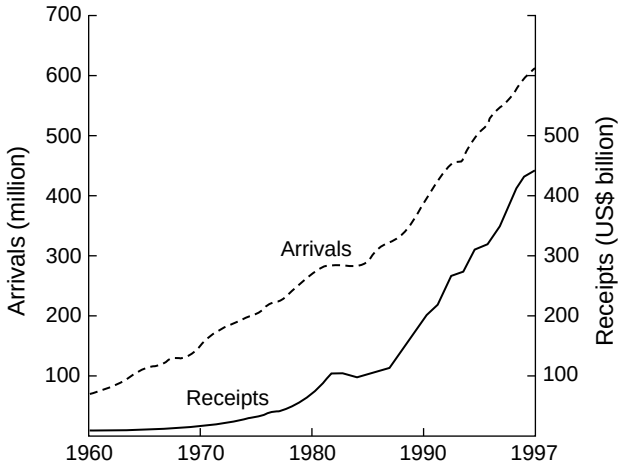

Figure 1 World tourist arrivals and receipts, 1960–1997. (Data source: WTO, 1998)

preliminary figures were 612 million tourists generating an estimated US$444 billion (excluding international transport). By 2010, tourism is projected to reach more than one billion tourists generating US$1500 billion (WTO, 1998). Its economic importance has grown more rapidly than the number of tourists. It had registered double-digit growth from 1950s except in the 1990s. As a group of economic activities, tourism is the world s largest industry in terms of employment. According to the World Travel and Tourism Council, 230 million or about 10% of the world s workforce are employed in the tourism sector. This is projected to increase to 328 million in 2010.

Tourism is unevenly distributed and highly concentrated in certain regions and countries. WTO, the most important intergovernmental body for the tourist industry, divides the world into six tourist regions: Africa, the Americas, East Asia/Pacific, Europe, the Middle East and South Asia. Europe and the Americas account for the lion s share of the world s tourism but are decreasing in favor of East Asia/Pacific and Africa. East Asia/Pacific has more than doubled its share since 1980 (Table 1). The remaining regions, each averaging a few per cent, have increased marginally.

Table 1 Regional share of world tourism, 1960, 1980, 1996

	Arrivals (per cent)			Receipts (per cent)		
Region	1960	1980	1996	1960	1980	1996
World	100.0	100.0	100.0	100.0	100.0	100.0
Africa	1.08	2.57	3.62	3.54	2.57	1.92
Americas	24.10	21.51	19.61	35.71	24.11	26.01
E Asia/Pacific	1.02	7.53	14.99	2.84	8.28	18.75
Europe	72.64	64.99	58.67	56.56	60.28	50.63
Middle East	0.91	2.62	2.37	0.84	3.29	1.78
South Asia	0.26	0.79	0.73	0.51	1.46	0.90

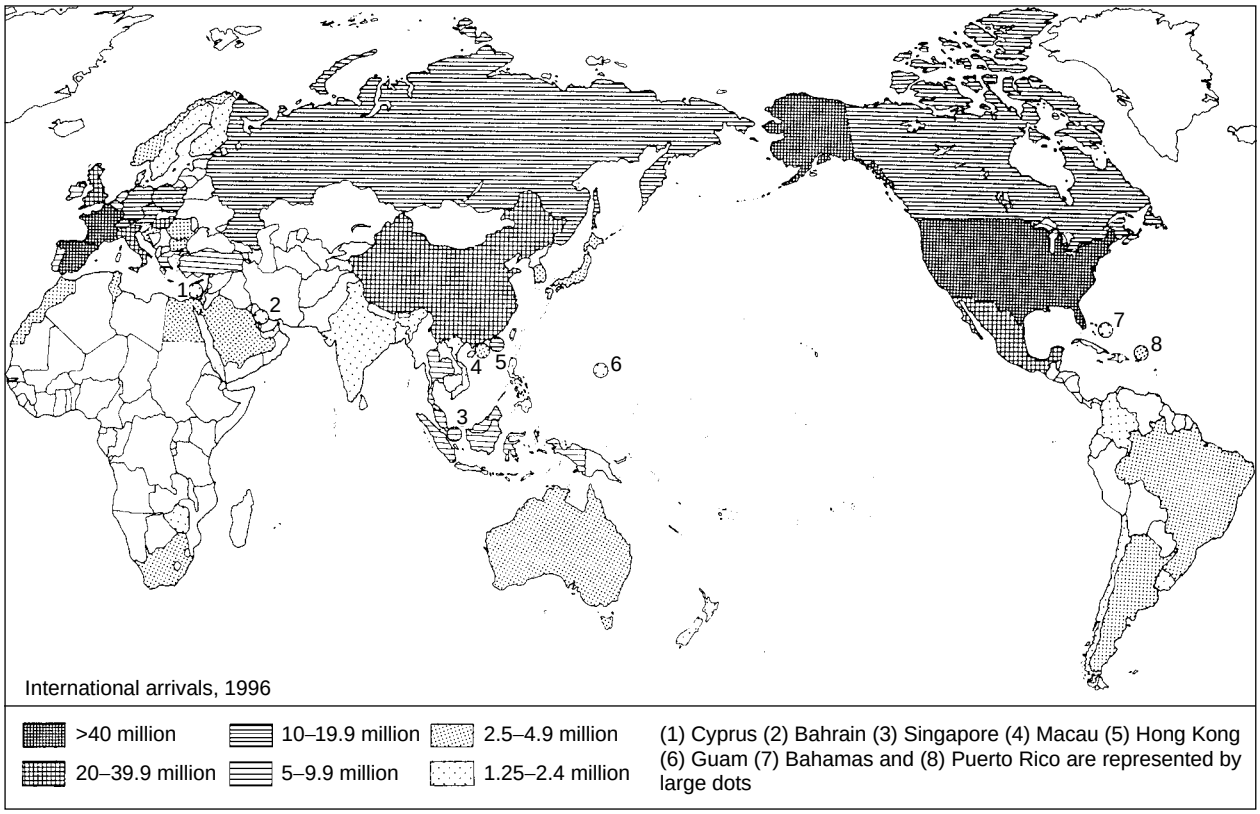

Figure 2 World tourism, 1996. (Data source: WTO, 1998)

Table 2 World's top tourism destinations, 1996

Rank 1996 (1980)	Country	Arrivals, 1996 (millions)	% of World's arrivals, 1996
1 (1)	France	62.41	10.49
2 (2)	United States	46.49	7.82
3 (3)	Spain	40.54	6.82
4 (4)	Italy	32.85	5.52
5 (7)	United Kingdom	25.29	4.25
6 (18)	China	22.77	3.83
7 (8)	Mexico	21.41	3.60
8 (10)	Hungary	20.67	3.48
9 (13)	Poland	19.41	3.26
10 (6)	Canada	17.33	2.91
11 (5)	Austria	17.09	2.87
12 (•)	Czech Republic	17.00	2.86
13 (9)	Germany	15.21	2.56
14 (•)	Russian Federation	14.59	2.45
15 (28)	Hong Kong SAR	11.70	1.97

A more quantitative idea of the volume of global tourism can be obtained by looking at individual countries. Tourism remains largely an activity between developed countries with the developing countries accounting for a 30% share of global arrivals. There is a high concentration of international tourism within certain developed and developing countries. Outside Europe and North America, the countries receiving more than 5 million arrivals in 1996 are limited to China, Hong Kong, Mexico and some countries in Southeast Asia (Figure 2). This picture is further supported by the top tourism destinations (Table 2), the top tourism spenders (Table 3) and the largest flows between generating and receiving countries. The most significant change has been China which has developed rapidly as a tourist attraction since its opening to the outside world in the late 1970s. The biggest spenders are

Table 3 World's top tourism spenders, 1996

Rank 1996 (1980)	Country	Tourism expenditure, 1996 (US$ billions)	Tourism expenditure, 1996, % of World
1 (1)	Germany	50.82	13.40
2 (2)	United States	48.74	12.86
3 (6)	Japan	37.04	9.77
4 (3)	United Kingdom	25.45	6.71
5 (4)	France	17.75	4.68
6 (13)	Italy	15.52	4.09
7 (10)	Austria	11.81	3.12
8 (5)	Netherlands	11.37	3.00
9 (9)	Canada	11.09	2.93

11 (8)	Belgium	9.90	2.61
12 (12)	Switzerland	7.48	1.97
13 (37)	South Korea	6.96	1.84
14 (24)	Taiwan	6.49	1.71
15 (21)	Sweden	6.44	1.70

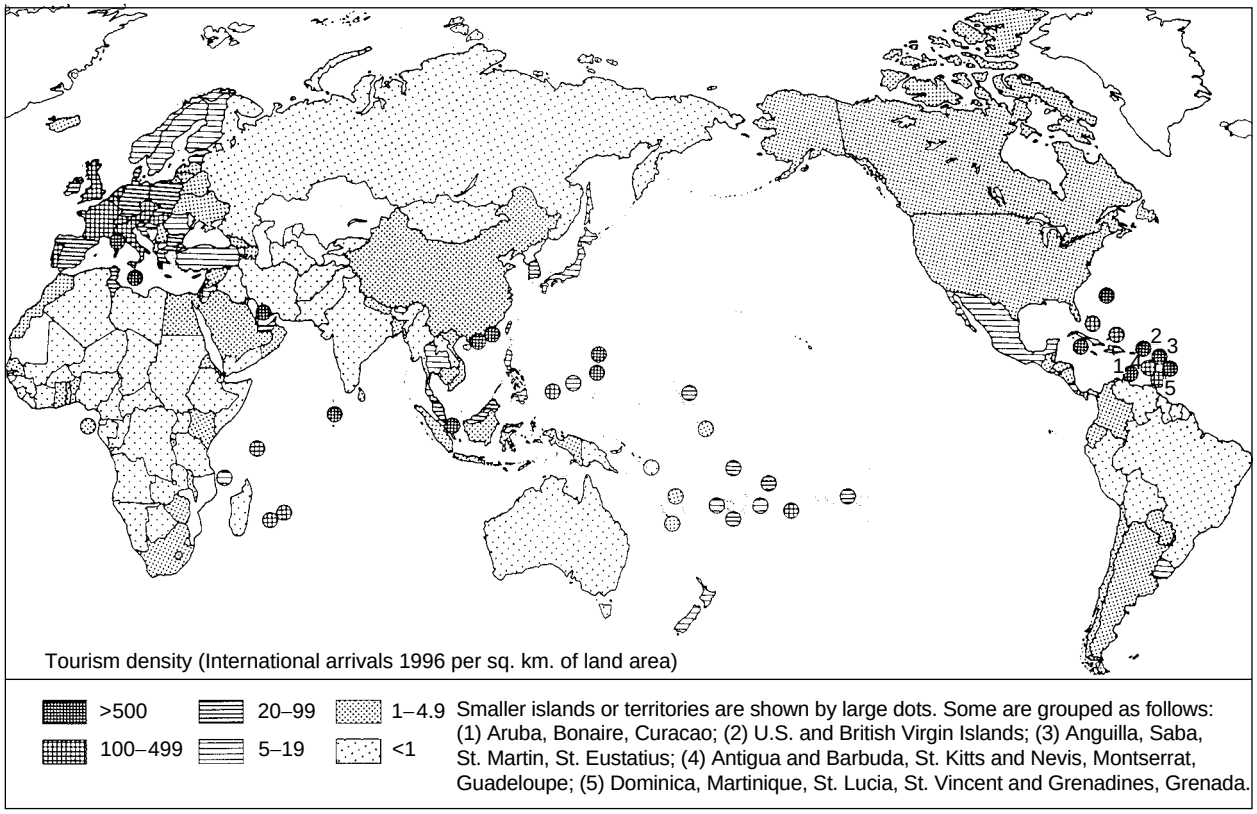

Figure 3 World tourism intensity, 1996. (Data source: WTO, 1998)

from the developed countries, joined by South Korea and Taiwan.

Available WTO data for 1996 and 1995 also show well-developed global patterns of flows between generating and receiving countries. The largest flows are across the Canada United States border. Except for the Mexico flow to the United States, the other largest flows are between neighboring countries of Europe, with Italy, France and Spain being the major recipients. More than 3/4 of international travel is short-haul and often between developed countries in Europe, North America and Asia. Most arrivals are intra-regional rather than inter-regional flows.

The picture of global tourism is markedly differently in some cases, when tourism intensity is compared to the land area of the various countries (Figure 3). Many island states of the Caribbean, Micronesia and the Indian Ocean, and

city-states are heavily frequented by tourists. Those in the medium-sized range include the European countries. The large countries of more than 1/2 million km^2 have lower densities.

Domestic tourism or travel entirely within a single country, may be more important than international tourism, as it involves about 10 times more people than the international trade. Up to 80% of the population of industrialized countries is involved in domestic tourism. Domestic tourists outnumber those traveling abroad in countries of large size (e.g., US) or geographical diversity (e.g., France). The potential for further growth of domestic tourism is in the developing regions, e.g., Southeast Asia.

Several factors and processes make tourism a global force. The most significant has been the technological innovation in global transport. Before 1945, travel was mainly by trains, boats or coaches. The airplane has made distant destinations tourist attractions. The Mexican resort of Acapulco was probably the first international resort to depend primarily on airborne tourists. After 1945, the airplane made possible the merging of the pleasure peripheries of different continents to global tourism (Turner and Ash, 1976). The Europeans have the Mediterranean, the Americans have the Caribbean and the Japanese are in the Far East. Mass tourism by air transport produced several distinct tourist flows: the annual flood of North Americans to Europe and the Caribbean, the Europeans to the Mediterranean resorts particularly in Spain, and the Japanese to other parts of East and Southeast Asia.

The introduction of wide-bodied jets in the 1970s reduced the price of air travel and increased affordability of tour packages. Overall, travel costs have declined 40% in real terms (after adjusting for inflation) in the past 40 years. The decrease in real cost of travel has been accompanied by rising disposable incomes and longer holidays for workers. Modern tourism has become particularly attractive, as there is a high level of professionalism in making travel safe, comfortable and enjoyable. A wide range of facilities and services is available, new travel products are being created and new destinations developed to increase the volume of tourist traffic.

ENVIRONMENTAL CHANGES

The realization that tourism is a portent force in environmental change is fairly recent (Table 4). In the 1950s, there was little concern about the environment when tourism was just beginning to develop rapidly. Conservation that started earlier in the century was limited to specific environmentally outstanding areas which themselves were attractions for tourists. Tourism grew rapidly in the 1960s and concern about its negative environmental impacts started in the 1970s. In the early 1980s, the WTO published reports on carrying capacity, saturation and management while tourism growth extended to more exotic areas. By the 1990s the response of tourism to environmental concerns has been in two major ways, ecotourism and sustainable tourism development (Hudman, 1991).

The environmental change by tourism is underpinned by the fact that the environment is and remains the foundation of the tourism industry. Mathieson and Wall (1982, 97) wrote:

> In the absence of an attractive environment, there would be little tourism. Ranging from the basic attractions of sun, sea and sand to the undoubted appeal of historic sites and structures, the environment is the foundation of the tourist industry.

The environment can mean both natural and built environments. Whether natural or man-made, it is inevitably changed or modified by the tourism process, as tourism is an environmentally dependent industry. Many impacts are related to the construction of general infrastructure and tourism infrastructure itself.

Environmental change by tourism is influenced by tourism s spatial concentration in specific types of environment, such as coastal areas, mountain and wilderness areas, rural areas, urban areas and small islands. Each ecosystem has its inherent environmental characteristics (Thuens, 1993). Environmental change is dependent on several

Table 4 Environmental concerns and tourism's response

Decade	Environment	Tourism
1950s	Enjoy and use	Age of exploration and involvement. Beginning of mass tourism
1960s	Awareness, public involvement and protests	Development, great growth. Elements of environment as attractions
1970s	Institutionalization. Creation of Environmental Protection Agency in USA. Concern over visual pollution, air and water	Growth and achievement. Marketing. Academic studies on impacts
1980s	Concern for toxic substances in the environment. Acid rain, global warming, ozone layer	Expanding world markets and technological advancements
1990s	Deforestation, desertification, climate change, global impacts	Ecotourism. Sustainable development

factors, such as the resilience of the ecosystem, the intensity of tourist use, the time factor and the transformational character of the tourist development (Cohen, 1978). Generally, environmental stresses increase with increasing volume and concentrations of tourists. One can expect little impact from an individual tourist but when the numbers are large and the tourist site is overused, negative impacts will occur.

To date, the verdict on the environment impact of tourism is that it is detrimental. The consensus is that the net economic impact is usually beneficial, but the evidence on environmental and social impacts shows more conflicts than benefits. The environmental impacts of tourism are known to have been overwhelmingly negative, based on well-documented examples from developed and developing countries. In some cases, the causal links to tourism may be debated, but harmful environmental impacts have occurred and the concern seems justified. Some environmental benefits are brought by tourism, such as in the conservation of some areas or environmental enhancement, especially in the re-development of derelict and redundant waterside areas.

As the impacts of tourism on the environment are varied and complex, there are several ways of classifying them. One simple approach differentiates direct impacts from indirect impacts; the former arise from the presence of tourists and the latter from the infrastructure created for tourism. Tourist impacts can be graded in terms of degree or intensity of impacts, such as the pressure on physical resources, the damage on the natural and the built environment, and the destruction or loss of land, ecosystems and built environment (Cazes, 1992). It is useful to distinguish impacts on the natural environment from impacts on the built environment. This has been incorporated into the classification of adverse environmental impacts of tourism (Table 5).

Table 5 Adverse impacts of tourism on the environment

Natural environment

(A) Pressure on natural resources
  1 Energy depletion
  2 Water supply
  3 Land use
  4 Soil erosion

(B) Harm to wildlife/habitat and biodiversity loss
  1 Trampling and clearance of vegetation
  2 Loss of forest cover
  3 Disturbance to wildlife
  4 Damage to coral reefs
  5 Damage to species

(C) Pollution
  1 Air pollution
  2 Untreated wastewater
  3 Solid waste and litter
  4 Noise pollution

Built environment

(A) Over-urbanization
(B) Destruction of natural landscapes

Given the scale and continued growth of global tourism, its impacts are wide ranging and are of increasing concern. The following sub-sections look at tourism as a force in global environmental change using examples from Asia, Africa, Europe and Australasia.

Air Pollution and Global Warming

Tourism contributes to air pollution, as cars, buses and air travel are the most important modes of transport of tourists. Within resorts and tourist sites, pollution from tourist vehicles is likely to be significant. In cities, tour buses, taxis and recreational driving are the main causes.

Air travel contributes to air pollution in the stratosphere. It is estimated that 60% or more of all air travel is for tourism, which is thus responsible for a significant share of air pollution by aviation (Genot, 1997). Airplanes are major sources of greenhouse gases particularly carbon dioxide, water vapor and nitrogen oxides, which are known to be harmful to the ozone layer. Although air travel accounts for 3% of nitrogen oxide emissions arising from human activities, as much as 25 30% of the total nitrogen oxide in the upper troposphere could be due to aircraft emissions (*see* Aircraft Emissions, Volume 3).

Land Resources Consumption and Land Degradation

In modern times, tourism contributes to land resources consumption and land degradation in various ways. To begin, tourism has a voracious need for land for airports, hotels, leisure complexes, golf courses and infrastructure. In extreme cases, this has led to the displacement of local communities and the loss of access to public areas for the local population. The problem is most acute in developing countries as the local population loses land resources that could sustain them, for example, the Kenyan fishing communities lost their livelihood as fishing area was designated for marine parks. The Indonesian farmer is displaced as coastal land in Bali and Lombok is taken up for resort development.

In Southeast Asia, the development of golf courses for tourists, especially the Japanese tourists, is an issue. Golf is increasingly a popular game and a status symbol in Japan. Due to high membership costs and lack of land, most of the estimated 15 million Japanese golfers never have a chance to play except on driving ranges. While detailed statistics are not available, it is estimated that 1.5 10% of Japanese travelers play golf while on overseas trips (Cameron, 1996). Many golf courses have been developed in Southeast Asia to cater to Japanese tourists, who numbered 2.49 million

in 1996 (*see also* Geomorphological Change: Landscape Modi cation for Recreation, Volume 3).

Golf courses create a number of environmental problems. The clearing of land sometimes leads to the removal of forests and forest reserves. Large amounts of water, chemicals and often non-native greenery create artificial ecosystems. In Malaysia, over 160 courses were created mainly by clearing rainforest areas. Each course uses enough water to meet the needs of 100 Malaysian farming families. In Indonesia, farming land and nature reserves were replaced by some 90 golf courses which annually consume more water, pesticides and fungicides than all the country s farms combined. Thailand s 200 courses are a drain on water resources (Cameron, 1996). Fertilizers and pesticides are used on golf courses and posed a threat to water resources. If water quality is reduced through pesticides and fertilizer run-off, it is almost impossible to restore the land back to its natural state.

Tourism is known to be a major consumer of water and competes with other land uses. For example, water is required for the tourists, swimming pools, the washing of bed linen and floors, watering gardens and golf courses. Tourists consume many more times *per capita* consumption of water than do the local populations. This situation becomes critical when a destination suffers from water shortage (seasonal or chronic) and water has to be diverted from other users, such as the farmers and inhabitants. In the Mediterranean, water is a major issue as tourism peaks during the dry season. On one Mediterranean island, each tourist uses enough water for eight local inhabitants (Genot, 1997). In Barbados, the tourist per capita consumption of water is 6 10 fold of that of the local population (Gajraj, 1989).

Tourism can contribute to soil erosion, which is usually associated with the removal of protective vegetation cover. Tourists moving constantly over vegetated areas create several impacts. Careless scrambling can cause the rate of movement downslope of unconsolidated chalk-rubble-soil, in a temperate woodland, to rise from its usual 5 cm year^{-1} to 30 cm year^{-1}. Normally, leaf litter layers help to prevent soil erosion and increase moisture. However, a newly opened nature trail in a temperate woodland, used by 8000 people, can lose 50% of its litter in a week (Ceballos-Lascuráin, 1996). Litter is broken up and easily dispersed by the wind.

Soil compaction occurs from trampling by people and the hooves of ponies and pack animals. This occurs along trails and is very common at campsites. It leads to impeded drainage in the soil, increased runoff and finally soil erosion. The problem is accelerated in areas where wind and water can remove soil easily. For example, in tropical areas with heavy rainfall, rills develop rapidly and form gullies. Sand-dune systems are particularly vulnerable to wind erosion when the vegetation cover is broken.

Mountain areas have been traditionally used for agriculture, forestry and reservoir development. In recent years, tourism development in mountainous areas competes with such uses and has an impact on the environment. Skiing is particularly popular in the mountain areas of developed countries. In Europe, the Alps have approximately 40 000 ski runs and 14 000 ski lifts (Ward *et al.*, 1994). Visually, the resulting steel pylons, overhead cables, lifts and tows are unattractive. More seriously, the construction of ski resorts means trees are removed, slopes reshaped and there may be an increase in avalanches. During seasons of insufficient snow, ski resorts depend on snow machines using compressed air and water sprayed at high pressure when temperatures are below freezing. This results in a serious drain on the local water supply. Through the use of snow machines, the skiing season is extended which has an impact on wildlife habitat and flora, increased damage to slopes and accelerated soil erosion. It is estimated that a cubic meter of alpine pasture can hold 90 liters of water. If dug up and prepared for skiing, it retains only 40 liters of water (Ward *et al.*, 1994). The higher proportion of unabsorbed water increases the likelihood of soil erosion and flooding.

In recent years, trekking tourism has been increasingly popular in the mountain areas of some developing countries and its impacts have, to date, been detrimental (Box 1). Trekking in more gentle or tropical highland environments shows similar environmental results. In the hills of Northern Thailand, trekking started in the early 1960s and has become an established industry with more than 200 outlets handling this activity in Chiang Mai, the major city in northern Thailand. It involves about 100 000 trekkers per annum. With an average of 3 nights per trek, they generate a minimum of 300 000 trekker nights per year (Dearden, 1993). Overall, the direct economic benefits are small but significant in an area of poverty. However, there are serious environmental impacts, particularly deforestation of the bamboo, which is used to make rafts for trekkers. An estimated 400 000 stems of bamboo are required annually (Dearden, 1993). Trekking has an impact on water quality, arising from sanitation and from solid waste disposal, as few sanitary facilities are available in the villages.

Biodiversity Loss and Habitat Destruction

According to various estimates, the global extinction rate of all species is 3 130 species daily or 2 8% of all species from 1990 2015. Plants are disappearing at the rate of 2000 species per year (German Federal Agency for Nature Conservation, 1997). Although tourism contributes marginally to overall biodiversity loss, it assumes a more significant force when it is located in or near fragile habitats or habitats of high biodiversity, such as coastal ecosystems, coral reefs, ocean islands, rainforests and mountain ecosystems (*see* Tourism and Ecosystems, Volume 3).

Box 1 Impacts of tourism in the Himalayas

Nepal is a landlocked country of 141 415 km^2 in the Himalayan mountains. Four-fifths of its 33 million people are in agricultural activities. Although opened to mass tourism in 1951, the country did not develop rapidly as a destination for adventure travel until the 1970s. The number of tourists increased from 4000 in 1960 to more than 100 000 in 1977, 200 000 in 1986, and about 365 000 in 1995 (Weaver, 1998). The tourists are attracted to the country's natural resources and typically 20% go for mountain trekking and another 60% for a combination of trekking, jungle safaris, river rafting and ethnic tourism. Although tourism has become the largest foreign-exchange source, it has also caused severe environmental degradation.

Environmental problems caused by tourism include deforestation, solid waste management, sanitation and water supply, overgrazing (by pack animals) and erosion of paths and trails. Large amounts of litter and garbage are left along mountain trails and campsites. The Everest trail is often described as the Mount Everest garbage trail, and this is true of many other trails. Non-biodegradable materials are the biggest concern but even bio-degradable materials take years to decompose due to the low temperatures. An average group of 15 people trekking for 10 days can generate 15 kg of non-biodegradable and non-burnable garbage (Rai and Sundriyal, 1997).

The Nepalese rely virtually on wood as the only source of energy for cooking and heating. This has resulted in deforestation, which has been aggravated by tourism. It is estimated that each trekker in the 1970s used 106 kg of firewood for a 15-day trek (Weaver, 1998). Fuelwood consumption is itself influenced by several critical factors, such as the type of tourist activity, length of trip, number of support staff and the use of fuelwood substitutes. The deforestation problem became extremely serious by the early 1980s and the government instituted regulations for trekkers to carry fuelwood, so as to eliminate gathering of fuelwood along the trekking routes. However, this regulation did not apply to the tourist lodges, and the problem is thus transferred to them. The result can be devastating. Depending on the concentration of tourists, a tourist lodge in one area was using 220 kg of fuelwood per day or ten times that of a local household (Gurung, 1991). Deforestation leads to soil erosion and landslides. One hectare of cleared forest is estimated to lose 30–75 tons of soil annually. The lodges are also poorly equipped for the disposal of human waste and litter, leading to water pollution and odor problems.

As tourism in Nepal remains a much-needed economic alternative, measures have been taken to lessen the environmental impact. The Annapura Conservation Area Project was set up in 1986 to address problems of nature conservation, human development and tourism management. It has a program of integrated conservation and development implemented in stages. The deforestation is tackled by many measures, including alternative energy sources, energy-saving technologies, reforestation and community forestry management. The tourist carrying capacity is not necessarily fixed but is a function of technology and resources available to tackle the impact. If tourism is managed properly, it is possible for an area to recover (Gurung and De Coursey, 1994).

When tourism development has taken place in or near to some areas of high levels of biodiversity, its impacts lead to irreversible damage, including species extinction as in the case of the destruction of tropical rainforests and coral reefs. The impacts from tourism can set off a chain reaction with results seemingly out of proportion to the initial impact. For example, the collection of the triton mollusc (Giant Triton) by recreational divers has been linked to the spread of crown-of-thorns starfish, which has destroyed large areas of coral reefs in the Pacific.

Tourism can change the percentage cover, species diversity, growth rate, age structure and habitat diversity of vegetation. The impacts range from the complete removal of natural vegetation to other impacts not immediately evident. The greatest damage to vegetation cover is in the initial use of the area where fragile species disappear and recovery is dominated by other species. The reproduction rate is reduced in trampled areas. Innocent acts by tourists, such as flower picking and plant collecting, can lead to a loss of individual species.

Camping and hiking contribute to further negative impacts on the vegetation cover. Vegetation is removed for walking sticks, tent poles and firewood. One study found that the quantity of small timber declined significantly up to 100 metres from the side of the road and this is attributed to campers collecting wood (Ceballos-Lascuráin, 1996). An additional danger is fire. In general, the damage from trampling is greater than that caused by camping. The creation of rubbish dumps favors soil alteration and the introduction of exotic species. For example, Australian country roads are lined with apple and pear trees originating from fruit thrown from cars. Clothing or horse riding, particularly on certain trails or camping sites in national parks, also carries seeds.

Tourism impacts wildlife in several ways, such as loss or changes to habitats, impacts on natural patterns of feeding, breeding and predator-prey relationships (Mathieson and Wall, 1982). In particular, the consumption of wildlife by tourists has a harmful effect. For example, the demand for seafood has a severe impact on local fisheries and threatens wildlife population in marine parks. In the Caribbean, the spiny lobster and conch shell have been much reduced by the demand from hotels (Jackson, 1986).

The market for souvenirs has led to an over-exploitation of a number of now endangered species. The demand for tortoiseshell is a threat to the loggerhead turtle in Sri Lanka. Black coral for jewelry is widely in demand in the Caribbean and the species is now confined to areas where

collection is difficult. Tourism is largely responsible for growing demand for other wildlife souvenirs such as gorilla hands for ashtrays, fur from endangered cats, reptile skins for boots, belts and bags, ivory and horn, many of which are being poached from protected areas. While the Convention on the International Trade in Endangered Species puts a ban on international trade of listed species of animals and plants threatened with extinction, it is ineffective on such trade within countries.

An idea of the impact of tourist vehicles on large animals can be seen in the Maasai Mara National Reserve of Kenya. The tourist vehicles usually approach close to the cheetah, leopard and the lion and encircle them for photography. The angle (arc) of encirclement can vary from a quadrant (90°) to a full circle (360°). An increase in encirclement results in increased levels of walking by cheetahs and lions, particularly between 90° and 270°. Presumably, at less than 270° animals can still escape, but at 360°, escape is extremely difficult. The animals walk away when tourists approach them too closely. With distances of under 5 meters, they are greatly disturbed. The more sensitive cheetah moves off at distances of more than 20 m. Overall, the vehicles interfere with animal activities, particularly their mobility, which restrict their search for prey, mating and seeking cover (Ceballos-Lascuráin, 1996).

Coral Reef Degradation

Coral reefs are one of most severely endangered habitats. They are rapidly being destroyed by activities such as dredging, mining and over-fishing. This occurs in the areas near to, and of, high population density in coastal southeast Asia, around the Indian Ocean and tropical islands. In many of these countries, coral mining is a traditional activity as the material is used for construction and production of lime. Local fishers use destructive methods of fishing, such as the use of dynamite and poison. Compared to barrier reefs and atolls, fringing reefs have suffered the greatest damage from overexploitation. The most serious cause comes from sedimentation resulting from human activities including tourism. Other causes include unsound agricultural and forestry practices, poor management of watersheds, exploitation of mangroves, construction and dumping of mining tailings and effluents (*see* Deforestation in Historic Times, Volume 3). In Sri Lanka, the major portions of reefs along the west and south coast have been destroyed. In the Philippines, almost 70% of the reefs are seriously damaged and about 80% or more in certain areas of eastern Indonesia (Lundin and Lindén, 1993). In Indonesia, coral reef destruction has accelerated dramatically in recent years and is reaching epidemic proportions as the economic and social crisis deepens in the country.

Coral reefs are an attraction for tourists and often provide the major impetus for resort development in the tropics. At the same time, tourism has been responsible for their degradation, arising from the direct effects of diving and snorkeling, to infilling and sedimentation caused by tourism construction (Table 6). Structural damage occurs when reef flats and adjacent coral reefs are used for the construction of landing strips on small islands. Construction of hotels and condominiums may seriously disturb the sandy beaches and lead to their erosion (Maragos, 1993). Tourism activities have increased the rate of destruction not only through construction, but also through removal of corals for sale as souvenirs, damage from diving, boating, snorkeling, and other recreational activities. Also, the quality of water, which is critical to coral growth, is affected by pesticide or fertilizer runoff from golf courses and untreated wastewater from hotels and supporting facilities (Dubinsky and Stambler, 1996).

Tourism and recreation have already damaged the coral reefs in Kenya, Tanzania, Mozambique, Madagascar, Reunion, Mauritius, Comores, Seychelles and Sri Lanka in the Indian Ocean and in Malaysia, Thailand, Philippines and Indonesia in Southeast Asia. Tourism is considered by the World Conservation Union to be a problem for coral reefs in Thailand, Philippines, Indonesia, Kenya and some of the oceanic islands, particularly the Maldives and Seychelles. Often, the main impact on coral reefs is not from the activities of tourists. The significant impacts are from tourist-generated pollution and coastal development (Box 2). Tourist facilities are often concentrated in narrow coastal strips and semi-enclosed bays. Coastal structures such as breakwaters and jetties lead to an alteration in water circulation, beach erosion and sedimentation. Coastal pollution results from the discharge of poorly treated wastewater into the sea.

Box 2 Effects of tourism on coral reefs in the Red Sea

The Red Sea has unusually warm water. Helped by favorable physical conditions, the reefs at the Gulf of Aqaba typify the northern Red Sea coral reef, consisting of a narrow reef flat and a reef slope plunging almost vertically into deep water. The calm sea, clear water and rich coral reefs form the basis of the Red Sea's rapid development as a tourist destination shared by three countries, Egypt, Jordan and Israel.

Approximately 19, 50 and 100% of the Red Sea coast of Egypt, Jordan and Israel, respectively, are developed for coastal tourism that already has had several effects on the coral reefs (Hawkins and Roberts, 1994). At Hurghada, the inshore reefs are seriously damaged and only the offshore reefs 4–16 km from the coast support the diving industry. Both fringing reefs and those farther offshore are still healthy at Sharm-el-Sheikh. Several impacts arising from construction and infrastructure have occurred: coastal infilling; sedimentation from construction (large amounts due to dust blown by wind and not through rain wash, which occurs in other tropical regions); sewage disposal, irrigation, desalination and solid waste (through inadequately processed wastewater or seepage from hotel gardens which use treated wastewater); effects on local fisheries (demand for fresh seafood, marine-curio trade); direct impacts of diving and snorkeling.

The intensity of use of reefs is expected to increase as Israel plans for a further 43% increase in coastal tourism, Jordan 100% and Egypt a massive 11-fold expansion. More than half of the planned expansion in Egypt is concentrated in the established resorts of Hurghada and Sharm-el-Sheikh. The reef ecosystem does not have the resilience of a sandy ecosystem and cannot support the same density of tourists as sandy coasts. Attempts have been made to work out the carrying capacity of reefs for diving. Hawkins and Roberts (1994) suggested that Sharm-el-Sheikh can support 10 000–15 000 dives per site per year without serious degradation compared to 4000–6000 dives per site per year in Bonaire, Netherlands Antilles. However, with the planned increase in tourism development, Sharm-el-Sheikh will have 40 000 dives per site per year despite doubling the number of sites and spreading out the dives. In Israel, increased pressure is on the existing reefs and development has proceeded south to encroach on the Eilat Coral Reserve.

If tourism development in the Red Sea proceeds as projected, widespread reef degradation is expected. To some extent, this can be ameliorated by other measures, such as limiting pollution to reefs, preventing sewage discharge and nutrient-rich effluents, and reducing the proportion of visitors who dive. On a more positive note, industrial development has been restricted by tourism as reefs have an economic value to be preserved. In the long run, tourist development would still determine the fate of the coral reefs: the option of a long-term controlled development or short-term financial gains.

The damage on corals is dependent on the fragility of the corals and percentage cover by living corals. Branching or leafy corals are easier to damage than rounded corals and visible damage is more conspicuous on reefs with a high percentage coral cover. For example, a ship s anchor and chain can damage up to 20 square meters of corals on a good reef. Consumptive pursuits, collecting and spear fishing, have selectively depleted certain species, such as spider conch, murex, cone and cowrie shell, pearl oyster, seafan, black coral, grouper and lobster. The crown-of-thorns starfish usually devastates large areas, and the reefs take up to 10 40 years to recover, provided no fresh infestation occurs.

Coast and Small Island Degradation

On a global scale, tourism has the most impact on coasts and small islands as they are highly favored by tourists (Figure 4). Both coasts and small islands are particularly fragile areas, partly because they are comprised of closely linked ecosystems such as the beach, coral reefs and mangroves (Knight *et al.*, 1997). Also, other land uses and activities are attracted to these ecosystems and altogether they combine to have an impact greater than tourism. Tourism itself has been responsible for many distinctive urbanized coasts.

The Mediterranean Sea was the world s first major coastal tourism area, developed for Europeans to escape the northern winter. It has experienced severe pressure from urban growth, much of it associated with tourism. About 4400 km^2 of land around the Mediterranean Sea is for tourist accommodation and supporting structures. Water pollution is of increasing concern particularly for the older tourist resorts. Data from the Mediterranean Action Plan showed that the average water consumption for the international and the domestic tourist was 250 and 150 $l\,person^{-1}\,day^{-1}$, respectively, and 60% of this was for sewage disposal. Each tourist generated 0.9 $kg\,day^{-1}$ of garbage (German Federal Agency for Nature Conservation, 1997). Tourism development along the coasts of Spain, France, Italy, Greece, Yugoslavia and Tunisia contribute to large quantities of waste materials. Pathogens are introduced into the sea through raw or inadequately treated sewage. The addition of nutrients has hastened the process of eutrophication and results in algal blooms and red tides. Diseases such as cholera, typhoid, viral hepatitis and dysentery can be transmitted through contaminated seafood. There is a growing concern in the European Community at the environmental pressure generated by tourism expansion (*see* Land Degradation in the Mediterranean, Volume 3; Blue Plan, Volume 4; Mediterranean Sea, Volume 4).

The fragility of the coastal systems and its impact by tourism is being repeated in the developing countries, especially those in the tropics. Blessed with beaches, year-round sunshine and the added attraction of coral reefs,

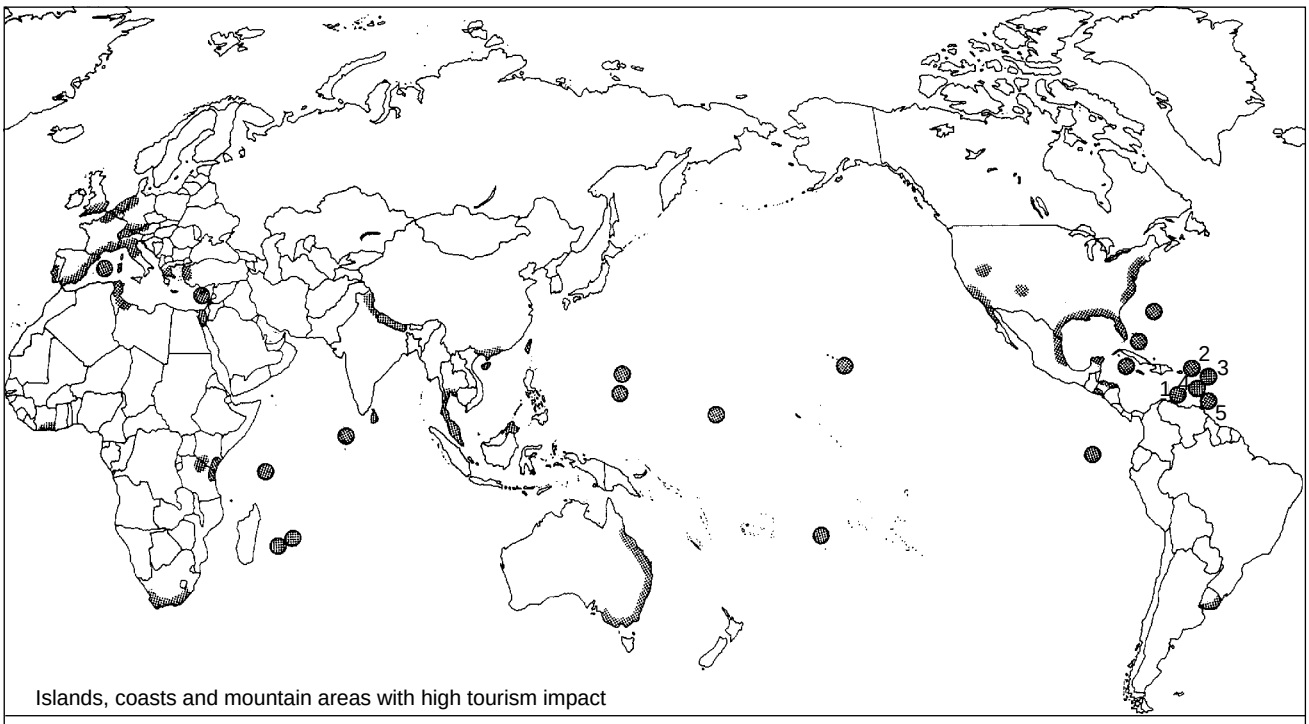

Figure 4 Areas of high environmental change by tourism

many tropical developing countries and small islands have become coastal honey pots. They attract tourists throughout the year from America, Europe, Australasia and Japan, each group replacing the other, depending on the season. Tourism development has largely proceeded spontaneously in these countries and has given rise to many problems. The tropical marine-coastal ecosystem with its coral reefs and coastal forests is one of most severely affected by tourism development (Figure 5). Coastal water pollution is a common problem where tourism development has been unplanned and wastewater facilities are inadequate (Box 3).

Tourism is a significant economic activity on many islands in the Caribbean, the Mediterranean, the Pacific Ocean, the Indian Ocean and Southeast Asia (Figure 4). Some have been developed exclusively for tourism. Extreme cases are the island resorts or ıles-hotels of the Maldives in the Indian Ocean. They are basically coral islands of atolls and are actively sought for tourism development because of their insularity, an easily recognizable and marketable image and a unique combination of land and sea. They have become very accessible with modern transportation. In most cases, the small population rules out domestic tourism and they are dependent on international tourists. But they are very vulnerable because of limited size and less diversified resources. Solid waste production *per capita* is higher than the Maldivian average, up to 16.5 kg of solid waste per visitor per week (Brown *et al.*, 1997). Traditionally, the water is obtained from groundwater wells and rain-fed cisterns. Water availability and quality decline as tourist demand increases. The freshwater lens is reduced and the mean salinity of the depleted water source has more than doubled. The resorts are dependent on desalinated water and imported bottled water. Also, rising sea level is a long-term threat to the island resorts. Erosion has occurred and in some cases, inappropriately designed coastal structures have been deployed.

It should be noted that the impacts of tourism on island ecosystems could be less than from other industries, such as agriculture, fishing or mining. Such islands also suffer from pressures of overpopulation, inappropriate urban development and land clearance. Tourism is sometimes an easy target for blame, as it is often owned by foreigners.

ECOTOURISM AND SUSTAINABLE TOURISM DEVELOPMENT

The global concern of the negative environmental impacts of tourism became evident in the 1980s. Tourism could not be considered purely in terms of economic gains without attention to the environment. Further environmental change

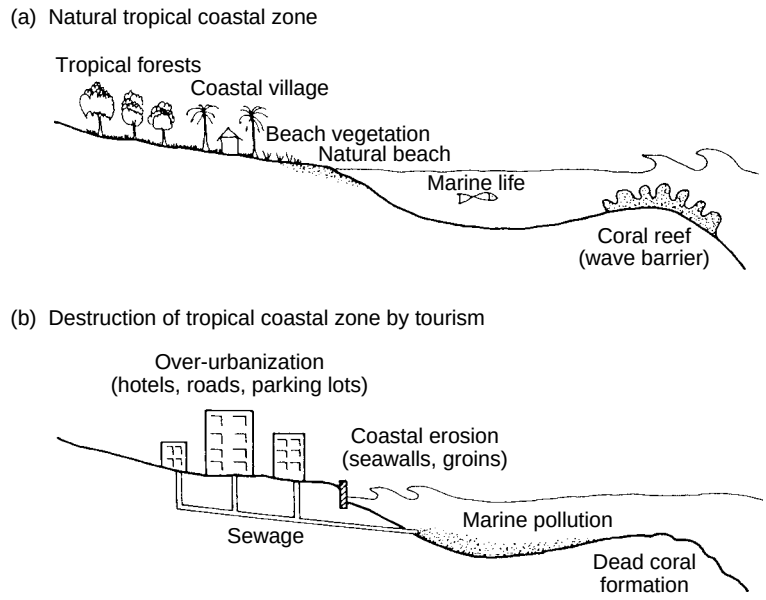

Figure 5 Environmental change to a tropical coastal zone by tourism

Box 3 Water pollution at Pattaya

Pattaya is located 140 km southeast of Bangkok, Thailand. It grew rapidly from a fishing village to a major tourist resort in less than three decades. Its first international hotel was constructed in 1964 and significant tourism development started in the late 1960s. The number of visitors increased from 259 000 in 1972 to 600 000 in 1982, and 2.45 million in 1990 (Smith, 1992).

As coastal land was developed for tourism, land farther inland came under development. The traditional coastal land use was replaced by a more typical strip or ribbon development in which the physical form of the resort was linear and parallel to the coast. The resort developed into a concrete jungle of buildings crammed tightly together, alternating with roads parallel to the coast. Traffic congestion, noise and overcrowding were common. One 300-m stretch with bars, nightclubs and massage parlors known as 'The Strip' gives Pattaya its unsavory image.

As Pattaya developed its tourism, there was a demand for infrastructure, particularly for water supply and wastewater treatment. Water supply was a problem. Water was trucked to the resort until the supply mains reached Pattaya in 1981. However, the increasing demand for water as the resort expanded has resulted in water supply deficiencies since 1989. Water shortages also occur during the dry season.

By the mid-1970s, the seawater was polluted by resort-generated wastewater as well as effluent from the tapioca factories in the Pattaya hinterland. Two wastewater treatment plants were established in 1984 and 1986. The total wastewater of Pattaya more than doubled from 36 500 m^3 in 1986 to 76 000 m^3 in 1990, but the plants could handle only 13% of the total before discharging the rest into the sea. In 1989, sea pollution became critical and the water was declared unsafe for swimming. In 1991 and 1992, measurements of total coliform count were 10–24 times above the recreational water quality standard set at 1000 MPN 100 ml^{-1} (Charoenca, 1993). By 1992, marine pollution was cited as the major cause of Pattaya's declining number of tourists.

Clearly in Pattaya, the major cause of marine pollution is the overload of treatment plants and the insufficient collection system. More than 200 hotels and many condominiums do not comply with official environmental standards. Some major hotels with water-treatment facilities keep them switched off to reduce costs. Also businesses and restaurants contribute to the wastewater problem.

The urban growth of Pattaya has produced other negative environmental impacts, such as the removal of tree cover, replaced by a mix of buildings, roads and overhead wires and a maze of signboards. The wetlands and rivers are filled or converted into open sewers. The beach is littered by solid waste, and wildlife habitats have been destroyed. The coral reefs have been removed or destroyed by recreational activities and wastewater. Beach erosion occurs because of the unnecessary use or poor design of coastal structures. Garbage collection is inadequate to deal with the solid waste generated within the resort.

In light of declining tourist arrivals to Pattaya, the government has set up a program to reduce water pollution and improve the environment. Attention is given to improve the capacity of the existing wastewater treatment plants and to provide two new plants that would service North Pattaya and South Pattaya, respectively. Other measures are to improve traffic conditions and the beach (Wong, 1998).

by tourism will be influenced by two major developments: development of ecotourism as an alternative to mass tourism and sustainable tourism development (*see* Agenda 21, Volume 4; Sustainable Development, Volume 4).

Ecotourism had its origins in the late 1970s, growing from the concern about environmental impacts and the search for an alternative to mass tourism. It is defined as environmentally responsible travel to relatively undisturbed natural areas to enjoy nature and local culture; it has a low visitor impact and provides for socio-economic involvement of the local population (Ceballos-Lascuráin, 1996). Ecotourism is supposed to promote conservation. But it has quickly become the buzz word to sell a variety of products, such as ecotour, ecotravel, ecologically sensitive adventures, eco(ad)ventures, ecocruise, ecosafari, which may not be committed to conservation at all (Goodwin, 1996).

Due to a lack of reliable data, various estimates put the ecotourism industry at US$10 billion in 1989 to a liberal US$200 billion in 1990 and as high as 20 25% of leisure travel. Anecdotal evidence from companies offering ecotours indicates a growth rate of about 20 25% per year (Weaver, 1998). Ecotourism is expected to grow rapidly in the next 20 years.

The growth of ecotourism and related forms has serious implications on rates of environmental change and this depends on the scale of ecotourism and a number of other factors. Weaver (1998) sees ecotourism operating at several scales: comprehensive, where the entire country is oriented to deliberate ecotourism; diversionary, where isolated ecotourism sites are near and augment mass-tourism products; and regional, which involves the adoption of deliberate ecotourism at a subnational scale, such as in the mountains or wilderness. The pace of environmental change depends on the relative development of ecotourism at these three scales.

The future development of ecotourism also depends on a number of factors.

One significant factor is the extent of protected areas. Ecotourism can become a threat to protected areas and ecosystems that are already under threat from other pressures (Goodwin, 1996). There is not enough formal protection for natural habitats that are being destroyed by lumbering, agriculture and other activities incompatible with the maintenance of a natural state. Only 4.6% of Africa, 4.4% of Asia and 6.4% of South America are formally protected. Often the nature parks are not well protected. Ameliorating measures, such as buffer zones (Costa Rica) and the maintenance of adjacent natural habitats along a common frontier (Tanzania, Kenya) are required. The measures taken to protect the environment must include better co-ordination of land use, the involvement of local population and integration with other economic sectors.

Another factor is local community involvement. Generally, it is vital to include the local population in decision-making and implementation for moral, conservational, economic and practical reasons. Tourist organizations, including government and international agencies and NGOs are important in regulatory and facilitating roles. Lastly, political and social stability are essential, as ecotourism cannot be divorced from the broader socio-political context. For example, in Rwanda, successful local ecotourism based on the mountain gorilla collapsed suddenly in the wake of social and political upheaval.

Sustainable tourism development has become a desirable goal with the spread of the concept of sustainable development. It can be defined as tourism meeting the needs of present tourists and hosts while protecting and enhancing the opportunity for the future . The concept is clear but is difficult to put into practice and there may be an inherent contradiction. It is not possible to create culturally and environmentally benign forms of tourism, when tourism is essentially structured upon exploitation of these very resources.

Sustainable tourism and ecotourism are not synonyms as many forms of ecotourism may not be sustainable, and if ecotourism is to contribute to sustainable development, then careful planning and management will be required. Griffen and Boele (1997) concluded that there is no universally applicable model for sustainable tourism development at the national level. Much depends on the expectations of the tourism sector, the destination s own political and administrative structures, differing standards of economic development and socio-cultural characteristics. Tourism generates changes, many of which are detrimental. One must be realistic in acknowledging that the problem is complex, and any solution has to be based on the necessity of accommodating further growth.

One approach is to look at the innovations related to environmental issues that could reduce the negative environmental impacts of tourism. According to Buckley (1996), much of it can be found in the research of environmental science, engineering, information systems and management. The innovations should cover not only product innovations, but also process innovations (e.g., energy saving, water saving, better waste management) and management innovations (e.g., procedures to motivate staff, local inhabitants and tourists into acting responsibly on environmental issues) (Hjalager, 1996) (*see* EA (Environmental Assessment), Volume 4). For fragile ecosystems such as a coast, a more interdisciplinary approach is required.

> The work of the architects, engineers and hotel accountants needs to be complemented by social scientists studies of tourist demand, use and satisfaction, by more detailed environmental examination from coastal geomorphologists, biogeographers, ecologists and other natural scientists and by research from environmental and resource economists.
>
> (Pearce and Kirk, 1986)

Integrated Coastal Management can be used for coastal ecosystems and for reefs facing multiple threats (White *et al.*, 1997; Wong, 1998).

SCENARIOS FOR ENVIRONMENT CHANGE

Ecotourism and sustainable tourism development have yet to make a substantial impact to redress the environmental change wrought by mass tourism. Many areas of the earth and several ecosystems, especially mountain areas (*see* Tourism: Climate Change and Tourist Resorts, Volume 3), coasts and small islands are still facing serious environmental change by tourism at present or in future (Figure 4). Based on these areas and the projected growth of tourism, some possible scenarios for environmental change caused by tourism can be suggested.

1. The coastal systems will continue to be assaulted by tourism as coastal tourism remains the most important type. This is especially true in many developing countries, which have the natural resources of sea and sand. Coastal tourism is likely to proliferate without adequate measures to protect the environment. By 2025, 95% of the Mediterranean coast will be urbanized, supporting 500 million people and 200 million tourists with 150 million cars (Gajraj, 1988). While there is a plan to alleviate the problems in the Mediterranean, which has experienced some of the worst of coastal tourism development, other coastal areas may be severely affected before similar plans are implemented.
2. Many natural ecosystems will continue to bear the impact of increasing numbers of tourists. The extent of change will depend very much on the carrying capacity, the resilience of terrestrial ecosystems and the implementation of management strategies to lessen the negative impacts. The adoption of environment-friendly technologies can also help to reduce the negative impacts.
3. Many studies show that tourist attractions follow a product-life cycle, going through stages of discovery/exploration, involvement, development, consolidation, stagnation and finally, decline (Butler, 1980). All new tourist areas, including forested and mountainous areas face this prospect. Of international concern is the continent of Antarctic, which had attracted more than 40 cruises with 5600 tourists in the 1991 1992 season (Gartner, 1996). The increasing number of cruise ships and tourists poses a threat to the fragile polar environment.

CONCLUSION

In the latter half of the 20th century, mass tourism, or people moving within and between countries in pursuit of leisure, was on an unprecedented scale. This has wrought changes to the environment, many of which have been negative. This was not fully realized until the 1980s. Some measures have subsequently been taken to prevent and minimize the environmental degradation.

The concern and response of tourism to environmental change has crystallized around ecotourism and sustainable tourism. New ways in technology and management can help to achieve sustainable tourism development. But both have yet to make a substantial impact.

At the same time, there are still many areas and fragile ecosystems under threat from tourism. Environmental change will spread to new tourist areas especially in the developing countries of Asia and Eastern Europe.

Tourism: Climate Change and Tourist Resorts

Jörg Stadelbauer
Albert-Ludwigs-Universität, Universität Freiburg im Breisgau, Germany

The increasing economic and social importance of tourism is challenged by global changes, above all climate change. Rising rainfall instead of snow in mountain regions of medium altitude, earlier snow melting in spring, shortening of the annual snow cover period in high mountain skiing areas, rise of the sea level and withdrawal of the coastline are the main consequences in the temperate zone. They mainly affect coastal and mountain tourism. In semi-arid and arid parts of the sub-equatorial zone, water de cits will cause a fall in lake levels so that present-day resort tourism will be threatened directly. Indirect consequences are caused by de cits in the water supply for inhabitants and resorts. In the tropics some small islands whose population is currently living from tourism are threatened by increasing sea level and may disappear totally. The article examines the general features of probable climate change and its consequences for tourism and gives regional examples taken from different continents and regions.

INTRODUCTION

Economic Significance of Tourism

Today, tourism is one of the most important global economic activities. In 1998, 625.5 million international tourists were estimated to have spent a total of US$445 billion. These figures are based on the statistical definition of the World Tourism Organization, which classifies tourists as foreigners crossing an international boundary and staying at least 24 hours in the other country, with the exception of transit passengers and foreign workers. In addition, the expenditive data are incomplete because only the official money change is registered and additional expenses are estimated. A larger number of local tourists, estimated at 5 to 5.2 billion, do not cross international boundaries. Thus, tourism is the most important element of overall population mobility. At the same time, it is still a growing economic factor. It is believed that about 12 13% of worldwide gross domestic product (GDP) is gained from tourism, and that almost one in eight jobs depends on it. In addition, indirect economic effects result from influences on other economic sectors (including transportation, construction, agriculture, local manufacturing, information and communication services). The annual rates of growth differ regionally from each other; even on the economically

weak African continent they reach up to 15%. The highest number of tourist arrivals was recorded in Europe, with 372 million or 59.5% of the total number of international tourists. The so-called developing countries are not among the leading participants in international tourism, but add 27% to the global income gained from tourism. A significant decline has occurred in the Commonwealth of Independent States (CIS) where international tourism collapsed after the break-up of the Soviet Union. Some countries depend to an extremely high degree on incomes from international tourism. Island states like the Bahamas, Antigua and Barbuda, Barbados and the Maldives have more than 55% of their total of trade and services involved in tourism (Gormsen, 1996). In Europe, Spain, France and Italy are the leading recipients of arriving guests. Among the smaller countries, tourism adds nearly 8% to the Swiss GDP and contributes 9% of jobs. Tourism holds third place among Swiss exports after the chemical industry and machine building. The highest gross incomes gained from international tourism are obtained by countries that are strong in other economic sectors as well (US, France, Italy, Spain). Social phenomena like migration directly depend on tourism.

Global Change and Tourism

Global change comprises not only climatic or other environmental changes, but also includes a large number of phenomena such as the consequences of population growth (development of total population, increase of the concentration in urban settlements, especially in megacities, change of the age structure with overproportional increase of aged persons in highly developed countries, socio-demographic differences between highly and less developed countries (cf. Rayner and Malone, 1998)); pressure on the use of natural resources, mainly energy, soil and water, technological changes, especially in telecommunication and the internet and their economic consequences, economic globalization, political change, social change and ethnic and cultural diversity. The following discussion emphasizes the likely consequences of climate change and only partially considers the other processes of change.

Tourism and Climate

Tourism is not only an important economic factor and social structure; it also depends highly on climatic conditions and is sensitive to climate change. Therefore, global climate change will exercise a significant influence on tourism. This can be assumed not only for different types of landscapes (mountains, coastal areas and small islands), but also for different climatic zones. While in regions near to the poles, warming will occur and the temperate zones may see improved climatic conditions, the subtropical continental regions will undergo higher aridity and experience significant water supply deficits. In the mountains of the temperate zones, global warming will cause decreasing snow cover and increasing rainfall and, thus, shorten the skiing season and generally alter seasonal patterns of tourism. It is necessary, indeed, to take into consideration the inter-annual variability of weather conditions, which normally exerts a significantly higher influence on leisure and tourism activities than simple climatic means suggest. Particularly threatened are low-lying islands, where already a small rise in sea level threatens the economic basis of tourism. In this respect, peripheral centers of tourism remote from major urban areas are more affected by climate change because they have fewer possibilities of adaptation and cannot compensate for the change by attracting visitors from nearby regions.

Due to the large number of influencing factors, scholars dealing with the consequences of climate change deny any climatic determinism, and emphasize the whole range of factors influencing the spatial relationships of tourism (Elsasser *et al.*, 1998). Research on the effects of global climate change is rather recent, but refers to earlier works in which the relationship between climate and cultural development was constructed deterministically on consequences of climatically induced hazards. These were analyzed in simple causal chains (impact approach) because climate seemed to be the determining factor of touristic development. A main reason for this line of argument was that global change was merely identified as climate change without taking notice of indirect consequences. Gloomy future predictions of the consequences of climate change for tourism do not take into account how tourism is constantly subject to changes in fashion and to the development of new alternative opportunities and attractions. Thus, in reality tourism has to adapt and change, and climate change is but one factor in the dynamism of the industry.

General Indirect Consequences of Global Change Influencing Tourism

Global climate change will influence tourism at first, and above all, in coastal and in mountain regions. If sea level rises by a few meters as expected, present coastal settlements will be threatened, including important tourist destinations. For yacht harbors and modern marinas, this development causes high additional costs so that some investments will be unprofitable. For the tourist centers in mountain areas, quantity and the annual distribution of snowfall will be modified and cause changes in seasonality. Another consequence will be the changing runoff from the mountains, not only altering the natural water balance, but also affecting the availability of water for agricultural, industrial and human use including water-based recreation. In high mountain regions the length of the winter season

will decrease, thus forcing the tourist industries to either use artificial snowmaking or to move to higher altitudes (if possible) or to diversify by offering additional attractions in order to extend the tourist season.

A significant part of the temperate zone will experience a rise in temperature. This may be positive in respect of demand for recreation, but higher temperature also causes higher evaporation so that the availability of fresh water diminishes. Furthermore, such activities as hunting and fishing are influenced immediately if the animals alter their habits or migrate into other zones and regions.

Increasing aridity may cause human migrations in areas like the near and Middle East with urban population increases (Watson *et al.*, 1998, 246). Such developments could reduce the political stability and affect the tourist resources of those regions.

Climate change also affects human health care (*see* Environmental Change and Human Health: Extending the Sustainability Agenda, Volume 3). If social services of highly developed countries are to be maintained, the threats to health may increase the demand for climatic health resorts and spas. However, higher temperatures will extend the areas in which tropical diseases originate, particularly those of dengue and yellow fever (Loevinsohn, 1994). The Aedes mosquito, which spreads dengue fever, reacts sensitively to changes of temperature and precipitation. It has already spread over larger areas probably as an effect of changed climatic conditions (Hales *et al.*, 1966). The dangers of the transfer of pathogenic agents increase with tourism.

REGIONAL ASPECTS

Polar and Subpolar Zones

In the Polar Regions, forecasts indicate that indigenous peoples may have to change their lifestyles. Economic gains from tourism could increase with global warming. In the Northern Hemisphere, this effect will occur earlier than in the Southern Hemisphere, where it will be slowed down by the ice cover of Antarctica. Adventure tourism and cruises to Antarctica could be threatened by global warming because of its impacts on the fauna. Although the polar and subpolar zones will experience the greatest climatic change, they have considerably less significance for tourism than the warm temperate zone and the subtropics.

North America

In North America, the mountain regions will show a rise of the regional snowline and a decrease of natural runoff during the snowmelt period. Consequently, the winter ski season will be shortened. For the downhill ski season in Ontario, Wall (1988) (cf. McBoyle and Wall, 1987) calculated an increase of temperature by 3.5 to 5.7 °K and a total increase of annual precipitation by 9%. An analogous calculation for Quebec (Lamothe and Peáriard Consultants, 1988) quotes a shortening of the ski season by 50 70%. Some lost days may be made up by snowmaking devices. Further consequences are seen in the transport sector if less has to be spent, and fewer jobs are involved in snow clearing and winter road maintenance. On the other hand, the summer recreation season may become longer. Districts that are not connected to large regional water supply systems may suffer a seasonal water deficit, which would influence tourism.

Europe

For Europe, all modeling of climate change must take into consideration not only global warming but also several anthropogenic factors, impact of changing land-use cover and even the influences of environmental politics. The most probable forecast indicates an increasing winter temperature. At the same time, it is assumed that winter precipitation will increase by up to 20%. In Northern Europe, summer precipitation will also increase (Watson *et al.*, 1998, 158). Severe storms may occur in NW Europe and threaten the coastal regions. Great Britain may experience summer warming, by increasing summer tourism and the income so derived (Abegg *et al.*, 1997, 107). In the more continental regions of Central Europe, water deficits and a decline in touristic traffic could occur.

In lakes, the changes to runoff regimes will have an impact on tourism. Lake levels will probably be almost the same as at present, but a possible decrease in water input and outflow will affect the water quality and its suitability for swimming, because nutrient loadings will increase and lead to eutrophication.

In the European Alps, this climatic change will cause a deficit of snow during winter months. If the regional warming in the Swiss Alps reaches only 2 °K, the snowline for adequate skiing will be elevated by 300 m. At the moment, ski resorts above 1200 m enjoy an abundance of snow. However, after significant warming, only stations above 1500 m, and on slopes facing the sun, above 2000 m, will have sufficient snow (Abegg and Froesch, 1994, 330). This might cause a decrease of secure skiing areas from 195 (85% of all 230) to 144 skiing areas (or 63%) (Burki, 1998, 155; Elsasser *et al.*, 1998, 152). For winter resorts, the consequence would be either artificial snowmaking or an institutional change to new touristic attractions, with greater regulation of visitor movements if the burden of the remaining snow-reliable areas grows too quickly.

In the Mediterranean region, the main problem will be the growing water deficits. The declining runoff from large rivers will probably cause an intrusion of saline water into

coastal aquifers and make freshwater supply more difficult. Sea level rise will exert additional stress on coastal zones and resort and harbor infrastructure.

Asia

As for Asia, it may be supposed that in the forthcoming years and decades, the intensified melting of high mountain glaciers will cause an increase in runoff, which may threaten touristic infrastructure. Within the mountainous areas, the altitudinal belts will be elevated so that touristic infrastructure also must move. The consequence is an increased need for development of hitherto less accessible areas. Tropical Asian countries have only recently become involved in tourism but are gaining more and more income from such activity. In areas threatened by higher flood risks from increased runoff or more intense typhoons, threats to rural areas will lead to higher migration to urban centers where better flood control may exist. Changes in the timing and intensity of the monsoon could have consequences for mountain tourism in the South Asian Himalaya (Price and Barry, 1997, 433). Tourist infrastructure near coastal zones is menaced by the rise of the sea level, which will create enormous difficulties for island tourist destinations such as the Maldives. But such a rise in sea level would also affect the coastal zone of South East Asia and the delta regions of some large rivers like Indus, Brahmaputra, Menam Chao Phraya and Mekong.

Africa

Tourism in Africa is expanding rapidly despite the continent s economic, social and ecological difficulties in particular rivers. Wildlife tourism in the national parks and resort tourism in West and East Africa have grown. Water availability will be the restricting factor. If, within the next 50 years, mean annual temperatures increases by 1.6 °K in the Sahara and by 1.4 °K in the inner tropical zone (Hernes *et al.*, 1995), decreasing water supplies will affect both the population and short-term visitors. Already, two-thirds of the rural, and one-quarter of the urban population lack secure access to good drinking water. By 2025, as many as 600 million Africans may not have an adequate water supply (Watson *et al.*, 1998, 49). Increasing aridity will lead to a decline in the wildlife population and diminish the attractiveness of some nature parks in the Sahel zone, and in East and South Africa. This effect will have negative consequences for tourism. In the coastal regions, small rises of sea level may threaten the existence of tourist resorts and the livelihoods that depend on them. Natural attractions like Victoria Falls can lose their appeal if the water volume decreases as it did in 1992, and thus visitor numbers may decline. Water sports on lakes (sailing, water skiing, fishing, etc.) may decline, and attractive wetlands like the Okavango Delta may be threatened. Economic investments in the tourism sector will have difficulty repaying shareholders. Hotels near inland lakes and rivers will see a reduced number of visitors if the water deficit increases. Finally, increasing interannual climatic variability, decreases in water supply and water quality and resulting migration will increase the problems of disease control and the fight against epidemics, making Africa a more risky area to visit. Africa is indeed extremely vulnerable to the impacts of climate change.

Australia and New Zealand

In Australia and New Zealand tourism is already the most important earner of foreign exchange, accounting for 13% of all export income. Its importance is increasing (Watson *et al.*, 1998, 111, 135). Global warming will probably cause a sea level rise of 15 100 cm by the year 2100, which will threaten the most frequented shore regions, some coastal resorts, and some marinas. Primarily, it is expected that severe storms will cause large floods. On the other side, sea level rise may favor the growth of corals within the large reefs, and thereby strengthen the attractiveness of the Great Barrier Reef. In the mountainous regions, winter tourism will decline due to the retreat of snow cover and snow security. Thus, the ski season will shorten and become increasingly marginal (Konig, 1999, 147). This will mainly influence ski centers of some national parks (Kosciusko National Park, New South Wales; Alpine National Park, Victoria). The consequence is the potential loss of nearly 12 000 seasonal jobs (Konig, 1999, 148). It is estimated that at least 60 70 days of winter season are necessary in order to maintain the skiing industry financially. This will be possible in most winter resorts if the increase of temperature during the next three decades does not exceed 0.3 °K (favorable scenario); a warming of 1.3 °K (negative scenario) would put the future of winter tourism in doubt (Konig, 1999, 250).

Oceans and Islands

In some small island states in the Caribbean Sea, the Pacific and the Indian Oceans, tourism has become the most important economic sector. On some of those islands, the number of visitors greatly exceeds the number of inhabitants. In Antigua, tourism accounted for 69% of the GDP in 1995, in the Bahamas 53%, and in the Maldives 50%. Sea level rise will increase the loss of beaches by erosion, the danger of flooding and the salinization of freshwater aquifers. Thus, tourism would become unsustainable. On the atoll islands in the Pacific, which only rise 1 2 m above sea level, sea level rise threatens the very existence of the islands. In a scenario from the early 1990s, calculating

a sea level rise of 2 9 mm year^{-1} menaces all touristic activities concentrated near the shoreline. On the islands of the Caribbean Sea, 50% of the population, and an even higher percentage of tourists, are concentrated in a 2 km broad coastal strip that is extremely vulnerable. It might be possible to erect protective barriers against the sea but the high costs of such an undertaking and a loss of scenery would be involved.

Conclusion

Abegg *et al.* (1997, 107) stress the fact that in the temperate zone, seasonal and spatial shifts in regional and local climate change will affect the tourist industry. However, it is not possible to identify local winners and losers among the regions because the changing structure of tourist opportunities will alter the status of localities, and cannot be predicted. The response and adaptation of the tourist industry to changed natural conditions is not well understood. Added to this is the fact that models of climatic change cannot provide small-scale detail. Today one supposes that changes of the structure of tourism will not be caused by first-order, but by secondary consequences. Therefore, how far climate change reduces the economic significance of tourism will depend on the adaptive capability of the tourist industry itself.

Toxic Wastes: Generation and Disposal: a Case Study of UK Practice and Legislation

Stephen L Willetts
The Willetts Partnership, Atherstone, UK

This essay deals with the past practices for the disposal of toxic wastes generated by industry in the UK. It then explores how and why legislation evolved in order to control the potential effects of such disposal practices.

Many practices for the disposal of toxic wastes were gradually phased out because of the implementation of the legislation, both domestic and, more recently, international. Disposal by way of land ll became the preferred route - if not the only remaining option. It might be said, therefore, that the UK has a legacy of land lled toxic wastes and that this may well erupt because of the predicted forthcoming global environmental changes.

The size and scope of the potential legacy is quanti ed and some of the predicted effects discussed. The conclusion of the study is that, whatever the predicted effects might be, they are, at least, manageable and should not be disastrous!

So-called toxic wastes have always been disposed down the drains, up the chimney or dumped on land: the options are straightforward sea fill, air fill or landfill! The former two methods have the added advantage that the wastes are swept away from the place even the country where they were produced. This is the classic *dilute and disperse* philosophy and some would argue that there is nothing at all wrong with this approach to waste management so long as we do not overload the self-purification capacity of the receiving environment.

The landfill approach perhaps unfortunately, keeps the problem closer to home and, therefore, warrants a more diligent management philosophy. In the UK, toxic wastes have generally been co-disposed with household and other readily biodegradable rubbish. Proper site management should avoid the obvious problems of violent and potentially destructive chemical reactions taking place as a result of mixing incompatible types of wastes.

There is a more insidious problem with landfills however, and that is the inevitable generation of highly polluting liquors called leachate: this is the liquid formed as a result of rain flushing through the wastes and dissolving chemicals from the wastes themselves and their products of biodegradation. The chemical constituents of the toxic wastes landfilled can, therefore, be leached out: this is especially so in the aggressive, acidic conditions produced initially during the, usually anaerobic, biodegradation process.

This leachate, if not contained within the site by natural or artificial barriers, can seep through the base and sides of the site and contaminate groundwater or can overtop the site and pollute surface streams: both of these water bodies can be sources of potable water, of course.

Toxic wastes were not recognized as being problematic in terms of their disposal in the UK at least until a celebrated incident near Nuneaton in 1972. Certainly, prior to that date, controls on their discharge to sewers and other waters were strictly controlled by virtue of a system of formal consents, as were discharges to the atmosphere from their incineration: disposal to land, however, was not expressly controlled by legislation. The seminal incident that forced a rethink on their disposal to land involved the discovery of several abandoned drums of cyanide wastes on derelict land on which children regularly played.

That is not to say, however, that toxic and other wastes had not already been recognized singularly as being in need of proper management as regards their pollution potential. Indeed, as early as 1953, the then Minister of Housing and Local Government commissioned a technical committee to report on The Pollution of Water by Tipped Refuse : it concluded that controlled tipping was generally a satisfactory method of refuse disposal.

In 1964, another technical committee was commissioned to report on The Disposal of Solid Toxic Waste : it concluded that there was a definite need for a formal authorization procedure administered regionally and established by legislation.

Events rather overtook themselves with the Nuneaton incident, however, and the Deposit of Poisonous Waste Act was hurriedly implemented on 30th March 1972. Producers of poisonous, noxious or polluting wastes were required to give at least three days notice of any intended deposit to the statutory local authorities. Such wastes were not, in fact, defined in the Act, but the terms had been given legal recognition as a result of earlier court cases. The local authorities were thus in a position to build up a picture and database of such poisonous waste disposal transactions throughout the UK.

During this period, the environment was being firmly pushed onto the political agenda: Rachel Carson s *Silent Spring* and the Club of Rome s *Limits to Growth* were raising serious concerns about the consequences of environmental pollution. These publications helped to encourage the promulgation of several new pieces of waste management legislation.

For example, the attractively descriptive Dumping at Sea Act of 1974 came about as a response to the Oslo and

London Conventions, which sought to prohibit the dumping in international waters of certain categories of wastes and to provide the requirement for formal permits to dump those wastes that were to be allowed with precautions. At its peak, sea dumping accounted for around one-and-a-half million tonnes of industrial waste and 10 million tonnes of contaminated sewage sludge each year. The practice has now been phased out as a result of international agreements.

Incineration of wastes at sea, usually in the North Sea, accounted for the disposal of over 100 000 tonnes per year of halogenated residues during the 1970s. The advantage over land-based incineration was simply that no expensive gas cleaning systems were employed. The practice was phased out in the early 1980s.

During this time, the UK government seized the opportunity of taking stock of its existing piecemeal environmental legislation, replacing it with the encyclopedic Control of Pollution Act in 1974. This was the first integrated approach in the world to protecting the environment. The Act dealt with four major areas in pollution: waste on land; water pollution, both of the sea and inland water; pollution of the atmosphere; and pollution by noise.

The greatest impact on the waste disposal industry came from the introduction of a formal licensing regime for all waste disposal sites. The authorities could impose any condition they saw fit in a license. These conditions became ever more stringent as environmental concerns grew, particularly over groundwater protection, and from the requirements of European Directives.

The old-style *dilute and disperse* landfills or as the then Secretary of State for the Environment euphemistically termed them, *dilute and attenuate* were gradually to be phased out. The new *concentrate and contain* philosophy of landfill management demanded impermeable liners on the base and sides of sites and the managed removal of leachate for proper treatment and disposal elsewhere in order to prevent any migration of polluting leachate either downwards or laterally from the site. Upon their closure, sites would have to be sealed by impermeable caps to keep rainfall out thereby reducing the amount of leachate produced.

It also became common to set loading rates for the types and maximum amounts of toxic wastes to be deposited as a proportion of biodegradable wastes. The theory behind this was that organic species in the toxic wastes would eventually biodegrade so long as their concentrations were kept modest and the practice of co-disposal, as in the UK, would work as long as the remaining disposed refuse provided sufficient biological buffering that the microorganisms could cope with the otherwise toxic loading.

Even materials that might be thought to be extremely refractory to biodegradation for example, polychlorinated biphenyls (PCBs) and cyanides will biodegrade in the right conditions.

The 1974 Act also made special provision as to the disposal of waste of a particularly dangerous kind or of a kind that was difficult to dispose of: the term special waste was introduced. This predated the European Hazardous Waste Directive by some eleven years. The implementing regulations came into force in 1981 at which time the Deposit of Poisonous Waste Act was repealed.

Essentially, the term *special waste* was defined as any controlled waste which was dangerous to life ••• or has a flash point of 21 degrees Celsius or less and waste was to be regarded as dangerous to life if a single dose of not more than 5 cm^3 would be likely to cause death or serious damage to tissue if ingested by a child of 20 kg body weight or exposure to it for 15 minutes or less would be likely to cause serious damage to human tissue by inhalation, skin contact or eye contact .

It is difficult to imagine how this definition could be tested practically. The idea of rows and rows of 4-year old children queuing up to have waste samples rammed down their throats, rasped into their skin and douched into their eyes is both unacceptable and unrealistic.

The regulations introduced a comprehensive system of consignment notes to document the movement of the waste from cradle to grave thus providing proper records of waste sources and destinations.

These regulations continued until repealed and replaced in 1996 by new ones that fulfill certain European Community (EC) Directive obligations. The current definition of *special waste* is now far less prosaic referring, as it does, to the European Hazardous Waste List.

The 1999 Landfill Directive ensures that toxic wastes are only deposited into effectively sealed landfill sites independently from other wastes. The apparent driving philosophy is that future generations will be able to recover them if technologies are developed for the reuse or recycling of the wastes. If not, at least they will, henceforth and in perpetuity, have been entombed, bottled-up, isolated, for all intents and purposes, from the environment: the Directive will see to that!

Essentially, then, the UK has a legacy of toxic wastes in landfill sites with little control and even less knowledge up until the mid-1970s. Thereafter, landfill sites were subject to rudimentary regulatory controls that have evolved into our present-day management practices. For about two decades, toxic waste landfill sites were not specially lined and leachate has gradually or sometimes suddenly seeped, leaked or spilled away into the aquatic environment. Concentrate and contain is now the dominant philosophy as is the maintenance of accurate and rigorous records for posterity: if previous practices were suspect, they have now effectively been, or very soon will be curtailed.

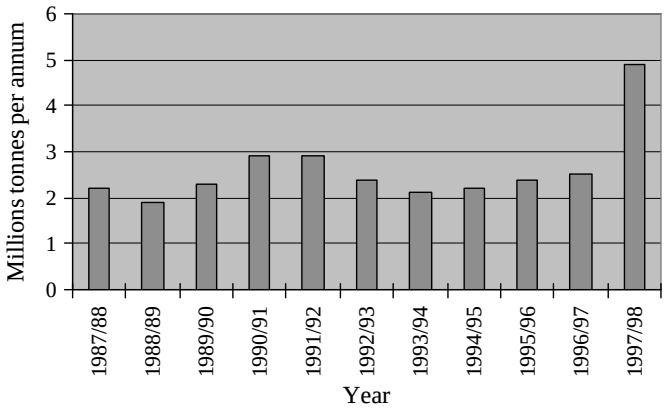

Figure 1 UK special waste arisings 1987/1988–1997/1998

The legacy can be roughly quantified from official data first published from about 1984/5, although the government always heavily qualifies the accuracy of the figures. The big jump to the 1997/98 levels is said to be a consequence of the change in definition of special wastes in late 1996. The picture is illustrated in Figure 1.

As can be seen in Figure 1, between two and three million tonnes of special wastes have been produced each year and with some consistency until the change of definition. Although a large mass, this tonnage is only some 0.005% of the total waste produced each year.

The disposal routes used for special wastes have remained relatively constant and are illustrated in Figure 2.

It has to be noted, however, that incineration will typically produce anything up to 30 40% by weight of ash and gas cleaning residues: chemical treatment will produce anything up to 60 70% by weight of residues. These will ultimately need disposal to landfill.

From 1970 to the present, possibly up to 5 6000 licensed landfill sites operated in the UK at one time or another. Those already closed will remain capped and forgotten unless and until something untoward happens and leachate starts to emerge. Only a select few of these, perhaps no more than a hundred, will have received significant amounts of toxic waste.

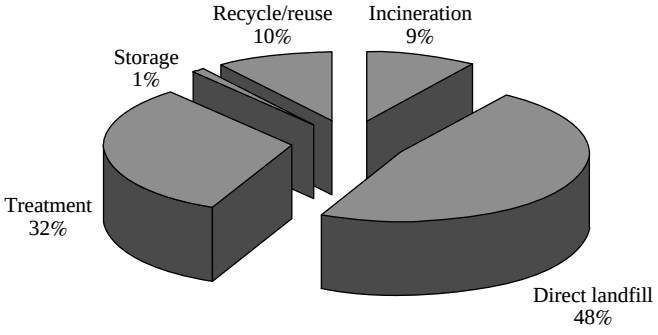

Figure 2 Special waste disposal routes

The useful Friends of the Earth Landfill Campaign Guide of June 1997 estimated that there were then about 3700 operational landfill sites in the UK. Of these, about 100 sites accounted for almost one half of all waste that is landfilled: these are the ones most probably taking special wastes. The picture is one of a few, large, strategically located sites and hundreds of others apparently serving purely local markets.

Most of the landfill sites used for special wastes will have been located in naturally impermeable clay strata for water pollution prevention reasons and logic dictates that they will also have been located as close as possible to the manufacturing industries that generated the wastes.

How will the predicted global environmental changes affect these sites? The main aspects to consider here are coastal erosion, coupled with, or as a consequence of, a rise in sea levels, increasingly heavy rainfall and rising groundwater levels. The issue of most significance will be the release, sometimes sudden, sometimes insidious, of toxic, heavy metals into the environment.

It is reasonable to discount any significant effects from landfill gas since the proportion of biodegradable organic species in toxic wastes is insignificant compared with that provided by ordinary domestic and commercial wastes: the relative contribution of methane derived from toxic wastes and the consequent contribution to global warming can, therefore, be discounted. In any event, in the long term, biodegradation of these organic species will result in the wastes becoming environmentally benign, leaving only the toxic heavy metals to consider.

Of course, landfill sites located in the coastal zone will be prone to inundation and scouring out by rising sea levels and coastal erosion. Such wholesale removal of the wastes into the sea would, almost certainly, produce

immediate toxic effects on marine organisms. Longer term bioaccumulation in these organisms is, also, almost certain with the scope and extent of the resultant damage being dependent upon the dispersion caused by tides and currents. Shellfish will be the most susceptible to poisoning by heavy metals and especially their bioaccumulation but short-term damage to commercial fisheries could be expected, too.

As regards increasingly heavy rainfall, this will inevitably lead to increased volumes of leachate being produced from active and closed landfill sites: even sites capped with clay and/or synthetic materials do allow infiltration which contributes to leachate production. The consequence will be a need for vigilant leachate monitoring, removal and treatment or an otherwise accumulation within the sites with the real prospect of escape into both ground and surface waters. If this does happen, there will be increased costs of treatment of any abstracted water prior to its supply for use: either that or the need to abandon specific polluted sources as a consequence of contamination by leachate.

It is also possible that increased river flows will inundate and scour out landfills situated on or close to the river banks or in the river flood plains. This might result in potentially catastrophic release of toxic substances causing fish kills and other damage. Fortunately such incidents tend to be transient in their effects simply owing to the volume and flow rate of the water, but not always so: there are cases of the plug flow of pollutants wiping out huge stretches of rivers.

Rising groundwater levels will also affect landfill sites. There is the potential for sealed sites to be floated out of the ground by upward hydraulic pressure: certainly, there have already been instances of liners having been lifted out because of rises in local groundwater levels owing to pump failure. If this were to happen, then the result would be land contamination in the immediate vicinity with the need to collect and remove the wastes elsewhere for disposal followed by remediation with clean materials of the former landfill site.

There is also the prospect of rising groundwater entering into landfill sites, including entry through lining systems by virtue of increased hydraulic pressure, contributing to increased volumes of leachate and its potential escape.

All of these impacts of global environmental change on our legacy of tipped, toxic wastes are credible, the probability depending upon the location and circumstances of individual sites. None of the impacts needs be disastrous: all are manageable.

What is needed to avoid real problems is vigilance and an accountable responsibility for this. Fortunately, policy on this is emerging: someone out there is listening.

Transboundary Movements of Hazardous Wastes

Iwona Rummel-Bulska

United Nations Environment Programme, Geneva, Switzerland

The transboundary movement of hazardous wastes became of global concern in the 1980s. This is because of the growing export (both legal and illegal) of hazardous wastes from industrialized to developing countries. The practice was a response to rising costs for hazardous waste disposal in rich countries at a time when costs for such disposal in developing countries were minimal. The export of hazardous wastes from the highly industrialized Organization for Economic Cooperation and Development (OECD) countries to less developed non-OECD nations grew dramatically from 1970 to 1995. Greenpeace estimated that in the 20 years before 1989 approximately 3.6 million tons of hazardous wastes were exported, but as much as 6662.6 million tons were shipped in only 5 years between 1989 and 1993. Exact gures on the quantity of hazardous wastes involved are not available but the United Nations Environment Programme (UNEP) estimates the total annual transboundary movement of such wastes amounts to be between 300 and 500 million metric tons.

Among the highly publicized cases contributing to media attention and consequent public concern about transboundary movements were the dumping of polychlorinated biphenyls (PCBs) from Italy into a farmer s field in Koko, Nigeria, and the case of the toxic waste ship Khian Sea in 1987 1988 (Kreuger, 1999). As a result, UNEP sponsored negotiations on drafting a global treaty (the so-called Basel Convention), which was adopted by 116 governments in 1989, and which came into force in May 1992, when it received the necessary 20 ratifications. In March

1994, the second Conference of the Parties of the Basel Convention adopted a full ban on all hazardous waste trade to developing countries (*see* Basel Convention, Volume 4).

Eager to avoid negative publicity as well as to circumvent laws against the dumping of toxic wastes, many companies are said to disguise their deadly exports with benign labels. Greenpeace estimates that 86 90% of all hazardous waste shipments destined for developing countries are purported to be materials for recycling, reuse, recovery, or humanitarian uses. Many importing countries have discovered that toxic wastes by another name still pose major problems. Indonesia was importing foreign plastics for recycling until 1992 when it found that 40% of the imported material could not be recycled and that approximately 10% of it was toxic and imposed a ban on all importation of plastic waste.

The environmental and human impacts of the transboundary movement of hazardous waste may be severe. Reports from the Philippines reveal that even legitimate hazardous waste recycling operations approved by the government are causing toxic emissions, and in many cases creating residual hazardous waste more toxic than the original waste. During 1993 1996, Singapore, Saudi Arabia and Australia were the three main exporters of drained or undrained scrap batteries to the Philippines. People living near a lead re-smelting facility at the recycling plant complained of nausea, burning eyes, sore throats and various respiratory ailments. Tests on the blood lead levels of children in the area revealed blood lead levels ranging from 8 micrograms per deciliter ($\mu g\,dl^{-1}$) to as high as $29\,\mu g\,dl^{-1}$. Blood lead levels as low as $10\,\mu g\,dl^{-1}$ cause problems such as decreased intelligence, impaired hearing and stunted growth. Soil, river sediment and vegetation samples collected near the recycling plant had lead levels greatly exceeding the limits of lead in soil and plant matter for crop cultivation and human consumption. The problem of transboundary waste disposal has not yet gone away, even between OECD countries. For example, after considerable public outcry and political debate, the City Council of Toronto (Canada) recently decided (October 2000) to send garbage to a land-fill site near Detroit (USA) rather than to an abandoned mine (Adams Mine) 570 km to the north in a relatively unsettled part of the Province of Ontario. Although admittedly, the wastes will not technically be hazardous, the example shows that the temptation to dispose of waste materials in any way possible is still an option that is considered by political bodies.

Transport and Species Dispersal

Ian F Spellerberg
Lincoln University, Aotearoa, New Zealand

With increasing volumes and speed of transport of people and cargo around the world, it is no surprise that transportation has aided the distribution of species and consequently has contributed much to environmental change. Roads and vehicles, trains, barges, ships and aircraft have all contributed to species dispersal. Road vehicles transport seeds, trains carry dust mites, ships have transported African mosquitoes to Brazil. Ocean liners have been vectors for land birds, butter ies and other insects have been have been found in cars transported across the world, and bats have been transported from France to the UK amongst a load of oak planks. Containers have been found to be vectors of many organisms including a raccoon transported from the US to France.

For thousands of years humans have contributed to changes in the dispersal of plants, animals and other organisms. We have mixed and stirred the world s biogeography either deliberately or by accident. Some people talk of homogenization of the world s biota. Many species have been deliberately introduced to new areas mainly as a new source of food (or some other kind of resource) and to control pests. One of the best known examples of programs of intentional introductions was in New Zealand. Plants and animals were transported from Europe, North America and other countries under a series of legislative acts commencing in 1861. Some of these introduced species are now extremely abundant and invasive pests. In Australia, one of the most spectacular examples of invasive species was the spread of the European rabbit. This originated from a shipment of rabbits imported from England in 1859 and within three years they had become a potential pest.

The infrastructure for transport has also contributed to the dispersal of species. Roadsides, edges of railway tracks and canals have all in some way acted as linear habitats and helped to facilitate the dispersal of many species. The story of the Oxford Ragwort (*Senecio squalidus* L.) is a classic example. This South European species, now abundant in many parts of Britain was once growing in the Oxford University botanical garden in 1770s. By the 1830s, it had spread to the Oxford railway station and from there it spread along the Great Western Railway.

Perhaps the most well researched example of species being dispersed by transport (Laird, 1984) is that of the

role of road vehicles in the dispersal of plants (particularly weeds) and seeds (Wace, 1977). As early as 1930 it was suggested that the spread of weeds along roadsides had occurred as a result of seeds being transported in mud attached to vehicles. A study of seeds found in the mud on a car that had traveled over 15 000 km around Germany revealed 124 species with a total of 3926 seedlings (Schmidt, 1989). In Australia, Wace found seeds from 259 species collected over 2.5 years from cars in Canberra. Some concern has been expressed about the danger of alien and invasive weed species being transported by cars into protected areas. Weeds are indeed transported into national parks by cars but it is believed that rather than attempting to prevent this movement, it is better to detect and eradicate existing weed infestations.

Ships and other forms of aquatic transport (together with fishing nets and other equipment) are vectors for dispersal of species. For thousands of years, marine life such as barnacles, molluscs, seasquirts and algae must have been dispersed around the world on the bottoms of the many forms of marine transport. Beetles native to Europe (especially ground dwelling and from dry conditions) have been transported in ships ballast to eastern North America. Shipping, and even recreational boating, have been important in the relatively recent invasion of North American fresh waters by the Zebra Mussel (*Dreissena polymorpha*). This species is now the most important fouling organism in the US and Canada causing much ecological damage and causing considerable expense.

Cargo ballast water has been known to be a vector for dispersal of marine species since the start of the 19th century and the transportation of pathogenic species is of increasing concern. Ships from Latin America have been found to have cholera in their ballast on arrival in Australia and the US. The ballast water and sediments in the ballast tanks are known to have contributed to the spread of many planktonic species and benthic species (Williams *et al.*, 1988) and ballast water is now considered to be the largest single vector of exotic species. More and more invasions of exotic marine species are being linked to ballast water and there are considerable threats to aquaculture.

Aircraft are contributing to accidental species dispersal. The dispersal of mosquitoes, other insects and species of fungi via international aircraft has become a well-known phenomenon; particularly worrying has been the transport of disease vectors. Aircraft have unintentionally transported barn owls, bats, snakes and rodents.

The trade liberalization stemming from treaties such as General Agreement on Tariffs and Trade (GATT), together with the growing volume and speed of transport have increased the risk of unintentional spread of species via transportation (Laird, 1984). Many introduced species have become invasive and are contributing to unwanted global environmental change. Article 8(h) of the 1992 Convention on Biological Diversity calls for states to prevent the introduction of, control or eradicate those alien species which threaten ecosystems, habitats or species .

Dispersal and introduction of invasive and alien species by ballast water has been addressed and is being managed by several countries. The United Nations International Marine Organization (IMO) is also facilitating management to reduce the risks of change to indigenous communities caused by invasive species transported by ballast water. The biosecurity risks posed by air cargo are being researched and some authorities are ensuring that containers have been cleaned before loading at airports.

The huge volumes of road transport pose a considerable risk for the spread of weeds. Traditional mechanized commercial car washing is known to be merely a cosmetic operation leaving an abundance of weed seeds in the vehicle borne biota (Wace, 1977). More effective cleaning methods will need to be developed especially for vehicles being imported. A very recent issue has been the potential spread of foot and mouth disease from Europe to North America.

Transport: Global Freight and Passenger Flows

Peter Rimmer
The Australian National University, Canberra, Australia

The goal of global transport is to provide links for movements of freight and passengers between and within six continental areas: Africa and the Middle East, Asia, Australasia,

Europe, North America and Central and South America. Over time, the relative importance of transport modes performing this task - water, road, rail, pipeline and air - has changed with innovations in transport (and communications) technologies, and shifts in institutional and organizational formats. Canals, railways, private motorized transport and commercial aviation represent past technological jumps; and shifts from anti-monopoly through central control and nationalization to competitive policies, re ect historical movements in the nature of regulatory regimes. All transport modes are environmentally intrusive but only since the early 1970s has the nature and scale of their global impact become a key issue for policy makers. The industrialization of Asia has led to fundamental changes in the structure of the world's transport system. Asia is now linked, through an east- west main street in the Northern Hemisphere, with Europe and North America. Conversely, Africa, Australasia and Central and South America in the Southern Hemisphere have been relegated to the status of cul-de-sacs. They are connected to main street by north- south feeder links through major hubs in the Northern Hemisphere, which are already served by extensive continental feeder systems.

The stark representation of the present global transport infrastructure shown in Figure 1 reflects an ongoing search for full efficiency from integration. The development of the global hub and spoke system aimed at reducing costs to the user and stimulating technological and organizational innovation, has been accompanied by greater public concern about environmental degradation. Regional emissions of nitrous oxides, and global emissions of carbon dioxide, compound local problems of noise, atmospheric lead pollution, vibration, and visual intrusion and community severance. Thus, two issues are raised: how has this pattern of global transport emerged since the early 1970s, and what are the environmental challenges and policy implications of transport development?

In pursuing these issues, a distinction is made between freight and passenger movements between and within the six continents. This distinction reflects the fact that the restructuring of the world s transport system since the early 1970s was to meet the two-fold needs of transnational corporations for: (a) door-to-door freight systems to knit together their dispersed production sites, and (b) seamless passenger services for personnel and their diffused clients. The extent to which these global local needs have been met, and their resultant environmental repercussions, are discussed in separate studies of freight and passenger systems.

A major drawback to this analysis is the quality of transport statistics. There are useful data on global bulk and liner shipping and air transport movements (FR, 1999; CIY, 1998; IATA, 1999; UNCTAD, 1998). Data on local (regional) movements are inadequate except for the European Union (EU) and North America (Gerondeau, 1997; DETR, 1998; ECMT, 1995; ECMT, 1999). The UN (1997) covers all modes road, rail, sea, air and inland waterways but recourse has to be made to commercial sources to compensate for many omissions (JUTS, 1998; IUR, 1999; TMC, 1997).

Even then, information on road transport is restricted to numbers of vehicles in use worldwide and their uneven distribution (Table 1). There are 494 million passenger cars worldwide, or one car for every 11 people (TMC, 1997). Countries with more than 400 cars per 1000 people include Australia, New Zealand, United States and Canada; and those experiencing marked congestion include Germany,

Israel, Italy, Japan, Kuwait, Mexico, Romania, South Korea, Switzerland, Taiwan, Thailand, United Arab Emirates and the United Kingdom (IRF, 1996; IRTU, 1996). This information is inadequate for any in-depth discussion of world motorization and its environmental repercussions. Indeed, there is little information covering the expected growth in car ownership and traffic in low-income countries and their impact on trans-boundary pollution problems. Given these data problems, attention is concentrated on freight and passenger movements between continents, with only scant reference to those originating and terminating within continents.

FREIGHT

The demand for freight transport is derived from economic growth and the volume of international trade. An increase in industrial production, and an expansion of trade, result in an increasing demand for freight transport. Although the rate of economic growth has been declining since the early 1970s, it has been uneven, as witnessed by strong economic growth in East Asia and low-income countries. While the rate of production has been declining, world trade has been reviving buoyed by the global integration of production, reflecting fewer impediments to trade and innovations in transport and communications.

Intercontinental Systems

Land connections are possible between Asia, Europe and Africa, and North, Central and South America. Much effort has been invested in intercontinental rail freight systems between Asia and Europe, but the Trans-Siberian Railway is of diminishing importance and the Trans-China Railway has yet to prove itself. Consequently, deep-sea shipping dominates mainline intercontinental freight systems ahead of air cargo, with road, rail, water, air and pipeline providing the necessary urban and regional feeder systems within individual continents.

Deep-sea Shipping

A distinction is made in shipping between carriers that handle commodities in bulk (e.g., oil, iron ore, coal and grain) and liners that handle general cargo on a regular schedule. Bulk cargoes, as has been the case since the 19th century, still depend on either shipper or manufacturer (e.g., car carrier or pulp and paper vessels). Deep-sea liner shipping has undergone marked organizational changes since the early 1970s to meet the increase in container cargoes. There is an active market for the sale of bulk ships but only a small resale market for container ships. Bulk operators buy assets, but container operators purchase transport and communications networks. Bulk carriers are still involved in the shipping business, but increasingly, liner shipping is part of the wider maritime global hub and spoke transport system, which seeks to meet the demands of manufacturers for a truly global reach in door-to-door services (logistics).

Bulk Shipping

Bulk ships transport high volume low unit value substances such as crude oil, iron ore, coal and grain in shipload lots between producing areas and major industrial processing centers. This freight business is transacted in the ship charter market, which is characterized by marked daily fluctuations in freight rates. As many variables are involved, the ship charter market is risky. Freight rates on some bulk commodities can account for over one-third of the delivered price. Given these slim margins, a few cents difference can determine trading profitability or loss. This explains the close attention paid by maritime research institutes to forecasting likely short- and long-term trends in the bulk shipping market for major commodities, notably crude oil, iron ore and coal (no figures are available for the transport of hazardous materials).

Movements of crude oil totaled 1415 million tonnes in 1995 16% smaller than the peak year of 1979 due to conservation efforts and a switch to other energy types. The Middle East played a pivotal role in supplying major markets in East Asia that were supplemented by Southeast

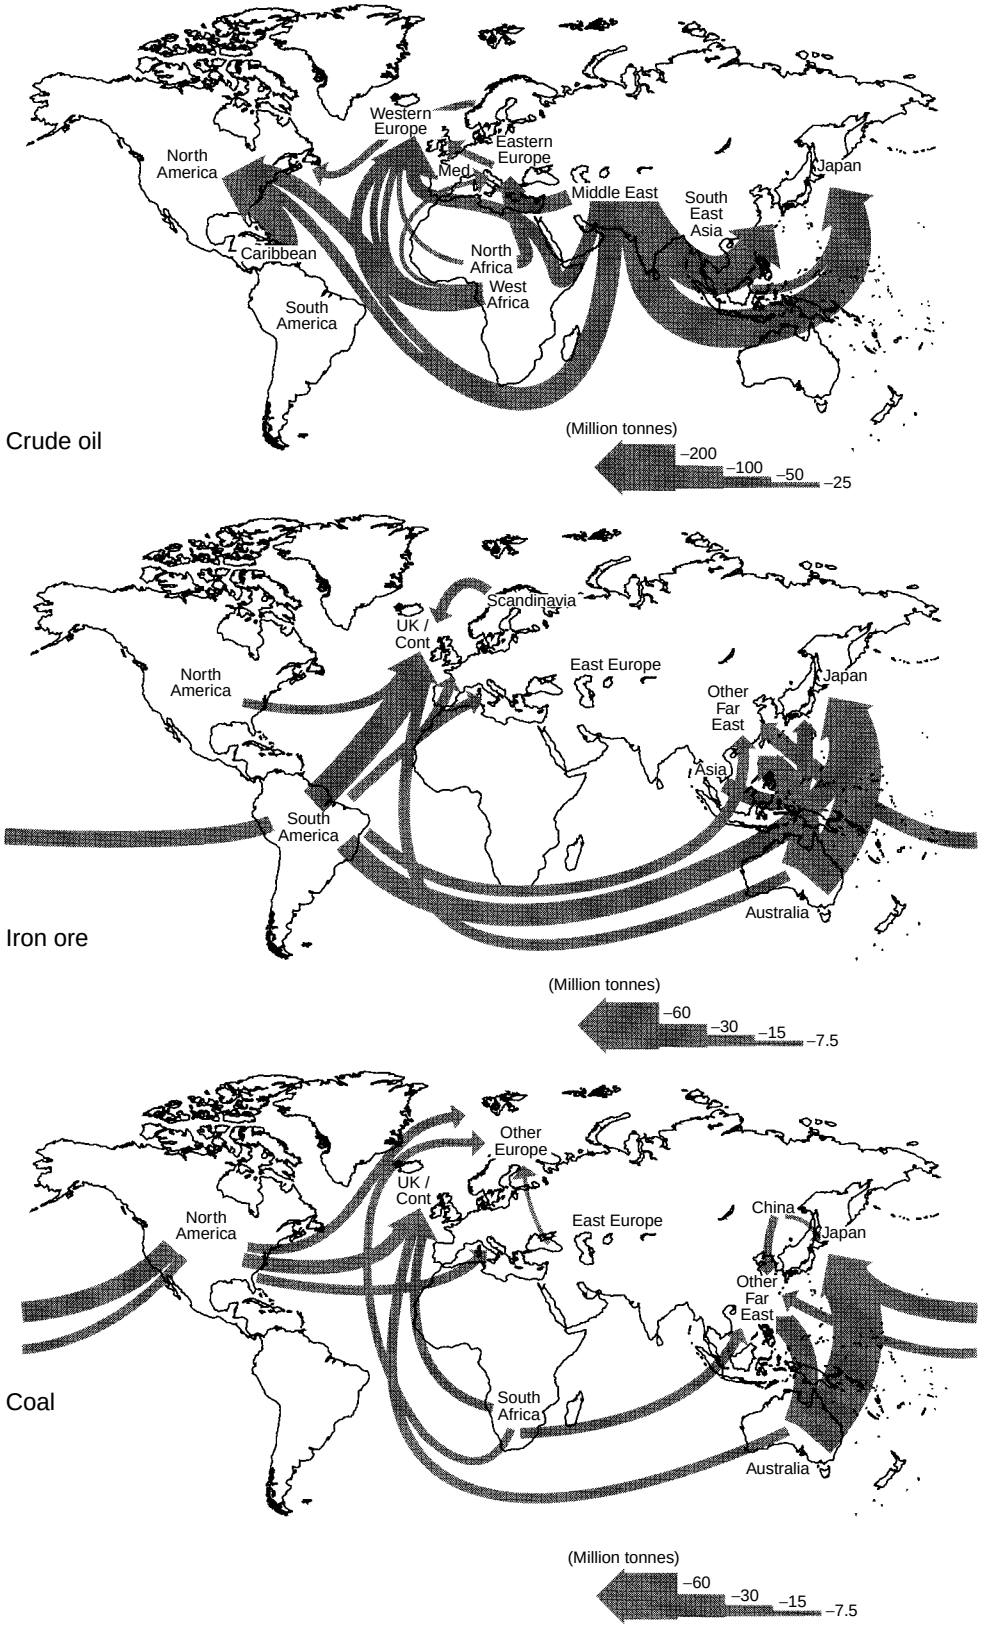

Figure 2 Major crude oil, iron ore and coal movements, 1995. (Reproduced using data from FR, 1999)

Asia (Figure 2). Western Europe augmented its Middle Eastern supplies with those from the Near East, North and West Africa and North America from the Caribbean, West Africa and the North Sea.

In 1995, sea-borne trade in iron ore, totaling 402 million tonnes, was closely patterned on crude steel production. South America, notably Brazil, was the largest producer that supplied Europe, the largest market, supplemented by Australia. However, Australia s main markets were in Japan and other Asian countries (China, South Korea and Taiwan), each of which also received smaller amounts from South America.

International sea-borne trade in coal of 423 million tonnes in 1995 made it the largest dry bulk commodity trade. Australia was the major supplier to Japan and the Far East. It also supplemented flows to Europe that were largely drawn from North America and South Africa.

The emphasis on forecasting demands for these major commodities stemmed from the bulk shipping market adhering closely to the principles of classical economics. Trends in commodities are matched against the mid-year supply of available shipping tonnage, to identify the supply-demand gap. A comparison of the supply-demand gap with freight rates provides the basis of forecasting longer-term trends in the shipping markets. When the tonnage is tight, freight rates rise. Conversely, when it is slack, freight rates decline.

Since the late 1960s this simple world of the classical economist has been mired by environmental problems reflecting an apparent decline in the standards of bulk shipping. In 1967, the Torrey Canyon ran aground off the coast of southwest England, spilling 120 000 tons of oil into the sea (*see* Torrey Canyon, Volume 5). Photographs of birds covered with oil had a profound impact on public perception of environmental degradation. This disaster led the International Maritime Organization to adopt a series of measures aimed at preventing operational oil pollution and accidental pollution, reducing the impact of accidents, providing compensation and helping implementation.

Shipping safety and pollution from ships improved, but a series of disasters from the late 1980s highlighted the need for fresh actions. In 1989 the tanker, Exxon Valdez, spilled oil off the coast of Alaska (*see* Oil Industry: Cultural Impacts and Environmental Risk Tolerance, Volume 3; Exxon Valdez Oil Spill, Volume 5); between 1989 and 1991 several bulk ore carriers sank off the Australian coast; in 1992 oil was spilt by the tanker Aegean Sea off Spain; in 1993 the tanker Maersk Navigator collided with an empty Japanese tanker in the Straits of Malacca and the tanker Braer was stranded off the Shetland Isles.

This spate of shipping disasters led to investigations by ship classification societies that attributed the sinkings to physical causes of failure corrosion, damage to the side structure and local overloading. The Australian government s Ships of Shame Inquiry pinpointed low freight rates as the underlying cause of a reduction in maintenance and a loss in structural integrity (Australia, 1992). The high-risk ships that foundered off Western Australia were found to be over 15 years old, carried iron ore, registered with flag states with high casualty rates and lacked seaworthiness due to corrosion (BTCE, 1994). An identical picture was echoed by the British government s Donaldson Inquiry (1994) into the Braer stranding that also emphasized shipping and transport mismanagement as key factors (e.g., crew proficiency, the chain of command, and better training and avoidance of fatigue).

Following these inquiries, a package of regulations designed for safer ship operation and environmental protection has been developed (Figure 3). This package includes international conventions and codes agreed to by governments and implemented by flag states. Individual states have also implemented measures to compensate for flag states and ship owners unwilling to accept their responsibilities for ship maintenance, management and operation. Private organizations likely to suffer financial damage from sub-standard ships have also taken further steps to eliminate rogue ships and reduce the risk of accidents (e.g., oil companies have proposed tanker traffic safety zones). These measures stemming from the hostile, political and regulatory environment generated by the ships of shame has not succeeded in eliminating the real culprits. A more targeted approach focusing on attacking the defective vessels, which account for less than 25% of the world s fleet may be more effective.

Liner Shipping

The present pattern of long-distance, deep-sea liner shipping is reflected in the large volume of container movements along main street, with its distinct east west alignment (Figure 4). The next largest set of flows is the north south movements that link a number of hub ports or load centers on the east west route. Gateway hubs include Singapore between Asia and Australia; Rotterdam between Europe and Africa; and Los Angeles Long Beach and Miami between North and South America.

This pattern of deep-sea liner shipping was brought about by technological change, undermining the previous historic system in which shipping companies were organized into rigid cartels or conferences. They operated regular multi-port routes for general cargo using a complicated rate schedule. The high cost of handling conventional cargo under this system led to the progressive introduction of containerization. Although the costs of operating container vessels and shore-based handling equipment exceeded those of conventional shipping, the companies merging their conference rights and establishing consortia offset the high fixed costs. Newcomers, mostly based in East Asia, challenged these consortia, by introducing cheaper container ships, lower

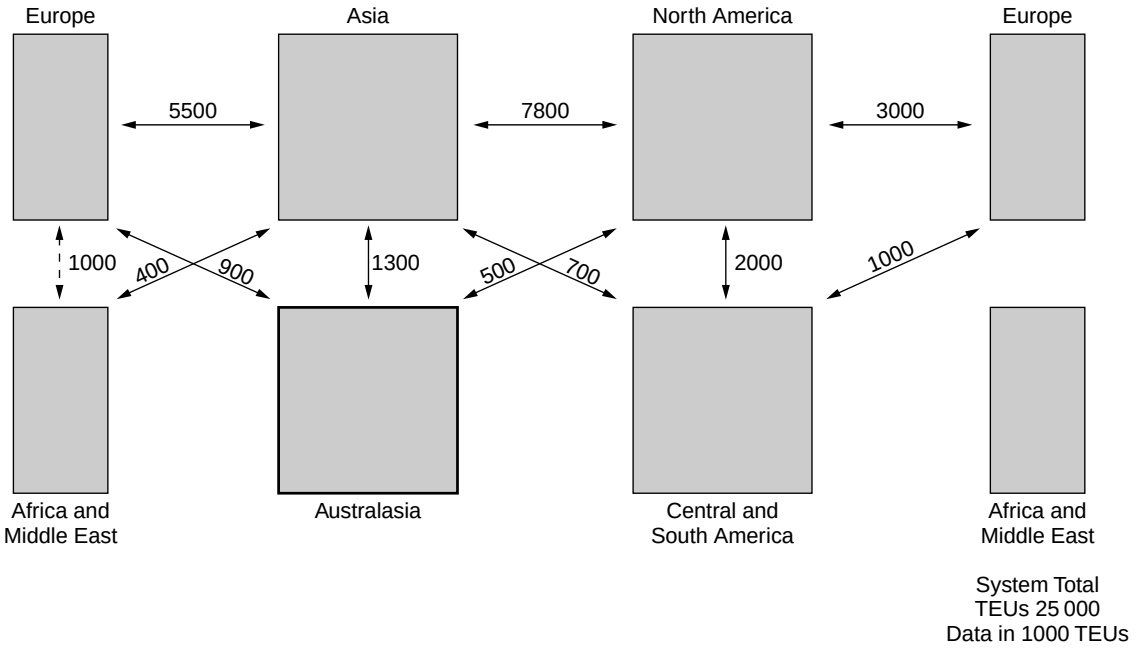

Figure 4 World container movements, 1996. TEU stands for twenty-foot equivalent units. (Reproduced using data from Iten, 1998)

freight rates and more flexible route configurations (e.g., round-the-world and pendulum services). The intensified competition led the established consortia to improve productivity and reduce costs. As these strategies did not provide a decisive competitive edge, many new entrants from Asia were allowed admittance into consortia.

These developments resulted in East Asia being recognized as a market in its own right, and direct Europe Far East and Far East North America services ensued. This strategy was supported by the introduction of ever-larger vessels, fixed day-of-the-week services, speedier turnaround, and faster and more reliable land-based transport connections. The shipping companies also used double stack container trains to extend their reach across North America to link their trans-Pacific and trans-Atlantic services. In the process, shipping companies were transformed into multimodal transport operators (MTOs) with interests in both sea and land transport.

During the 1990s, the MTOs ordered larger ships and formed transnational alliances that allowed the diversification of risks through the joint use of containers, container ships, terminals, feeder services, equipment and inland transport. Although individual alliance members maintained separate marketing identities, these groupings were designed to meet the demands of producers, such as IKEA, Nestlé, Philips, and Wilson Sporting Goods, for a global, door-to-door logistics package. Without the base load provided by these contracts, operators were at a distinct disadvantage and only about 20 of them could operate at this global scale.

Some operators have also taken shares in intercontinental cargo airlines to complement their shipping activities. These activities encompass both the activities of: (a) general cargo carriers handling high-value merchandise and operating on an airport-to-airport basis in collaboration with local freight forwarders, and (b) integrated express carriers, typified by DGS, Federal Express, TNT, and UPS, handling time-sensitive documents, parcels and packages.

The environmental impacts of changes in deep-sea shipping and air cargo driven by global forms of production are less marked than those associated with bulk shipping. Essentially, they are local, being concentrated around international gateways. Plans are afoot to move these gateways to more remote sites. Already, conventional container ports on the east west route are being replaced by a necklace of deep draft, offshore, mega transshipment hubs to accommodate the larger vessels (e.g., Gioia Tauro in Italy, Mina Raysut in Oman, Freeport in the Bahamas, and Manzanillo in Panama). Cargo will be transshipped from these hubs to smaller ports by feeder vessels.

Feeder Systems

Changes in the role of transport within the production process has resulted in the increased integration of intercontinental transport activities with national transport systems, through the optimal development of intermodal transport operations capable of handling intermediate and final product movements. Mega-carriers have linked their intercontinental sea and air container operations, through gateway

hubs, with domestic road, rail, water and air transport systems to seek full efficiency gains as part of just-in-time systems and reduced stockholdings.

This process of integrating national economies into the global market place has been facilitated by the deregulation and privatization of national transport sectors, which hitherto had been used as instruments of regional industrial and social policies. This change has allowed increased foreign participation. Consequently, longer-haul, container freight systems cutting across national borders are being developed through the EU, and the North American Free Trade Agreement. These pan-continental systems are still embryonic in Asia (though progress has been made in China). The full range of cost savings from these multimodal activities between firms operating at a global scale has yet to be attained. Investments in key bottlenecks are still required. Gaps in international transport networks have still to be overcome, particularly in Africa and the Middle East, Australasia and Central and South America. All have utopian plans for integrated transport networks long-distance highways, railways, land bridges and inland waterways to open up their continents.

Over time, there has been a shift towards movements by road and air, at the expense of water and rail transport (trends which the EU is trying to reverse, given the expected saturation of roads and airports). Most growth has been focused on short-distance, frequent delivery, road-based local systems handling final product movements through new logistical systems. Heavier road vehicles have also had an impact in urban areas though their intrusion has been perceived largely in terms of social impacts (noise and safety) rather than as noxious gas emissions. Efforts to mitigate the effects of urban goods movement have included the provision of loading spaces, peak hour truck restrictions, transport corridors to port areas, restrictions on truck size, hazardous material truck routes and urban distribution centers (Ogden, 1992). The proper pricing of freight and passenger road traffic may offer the best way of overcoming conflicts between economic and environmental objectives.

PASSENGERS

Intercontinental passenger services by rail and road are possible between Asia and Europe and Africa, and North and Central and South America. However, air transport has dominated intercontinental passenger movements since the introduction of jet aircraft in the 1960s, which reduced sea passenger services to leisure travel, except for short-distance trips. Air, rail and, on occasions, water transport provide regional connections with intercontinental airport gateways but road transport is important and dominates urban connections.

Air

Intercontinental air passenger traffic patterns, like those of deep-sea liner shipping, exhibited a strong east west pattern of flows along main street in passenger kilometers during 1998 (Figure 5). Again, north south flows are closely linked with hub airports on main street. These gateway hubs include Los Angeles and Miami between North

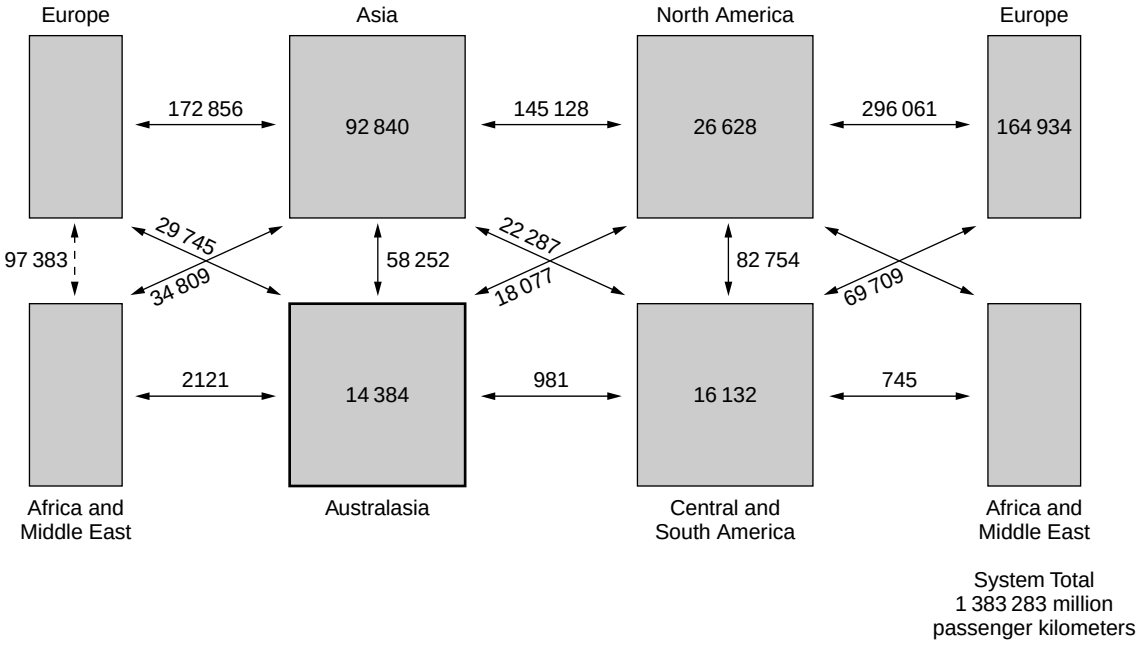

Figure 5 International air traffic on scheduled flights, 1998. (Reproduced using data from IATA, 1998)

and South America; Singapore and, to a lesser extent, Hong Kong and Tokyo between Asia and Australasia; and London, Paris, Rome and Athens between Europe and Africa. The hub function is used by resident airlines to take advantage of economies of traffic density.

There is, however, no freedom of the skies in air transport to match the freedom of the seas in deep-sea liner shipping. Although passenger airlines operate commercially, they do so under a franchise from national governments. Traffic rights are allocated by national governments through bilateral air service agreements established under the 1944 Chicago Convention, and have the status of treaties. While airlines can choose the type of aircraft and schedules, their route structures, seat numbers, number and frequency of flights and seat prices are dictated by these bilateral agreements.

Since the late 1970s, the airline industry has been restructuring to accommodate the demands of multinational corporations for seamless services and greater international social mobility involving migrants and seasonal tourist traffic. As traffic rights are not easily renegotiated, there has been pressure since the 1978 US Airline Deregulation Act from the US government to progressively liberalize the right to fly on specific international routes. There has also been an associated drive to privatize or commercialize national flag carriers still in public ownership. This strategy allows the entry of low-cost carriers and reduces state subsidies. Some airports have also been privatized.

The introduction of progressively larger and faster aircraft since the 1980s, especially the Boeing 747-series and 777-series and the 555 seat super jumbo the Airbus A3XX has promoted organizational changes. Managements have sought to transform their airlines into very large companies or mega-carriers that offer long, non-stop intercontinental flights between metropolitan regions. The corporations have expanded their route networks and dispersed operations to different parts of the globe to meet the greater competition between airlines unleashed by deregulation and the need to increase returns to shareholders.

Globalization, deregulation and privatization have profoundly affected the air industry s workforce as they provide the basis for exploiting an international division of labor, because airlines recruit cabin staff from countries with lower labor costs. Some workers have experienced pressures aimed at cutting labor costs through the threat of outsourcing to meet global industry benchmarks (e.g., catering, maintenance, cleaning, ground handling and information technology). Others have been urged to be flexible and intensify their labor effort through quality programs so that higher productivity and improved service quality can be provided at key points of customer contact.

Further restructuring has occurred as mega-carriers have experimented with strategic alliances to grow globally by evading the myriad of government restraints on access to markets and restrictions on the majority ownership of national carriers. Since the 1980s, alliances have grown ten-fold to number 500 in May 1998. The growth of intercontinental alliances among this number has been slow because of limited progress with deregulation on a global scale, and the difficulties of securing partners in dispersed markets. However, four major global alliances comprising most of the world s top 25 carriers have been formed, which collectively account for half of the world s passenger market. They are Star (12 members including United Airlines and Lufthansa); Oneworld (nine members including British Airways); Atlantic Excellence (three members including Air France and Delta); Qualiflyer (eight members including Swissair); and Wings (four members including Northwest and KLM Royal Dutch Airlines). Although further realignments among alliances are possible, real mergers are still precluded by bilateral regulations.

Global alliances have allowed large carriers, who dominate key airports, to generate hub-and-spoke operations in a more open market, in a way not dissimilar to those in deep-sea liner shipping. Mega-carriers have gained from economies of scale and scope through the expansion of their networks and the use of computer reservation systems to consolidate their market position. Certain airports have been advantaged when they have become most-favored hubs for an alliance. Some air passengers have enjoyed greater convenience and service quality and reduced fares from the restructuring of the airline industry, though gains to other passengers and some workers are less clear. The objective of a seamless service for transferring passengers from one carrier to another still remains a distant goal. It depends on the international air transport network being integrated with urban and regional planning. Much attention is being paid to moving airports from urban areas to mitigate the effects of noise and overcome the problem of curfews.

Feeder Systems

The car dominates interurban trips, with the road to and from the airport being often the most heavily trafficked. Use of rail and air transport increases with the distance and duration of the journey. Car usage hinges on the size of the city-region. The modal split between car and bus/rail depends on the efficiency of the mass transit system and the general policy for land use, parking, traffic control and general infrastructure capacity. This trend towards increased car use in urban and regional areas affects the mix of work and leisure travel. Despite energy and pollution problems, car use has continued to expand, even during periods of high fuel prices. The major task facing planners is safety problems as there are no medium-term problems with energy.

Exceptions are the major metropolitan city-regions where congestion and pollution from traffic are serious issues,

particularly in the suburbs. Traffic calming measures and noise limits have been employed. Urban mass transit and suburban rail transport offer alternatives to some car use for individual transport. If the railways, underground and light transit are to attract passengers from cars, these services not only have to offer low tariffs but high quality services (frequency, speed and comfort). Attractive interurban services are provided by high-speed trains (Japan s Shinkansen and the French TGV). Planners in the EU want to develop regional inter-metropolitan services, typified by Eurostar (Paris Brussels London) and Thalys (Paris Brussels Amsterdam). Separating railway undertakings into track and rail operators would assist the efficiency of this process. Efforts to link integrated railways with regional air transport networks have also been made. Regional air travel has also been assisted by open skies accords within the EU, which match those adopted in North America. These have led to the introduction of low cost airlines in Europe such as buzz, easyJet, Go, Ryanair and Virgin Express.

CONCLUSION

Should transport follow the demands of business and the public? Contradictory pressures are placed on policy makers as we all wish to be protected from transport s environmental nuisances where we live, but want quality infrastructure to save time when we travel. There is no sign of any slackening of long and short-distance transport demand due to economic globalization and leisure travel.

Salvation is still being sought in technological advances. Teleworking and the virtualization of our economies may mean less travel. However, communications technologies may merely complement or encourage further personal transport because there is no immediate substitute for face-to-face contact in transferring complex knowledge. Thus, there is no guarantee that information technology will diminish our use of transport until a saturation level is reached in face-to-face contact (Ciccantell and Bunker, 1998; Nijkamp *et al.*, 1998).

We will still have to reconcile our conflicting aspirations between respecting the environment and meeting economic needs, to achieve sustainable development. There are contrasting opinions as to whether our current global transport system is sustainable. Some think technological developments and building more infrastructure will be sufficient while others, conscious of current traffic trends in lower income countries, do not. Even where the imperative of becoming more environmentally conscious is accepted, many motor vehicle restraint measures to achieve this end are unpopular (e.g., road pricing adopted in Singapore). The challenge will be to make these measures palatable at a political level.

Transport Infrastructure

William Young
Monash University, Victoria, Australia

Transport infrastructure provides the life-blood of our society. Ensuring it is sustained at a high level in the new millennium is essential for our quality of life to continue. Transport provides the ability for people to move (mobility) and to partake in activities (accessibility). It is a derived demand. That is, it provides an opportunity to satisfy another demand. Transport is rarely undertaken for its own sake. It is undertaken to carry out some other task. Within the context of a derived demand, transport is also a service, which can be purchased and used. Notwithstanding the importance of transport in providing quality of life, there are costs associated with its provision. These include: construction and maintenance of transport infrastructure; the opportunity cost associated with the land used to provide transport; the growth of cities and the reduction of agricultural land; road trauma; the use of energy resources; emissions and their impact on human health, the biosphere and the build-up of greenhouse gases; and stratosphere ozone depletion. The trade-off between the bene ts of transport (mobility, accessibility) and it costs (safety, pollution, energy use) cannot be overlooked and must be incorporated into transport decision-making. This paper addresses the global impacts of transport on the environment. It provides a history of transport infrastructure development, emphasizing the progressive improvement in mobility and access. It explores the impact of transport on the distribution of urban activity, energy, greenhouse gas emissions and ozone depletion. The paper concludes with discussion on transport infrastructure policies and how they relate to the environment.

THE BENEFITS OF TRANSPORT INFRASTRUCTURE

Improving mobility and accessibility have driven the development of transport infrastructure throughout human existence. Transport infrastructure has moved through a number of revolutions as people have created new ways of increasing mobility and accessibility. The main improvements have been in speed, comfort, reliability, flexibility, and cost of travel. The transport system most desired by the community dominates at any one point in time. Previous transport modes do not become extinct; their use may persist long after they have been replaced by new technology.

Land Travel

About four million years ago early humans were distinguished from other great apes by their erect walking style. Human creativity enabled them to built crude toboggans in 7000 BC. Draught animals revolutionized transport by dragging loads in 6000 BC. The development of the wheel dates to 3550 BC and two-wheel chariots were used in 2000 BC (McWhirter, 1999).

Roads and Cars

For many years wheeled vehicles moved over open land. Tracks were developed when vehicle movement occurred regularly. The development of roads substantially increased the speed to travel. The development (52 AD) of a road network of over 85 000 km enabled the Romans to move their military vehicles rapidly from one location to another. The Silk Road was forged in 130 AD, running 6400 km between Shanghai and Xian. The Incas (1534) developed an impressive early road system in South America. The development in travel by land allowed the exploration, settlement and development of continents.

In the 18th century, new methods of road building were pioneered in the UK and Europe. A series of layers of stone was used to even out the road surface and increase the speed of movement. Asphalt, a mixture of stones and bitumen, was first used in 1835 in France (Lay, 1992). Traffic lights were first installed in 1868 with freeways, motorways and parkways introduced in the 1900s (McWhirter, 1999). Improved civil engineering construction techniques, materials and design have allowed bridges to increase from spans of 4.3 m (14 AD) to 1780 m in 1998 (Bennett, 1998), and tunnels to increase from 1.0 km in 550 BC, to the tunnel under the English Channel (37.98 km) built in 1994 (McWhirter, 1999). These improvements allow people to move more quickly and to have an increasing set of options available to them, hence improving both mobility and accessibility.

The automobile s history began with the steam-powered gun carriage built by the French military engineer Nicholas Cugnot in 1769. Gottlieb Daimler and Karl Benz built the first petrol-driven internal combustion engine in 1885. By 1895, there were 300 cars manufactured in the US. Mass production of cars was started in 1901. The number of vehicles in the world has grown from 35 million in 1930 to 666 million in 1997. The availability of cars varies across the world. The US had 760 vehicles per 1000 people in 1997. Italy, Canada, Germany and the UK had 575,

557, 536 and 478, respectively (McWhirter, 1999). The flexibility, comfort, convenience, reliability and speed of the automobile have ensured its adoption by many people as a preferred method of travel. People have shown their desire to purchase mobility and accessibility. Moderate long-term economic growth of a few percent a year contributes to a growth in car ownership and mobility (Nijkamp and Perrels, 1991). Clearly there is still considerable potential for growth in car use in countries like China and India, which have only eight and six vehicles per 1000 population, respectively.

Rail

Wheels running on track can be traced back to the Babylons in 2250 BC. The railway was first used in 1681. Its rapid growth in the period 1840 1900 allowed cheap mass transport. This rapid growth occurred because of, and supported a number of developments. The industrial revolution provided the mechanism for building rail infrastructure. Rail allowed the movement of large volumes of workers from suburban home sites to industrial areas. Rail infrastructure began to decline as cheap reliable methods of road travel were introduced.

Pipelines

Aquaducts and pipelines provide an alternative to road and rail for transporting water, gas and oil.

Water Travel

Even in early days, people could ford rivers and reach some islands at low tide. The use of logs, row-boats, papyrus reeds lashed together (3500 BC), sails (3500 BC), improved navigation techniques (first compass 1150; satellites, global positioning systems in the 1990s), steam engines (1800), iron hulls (1850), turbines (1880), hydrofoils (1910) and hovercrafts (1955) have provided substantial increases in speed and facilitated the movement of large numbers of people (McWhirter, 1999). The development of travel by sea allowed the exploration, settlement and development of remote regions of the earth.

Only natural landforms and nature (sea currents, ice, wind), at sea limit the movement of boats. The access to land is constrained by the size, depth, and efficiency of ports. Freight movement has been made more efficient with the introduction of containers and more recently improved work practices and technological innovation (crane design, etc.). Passenger transport by sea has decreased over the last few decades but was the major form of movement between countries separated by sea up until the first half of the 20th century.

Harbors, lakes and rivers facilitated movement within continents. The major transport infrastructure, other than ports, developed to facilitate water travel was canals and lochs. Canals can be traced back to 5 BC, where they were constructed in Iraq. The world s first great canal was China s Great Canal, started in 6 AD and completed in 1283. It was 1700 km long. Canals were introduced in approximately 1760 in the US. Their use grew and more canals were constructed until land based rail systems replaced many of them.

This history of sea travel presents a move towards increased speed (below one knot to in excess of 60 knots (111 km hour$^{\bullet 1}$) presently), increased carrying capacity (below 1 m^3 to over 250 000 m^3 presently), at a decreasing cost per unit moved.

Air

Initially people movement in the air involved balloons (1793). Kites were used in China in 1000 BC, but the first free flight took place in the summer of 1853 in the UK using a glider. The first heavier-than-air flight was by the Wright brothers in 1903. Jet engines were introduced in 1937 and now there are Boeing 747 jumbo jets with a seating capacity of 340 persons, and the possibility of 1000-passenger double deck airbuses being introduced in 2003 (McWhirter, 1999). These improvements are reducing the cost of travel. For instance, in 1945 an air trip between Sydney and London represented approximately 130 weeks work for the average person, in 1998 it took 2.5 weeks to earn the fare. Clearly air travel is increasing mobility and accessibility through increased speed (below 1 km hour$^{\bullet 1}$ to over 700 km hour$^{\bullet 1}$), passenger carrying capacity (one person to over 340 passengers) and decreasing cost per trip.

Recent developments in air travel have moved humans into space. Space travel moved from the first manned space mission in 1961 to regular space shuttles in 1981. Travel in space is allowing the exploration, and ultimately, the settlement and development of other parts of the universe.

These developments provide people with greater choice, and increasing use of air travel indicates that people want this opportunity. In contrast with automobile travel, the movement of airplanes is not constrained by roads, although air traffic is coordinated by air traffic control. The airports provide a major infrastructure constraint and cost. Considerable expense is directed at planning, building and maintaining these facilities.

Communications

Transport enables the movement of people and goods. An important dimension of transport is the facilitation of communication. Substitutes for communication-related travel involve semaphore (140 BC) and telegraph (1844), with teleconferencing, e-mail, internet, world wide web

and facsimile machines revolutionizing communications in the 1990s. Considerable debate is directed at whether communications will decrease the need for travel. Evidence is present on both sides (Salomon, 1998) with the clear conclusion that communications will decrease the need for some travel (e.g., work) but will increase the need for other forms of travel (e.g., freight).

Remarks

The history of transport and communications is categorized by improving mobility and accessibility through increased speed, comfort, reliability and affordability. The desire for increased mobility and accessibility is unlikely to decrease. However, the costs associated with the provision of transport infrastructure, along with the social and environmental costs, may result in mobility and hence accessibility being constrained in some manner. The trade-off between the benefits of transport (mobility, accessibility) and the costs (safety, pollution, and energy use) cannot be overlooked and must be incorporated into transport decision-making.

THE COSTS OF TRANSPORT INFRASTRUCTURE

There is a clear interaction between the world s social, economic and physical environment. A healthy economy facilitates social and physical growth. A healthy social environment encourages economic and physical development. A healthy physical environment provides a basis for sustaining economic and social activities. Within this broad interaction, transport has a direct impact on the distribution of land use and the environment. The interaction between human activity, transport and the environment is shown in Figure 1.

Transport's Interaction With Land Use

Transport infrastructure provides the platform on which travel decisions are made. Activity between land uses generates the trips made on the transport system. For instance, a university may create one trip per day per student, while a shopping center may generate one trip per day for each 100 m^2 of shopping space. The provision of transport infrastructure influences this demand, in that better provision of transport will encourage more people to travel. This influence has been formalized in the context of a law of the road, which states that building more and better quality roads will increase traffic.

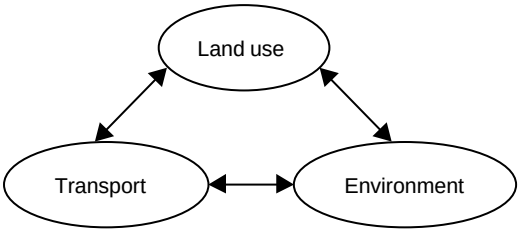

Figure 1 Land use/transport/environment interaction

Equally important is the impact of transport on land use. This comes in two forms. First, the provision of transport takes up land and hence will reduce the amount of land that can be used for other purposes. Some types of transport infrastructure are more land intensive. Secondly, transport influences the distribution of land use. A high speed, flexible transport system allows people to choose from a variety of homes and workplaces. The low-density nature of cities in Australia and North America are consequent on the rapid growth of these cities at a time when residents had ready access to an automobile and a considerable road network.

Hence, the provision of a high quality transport system may result in a decrease in the land available for other activities. Since many cities are often built on prime agricultural land, the progressive spread of cities and the use of land for transport means less high quality land is available for the production of food and flora. The reduction in flora will have a direct impact on the quality of life in cities.

The Impacts of Transport on the Environment

The impacts of transport on the environment are many. These impacts may occur locally or globally. Local impacts may include automobile accidents (including property damage, injuries and deaths), noise, vibration, road trauma, photochemical air pollution (smog), lead pollution, air-borne particulates, visual intrusion, roadside pollution, heavy vehicle movement, and construction. Global impacts are related to the use of arable land, energy, and emissions (as related to climate warming, stratospheric ozone depletion and acid rain). This section will focus primarily of the global energy and emissions questions.

Energy

Transport is one of the many activities that consume energy. Hence when considering energy use, the broad range of consumption activities should be considered. The interactions between the long term creation of energy sources, increases in human consumption of energy, changing population preference, and economic prosperity mean that existing forms of non-renewable energy may eventually disappear or become prohibitively expensive as they become more scarce. For instance, transport accounts for approximately 27% of the total energy consumed in Australia (BTCE, 1991). Road transport accounts for 23.6%, rail

1.3%, air 1.8%, and sea 0.7%. The present increase in fuel use is approximately 2% per annum. If energy usage in transport continues to grow, as predicted, at 2% per annum, fuel consumption will be approximately 50% higher in only 20 years.

The spread of fuel usage is not consistent across the world. Newman and Kenworthy (1989) compared the transport fuel usage in 32 cities. They found that the average resident in a US city uses approximately twice as much fuel as Australian city residents, 4 times that of a European resident and 10 times that of residents in Hong Kong, Tokyo and Singapore. This discrepancy is influenced by the fuel efficiency of vehicles, the private/public transport split, cultural norms, social expectations and the personal mobility of the residents.

Improving the fuel efficiency of cars is a key factor in reducing fuel consumption. Consideration of this can be divided into two parts: reducing the fuel consumption of new vehicles and removing old vehicles from the fleet or improving their fuel consumption. The introduction of vehicles with lower fuel consumption $km^{\bullet 1}$ may reduce overall fuel consumption. General decreases in fuel consumption in European and North American countries are of the order of 1.5% per annum with average levels of approximately 8.0 litres per 100 km travelled (BTCE, 1991, 1996). These improvements in fuel economy are not reflected directly in the consumption of the total car fleet since not all cars are new. Reductions in the fuel consumption of the vehicle fleet of 0.8% have been measured in the same regions as above with the average consumption being of the order of 10 litres per 100 km travelled (BTCE, 1991, 1996).

Even within the context of moving people and goods, transport fuel consumption is only part of the total fuel cycle which also includes: the amount of fuel used to deliver energy to the end use; the generation and transmission losses for electricity; and the energy used in fuel extraction, refining and distribution. In the case of liquid fuels used in transport, adjustment to the full fuel cycle basis is estimated by adding around 10% to the end-use energy consumption.

The desire for travel by motor vehicles is unlikely to diminish because of the quality of the mobility and accessibility it offers, even though the frequency of traffic gridlocks may increase. Hence the method of propulsion needs exploration. Alternate fuels, electrical power or solar power may provide opportunities to reduce energy consumption by cars.

Emissions

Vehicle emissions include carbon dioxide (CO_2), carbon monoxide (CO), hydrocarbons (HC, including methane (CH_4)) and other volatile organic compounds (e.g., aldehydes), nitrous oxides (N_2O), nitrogen oxides (NO_x), lead (Pb), particulate matter of varying composition, and chlorofluorocarbons (CFCs). These can have detrimental effects on humans and the biosphere. These impacts can be local (smog, increasing toxicity, respiratory infections), regional (formation of reactive substances, acid rain, suspended particles reducing visibility) and global (depletion of stratospheric ozone layer, greenhouse effect). Weather conditions (such as wind), sunlight levels (photochemical pollutants) and local geography (such as hills and valleys) complicate the occurrence and reactions involving emissions and their impact on a region. The sources, sinks, health and welfare effects, greenhouse gas impacts, and basic chemical interactions of transport emissions, illustrate the need to consider all pollutants when looking at the impacts of particular changes, not just those relating to the major greenhouse gas (CO_2). The impacts of each greenhouse gas are:

- Equilibrium in the global carbon cycle is necessary for continuous human existence. Urban transport contributes carbon dioxide to the atmosphere. The other contributors are agriculture, commercial firms, manufacturing, mining, and residential. The automobile is the main source of transport carbon dioxide emissions in many countries. Carbon dioxide is non-toxic, but is a major contributor to the greenhouse effect. It can also dissolve to produce acid.
- Carbon monoxide primarily arises from the incomplete combustion of hydrocarbons. Although a rich air fuel mixture produces high levels of carbon monoxide emissions, they are also produced with lean and stoichiometric air fuel mixtures. Carbon monoxide interferes with the absorption of oxygen by red blood cells, impairing perception and muscle response. It has been associated with reduced work productivity through its impact on respiratory functions and circulation.
- Nitrogen oxides (NO, N_2O_2 and NO_2) are created by fossil fuel combustion. Natural sources of such gases are negligible, and motor vehicles create most urban concentrations. Nitrogen oxides are absorbed by plants and are significantly reduced by the use of catalytic converters on motor vehicles. Like CO they are considered an indirect greenhouse gas since they contribute to ozone formation. They cause lung damage and increase susceptibility to respiratory infections. They can damage plants and contribute to acid rain and brown pollutant haze.
- The main sources of CH_4 are fossil fuel combustion, release from coal mining and natural gas distribution, fermentation in livestock, wood fires, release from rice paddies and landfills. The main absorber for CH_4 is the hydroxyl radical, forming carbon dioxide and water. Reduction in concentrations of this radical has

increased the average time CH_4 emissions remain in the atmosphere to 11 years. This may account for current CH_4 levels being double those of pre-automobile days. Methane is a direct greenhouse gas and also acts as a minor ozone precursor.

- Non-methane hydrocarbon emissions have a variety of sources. They are created through incomplete combustion of fossil fuels in motor vehicles, evaporation of fuels in refineries, and in petrochemical manufacturing. Significant levels of non-methane hydrocarbons also come from the evaporation from fuel in motor vehicle tanks, carberators and crankcases. About half of these emissions come from motor vehicles.
- Motor vehicles are minor sources for nitrous oxide (N_2O).
- Sulfur oxides generally occur because of impurities in fossil fuels. Motor vehicle emissions account for about 15% of urban SO_x. These emissions generally stay in the air for about a week before being removed by rain, absorbed by vegetation or consumed by soil bacteria. They cause coughing and aggravate asthma, bronchitis and lung disease. Sulfur oxides are the main precursors to acid rain, which destroys vegetation, acidifies lakes and damages buildings.
- Stratospheric ozone depletion is facilitated by CFCs. These are man-made compounds that are used as solvents, refrigerator fluids, spray-can propellants and foam agents, due to their stability and safety. A major emission source has been motor vehicle air-conditioners. Since they are stable compounds, CFCs have a long atmospheric lifetime, and no natural sinks. High radiation levels are required to decompose the CFCs and release chlorine. In turn, the chlorine reacts strongly with stratospheric ozone, creating the Antarctic ozone hole (*see* several articles in Volume 1, e.g., Stratosphere, Ozone Trends, Volume 1). The Montreal Protocol called for a 50% reduction from the 1986 levels in the use of CFCs, by 1996. CFCs are being phased out in many countries, since current policy is to control losses of CFCs in their use in and servicing of air conditioners. However, the greenhouse contribution of their replacements may still be considerable (*see* several articles in Volume 4, e.g., Environmental Responses: an Overview, Volume 4).

Given the unlikely move towards lower levels of mobility and accessibility, there is a need to reduce emission levels through technological change or changes in fuel use.

BALANCING THE BENEFITS AND COSTS OF TRANSPORT INFRASTRUCTURE

Transport provides mobility and accessibility. These are desirable attributes, and the human race has spent many years trying to improve them. Unfortunately they come at a cost. For instance, increased speed increases the probability of being killed in an accident, traffic noise, emission levels, energy consumption, etc. To reduce these costs while maintaining the desirability aspects of transport is a challenge. The challenge should be seen within the overall constraint of sustainability. Sustainable development means using, conserving and enhancing the community s resources to increase and improve the total quality of life to guarantee the maintenance of ecological processes. In calling for a sustainable transport solution, the scale of the task can be reduced, transport can be made more efficient and/or alternate methods of propulsion can be used. These options can be facilitated by:

A Vision

An overriding vision of the future urban area is required (Black, 1992). A key issue is the development of assessment and evaluation procedures that take into account economic, social, and environmental factors to ensure that the best choices and solutions for the future are made. Some urban development objectives are: cater for population preference, increase efficiency, encourage economic growth, provide equitable access to urban services, reduce energy consumption, and improve the urban environment. It is obvious that there are conflicts amongst these objectives. Decreasing environmental pollution may result in increased energy consumption. Catering for population preference may result in increased urban inefficiency. Trading off these objectives may require putting sustainability into urban development decisions. A clear focus on the main areas of growth in travel (road and air) may also provide a clear direction for such evaluation and policies (BTCE, 1996).

Pricing

A key link between transport infrastructure provision and the demand for its use is the price paid for access to transport. Hensher (1993) points to the need to correctly price the social and environmental costs associated with transport use, in order that transport users may receive signals about the impact of their travel decisions. The BTCE (1996) points to road user charges which recognize the external costs associated with the environment as an effective measure for reducing greenhouse emissions and energy use. Competitive neutral pricing, where each mode bears the full cost of its operation, could be facilitated by road tolls, congestion pricing and road pricing (Taylor and Taplin, 1998).

Integration

The integration of transport and land-use planning, development and use, will ensure more efficient use of transport infrastructure. In countries with strong economies

and flexible social regimes, people often wish mobility and access to desired activities. The appropriate use of the transport system may require an integrated multi-modal view of transport (road, rail, tram, bike, bus, and pedestrian). The development of multi-centered cities with strategically located transport interchanges may optimize transport use. Locating workplaces, activity centers, service and other facilities closer to where people live may increase the sustainability of a city. Urban consolidation may allow more efficient use of public transport use for labor-intensive regional centers. Urban villages could reduce travel through the location of service industries closer to the users.

Technology

Technology can influence the driver, vehicle and road system, resulting in reductions in emissions and energy use. The reduction in fuel consumption has been discussed earlier. Vehicle control mechanisms can also reduce fuel consumption. ITS information systems can reduce travel time and provide information on driving behavior and route choice. Technology change will play a large part in developing a sustainable transport system.

Overlaid on these approaches to developing a sustainable future are people making decisions in a constrained environment. The general community, business, politicians, governments, planners and developers make transport decisions. Further, the ownership, operation and maintenance of infrastructure by the private sector is well underway. The responsibility for developing a more sustainable and equitable transport system lies with all members of the community. They clearly have a role in determining the vision since it is they and their descendants who must live with the consequences of their actions.

U

Urban Climate and Respiratory Disease

Jonathan A Patz
Johns Hopkins School of Public Health, Baltimore, MD, USA

As the 21st century begins, the concern about many local and regional air pollutants has become less acute in the United States, Canada, and other developed nations. The implementation of regulatory measures and the development of cleaner technologies have resulted in the improvement of some indicators of air quality. Many developing countries have a different experience because they have not yet developed or adopted many of the regulatory measures of the industrialized world to reduce the levels of local and regional air pollution (United Nations Environment Programme (1991); World Bank (1997)). However, for both developed and developing nations, evidence is growing that global climate changes, caused by the emission of greenhouse gases may exacerbate the impacts of air pollution on human health and the environment.

HISTORICAL PERSPECTIVE ON AIR POLLUTION

From Local to Regional to Global

Historically, the developed nations have gone through a series of transitions with respect to air pollution problems. By the mid-1800s, the combustion of fossil fuels had fouled the urban environment in industrial cities. At that time, smoke, soot (particles), sulfur dioxide (SO_2), and nitrogen dioxide (NO_2) were the predominant substances of concern. These pollutants caused respiratory irritation, hindered visibility, and blackened buildings. Later, the advent of the automobile introduced the problem of increasing concentrations of nitrogen oxides (NO_x) and volatile organic compounds (VOCs) in the urban environment. As chemical precursors to ground-level ozone, these pollutants resulted in a new type of photochemical smog, consisting primarily of ozone whose formation was catalyzed by sunlight, first studied in Los Angeles.

Following the 1952 disaster in London, England, where a four-day period of smog caused an estimated 4000 deaths (Logan, 1953), it became strikingly clear that local accumulations of air pollution were hazardous. The adage, the solution to pollution is dilution , was fervently followed, leading to the construction of higher smokestacks and the relocation of polluting industries farther away from urban centers. While local air quality benefited from the greater dispersion of pollution afforded by higher smokestacks, problems of regional air pollution, such as acid rain, emerged or were exacerbated.

Acid rain demonstrates the shortcomings of addressing pollution from only a local perspective. The regional problem of acid rain was actually first described in the mid-1800s in reference to the effect of industrial emissions on precipitation in the British midlands. It has long been recognized that acid rain is widespread in northern Europe and eastern North America. By the mid-1980s, roughly half of the sulfuric acid rain falling in eastern Canada originated in the US, just as much of the Scandinavian acid precipitation has been traced to industrialized areas of central Europe and the United Kingdom (Schindler, 1988). Recent studies have led to discoveries of areas affected by acid rain in the western US, Japan, China, the former Soviet Union, and South America.

FOSSIL FUELS: THE COMMON SOURCE OF AIR POLLUTANTS AND GREENHOUSE GASES

Fossil fuel combustion is a common source of emissions of carbon dioxide (CO_2) and the six criteria air pollutants: carbon monoxide, NO_2, particulates, SO_2, ozone, and lead. The use of fossil fuels, particularly gasoline, also releases air toxins, such as benzene, toluene, and VOCs. Fossil fuel combustion produces nearly all of the CO_2 released into the atmosphere from human activities.

Therefore, co-benefits can be achieved by reducing the emissions of fossil fuels that are a common source of criteria air pollutants, air toxins, and greenhouse gases. For

example, if nations abided by the Kyoto Protocol to reduce their emissions of greenhouse gases, what might be the benefits in terms of the effects on human mortality? An interdisciplinary working group examined this question by combining models of energy consumption, carbon emissions, and associated emissions of fine particulate matter (PM). PM has been linked to increased mortality (Dockery and Pope, 1994; Pope *et al.*, 1995). Even at levels below national ambient air quality standards (NAAQS), the presence of PM increases daily rates of cardiorespiratory mortality and total mortality in the US and Europe (Katsouyanni *et al.*, 1993). In children, PM levels also correlate with increased hospital admissions, school absences, and medication use, as well as a reduction in lung function (measured as peak respiratory flow rates) (Bascom *et al.*, 1996).

Under a climate policy scenario approximating that of the Kyoto Protocol (e.g., the US emitting 7% below 1990 levels of greenhouse gas emissions), approximately 700 000 premature deaths due to exposure to PM might be averted annually by the year 2020 as compared with the business-as-usual forecast (Working Group on Public Health and Fossil-Fuel Combustion, 1997) (*see* Business-as-usual Scenarios, Volume 5). This analysis showed the potential near-term co-benefits of long-term policies to mitigate global climate change.

CLIMATE CHANGE AND LEVELS OF AIR POLLUTANTS

Secondary Air Pollutants

Fluctuations in weather have the most influence on pollutants that arise from chemical reactions in the atmosphere. These *secondary pollutants*, such as ozone and acid rain, are derived from a mixture of pollutants directly emitted, which are termed *primary pollutants*. Even with the improving air quality in the US and Canada, urban ozone pollution and regional acid rain persist as problems, and have the potential to be exacerbated if air temperatures increase. Ozone forms secondarily in the lower atmosphere by a temperature- and sunlight-dependent reaction between NO_x and VOCs, precursors of the formation of ozone.

The major source of NO_x in North America is fossil fuel combustion used in transportation and electric utilities. Since 1970, the number of vehicle miles traveled (VMT) in the US has increased at a faster rate than that of the overall population (Figure 1). From 1970 to 1994, car ownership in Canada rose from 310 to 484 vehicles per 1000 people (Last *et al.*, 1998). Transportation is also a major source of anthropogenic VOCs. Other sources of VOCs include incinerators, gasoline vapors, paints and solvents, and some trees, wetlands and other vegetative sources.

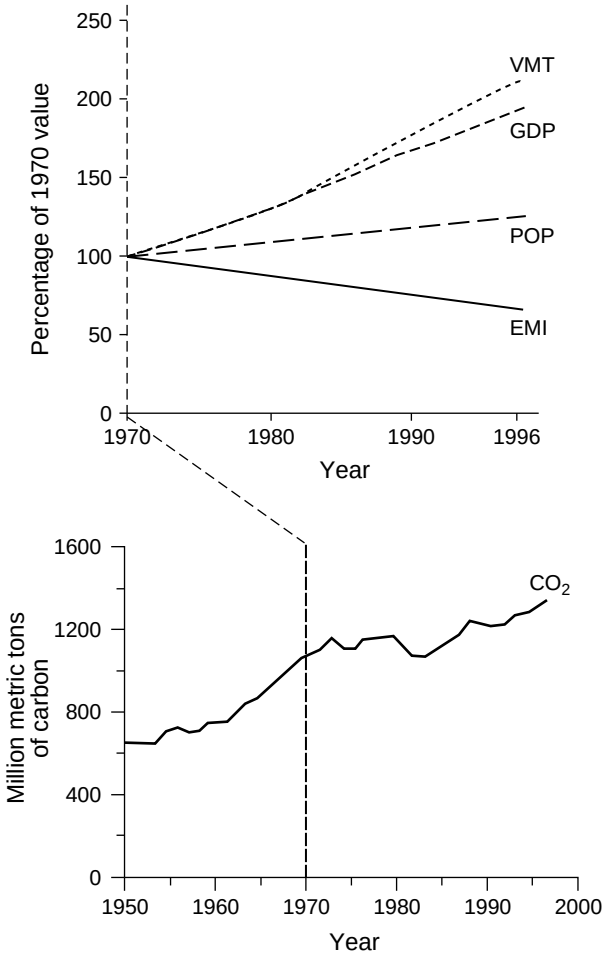

Figure 1 Trends in emissions of criteria air pollutants (EMI), emissions of carbon dioxide, and related factors. VMT • vehicle miles traveled

INFLUENCE OF WEATHER ON OZONE FORMATION

Tropospheric ozone, as a photochemical oxidant and the main ingredient of urban smog, is pervasive and difficult to control. The reaction between NO_x and VOCs to form ozone is catalyzed by ultraviolet (UV) radiation and requires relatively high ambient air temperatures. Meteorological factors that could theoretically influence the levels of tropospheric ozone include UV radiation, air temperature, wind speed, and atmospheric mixing and transport.

In general, there is a direct correlation between temperature and levels of ozone (Kamens *et al.*, 1982; Grey *et al.*, 1987; Samson, 1988). Increases in atmospheric temperature accelerate photochemical reaction rates in the atmosphere and tend to increase the rates at which tropospheric ozone and other oxidants are produced (Morris *et al.*, 1989, 1995). Studies of ambient temperature have reported that successive episodes of high temperatures characterize years

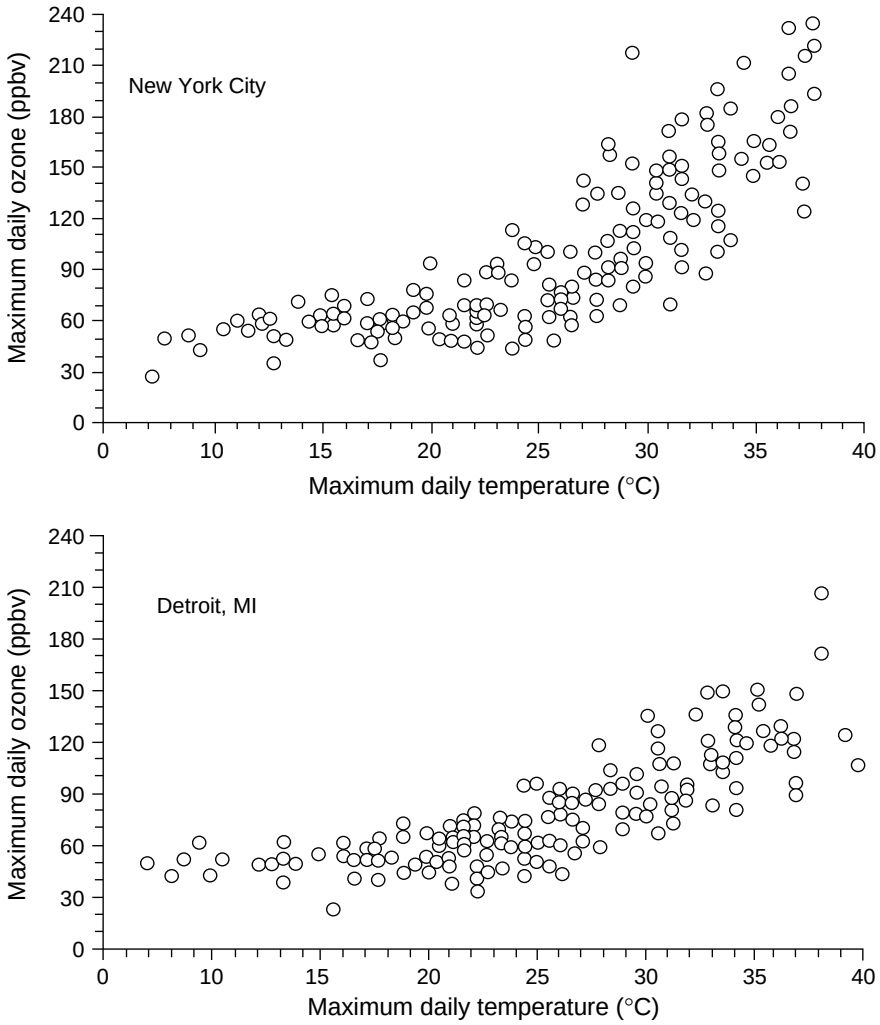

Figure 2 Relationship between maximum daily ozone concentration and maximum daily temperature in two US cities

with seasonally high levels of ozone. The relationship is nonlinear, and above a temperature of 32 °C (90 °F), there is a strong correlation between temperature and levels of ozone (Figure 2). However, levels of ozone may not always increase with an increase in temperature. For example, the production of ozone is reduced when the ratio of VOCs to NO_x is low.

In the eastern US and in Europe, the majority of days when the levels of ozone exceed air quality standards occur in conjunction with slow-moving high-pressure systems around the time of the summer solstice (National Research Council, 1991). This is the period of greatest sunlight when solar radiation is most intense and air temperatures are high. The relatively high levels of ozone in the US during 1988 and 1995 were likely due in part to hot, dry, and stagnant conditions. During 1995, one of the hottest years on record, 32% of Americans, or 71 million people, resided in counties in which ozone levels exceeded the NAAQS (Environmental Protection Agency, 1996). Episodes of high levels of ozone generally last from three to four days on average and extend over a large area, i.e., greater than 600 000 km^2.

Several factors are associated with high-pressure systems that are conducive to the photochemical production of ozone. Large high-pressure systems often create an elevated subsidence inversion of the normal temperature profile, trapping pollutants in the shallow boundary layer at the Earth s surface. Winds associated with major high-pressure systems are generally light, allowing greater accumulation of pollutants. Clear, warm conditions generally associated with large high-pressure systems afford ample sunlight to catalyze the photochemical production of ozone (National Research Council, 1991).

Conditions in Los Angeles illustrate how the combined characteristics of meteorology and topography can adversely affect the air quality. This area is dominated by a persistent high-pressure system off the Pacific Ocean, which forms an elevated inversion layer trapping pollutants over

the city. Topography (river valleys or regions surrounded by mountains) also provides pockets to trap primary pollutants and ozone, often capped by an inversion layer. Due to the region s low latitude and relatively clear skies, plenty of UV radiation is available for photochemical production of tropospheric ozone.

In recent decades, summer climatic conditions in the US may have become more suitable for the formation of ground-level ozone. From 1949 to 1995, the number of summer heat waves (defined as more than three consecutive days with average apparent temperatures exceeding the 85th percentile) increased by 20% (Gaffen and Ross, 1998). Climatic conditions could become more suitable for ozone episodes under projections of global warming, but the extent of ozone formation also depends on air mass and wind conditions.

INFLUENCE OF WEATHER ON OZONE TRANSPORT

Urban smog has long been viewed as a local issue. However, both ozone and its precursors can travel relatively long distances in the atmosphere and can be transported from region to region and across international boundaries. Such processes of transboundary pollution transport have implications for distant downwind populations. Analyses by such groups as the Ozone Transport Assessment Group (OTAG) has confirmed that, in the eastern US, some areas experience a considerable influx of ozone and cannot meet air pollution standards by local measures alone.

The distance that ozone can be transported ranges from 150 500 miles (roughly 240 800 km). For example, ozone precursors from New York City are transported by prevailing winds on a roughly 300-km northeast trajectory through Connecticut and as far as northeastern Massachusetts (Cleveland *et al.*, 1976). Consequently, southwestern Connecticut has the highest concentrations of ozone in this region. The mid-Atlantic and northeastern US are affected by even broader regional ozone transport. While the highest emissions of the ozone precursors, VOCs and NO_x, come from large urban metropolitan areas, the largest elevated point source of NO_x emissions comes from the industrial Ohio River valley (Guinnup and Collom, 1997). Based on spatial patterns and transport considerations, general control measures should clearly target urban nonattainment areas (areas that do not meet NAAQS), as they contribute significantly to their own ozone problems. However, with the Ohio River valley s high density of NO_x point sources, NO_x controls targeted for this region may be an important measure for effectively reducing ozone pollution for the entire eastern US and Canada.

HEALTH EFFECTS OF OZONE

Ozone causes irritation of respiratory and mucous membrane (eyes, nose, and throat). As a strong oxidant, ozone can cause both cellular and structural damage in the lung. Three types of respiratory responses to ozone exposure are: (1) irritative cough; (2) reduced lung capacity, as well as decreased expiratory flow rates; and (3) inflammation of the airway lining or submucosa (Bascom *et al.*, 1996). An inflammatory response usually develops within an hour after exposure and persists for up to 24 hours. Exercise, of course, can increase the dose inhaled due to higher ventilation rates, and the most vulnerable populations include asthmatic children in the northeastern US, where daily ozone levels may remain elevated for six to eight hours (Bascom *et al.*, 1996).

Epidemiological studies of emergency room and hospital admissions indicate ozone s significant health effect. During the summertime (when many viral respiratory infections have subsided), exposure to ozone contributes an estimated 10 20% of all admissions to hospital due to respiratory conditions. On the days with the highest levels of ozone, exposure to ozone can account for nearly half of all respiratory admissions (Environmental Protection Agency, 1996). Even levels below the NAAQS can cause reversible decrements in respiratory function, including airway constriction, reduced lung volume, irritating cough, and chest pain (Bascom *et al.*, 1996).

The effects of chronic exposure to ozone are less well understood. However, an analysis of pulmonary function data from the second National Health and Nutrition Examination Survey (NHANES II) revealed some association between ambient concentrations of ozone and the loss of lung function over time (Schwartz, 1989). Some evidence also suggests that increased incidence and severity of asthma are related to exposure to ozone, although it is difficult to separate the effect of exposure to ozone from concomitant exposure to PM (Environmental Protection Agency, 1996). In Mexico City, ozone has been linked to increased admissions to hospitals for respiratory infections and asthma in children (Romieu *et al.*, 1996). Ozone has been implicated in the exacerbation of asthmatic reactions by reducing the amount of allergen required to induce symptoms (Koren and Bromberg, 1995; Koren and Utell, 1997).

POTENTIAL IMPACTS OF CLIMATE CHANGE ON AIR POLLUTION IN THE US

As population growth and increases in energy consumption lead to increased fossil fuel emissions, the accumulation of CO_2, once thought to be a clean and harmless by-product of combustion, now poses indirect public health and ecological ramifications via global climate change. The change that is

likely to have the most effect on conventional air pollutants is an increase in temperature.

Higher temperatures due to climate change, all other things held constant, may increase concentrations of ozone and acid aerosols, as well as emissions of particulates and allergens (see the section on climate variability, biomass, air quality, and health: forest fires and allergens). A rise in temperature could affect concentrations of ozone by modifying the factors that affect the production of ozone (National Research Council, 1991; Patz *et al.*, 2000), including:

1. Elevated temperature Ozone formation is highly dependent on temperature. Urban areas tend to absorb and hold more heat, a process termed the *heat island effect* (*see* Urban Heat Island, Volume 3). The urban heat island effect can drive up air temperatures by 4 5 °C or more (Landsberg, 1981). The urban heat island may significantly contribute to the chemical formation of ground-level ozone (Quattrochi *et al.*, 2001). Also, NO_x and VOC precursors of ozone are concentrated in congested cities. Urban air quality could therefore be particularly altered by higher global temperatures.
2. Increased frequency and intensity of stagnation periods Climate change could result in more persistent or intense high-pressure systems that provide favorable conditions for the reactions that produce ozone in the atmosphere.
3. Increased water vapor concentration In addition to enhancing the formation of acid aerosols, increases in water vapor can potentiate the formation of ozone (Penner *et al.*, 1989).
4. Increased emissions of precursor pollutants Forests, shrubs, grasslands, wetlands, and other sources of natural hydrocarbons (VOCs) emit greater quantities of these compounds at higher temperatures (*see* Volatile Organic Compounds, Biogenic (VOCs), Volume 2). Soil microbial activity may also increase with warmer temperatures, leading to an increase in NO_x emissions.

On the other hand, factors that could lead to reduced ozone concentrations include the following:

1. Increased cloud cover A more vigorous hydrologic cycle due to global warming could lead to an increase in the frequency of cloudy days. More cloud cover, especially in the morning hours, could diminish reaction rates, thus lowering ozone formation.
2. Increased thickness of the boundary layer of air Higher temperatures might be associated with greater convection, resulting in reduced atmospheric stability and higher wind speeds. If precursor pollutants (VOC or NO_x) are mixed in a greater volume of air, they will be less concentrated and less ozone will be formed (Smith and Tirpak, 1989).

The net effect of these factors is unclear; however, modeling studies combining these variables are being performed to assess the effects of climate change on air quality.

CLIMATE VARIABILITY, BIOMASS, AIR QUALITY, AND HEALTH: FOREST FIRES AND ALLERGENS

Extremes in climate, such as heat waves or severe droughts, are difficult to predict, but are anticipated to become more prevalent under climate change scenarios. Severe droughts with accompanying forest fires have the potential to affect air quality. For example, in 1997 1998, El Nino-driven droughts contributed to the development of expansive forest fires in Indonesia, Mexico, Central and South America, Florida, Canada and several other parts of the world. The extended duration of biomass burning affected air quality over regions far greater than the areas where burning actually occurred. The exposure of humans to fire smoke has been associated with irritation of the throat, lungs, and eyes. In addition, fire smoke carries large amounts of fine particles, which exacerbate respiratory problems, such as asthma and chronic obstructive pulmonary disease (Duclos *et al.*, 1990).

In June and July of 1998, 2277 fires burned approximately 200 000 ha in both rural and urban areas in Florida (Karels, 1998). An analysis of records from several hospitals in Volusia and Flagler Counties showed that visits to the emergency department increased for asthma (by 91%), bronchitis (132%), and chest pain (37%) (Centers for Disease Control and Prevention, 1999).

Another interaction between climate variability and biomass may be found in the release and dispersal of spores and pollen, which can act as allergens. Allergens are not criteria air pollutants, but are included due to their temperature-dependent effect on air quality for allergic people. Pollen counts from birch trees (the main cause of seasonal allergies in northern Europe) appear to increase with increasing temperature (Ahlholm *et al.*, 1998). Pollen counts for Japanese cedar significantly increase in years when summertime temperatures are unusually high (Takahashi *et al.*, 1996; Tamura, 1997). Finally, in the aftermath of flooding, molds and fungi grow on interior surfaces, which can aggravate or trigger airway reactivity among susceptible asthmatics.

Urban Ecosystems

Ian Douglas
University of Manchester, Manchester, UK

Cities are often seen as places where people's lives are most removed from nature, but in many ways, as the consequences of severe geophysical events such as earthquakes and oods demonstrate, they are places where the vulnerability of people to the impacts of extreme climatic and tectonic events is heightened (Douglas, 1999). People and all other living beings in cities indeed are as dependent on nature and the global environment as in any other habitat. Urban settlements are globally important in the environmental context because they house over half the world's people, because they concentrate the burning of fossil fuels and the release of greenhouse gases, and because they are dependent on food and other resources from land and aquatic ecosystems throughout the world. Urban settlements occupy between 1 and 2% of the total land area of the world, and only 11% of the land in crowded England. However, the world urban area is growing rapidly and is often made up of good quality agricultural land that previously supported intensive food production.

There are the same basic kinds of interactions in cities as in other ecosystems. However, those interactions are greatly affected not only by the structures that people have built and the energy they import, but also by people's cultures, behaviors, social organization and economy. In addition, cities cannot provide all the energy, water, food and other materials their people require from the land occupied by the city alone. Cities have to import such things from outside their territory and necessarily export manufactured, used and waste items and substances back out to the rural environment. Thus great cities are biologically parasites in their use of the vital resources, air, water and food. The bigger the cities, the more the demands on the surrounding countryside and the greater the danger of damaging the natural environment host (Douglas, 1983). Thus the importance of urban ecosystems and other human settlements in global environmental change is related less to the area covered with buildings and other structures than to the role of settlement-related activities in promoting land-cover change generally, through land-use change and land-cover conversion to meet the requirements of urban metabolism (Douglas, 1994). Being centers of intense human activity and industry, cities are also nodes of concentrated atmospheric emissions. Per capita emissions of carbon dioxide and many other greenhouse gases tend to increase with urban development, as recent trends in China and India suggest. Thus the functioning of urban ecosystems is a key element in global environmental change.

INTRODUCTION

In many ways, urban areas are just a complicated kind of ecosystem, requiring new interactions among researchers to understand cities as ecosystems. Ecologists, social scientists, economists, and engineers are all involved, along with city, county, state and national agencies. Inevitably, interactions with individual citizens, families and community groups form a major part of the success of any applied urban ecosystem study. All attempts to improve living conditions and the environment of deprived urban areas indicate that no lasting progress is possible without community commitment and involvement.

Three broad views of urban ecology are current. One view sees urban ecology as the study of natural assemblages of plants and animals in the urban environment. Another approach views the city as a whole and examines the broad relationship between the human population, ecologically significant consumption, and the sustainability of essential energy and materials flows (Rees, 1992) (*see* Anthropogenic Metabolism and Environmental Legacies, Volume 3; Ecological Footprint, Volume 3). The third perspective sees urban areas as a series of varied habitats for human beings and other organisms. In urban social geography and sociology this standpoint is sometimes termed *human ecology* (Knox and Pinch, 2000). Cities are sometimes seen as the places where people are the most removed from nature, but in reality they represent a set of habitats to which organisms adjust. Every part of a city has some form of life, and some segments of cities teem with wildlife.

URBAN ECOSYSTEMS HABITATS FOR PLANTS AND WILDLIFE

In terms of the analysis of natural assemblages of plants and animals, urban ecology investigates the biosphere in towns and cities using ecological methods. Although urban growth appears to destroy wildlife habitats and reduce the diversity of flora and fauna (Bridgman *et al.*, 1995), open spaces and food sources in cities provide a great variety of ecological situations that are exploited by particular types of plants and

Table 1 Types of urban land cover and biogeographic conditions

Nature of land cover	Type of location	Nature of biotic zone	Type of urban ecosystem	Trend over time
Paved, roofed, densely urban complexes devoid of open areas of vegetation and water bodies	City central business districts. Large shopping centers and car parks. Some industrial zones	Cliff/organic detritus (Walls of tall buildings are cliff-like. Organic waste may litter streets and other spaces between buildings)	Anthropogenic	Birds and insects develop an increasing number of niches. Micro-organisms colonize
Suburban mosaic of houses, roads, gardens and mature trees	Older, spacious inner suburbs	Old urban savanna	Urbanophile	Already diverse and mature, future changes depend on management
Corridor zones of wild plants	Railway, canal, power line and some arterial road reservations	Grassland/weed complex	Peripheral	Increasing biotic diversity unless interference occurs
Landscaped parks and open spaces	City parks, recreation grounds, golf courses	Mowed grassland	Anthropogenic and modified natural	Careful management keeps biotic diversity low
Derelict land construction sites	Abandoned industrial sites, old waste tips	Abiotic/weed complex	Urbanophile	Temporary opportunities for plant colonization removed when development is completed
New suburbs, devoid of mature trees and high grassland: cultivated/garden ratio	Outer suburban areas, new housing estates, some modern industrial estates and office building complexes	New urban savanna	Urbanophile	Biotic diversity increases as gardens become established. Rate of increase depends on occupants' attitudes
Grassland on reclaimed soil with streets, car parks and buildings but few or no mature trees	Inner city redevelopment areas with large open spaces, modern flats or row houses, some new industrial estates	New urban savanna/mowed grassland	Anthropogenic/ urbanophile	Management tends to preserve low biotic diversity
Small woodland and rural areas within the city	Patches of woodland left as quasi-natural areas, urban commons or heaths	Remnant ecosystem/natural islands	Relict	Old woodland diversity maintained if human interference is not increased
Water bodies	Lakes, rivers and reservoirs	Lake/stream aquatic complexes	Modified natural	Status dependent on management
Wetlands and much modified water bodies	Marshes, sewage farms and gravel pits	Derelict/weedy grassland and aquatic complex	Urbanophile	If neglected, biotic diversity increases. Likely to be much disturbed

Source: Douglas, 1983.

animals. Within each of these urban habitats, equilibrium develops between the colonizing plants and their physical and biological environment.

The nature of the land cover affects the climate, nutrient status and diversity of intra-urban ecosystems, as city habitats and biotic communities may be called. At one extreme is the completely covered, built up central business district, at the other, the relics of the rural landscape in the form of remnant woodlands, bush land, copses, commons and urban heaths (Table 1). Between these two extremes is a gradation from near natural ecosystems to completely artificial ones (Table 2). Only a small part of any urban area is totally paved and roofed; most of it is a mosaic of such impermeable surfaces and vegetated areas. For example, roads and parking lots cover 10% of Los Angeles. The vegetated areas range from carefully tended gardens to patches of derelict industrial land (*brown elds*) and areas of mature trees and shrubs. This floristic diversity is related in part to the nature of the urban soil, much of which is fill or rubble, often highly compacted, on which many native plants have difficulty in becoming established. The plant diversity also reflects the deliberate or inadvertent introduction of exotic species and modification of the plant nutrient status of soils by fertilizers, compost, dumping of wastes. The nature of intra-urban ecosystems is thus partly a function of land management, varying in time and space according to changes in land ownership and land use. The changing, impermanent, patchwork nature of the factors affecting these plant and animal habitats means that no accurate, comprehensive classification of intra-urban ecosystems can be made. Table 1 merely indicates some broad types of urban biotic zones particularly relevant to European, North American and Australian cities.

Trees form a significant part of any urban landscape. Their major benefits vary with situation and climate. In hot climates they provide welcome shade, in windy areas, shelter and in polluted places they help to remove some of the atmospheric contaminants. In urban settings, deciduous trees can reduce dustfall by 27% and intercept 9% of suspended particles in the air. Coniferous trees have even greater capture rates, reducing dustfall by 38% and intercepting 13% of suspended particles (Wheater, 1999). Trees remove other pollutants, such as nitrogen oxides, sulfur dioxide, carbon monoxide, ozone and halogens, although some, especially sulfur dioxide, fluoride and ozone, damage receptor trees. Possibly 5% of total air pollution is eliminated by urban trees in suburban Chicago. Trees also reduce noise, double rows of evergreen trees being highly effective.

Trees use large quantities of water. While this may help to alleviate some urban drainage problems, large trees of certain species can so lower local water tables that settlement of building foundations occurs or roots penetrate drain pipes. Nevertheless, urban forestry is now a major part of city management and for many organizations urban ecology is primarily concerned with trees in cities.

In the US, 80% of the population lives in metropolitan areas and on average, tree canopies from about 75 billion trees cover 33% of this land area. The impact of these urban forests on runoff is of growing interest as efforts to protect water quality focus on non-point sources within urban watersheds. Tree planting is one of several *best management practices* examined in an experimental residential

Table 2 Schemes for characterizing urban ecosystems[a]

Areas used by Simms (1975) to discuss urban birds	Types of urban ecosystem	Urban biocenoses as described by Duvigneaud (1974)	City land use types described by urban geographers
Central business district	Cliff/organic detritus Old urban savanna	Anthropogenic biocenoses	Central business district
Nearer suburbs	New urban savanna	Urbanophile biocenoses	Inner suburbs
Outer ring	Landscaped parkland	Anthropogenic and modified natural biocenoses	Outer suburbs
(1) Estates and factories			Industrial estates
(2) The open spaces			
Edge of the countryside	Remnant ecosystem Natural	Relict biocenose Peripheral biocenoses	Rural–urban fringe
Rivers, lakes and reservoirs	Lake/stream aquatic complexes	Modified natural biocenoses	Water based recreation areas
Marshes, sewage farms and gravel pits	Derelict/weedy grassland and aquatic complexes	Urbanophile biocenoses	Industrial wasteland and wetlands

[a] Duvigneaud uses biocenosis (plural: biocenoses) as a term for a plant and animal habitat that is not necessarily exactly parallel to what most ecologists would call an ecosystem. The emphasis is more on the life support conditions than on specific assemblages of life forms.

retrofit in Los Angeles. The area has been converted into a mini-watershed that retains runoff on site and stores roof runoff for landscape irrigation. Such regulation of urban drainage at source, around the roofs and gardens, on which the rain falls, has major implications for groundwater levels and river flows in and out of urban areas. It would exert some influence on the global flux of water to the oceans if applied on a citywide scale over most major urban areas.

THE METABOLISM OF URBAN ECOSYSTEMS

Cities exist by bringing things together from different places and transforming them into other things. This supply and conversion of food and raw materials involves complicated chains and both good and bad side effects. These materials flows are assisted by monetary changes and by flows of energy and water.

Materials flows through urban areas can be envisaged as part of the global biogeochemical cycling of materials between the lithosphere, hydrosphere, atmosphere and the biosphere. People exploit biogeochemical cycles when they exploit substance stocks and create stocks in the economy, through the materials flows involved in industrial, agricultural and urban activities. This biogeochemical cycling can be conceptually extended to incorporate an urban, or industrial system, in which the urban fabric is added as an additional repository of substances, alongside the lithosphere, biosphere, hydrosphere and atmosphere (Odum, 1971; Douglas, 1983). Indeed, the urban fabric is constantly being renewed, demolition creating a recycling opportunity for crushed concrete to be used as aggregate. The urban fabric can thus be interpreted as the urban deposit (Wilburn and Goonan, 1998), a form of renewable resource, constantly being restocked with new structures. In this way, people s activities are seen as part of the processes changing the earth s surface at geological scales.

The acquisition, turnover, stocking and ejection of materials by human settlements was termed *urban metabolism* by Wolman (1965) (*see* Anthropogenic Metabolism and Environmental Legacies, Volume 3). His classic study concentrated on local problems of air pollution, waste and water supply, but since 1980 the metabolism approach has been extended to a broader concern about the impacts of the materials demands of human settlements on other ecosystems at the global scale (White, 1994). At least since the early 16th century, the European expansion of trade to a global enterprise has witnessed the richer people in the richer countries appropriating global ecosystems to meet the needs of their increasingly urban citizens (Jardine, 1996). Gradually the great cities have become more and more dependent on a wider and wider range of sources of food, raw materials and manufactured goods. No longer are vegetables and fruit seasonal in appearance, the places from which they come simply vary through the year. Thus it can be argued that urban ecosystems need far more land for their support than that which they actually occupy. To that extra area of land must be added land used for waste disposal, water supply and recreation. This land requirement, calculated on a per capita basis for any city, is termed the urban ecological footprint (Rees, 1992 and Ecological Footprint, Volume 3).

Nevertheless, many studies continue to examine urban energy, water and materials fluxes at the whole-city and intra-urban ecosystem scales. The Human Settlements as Ecosystems: Metropolitan Baltimore, Maryland, from 1797 2100 study (Pickett *et al.*, 1999), for example, focuses on surface/atmosphere energy exchange, hydrologic and nutrient flux, atmospheric deposition, the import/export of raw and processed materials and waste products, and fluxes of human populations and capital. It is based on the input/output mass balance concept that has been applied widely in ecosystem ecology. It considers the whole-city scale (sub-regional), and the small watershed scale in order to foster comparison with past, present and future studies of natural and human dominated ecosystems. The urban mass balance equation inevitably includes many fluxes normally not found in ecosystem studies (e.g., inputs of imported food, sewage outputs, fluxes of commodities and money).

URBAN ECOSYSTEMS AS HABITATS FOR HUMAN BEINGS

The city may be examined as a human habitat just as it is a bird or mammal habitat. Human beings have spent virtually all their evolutionary history in rural environments engaged in manual labor. Now more and more of them are engaged in sedentary occupations in cities. While there appears to be little evidence that mankind is ill suited to the life style of cities, there is evidence that some urban environments are quite unsuitable habitats. In the mid-20th century, French country children tended to be shorter, have slower growth rates and reach puberty later than city children. However, although such contrasts could be interpreted in terms of better living conditions and improved diet in cities, the physical superiority of city dwellers mainly arises from the inter-marriage of migrants coming from different parts of France to the cities. Parisian children whose parents were born in Paris were shorter than the children of in-migrant parents.

Human physique, the development of brain cells and mental processes are influenced by both socioeconomic status and environmental conditions. Children in poor housing in Western countries as well as those of squatter settlements in Third World cities may have their physical and intellectual development handicapped by their habitat even though the habitat itself is a result of the social economy of the city. The human environment is sometimes the result of

choice not solely of socioeconomic forces. The clustering of the Pakistani population in cheap but poor housing in certain British cities in the 1970s, for example, was seen as a desire to have surplus funds to repatriate to Pakistan and to gain the advantages of proximity to ethnic organizations and shops.

Little escape from poverty can exist in social systems that confine part of the population to poor housing that itself directly affects human wellbeing through health risks. Lack of basic sanitation in the housing of the bulk of the world s poor creates public health hazards through contaminated water supplies or other sources of pathogen transmission resulting from inadequately treated sewage. Depending on soil and water table conditions, human wastes in some cities may be handled by dug latrines (as in Addis Ababa) or by open ditches (as in much of Jakarta). Such conditions, amplified by crowding, increase the likelihood of many infectious diseases, of which typhoid fever and cholera are only the two best known. In spite of advances in epidemiological techniques, the interaction of these problems of health and housing is so complex that the evidence from empirical studies is by no means conclusive.

Many studies in Western countries indicate that relationships between urban physical environmental quality and many social problems are generally weak. The most important associations between social problems, disease and socioeconomic conditions in the US are links between poverty, sudden death, broken homes, lack of schooling, juvenile delinquency and drug offences. Nevertheless, before these conclusions are extended to other areas, it has to be remembered that living conditions in many deprived areas of American cities are far better than those in the poorest parts of cities in Latin America, Africa and most of Asia. When examining cities as ecosystems, the analyst has to follow a narrow path between environmental determinism and completely social explanations (Douglas, 1983).

Perhaps it is in the field of public health, whose significance for improvements in urban living conditions goes back to at least the early 19th century, that the view of the city as an ecosystem is most practically relevant. A specialist in preventive medicine may identify a death due to chronic bronchitis in a badly heated, poorly ventilated, one room aged person s dwelling as the result of excessive cold. A social worker on the other hand may see the excessive cold as the product of social inequality and a political system unable to cope with the need to redistribute wealth and to ensure adequate health care provision and geriatric services. In this example, the death could have been prevented by a better welfare system, but in the absence of the appropriate support, the victim was vulnerable to extreme cold weather. Analysis of human ecology in urban areas thus requires identification of the interplay of biophysical and social variables and definition of the levels of ecological analysis being pursued in any given enquiry.

One specific usage of the terms urban ecology and ecological analysis has been in the differentiation of residential areas within cities (Knox and Pinch, 2000). Sometimes known as *social area analysis*, this type of analysis generated a debate on people poverty versus place poverty in which attention is drawn to the so-called ecological fallacy of assuming that individuals in a particular area share the overall attributes of that area. The temptation in this analysis is to use readily accessible census data to characterize wards, or even census enumeration or collectors districts within wards, on the basis of such deprivation indicators as lack of a hot water supply, no bath or shower, unemployment, and low car ownership. While clear parallels emerge between patterns of ill health and living conditions in many such analyses, there are substantial differences in the kinds of poor people who live inside and outside areas of major concentrations of poverty. The complications of these delicate analyses and their interpretation should not be allowed to discourage their pursuit. If urban areas are to be made more habitable, and thus if the ideals of the United Nations Habitat Agenda are to be achieved, integrated biophysical and social analyses of urban ecosystems will be required.

CONCLUSION

Cities of all sizes, collectively, occupy pivotal positions in the patterns of global ecology. Cities consciously exclude natural processes, substituting mechanical devices made possible by intensive use of fossil fuels. Rather than using the solar energy continuously falling on their streets and buildings, they dissipate it as excess heat. At the same time, cities import immense quantities of concentrated energy in various forms, most of it derived from petroleum coaxed from the ground in distant landscapes. Urban centers evacuate the water falling upon their roofs and streets as runoff through concrete pipes and channels into the nearest bay or river and, at the same time, bring water in from distant landscapes through similar concrete channels. From other ecosystems throughout the world, cities import nutrients in the form of food, use it once, then send the residues out through pipes as sewage waste and packaging and solid remains are trucked to a convenient landfill or incinerator. Many cities however, have long had traditional rubbish collections for recycling, such as the rag and bone men that once toured London streets, or the rag pickers found in cities like Nairobi and Cairo today, with their modern equivalents of kerb side bottle, paper and can collections or recycling centers in supermarket car parks. Such resource re-use could be greatly increased to slow down the expanding impacts of cities on other ecosystems.

While the ecological footprints and global impacts of this urban metabolism are key elements in global environmental change, for the majority of the world s people who now live in urban areas, the day-to-day characteristics of intra-urban

ecosystems are perhaps more immediately important. Their housing and health conditions are intimately related to local vulnerability to geophysical and technological hazards and to the consequences of poor diet, smoking, lifestyle, educational opportunities and employment. With social differentiation becoming more marked, from China to America, the gulf between the urban dwellers who drive global change through their purchases and their waste generation and the city people who suffer the consequences of increased vulnerability and poor living conditions will inevitably widen. The analysis of global and within-city implications of the functioning of urban ecosystems thus makes a major contribution to the understanding of the factors driving global change and their local consequences.

Urban Heat Island

James A Voogt

University of Western Ontario, London, Canada

The urban heat island (UHI) is the characteristic warmth of urban areas compared to their (non-urbanized) surroundings. Generally it refers to the increase in air temperatures, but it can also refer to the relative warmth of surface or subsurface materials. The UHI is an inadvertent climate change that arises because of atmospheric and surface modi cations in urban areas. Changes to the surface radiation and energy balances lead primarily to reduced cooling rates in urban areas, compared to those of its surroundings. The UHI has important implications for human comfort and health, urban air pollution, energy management, and urban planning. UHIs of cities in hot climates are generally non-bene cial as they lead to larger cooling loads and energy use, increased human discomfort and higher air pollution concentrations. The high rate of urbanization of the world's population, particularly in developing countries, means that increasing numbers of people will be affected by heat islands in these cities. In temperate and cold climates heat islands may provide some bene ts, especially in the cold season because of reduced heating loads, thereby reducing energy use. In these cases impacts of the UHI may be mostly bene cial in the winter, and undesirable in the summer.

UHIs are not responsible for global warming because cities occupy only a tiny fraction of the Earth's surface. Urban climates are a local climate effect, but they do complicate our efforts to detect global climate change, because many climate recording stations have been located in or near cities, and their records may be in uenced by the UHI. Global climate change will add an additional thermal burden to urban areas, accentuating UHI impacts. Whether the relative warmth of a heat island will be enhanced under global climate change is less clear, because of unknowns regarding the speci cs of frequencies of future weather conditions, which exert a strong control on heat island magnitude. Efforts to mitigate UHIs in warm climates have shown promise. These provide not only local environmental bene ts but also result in feedbacks that reduce emissions of greenhouse gases and therefore contribute to mitigation efforts of global climate change. The UHI may serve as a current analog for future global environmental change.

TYPES OF URBAN HEAT ISLANDS

The UHI most often refers to the increase of air temperature, in the near-surface layer of the atmosphere within cities relative to their surrounding countryside. Observations

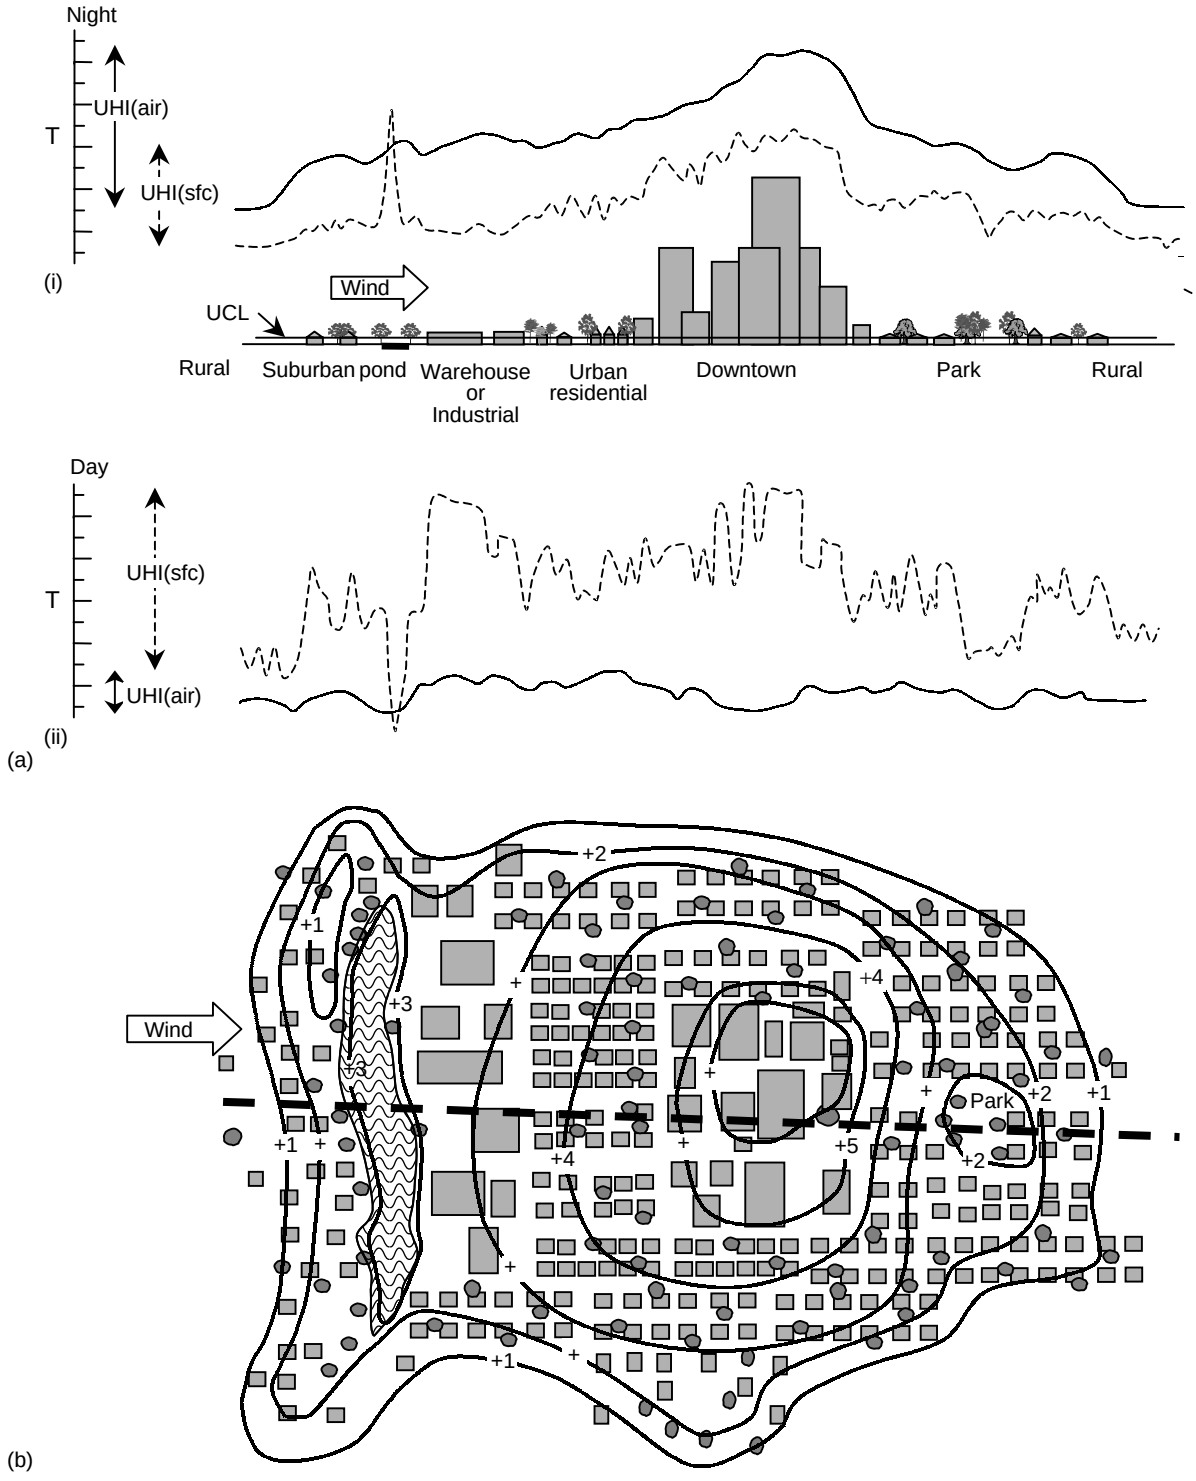

Figure 1 UHI characteristics. (a) Cross-sections of air temperatures measured within the UCL (urban canopy layer) and surface temperatures (e.g., as observed by a remote sensor) under optimum heat island conditions during (i) nighttime and (ii) daytime. (b) Plan view of spatial patterns of air temperature, which make up the nighttime UHI

of most UHIs are derived from air temperature measurements made within the layer of the urban atmosphere below the tops of buildings and trees, known as the urban canopy layer (UCL; see Figure 1a). These observations may be made using networks of fixed stations or from mobile traverses, for example of vehicle-mounted thermometers.

More recently, remote sensors operating in the thermal infrared wavelength region and mounted on aircraft or satellites have been used to observe the surface UHI, with high spatial resolution. These sensors detect radiation emitted and reflected by the surface, rather than temperature directly, so their output is often termed the apparent surface temperature. The temperature may be substantially different from the true surface temperature because of the preferential view of horizontal surfaces by the sensor, reduced transmission of radiation to the sensor by the atmosphere, and the reflectivity of the surface in the waveband of the sensor. The surface temperature is very sensitive to changes in surface conditions, and therefore shows much greater spatial variability and temporal variation between day and night, than does air temperature (Figure 1). Thus, although surface and air temperature heat islands are related, they are not the same, and care should be taken to distinguish between them.

URBAN HEAT ISLAND CHARACTERISTICS

Spatial Characteristics

The UHI is so named because the pattern of isotherms (contours of equal temperature) forms an island shaped pattern. The actual pattern for a given city depends on the configuration of the urbanized area, but typically a large gradient of air temperature forms near the urban rural boundary followed by a more gradual rise to the city core. Within the built-up area, the pattern is influenced locally by surface features such as parks, water bodies and more or less densely built-up areas of the city (Figure 1b). The spatial pattern of isotherms loosely follows the urbanized area, but may show evidence of being transported (advected) downwind. The topographic setting of the city (e.g., a coastline or valley location) may add further complexity to the spatial characteristics of the UHI, as topographic effects (e.g., sea breezes) interact with urban effects.

An overall measure of the magnitude of the heat island is the heat island intensity; the difference between the background rural and highest sustained urban air temperature. This definition avoids uncharacteristically large (or small) heat islands that could result from localized anomalously cool (warm) rural and warm (cool) urban measurements.

HEAT ISLAND FORMATION

Temporal Development

UHIs are primarily nocturnal features that arise as a result of differences in the cooling rates between urban and rural areas. Differences in the cooling rates are greatest when skies are clear and winds are light. Heat island intensities generally increase with time from sunset although exact timing of the peak value may vary depending on weather conditions and season (Figure 2). In some cases, negative heat islands or cool islands, may characterize some inner-city urban areas in the middle of the day due to the slow uptake of heat by the city and large shaded areas from tall buildings.

The temperature differences created by a strong UHI can influence local circulation patterns when regional-scale winds are light. A heat island circulation, similar to a sea breeze, may be initiated, with a low-level inflow towards the city center from outlying rural regions, rising air over the city, and a return flow aloft towards the rural areas. Advective (horizontal) transport of heat, humidity and pollutants by these circulations can have important implications on the dispersion of pollutants in and around urban areas and on the development of the UHI itself.

Formative Factors

The differences in cooling rates that underlie the formation of the UHI, are influenced by surface characteristics and atmospheric conditions. Direct addition of heat to the atmosphere through human activities, known as anthropogenic heat, can also play an important role in heat island formation. Typically, anthropogenic heating tends to be greatest

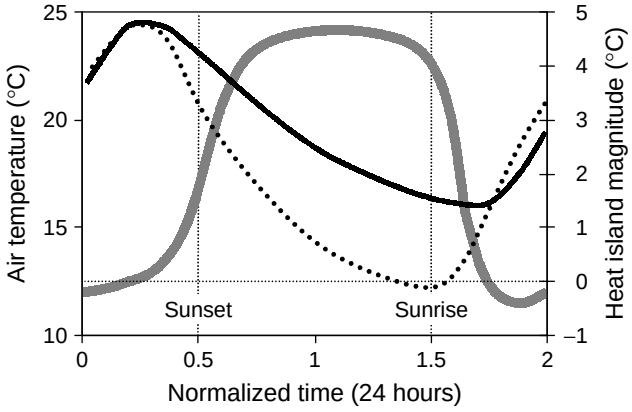

Figure 2 Typical diurnal development of urban and rural air temperatures (thick lines), and heat island magnitude (thin line) under clear and calm conditions. Results will vary depending on the climate region and season. (Adapted from Oke, 1982)

in the winter season in cold climates because of the need for space heating, but the magnitude of anthropogenic heating is affected by intensity of energy use, power generation and type of transportation system in the urban area (Taha, 1997).

Surface Controls

The primary surface controls for most UHIs are surface geometry and surface thermal properties (Oke *et al.*, 1991). Surface geometry refers to the obstruction of the sky by buildings and other objects on the urban surface expressed through a term known as the *sky view factor* (SVF). The reduced SVF of many urban surfaces, particularly those on the ground between buildings, restricts their ability to lose heat by radiative transfer, because the cold radiative sky is replaced by relatively warm surfaces of buildings, trees etc. Surface geometry may also provide a sheltering effect that reduces convective heat losses. Decreases in SVF almost always lead to increased UHI intensity: although if buildings are very closely spaced, shading may reduce absorption of solar radiation during the day sufficiently to produce a cool island.

Surface thermal properties, especially thermal admittance (μ) control the uptake and release of heat by the surface and subsurface. Dense or wet materials such as metal, stone, saturated clay soils, are easily able to absorb and release heat (high μ). Dry and less dense materials with good insulating properties such as wood, sand or aerated concrete have low μ values. Conditions favorable for large UHIs exist where and when the urban area is characterized by relatively dense building materials (and therefore larger μ) and the rural area by smaller μ (dry surfaces). Seasonal changes in the value of μ often affect rural areas, and highlight the importance of remembering that the UHI is a difference measure. Model simulations and observations suggest that the heat islands of humid tropical cities may be expected to be small because of large rural μ values, whereas tropical dry cities may have larger heat islands (see Table 1).

Table 1 Suggested causes of the UHI[a]

Cause	Description
Surface geometry	Increased surface area and trapping of solar radiation by multiple reflections leads to warming due to greater absorption of solar radiation Closely spaced buildings reduce the sky view factor and reduce radiative heat loss, particularly at night Sheltering of buildings reduces convective heat loss from the surface and near-surface air
Surface thermal properties	Urban building materials are better stores of heat; they have higher heat capacity, and larger surface thermal admittance
Surface conditions (dryness, snow cover)	Waterproofing of the urban surface by buildings and pavement reduces evaporation; more energy is channeled into sensible heat that can heat the air rather than into latent heat (heat taken up by evaporation of water) During periods of snow cover, plowing of city surfaces and increased soiling of urban snow cover can yield increased absorption of radiation in the city
Anthropogenic heat	Heat released by urban energy use in buildings and vehicles and from humans
Urban greenhouse effect	The polluted and warmer urban atmosphere emits more thermal radiation downwards towards the city surface. Enhanced urban humidity may also contribute to this effect

[a] Adapted from Oke (1982); Oke *et al.* (1991).

Atmospheric Controls

The primary atmospheric controls on UHI development are wind and cloud (Table 2). The strongest UHIs are observed when skies are clear and winds are calm. A clear sky enhances rural cooling by allowing radiative heat losses to the relatively cold night sky. As wind speeds increase, turbulent mixing exponentially reduces temperature differences in the near surface air. Atmospheric humidity acts similarly to clouds by reducing the net radiative cooling potential of the surface. High atmospheric humidity will reduce heat island intensity; lower humidity allows greater surface radiative cooling.

Advection is also an important control on UHI intensity. For example, with onshore winds, coastal cities may experience advective cooling of urban temperatures in the summer season when sea surface temperatures are cooler than those of the land, and advective warming during the winter season when the sea surface temperature is relatively warmer. Under such conditions, it is important to assess the relative impact of advection on both the rural and urban stations, because the UHI is a difference measure. Local-scale advection induced by heat island circulations can also modify local temperatures and humidity and alter cooling rates.

Table 2 Atmospheric controls on UHI magnitude

Control	Effect
Wind speed	Increased winds increase turbulent mixing, suppress UHI magnitude
Wind (advection)	Horizontal transport of heat: warm advection can enhance UHI, cold advection may suppress UHI[a]
Cloud	Cloud reduces radiative cooling by the surface Low, thick clouds have the largest effect (warmer), high thin clouds the least
Humidity	Variable effects

[a] Effects depend on the spatial extent of advection and the rural and urban measurement locations.

Heat Island Intensity

Combining the most favorable atmospheric and surface conditions, the maximum observed heat island magnitudes are approximately 12 °C (Figure 3). The maximum heat island intensity can be related to city population, but is more fundamentally related to surface characteristics such as the SVF. More typically, heat island intensities are in the range 1 3 °C, even for large cities, indicating the importance of wind and cloud effects. Seasonally, heat islands in temperate climates are a maximum during summer and fall when weather conditions are more favorable.

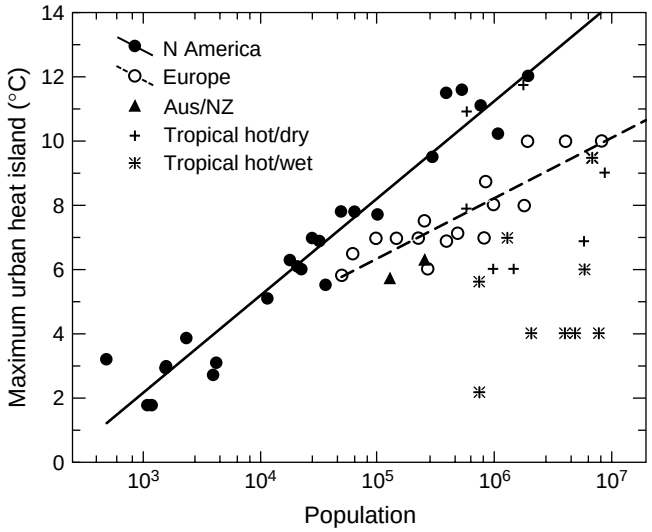

Figure 3 Maximum UHI magnitude plotted versus population. Slope of the relationships differ for cities in different parts of the world depending in part on the urban characteristics, the characteristics of the rural surroundings, and the prevailing climate. (Reproduced from Oke (personal communication))

IMPACTS OF UHI

Local Impacts

UHIs can provide both positive and negative effects for cities (see Table 3). For cities in warm climates, or temperate climate cities in the summertime, the UHI increases the use of energy for air conditioning (Figure 4a). The increase in utility demand can feed back to increase emissions of greenhouse gases used to generate electricity, which can further enhance the need for cooling, and also degrade local air quality. Higher urban temperatures can increase the formation of urban smog because both emissions of precursor pollutants and the atmospheric photochemical reaction rates, which produce smog, are enhanced (Figure 4a) (*see* Urban Sulfurous and Photochemical Smog, Volume 3). During heat waves, especially in temperate areas, the UHI effect exacerbates heat stress, particularly at night (Figure 4b). Further health implications arise from the fact that urban warmth provides a preferential site for spread of vector-borne disease.

In colder climates, UHIs may yield positive effects such as reduced energy use in the cold season, reduced length of snow cover, and a longer growing season.

Global Impacts

UHIs themselves are not responsible for global warming; they are a local climate modification, and altogether urban areas comprise less than 0.25% of the Earth s surface area (Sagan *et al.*, 1979). However, UHIs do have global impacts in other ways. Many of the long term observing stations used to construct the globally averaged surface temperature record have been subject to urbanization over their period of record. The effect of the UHI can lead to a contamination of the long-term temperature record, where the ability to detect global climate change is made

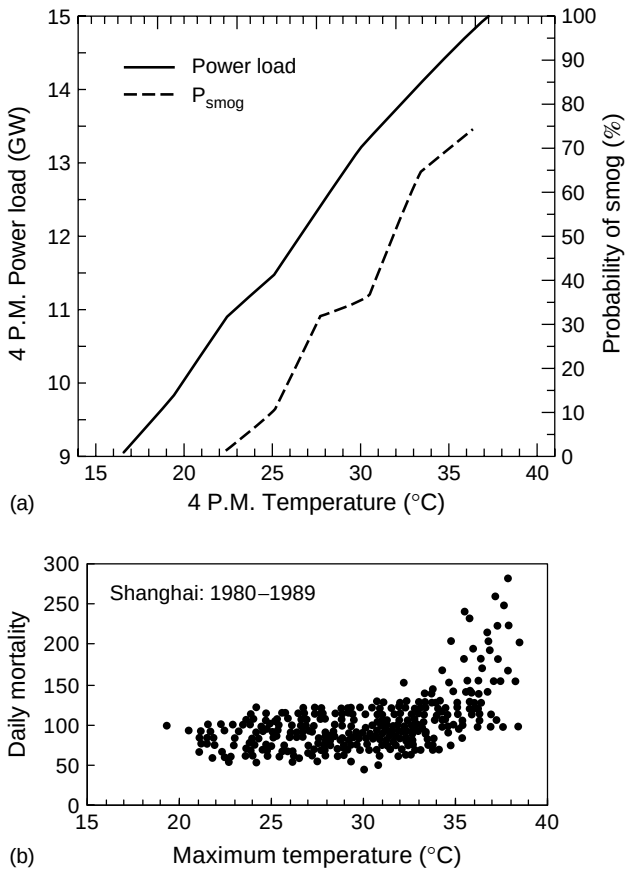

Figure 4 Impacts of warmer urban temperatures on (a) peak power load and probability of smog (reproduced by permission of Elsevier Science from Rosenfeld *et al.*, 1995) and (b) mortality (reproduced by permission of Birkhäuser-Verlag from Kalkstein and Smoyer, 1993)

more difficult because of the superposition of local climate effects. Current techniques (e.g., Karl *et al.*, 1988) used to remove urban effects may be inadequate (Oke, 1997; Changnon, 1999).

Urban areas are also the sites of most of the greenhouse gas emissions that contribute to global climate change. Emissions originating from urban areas contribute to both local and global climate modification. About half of the world s population currently lives in cities and this value is expected to increase to 61% by 2030 (UNPF, 1999). The most rapid rates of increases are occurring in the developing world (UNEP, 2000) where UHIs yield primarily negative impacts. Further urbanization will increase the area of altered local climates, the fraction of emissions originating from cities, and the number of people affected by UHI.

UHI as an Analog for Global Warming

The climate modifications that occur within urban areas may be used as an analog for examining changes anticipated from global climate change (Oke, 1997); many large cities have undergone substantial warming over the past 100 years due to local climate modifications arising from urbanization. These modified urban climates show similarities in terms of the rates and magnitude of climate change expected with projected future climate changes, and therefore cities may provide important laboratories for assessing impacts of, and adaptation strategies to climate change on both local and global scales (Oke, 1997).

MITIGATION OF URBAN HEAT ISLANDS

Reducing the magnitude of the UHI through various mitigation strategies is possible. Strategies that have received the most attention include the use of trees and vegetation to shade the surface and provide evaporation cooling, and increasing the reflectivity of surfaces such as roofs to reduce the amount of solar radiation absorbed (Rosenfeld *et al.*, 1995) (*see* Greening of Cities, Volume 3). Mitigation of the UHI can provide benefits in terms of improved air quality and human health through reduced energy use, and generally improved human comfort, particularly in cities with warm climates.

EFFECT OF GLOBAL ENVIRONMENTAL CHANGE ON URBAN HEAT ISLANDS

Finally, one might reasonably ask how UHIs may themselves be altered under anticipated global climate change. The answer to this question is not clear; the formative factors underlying the UHI will continue to operate, albeit from a warmer ambient temperature base. So we may reasonably expect UHI to continue, and to expect that cities will be warmer than they currently are. It is unlikely that the intensity of the heat island will increase with global warming because the temperature gradient between city and country is expected to remain similar. Further assessment of how the frequency of strong versus weak UHIs may change under future climates requires detailed knowledge about the type and frequency of future weather patterns expected for a given location, because of the strong controls exerted on the UHI intensity by weather factors. This information is poorly known at present. At best it seems reasonable to expect that, under future climates, cities will be warmer than they are now with the combined local impacts of the UHI and global environmental change, contributing negatively to the environment of future urban areas in warm climates, and the summer conditions in cities in cold climates, but with a possible overall benefit in temperate and cold climate regions. The high rate of urbanization, particularly in tropical cities, means that increasing numbers of people will be exposed to impacts resulting from UHI in the future.

Urban Population Change

David Satterthwaite
International Institute for Environment and Development, London, UK

By 2000, the world's urban population totaled some 2.8 billion people - a near four-fold increase in size since 1950 (United Nations, 2000) and a more than 10-fold increase since 1900 (Graumann, 1977). The proportion of the world's population now living in urban centers is close to 50%, having risen from less than 30% in 1950 and less than 15% in 1900. It is likely to exceed 50% within the rst decade of the new millennium (United Nations, 2000). Many aspects of urban change are unprecedented, including the size of the world's urban population, the number of countries becoming more urbanized and the size and number of very large cities.

It is important to understand these urban trends in terms of the very large economic, social, political and demographic changes that have underpinned or in uenced them. Foremost among these is the much increased scale in the world's economic activities and the shifts this has brought in employment patterns, from agricultural and pastoral activities (highly concentrated in rural areas) to industrial, service and information activities (highly concentrated in urban areas). The globalization of world production and trade (including the very rapid expansion in the value of international trade) has been an important part of this and has in uenced urban trends in most nations. Many cities owe their prosperity to key roles within this increasingly internationalized production system, including the world cities (see section on world cities herein). There are also the demographic changes that so in uence urban change, including rapid population growth rates in much of Latin America, Asia and Africa after World War II (although in most cases these have declined signi cantly) and changes in the size and composition of households and age structures (UNCHS (Habitat), 1996).

There are also many political changes that have had profound in uences on urban change in the last 50 years in many nations, especially the dissolving of the European powers' colonial empires that helped underpin rapid urban change in most of Africa and Asia between the 1950s and the 1980s, and, more recently, the dissolving of the Soviet Union and its economic bloc and the breaking up or reshaping of many nations in Europe. Wars and civil con icts in Europe and Africa have brought major shifts in populations; the number of international refugees has risen to unprecedented levels and a considerable proportion have come to live in cities, either for refuge or to seek new bases for their livelihoods (Castles and Miller, 1993). Changed political structures and economic policies have also brought major

urban changes in many other areas - notably in China with its very rapid economic growth and urban change since the late 1970s. In much of Latin America, urban systems and trends have been reshaped during the 1980s and 1990s by the introduction of or return to democratic rule, the shift in economic policies from import substitution to export promotion, serious economic problems and, in many nations, decentralization and stronger democracy at the level of local government. Thus, while we can discern broad trends towards increasingly urbanized societies in much of the world, the scale and nature of such trends and their underlying causes differ very much from country to country and even within each country, regionally and over time. In looking at global change, it is important not to forget how unique social, economic, political and demographic structures are in uencing urban change within each location.

INTRODUCTION

Despite the long-term trend towards more urban societies, more than half the world s population still lives in rural areas and a significant proportion of the urban population lives in small administrative centers and market towns in which much of the workforce depends on agriculture or on enterprises serving rural populations. Only a very small proportion of the world s population lives in very large cities (see section on the world s largest cities herein). Despite the speed at which urban populations have grown, there is also a perhaps surprising continuity among the world s most important cities. As the section herein on the regional distribution of the world s urban population will describe in more detail, most of the world s largest cities have long histories as important cities, and most such cities have also experienced significant slow-downs in their rate of population growth. Many had more people moving out than moving in during the last recorded inter-census period. And for many nations, the speed with which they urbanized slowed down during the 1980s, in part because of serious economic problems. The world in 2000 is less urbanized and far less dominated by very large cities than most people had predicted. For instance, Mexico City likely has around 18 million people by 2000 not the 31 million people predicted 20 years ago. Calcutta likely has around 13 million, not the 40 50 million people that was predicted during the 1970s.

We also know little about the scale and nature of urban change in recent years. For most nations, the most recent figures available for urban populations come from censuses held in 1990 or 1991, and we have little idea of the scale of urban change within nations and the growth (or decline) of city populations since then. This is why data on city populations in the tables in this article are for 1990. The scale and nature of urban trends during the 1990s will only become apparent when new data become available for censuses held in 2000 and 2001. All regional and global figures for 1995 or 2000 are therefore estimates made by extrapolating trends from the 1980s. For many African nations, there is no census data for the last 15 20 years so even regional data for 1990 may be inaccurate. There is also the fact that each nation uses different criteria regarding how it defines its urban population (or distinguishes urban centers from other settlements), which means that the scale of the world s urban population is strongly influenced by the urban criteria used within the largest population nations. If the Indian or Chinese government chose to change the criteria used in their censuses to define urban centers, this could increase or decrease the proportion of the world s urban population by several percentage points and there are good reasons for thinking that the current criteria used in China considerably understate the size of its urban population (Kirkby, 1994). Revisions by, for instance, the Nigerian or Brazilian census authorities could significantly alter their region s level of urbanization. Thus, the world s level of urbanization is best understood not as a precise figure (47.4% in 2000) but as being between 40 55%, depending on what criteria are used to define an urban center.

Another source of uncertainty regarding urban change arises from the different ways in which large city boundaries can be defined for instance, is a city s population that which is within the city proper, the built up area, the metropolitan area or a wider planning region? The current population of most of the world s largest urban areas, including London, Los Angeles, Shanghai, Beijing, Jakarta, Dhaka and Bombay/Mumbai can go up or down by many million inhabitants, depending on which boundaries are used to define the area within which their population is counted (Satterthwaite, 1996; UNCHS, 1996). Different boundaries also mean different population growth rates so London, Los Angeles, Tokyo, Buenos Aires or Mexico City can be correctly stated as having populations that have declined or expanded in recent decades, depending on which boundaries are used. This is why any international list of the world s largest cities and their population growth rates risks considerable inaccuracy, as some city population figures are for large urbanized regions with thousands of square kilometers while others are for older city boundaries with a few hundred square kilometers.

THE REGIONAL DISTRIBUTION IN THE WORLD'S URBAN POPULATION

Most of the world s urban population is now outside Europe and North America (Table 1). Asia alone contains close to half the world s urban population, even if more than three-fifths of its population is still in rural areas. Even Africa, which is generally perceived as overwhelmingly rural, now

Table 1 Some basic urban statistics

World	29.7	45.3						

The statistics for 1950 and 1995 were taken or derived from data in United Nations (1998). The data on the distribution of the world's 100 largest cities is an updated version of a table taken from Satterthwaite (1996).

has a larger urban population than either North America or South America.

Levels of urbanization in certain regions increased dramatically between 1950 and 1995 (Table 1) for instance, in Africa from 15 31%, in West Asia from 27 68% and in Eastern Europe from 39 70%. However, the growth rates of urban populations and the rates of increase in levels of urbanization are not unprecedented (Preston, 1979; Satterthwaite, 1996) Many countries in West Europe or North America had periods when their level of urbanization increased as rapidly. In addition, many cities in North America figure among the world s fastest growing cities during the 20th century (see section on world s most rapidly growing cities herein).

It is also important not to assume that the factors underlying urban change are comparable across time or across nations. For instance, one of the main reasons why many cities in Africa grew so rapidly during the 1960s and 1970s was that they began from such a small base, because the European colonial powers had kept down their populations by imposing restrictions on the rights of their national populations to live and work in urban centers. Thus, one of the reasons why urban populations grew so rapidly just before or after the end of colonial rule was the removal or weakening of the colonial apartheid-like controls on population movements (see Potts, 1995). Another reason why the urban population of many sub-Saharan African cities grew so rapidly during the 1960s and 1970s was the achievement of political independence and the development in their urban centers of the institutions associated with an independent state and the development of a higher education system that had been so undeveloped under colonial rule. A third reason was the division of what, under colonial rule, had been one country into two or more, with each new country needing a capital (Bairoch, 1988).

Data on how the regional distribution of the world s 100 largest cities has changed from 1800 through to 1990 (Table 1) show how, historically, Asia has always had a high proportion of the world s largest cities, and that South and Central America and North Africa also have long had large cities (Chandler and Fox, 1974; Bairoch, 1988). By 1990, Asia had 44 of the world s 100 largest cities and this proportion is likely to increase. In most of the world s regions, there is a perhaps surprising continuity in the list of the largest cities over time. An analysis of population trends among what are currently the world s largest cities found that more than two-thirds of the world s million-cities in 1990 were already important cities 200 years ago while around one-quarter have been important for at least 500 years (Satterthwaite, 1996). This analysis also showed

a perhaps surprising comparison in that it is North America and sub-Saharan Africa that stand out as having most new cities among their largest cities, i.e., cities that now have more than a million inhabitants that had not been founded or did not exist as urban centers by 1800 (ibid). Table 1 also highlights how few of the world s largest cities Europe had in 1990, unlike in 1900 when it had more than half the world s 100 largest cities. In part, this reflects the growing economic importance of other regions. But in part, it reflects the way that urban form has changed with much of the working population of European cities not living within city boundaries.

THE WORLD'S LARGEST CITIES

Most of the world s largest cities had relatively slow population growth rates during the 1980s (Table 2); more than half had growth rates of less than 2% a year. Many of these cities had more people moving out than moving in (so their population growth rate was lower than their rate of natural increase) including Mexico City, Sao Paulo, Calcutta, Buenos Aires and Rio de Janeiro. Among these 30 cities, only two had a population growth rate that exceeded 5% a year during the 1980s Dhaka and Lagos and the estimate for Lagos is probably too high (the 1991 census suggested a much lower population growth rate). However, as Table 2 shows, very large cities with relatively modest population growth rates can still have large annual average increments in their populations.

One notable change in recent decades is the scale of the world s largest cities and the size to which they have grown is unprecedented. While there are examples of cities over the last two millennia with populations of one million or more inhabitants, the city or metropolitan area with several million inhabitants is a relatively new phenomenon, London being the first to reach this size in the second half of the 19th century (Chandler and Fox, 1974). The average size of the world s largest cities has increased considerably. In 1990, the average size of the world s 100 largest cities was around 5.1 million inhabitants. This compares to 2.1 million inhabitants in 1950, around 700 000 in 1900 and just under 200 000 in 1800 (Satterthwaite, 1996).

Table 2 The world's largest urban agglomerations in 1990

Urban agglomeration	Population (thousands – 1990)	Annual average growth rate 1980–1990 (%)	Annual average increment in population 1980–1990 (thousands)
Tokyo	25 069	1.4	322
New York	16 056	0.3	46
Mexico City	15 130	0.9	124
Sao Paulo	15 082	1.5	214
Shanghai	13 342	1.3	160
Bombay/Mumbai	12 246	4.3	418
Los Angeles	11 456	1.9	193
Buenos Aires	11 144	1.2	122
Calcutta	10 890	1.9	186
Beijing (Peking)	10 820	1.8	179
Seoul	10 544	2.4	226
Osaka	10 486	0.5	50
Rio de Janeiro	9682	1.0	94
Paris	9334	0.4	40
Moscow	9048	1.1	91
Tianjin	8786	1.9	152
Cairo	8633	2.3	178
Delhi	8207	4.0	265
Manila	7968	3.0	201
Karachi	7945	4.7	292
Lagos	7742	5.8	336
London	7653	(0.1)	(9)
Jakarta	7650	2.5	167
Chicago	6792	0.0	1
Istanbul	6544	4.1	215
Teheran	6360	2.3	129
Essen	6353	0.0	2
Dhaka	6219	6.8	301
Bangkok	5901	2.3	118
Lima	5826	2.8	143

Although there is a large and growing literature on what are termed mega-cities (Rakodi, 1997; Gilbert, 1996; Lo and Yeung, 1996), which is well justified by the problems faced in managing such large population concentrations and by their key economic and political roles, two points should be noted: the very small proportion of the world s population that actually lives in them and the extent to which they are concentrated within the world s largest economies.

There is no agreement as to the definition of a mega-city but if a city becomes a mega-city only when it has 10 million or more inhabitants, there were only 12 mega-cities by 1990 and these included less than 3% of the world s population. The association between the *per capita* gross national product (GNP) of a country and its level of urbanization is well known i.e., that in general, the higher the *per capita* GNP, the higher the level of urbanization. Most of the nations with the most rapid increases in their levels of urbanization 1960 to 1990 were also the nations with the most rapid economic growth. What is perhaps less well known is the high concentration of the world s largest cities in the world s largest economies. In 1990, the five largest economies (US, China, Japan, Germany and the Russian Federation) had half of the world s mega-cities and 37% of the world s million-cities (Satterthwaite, 1996). All but one of the world s other mega-cities were in the next 10 largest economies which also concentrated close to one-quarter of the world s million-cities.

THE WORLD'S MOST RAPIDLY GROWING LARGE CITIES

Although the historical continuity in the world s largest cities was noted above, there are many important cities today that did not exist in 1900 or were only very small settlements. In some nations, the emergence of new large cities is fundamentally changing the spatial distribution of urban populations. For instance, in the US, what was originally considered as de-urbanization in the 1970s and 1980s was in part the emergence of new very large cities in the South and West which came to challenge the size and economic importance of the large Eastern cities (Bourne, 1995).

Very large cities rarely figure in lists of the world s most rapidly growing cities, although they inevitably did so when they were smaller. The larger a city s population at the beginning of any period for which growth rates are being calculated, the larger the denominator used to divide the increment in the city s population to calculate its growth rate. Although cities such as Lagos, Karachi and Dhaka are often said to be among the world s fastest growing cities, there are hundreds of smaller cities with higher population growth rates. In most nations, an analysis of urban centers growth rates in any inter-census period during the 20th century will show some relatively small urban centers with population growth rates of • 10% per year far above even the fastest growing city in Table 1.

Although it is often assumed that the world s most rapidly growing cities are concentrated in Latin America, Asia and Africa, this is not entirely true. Table 3 shows how several cities in the US rank among the most rapidly growing cities in the world during the 20th century. For instance, Nairobi is often held up as one of the world s most rapidly growing cities, but both Miami and Phoenix in the US had larger populations than Nairobi in 1990, although all were small settlements in 1900. The population of Los Angeles was around one-tenth that of Calcutta in 1900, yet in 1990, it had about the same number of people in its metropolitan area. The growth of Tampa (US) from a small town in 1900 to a metropolitan area of over 2 million by 1990 or Las Vegas from a small town in 1950 to a metropolis of more than a million inhabitants by 1995 also place them among the world s most rapidly growing cities during the 20th century. This should not be taken to imply that the social, economic, demographic or political underpinnings are comparable. In addition, these and other examples of rapidly growing cities in high-income countries do not alter the fact that most of the large cities in the world with the fastest population growth rates in recent decades are in low and middle-income countries.

THE WORLD CITIES

Structural changes within the world economy have helped to reorder the relative importance of cities around the world. Certain regions and cities have been particularly successful in attracting new investment and concentrating innovation for instance, Silicon Valley and Orange County in California, Bavaria in Germany, and certain cities in southern Europe and the Asian tigers (Castells and Hall, 1994). Meanwhile, many of the most successful regions had urban forms that were less dominated by a large central city and that had new enterprises developing in a network of smaller cities and greenfield sites. Most major port cities and traditional industrial centers in Europe and North America (and some elsewhere) that grew to become among the world s major cities during the second half of the 19th and first half of the 20th century lost importance and most had population declines during the 1980s.

The large and increasing share of the world s economy controlled by multinationals has led to certain cities becoming what are often termed global or world cities, as they are key command and control points of the world economy (Friedmann and Wolff, 1983; Sassen, 1994). Some are unambiguously world cities as they are the commanding nodes of the global system London, New York and Tokyo (Sassen, 1994). It is interesting to note that Tokyo

also remains one of the world s major concentrations of industrial production whereas New York and London do not. It is a reminder of how advanced telecommunications systems and logistical management of production can separate almost completely, in spatial terms, the production process from those who manage and finance it and the producer services that the managers and financiers need (ibid).

Another category of world cities are those that articulate large national economies into the system (Paris, Madrid, Sao Paulo) or subnational (regional) economies (Chicago) or simply have a commanding multinational role (Miami, Singapore) (Friedmann, 1993). Global cities are not necessarily the same as large cities as many cities that are not among the world s largest have major international roles for instance, Singapore and Zurich. Several of the world s largest cities do not owe their size and economic base to their role within global production but to being national capitals in more populous nations with a high concentration of political power there; for instance, Delhi and Cairo.

A PREDOMINANTLY URBAN FUTURE?

Most publications about the future predict or assume that the world will continue to urbanize far into the future, even if most now admit that the speed of the change and the size to which the largest cities are likely to grow have been overstated. In its most recent projections, which considerably reduce the scale of urban growth predicted up to 2025 compared to previous projections, the United Nations (UN) suggests that the world will have 59% of its population living in urban areas by the year 2025 (UN, 1998). Africa is predicted to have some 52% of its population living in urban areas by then. But such projections should be viewed with caution. Given the historic association between economic growth and urbanization, a steady increase in the level of urbanization in less urbanized nations is only likely to take place if they also have steadily growing economies. While stronger and more buoyant economies for the world s lower-income nations should be a key development goal, the current prospects for most such nations are hardly encouraging, within the current world economic system. Many of the lowest income nations have serious problems with political instability or civil war and most have no obvious comparative advantage on which to build an economy that prospers and thus urbanizes.

There are also grounds for doubting whether a large proportion of the world s urban population will come to live in very large cities. As noted above, many of the largest cities have very slow population growth rates. For some, further expansion is hindered by resource shortages; for instance, water shortages will inhibit the development of many large (and smaller) cities in semi-arid regions. Many large coastal cities are particularly at risk from the sea level rises and more frequent and severe extreme weather events that will come with global warming. Meanwhile, much new investment is going to particular medium size cities well located in relation to the largest cities, and to transport and communications systems, and these are helping to create less primate-city dominated urban systems. In addition, in regions with advanced transport and communications systems, rural inhabitants and enterprises can enjoy standards of infrastructure and services and access to information that historically have only been available in urban areas. Thus, both low- and high-income nations may urbanize less than anticipated, although for very different reasons.

Urban Poverty and Environmental Health

David Satterthwaite
International Institute for Environment and Development, London, UK

This contribution concentrates on the environmental health problems associated with urban poverty and overcrowding in countries where such problems are particularly acute. As such, it concentrates on urban areas in Africa, Asia and Latin America. This does not mean that there is no association between urban poverty and environmental risk in other regions such as Europe and North America. All over the world, low income groups generally face more serious environmental health problems than wealthier groups (as they cannot afford housing with the best environmental quality and as they take on more dangerous work) but the scale of the environmental health burden suffered by low income groups in high income countries is generally much smaller. So too are the differentials between low and high income groups. For instance, in many urban areas of Africa, Asia and Latin America, the risk of a child dying before reaching the age of ve is often 20 to 30 times higher in the poorest quality low income areas compared to areas with a predominance of middle or upper income groups and environmental health problems contribute much to this differential.

This concentration on environmental health problems associated with urban poverty should not be taken to imply that environmental health problems are less serious for the rural poor. But there are important differences in context: for instance as urban areas have different occupational structures (and associated health risks) and as they concentrate people, production and their wastes which contributes to very serious environmental health problems, in the absence of effective environmental and public health policies.

WHAT ENVIRONMENTAL HEALTH INCLUDES

The World Health Organization s (WHO) definition of environmental health includes not only the health aspects of the human environment but also the technical and administrative measures for improving the human environment from a health perspective (WHO, 1979, 1989). This means it must include a concern for the different environments in which women, men and children live and work; including homes and residential neighborhoods, workplaces, schools and other public facilities and the roads, walkways and transport systems that connect them. It also implies a concern for the environmental aspects of disease and injury prevention which include prevention oriented health care and disaster preparedness policies.

To help understand and manage them, environmental health problems can be grouped into various categories. The different ways of doing so reflect different professional disciplines or priorities and the ways in which different problems have been assigned to different public agencies. The basis for categorizing them can be:

- the nature of the problem (or the hazard it presents to people) e.g., infectious or parasitic disease-causing agents, chemical pollutants and physical hazards, lack of access to resources (for instance freshwater) and the generation of hazardous wastes;
- the context within which the environmental problems occur e.g., housing, workplace, school, city-wide problems;
- the sector into which the problem falls and/or the division of institutional responsibilities for its resolution (e.g., solid waste management, air pollution control);
- (for infectious and parasitic diseases) the biology of the disease causing agent or based on the media through which infection takes place (air, food, water, soil, animals, insects or other organisms that are disease vectors or carriers);
- (for chemical pollutants) the kind of pollutant, the concentration and whether it arises from point or non-point sources.

Here we consider the environmental health context within the residential areas in which low income groups are concentrated, and include some discussion of other serious environmental health risks and who is most vulnerable to them. But prior to this, there is a brief discussion of urban poverty and of its multiple links with environmental health.

URBAN POVERTY

Although historically, the definition and measurement of urban poverty have generally been based only on income

level or consumption level, there is now widespread agreement that this narrow focus excludes other important aspects of deprivation (Wratten, 1995; UNCHS, 1996; IDS, 1997). These include:

- *inadequate, unstable or risky asset bases.* Assets are particularly important for allowing low income groups to avoid deprivation because they provide the means by which economic stresses or shocks can be managed, including being able to afford the cost of treatment when sick or injured and to cope with the loss of earning when an income earner cannot work;
- *limited or no right to make demands within the political system.* The possibilities for poorer groups of obtaining appropriate public responses are generally much less if there is no legislative and political framework that guarantees civil and political rights: for instance the right to have representative government, the right to organize and to make demands and to get a fair response, and the right to procedural justice. Inadequacies in the provision for water, sanitation, drainage, garbage collection and health care for the urban poor and the lack of protection against forced eviction are often linked to undemocratic and unaccountable political structures;
- *poor quality/insecure housing and lack of basic services.* From an environmental health perspective, the most serious problem is housing that has inadequate provision for the infrastructure and services that are essential for environmental health. This inadequate provision imposes a large health burden and also high economic and other costs.

Another important aspect of deprivation which also contributes to poverty is *discrimination.* For instance for women, there is the discrimination they face in labor markets and in obtaining housing, credit and services or the discrimination faced by certain groups based on their ethnic origin or caste.

If urban poverty is understood in terms not only of inadequate income but also of deprivation associated with lack of assets, political influence and access to basic services, then urban poverty is itself the most significant predictor of environmental health problems (see WHO, 1995a; Bradley *et al.*, 1991).

HOUSING AND BASIC SERVICES

Housing and the basic services it should contain (including adequate provision for water, sanitation, drainage and garbage removal) provide the primary line of defence against environmental health hazards in the locations where most people spend most of their time. Estimates for 1990 suggested that at least 600 million urban dwellers in Africa, Asia and Latin America live in life and health threatening shelters and neighbourhoods because of poor quality and generally overcrowded housing with inadequate infrastructure and service provision (Cairncross *et al.*, 1990; WHO, 1992, 1999). Most of these live in tenements, boarding houses or precarious housing often built on illegally occupied or subdivided land. They also included tens of millions of people who have no shelter at all, including those who sleep outside (on pavements, in shop doorways, in parks or under bridges) or in public buildings such as railway, bus or metro stations (UNCHS, 1996). Although considerable progress has been made since 1990 in improving housing conditions, for low income groups, in certain cities and more effective approaches are now being more widely applied, the number of people suffering serious environmental health burdens in urban areas probably increased significantly during the 1990s. This is partly because urban populations continue to grow rapidly in most of Africa, Asia and Latin America, partly because of weak and ineffective urban governance, and partly because of continued increases in urban poverty in many nations (see for instance Kanji, 1995; Minujin, 1995).

The association between urban poverty and serious environmental health problems is obvious. Virtually all of those living in life and health threatening homes and neighbourhoods subsist on below poverty-line incomes, and it is their low income which is the main reason why they do not move to less dangerous kinds of accommodation. The health burdens they suffer and their economic consequences (in terms of work days lost and costs of treatment) are a major cause of their poverty (see for instance Pryer, 1993). In cities where most of those with low incomes live in shelters with adequate provision for water, sanitation, electricity and drainage and have access to health care, the environmental health burden associated with poverty is much reduced. The contribution that improved housing and service provision can make to poverty reduction is often forgotten, especially where urban poverty is conceived only in terms of income-levels.

Most of the environmental health burden for those living in poor quality housing that lacks basic services arises from infectious and parasitic diseases. These are environmental because they are transmitted through environmental media (air, water, soil, food) or via insect or animal vectors. Many diseases thrive when provision for water, sanitation, drainage, garbage collection and health care is inadequate or where it breaks down. As a result, cities can become among the most health threatening of all human environments as disease causing agents and disease vectors multiply, as the large concentration of people living in close proximity to each other increases the risk of disease transmission, and as health care systems become unable to respond rapidly and effectively (WHO, 1999).

At any one time, close to half of the urban population in Africa, Asia and Latin America is suffering from one or more of the main diseases associated with inadequate provision for water and sanitation (WHO, 1999). Every year, more than five million people die from illnesses linked to unsafe drinking water, improper excreta disposal and unclean domestic environments (WHO, 1995b). Improved water and sanitation can bring great benefits in terms of, improved health, reduction of expenditures (on water vendors and on treatment from diseases) and much reduced physical effort (especially for those who have to collect and carry water from standpipes or other sources far from their shelters).

The proportion of urban dwellers with provision for piped water and sanitation has increased over the last 20 years but with the rapid increase in urban populations, the number of people not served by water supplies and sanitation has increased, not declined. Recent estimates suggest that close to 300 million urban dwellers are still not served by water supplies and close to 600 million are without sanitation. But these figures understate the problem. For water supply to be adequate, it must be of good quality, close-by, and readily available. Many governments include in their official statistics of people adequately served all households with public standpipes, even when hundreds of people have to share each standpipe and fetching and carrying water from distant standpipes is a time consuming and arduous task. In addition, many public standpipes are poorly maintained or connected to water supply systems that function intermittently (Hardoy *et al.*, 2001).

For low income groups, provision for the removal and safe disposal of household and human wastes is generally even worse than provision for water. Most government statistics on provision for sanitation exaggerate the proportion of the urban population adequately served, as they include as adequately served those who have to share poorly maintained latrines or rely on communal latrines that are poorly maintained, difficult to access and lack facilities for washing. Tens of millions of urban dwellers have no access to a toilet and so have to defecate outside or into plastic bags (wrap-and-throw) (ibid). It is also common for much of the solid wastes generated not to be collected. It is usually the predominantly low income districts that have the least adequate provision which means that wastes accumulate on open spaces and streets, clogging drains and attracting disease vectors and pests (rats, mosquitoes, flies).

Overcrowded homes, inadequate water supplies and inadequate facilities for preparing and storing food greatly exacerbate the risk of food contamination and microbially contaminated food contributes to a high incidence of acute diarrhoea and to many other food borne diseases (McGranahan, 1991). Many environment related diseases are significant contributors to under-nutrition: including intestinal worm infections (it is common for a high proportion of the urban poor to have large worm burdens) and diarrhoeal diseases.

OVERCROWDING

Overcrowded dwellings are considered a major health risk but it is difficult to single out the precise impact of overcrowding from the other environmental health problems that are common in overcrowded housing (such as the inadequacies in provision for water, sanitation, garbage collection and facilities to safely prepare, cook and store food) and from other problems facing their inhabitants (for instance inadequate incomes leading to under-nutrition). It is also difficult to specify what aspect of overcrowding has the greatest health impact; for instance too many persons per room or per bed or inadequate indoor area per person.

Some of the world s leading causes of premature death are from airborne infections; for many, their transmission is aided by the overcrowding and inadequate ventilation that is so common in the housing used by lower income groups; from tenements and cheap boarding houses to one or two-room shacks. They include acute respiratory infections (the single largest cause of infant and child death worldwide) and tuberculosis (the single largest cause of adult death worldwide). They also include measles, also one of the largest causes of infant death and a major cause of infant and child morbidity and mortality in poor urban areas (Foster, 1990) although the health impact of measles has been considerably reduced through vaccination programmes. Overcrowding increases the risk of transmission for these and for other infectious diseases; it also increases the risk of multiple infections, the risk of infection early in life (when immune systems are still immature) and the risk of severe infection (UNCHS, 1995). However, overcrowding will have less significance as a risk factor where the population (especially children) are protected by immunization programmes and by health care services that provide rapid and appropriate treatment for acute respiratory infections.

Few studies have sought to isolate the health impacts of overcrowding. A study in the city of Bissau (Guinea Bissau) found that many persons per bed and many children under five within a family were among a range of risk factors for childhood mortality. In a low income settlement in Jakarta, persons per room and number of children under five per room were significant factors for diarrhoea and respiratory diseases (UNCHS, 1995). Accidents in the home are often among the most serious causes of injury and premature death among low income urban populations and overcrowding is likely to be a major risk factor, along with homes made of flammable materials and the use of open fires or mobile stoves and candles or kerosene lights.

THE RANGE OF ENVIRONMENTAL HEALTH PROBLEMS

Table 1 shows the range of environmental health problems that are common in urban areas in Africa and much of Asia and Latin America. The problems include not only those emphasized above but also those of the workplace and the wider city, including ambient air pollution and physical hazards from traffic accidents and disasters. These also take a heavy toll on human health. For instance, worldwide, more than 1.5 billion urban dwellers are exposed to levels of ambient air pollution that are above the recommended maximum levels and an estimated 400 000 additional deaths each year are attributable to ambient air pollution (WHO, 1999). Worldwide, around 900 000 people are killed each year by traffic accidents and many more are seriously injured (WHO, 1995a). In wealthier cities where provision for water, sanitation, drainage and garbage collection has improved, traffic accidents have often become among the most serious causes of injury and premature death. Environmental factors are also important contributors to psycho-social health problems and the contribution of these to total health burdens has been under estimated (Harpham and Blue, 1995). Low income groups in urban areas have greater exposure to the environmental stressors that can cause mental health problems e.g., overcrowding, high noise levels and poor quality infrastructure and services (ibid, Ekblad, 1993).

Looking to the future, there are also a considerable range of environmental health problems associated with global environmental change (*see* Environmental Change and Human Health: Extending the Sustainability Agenda, Volume 3) that could have very serious consequences for urban populations. For instance, global warming will bring rising sea levels and an increased frequency and severity of extreme weather conditions and this will greatly increase the risk of flooding in thousands of urban areas, including many of the world s largest urban areas that are located on coasts. There are also the health problems associated with more frequent and severe heat waves; and increased temperatures in cities can aggravate air pollution problems. Warmer average temperatures will permit an expansion in the area where many tropical diseases can occur. As in the case of most other environmental hazards, low income groups are generally least able to take measures to reduce these risks in their homes (and many of them live in high risk areas e.g., flood plains), while cities in low income countries have the least resources to build up defences against these risks.

VULNERABILITY AND SUSCEPTIBILITY

Certain people or households are more at risk from environmental hazards because they are:

1. Less able to avoid them;
2. More affected by them; or
3. Less able to cope with the illness, injury or premature death they cause.

Such individuals or households are generally termed as vulnerable groups. But to ensure a more precise understanding (from which more appropriate responses can be developed), it is worth distinguishing between susceptibility (where the increased risk is related to endogenous factors such as a person s nutritional status, the state of their immune system or genetic factors) and vulnerability (where it is social, economic or cultural conditions that increase the risk e.g., through an increased likelihood of exposure to environmental hazards or less capacity to cope with or adapt to an illness or injury).

The distinction between vulnerability and susceptibility is perhaps clearest when considering infants and young children since they are all particularly susceptible to a wide range of environmental hazards compared to most other age groups but those who live in poor quality housing are far more vulnerable. The nature of young persons susceptibility changes as they get older. They are particularly susceptible to certain chemical pollutants from the time of their conception through their development in the womb and infancy. They are particularly susceptible to many diseases from their birth onwards, until their immune system has developed (and, for many serious childhood diseases, strengthened through vaccines). Young children are particularly susceptible to physical hazards, from the time they begin to crawl: for among other reasons, no knowledge of danger and a desire to explore and experiment. However, their vulnerability to the environmental hazards to which they are particularly susceptible is much increased by poor quality housing that lacks adequate provision for water, sanitation, drainage and garbage removal and as such also lacks safe indoor and outdoor living and play environments (Bartlett *et al.*, 1999). People with limited mobility, strength and balance can be considered as more susceptible to physical hazards because they are at greater risk of injury. Young children, older groups and people with physical disabilities are more at risk from homes built on unsafe sites such as slopes or flood plains. Asthmatics are more susceptible to certain common air pollutants. Pregnant women as well as their foetuses are particularly susceptible to many external environmental agents (WHO, 1999).

Much of a person s vulnerability is determined by their income (and thus whether they can afford adequate quality housing with basic services) and by the quality and extent of provision for basic services, such as water, sanitation, drainage, garbage collection, health care and emergency services.

Some of these, such as the quality of housing and provision for water and sanitation, have a major influence

Table 1 A summary of the main city-related environmental problems

Context	Nature of hazard or problem	Some examples
Within house and its plot	Biological pathogens	Water-borne, water-washed (or water-scarce), airborne, food borne, vector-borne (including some water-related vectors). Insufficient quantity of water may be as serious in terms of health impact as poor water quality. Quality of provision for sanitation is also very important. Overcrowding/poor ventilation aiding transmission of infectious diseases
	Chemical pollutants	Indoor air pollution from fires, stoves or heaters. Accidental poisoning from household chemicals. Occupational exposure for home workers
	Physical hazards	Household accidents – burns and scalds, cuts, falls. Physical hazards from home-based economic activities. In poor quality housing, inadequate protection from rain, extreme temperatures
Neighbourhood	Biological pathogens	Pathogens in waste water, solid waste (if not removed from the site), and local water bodies. Disease vectors often breeding in standing water, drains or garbage. If sanitation is inadequate, many people will defecate on open sites, bringing faecal contamination. If a settlement is served by communal standpipes, latrines and/or solid-waste collection points, these need intensive maintenance to keep them clean and functioning well
	Chemical pollutants	Ambient air pollution from fires or stoves; also often from burning garbage if there is no regular garbage collection service. Air and water pollution and wastes from cottage industries and from motor vehicles
	Physical hazards	Site-related hazards, e.g., housing on slopes with risks of landslides; sites regularly flooded, sites at risk from earthquakes. Traffic hazards. Noise
Workplace	Biological pathogens	Overcrowding/poor ventilation aiding transmission of infectious diseases
	Chemical pollutants	Toxic chemicals, dust
	Physical hazards	Dangerous machinery, noise
City (or municipality within larger city)	Biological pathogens	Quality and extent of provision for piped water, sanitation, drainage, solid waste collection, disease control and health care at city or municipal level a critical influence on extent of the problems
	Chemical pollutants	Ambient air pollution (mostly from industry and motor vehicles; motor vehicles' role generally growing); water pollution; hazardous wastes
	Physical hazards	Traffic hazards. Natural disasters and their unnaturally large impact because of inadequate attention to prevention and mitigation
	Citizen's access to land for housing	Important influence on housing quality directly and indirectly (e.g., through insecure tenure discouraging households investing in improved housing and discouraging water, electricity and other utilities from serving them)
	Heat island effect and thermal inversions	Raised temperatures a health risk, especially for susceptible groups (e.g., elderly, very young). Air pollutants may become trapped, increasing their concentration and the length of people's exposure to them
City-region (or city periphery)	Resource degradation	Soil erosion from poor watershed management or land development or clearance; deforestation; water pollution; ecological damage from acid precipitation and ozone plumes
	Land or water pollution from waste dumping	Pollution of land from dumping of conventional household, industrial and commercial solid wastes and toxic/hazardous wastes. Leaching of toxic chemicals from waste dumps into water. Contaminated industrial sites. Pollution of surface water and possibly groundwater from sewage and storm/surface runoff
	Pre-emption or loss of resources	Freshwater for city pre-empting its use for agriculture; expansion of paved area over good quality agricultural land
Links between city and global issues	Non-renewable resource use	Use of fossil fuels and other mineral resources; loss of biodiversity; loss of non-renewable resources in urban waste streams
	Non-renewable sink use	Persistent chemicals in urban waste streams; greenhouse gas emissions, stratospheric ozone depleting chemicals
	Overuse of finite renewable resources	Scale of consumption that is incompatible with global limits for soil, forests, freshwater

on the extent to which environmental hazards can be avoided; others, such as health care services and emergency services, are a major influence on the extent to which a person can cope with any illness or injury. In general, low income groups are more vulnerable because they are the least able to afford the homes that protect against environmental hazards, treatment when sick or injured and time off work to recover.

Those groups within the population which face discrimination in obtaining access to environmental services (for instance particular ethnic groups or immigrant groups) are also vulnerable. Women are generally more vulnerable than men to many environmental hazards because of gender roles (i.e., as a result of the particular social and economic roles that women have). Women are generally more severely affected than men by poor and over crowded housing and by inadequate health care because they take most responsibility for looking after children, caring for sick family members and managing the household. Those who are responsible for water collection and its use for laundry, cooking and domestic hygiene suffer most if supplies are contaminated and difficult to obtain; these people are generally women or girls. In households with high levels of indoor air pollution, it is generally women (or girls) who inhale larger concentrations of pollutants over longer periods (WHO, 1992).

The greater exposure that women face to many environmental hazards is often linked to the difficulties they face in finding better quality housing. This in turn is linked to the discrimination they face in obtaining employment, purchasing or renting housing, and obtaining credit.

Certain low income groups are particularly vulnerable to environmental hazards because they live in particularly hazardous areas or particularly dangerous housing because these fulfill other more pressing needs, such as being cheap and well located for income earning opportunities. Examples include centrally located tenements, cheap boarding and rooming houses and illegal or informal settlements located on dangerous sites (for instance slopes at risk from landslides or flood plains).

Certain groups within the labour force are more vulnerable to environmental hazards because of high levels of risk within their occupational environment.

Urban Sulfurous and Photochemical Smog

Derek M Elsom
Oxford Brookes University, Oxford, UK

In trying to satisfy the demands of a growing population for energy, food, consumer products, water, waste disposal, housing, services and transport, vast amounts of air pollutants are being added to the atmosphere. Air pollution has become a severe problem in many cities in recent decades, particularly those experiencing rapid industrialization such as Bangkok, Beijing, Cairo, Calcutta, Delhi, Hong Kong, Mexico City, Manila, Santiago, São Paulo, Seoul, Singapore and Taipei (UNEP/WHO, 1992, 1994).

Serious air pollution problems also continue in industrialized cities such as Athens, London, Los Angeles, New York City, Paris and Tokyo. Although pollutant emissions from industrial and residential sources contribute signi cantly to the pollution problems, it is emissions from the world's 800 million motor vehicles which are giving rise to the worst urban air pollution problems.

Air pollutants can adversely affect the health of people. They can produce immediate (acute) symptoms in people, which may be reversible, as well as longer-term (chronic) effects, which may be moderated but not readily cured. In some cases pollution can result in premature death. The health of as many as 1.6 billion people living in urban areas throughout the world may be at risk from poor air quality (Elsom, 1996). Pollutants can acidify soils and freshwater, harm plants and animals, erode buildings and historic artifacts, reduce visibility, and affect local and global climate.

Actions are being taken to reduce pollutant emissions and improve air quality in urban areas but, in some cities, new sources of pollution are being added at a rate which is straining the ability of authorities to control them. Attempts to reduce emissions include tting pollution control equipment to industrial stacks and motor vehicles, changing to cleaner fuels, increasing the combustion ef ciency of furnaces, boilers and vehicles, implementing land-use plans which reduce the distances traveled by motor vehicles, improving public transport systems and placing restrictions on the use of cars. These measures may take many years to become fully effective and so, in the meantime, some cities have introduced emergency measures to reduce emissions from motor vehicles, industry and even homes during periods of very poor air quality (smog).

TYPES OF POLLUTANTS AND THEIR SOURCES

The type of pollutants emitted into the atmosphere depends upon the nature of the polluting activity, especially the type of fuel being burned and, for some activities, the raw materials being processed. Typically boilers and furnaces of manufacturing industries and electricity generating stations burn coal, lignite (brown coal) or heavy fuel oil and so emit sulfur dioxide, nitrogen oxides and particulates. If natural gas is used, then the emissions are predominantly nitrogen oxides. Industrial plants and waste incinerators may release toxic chemicals (chlorine, ammonia, fluoride) and metals (e.g., lead, cadmium).

Petrol engine motor vehicles produce a range of pollutants including carbon dioxide, carbon monoxide (indicative of incomplete combustion), nitrogen oxides (about 90% as nitric oxide and 10% as nitrogen dioxide) and volatile organic compounds (VOCs) such as benzene, 1,3 butadiene and other hydrocarbons. Diesel engine vehicles are more fuel efficient than petrol engine vehicles and emit lower amounts of benzene, carbon dioxide and carbon monoxide. However they emit sulfur dioxide and fine particulates. The latter are less than 10 μm (PM_{10}) or even smaller ($PM_{2\cdot5}$) and so are tiny enough to penetrate deep into the lungs. Research suggests that an increase of 10 $\mu g\,m^{\cdot 3}$ in PM_{10} concentrations in urban areas is associated with a daily rise in the death rate by 1% such that PM_{10} particles may be responsible for 60 000 premature deaths a year in the US and as many as 10 000 in the UK, mainly among the elderly and those with pneumonia and chronic lung disease (*see* Use of Epidemiological Data to Develop Air Quality Standards for Short-term and Long-term Environmental Health Bene ts, Volume 4).

Nitrogen oxides and VOCs, emitted mainly from motor vehicles, electricity generating stations and industrial plants, react with sunlight to create photochemical oxidants, notably ozone. Ozone levels show a strong diurnal variation. During the early morning, emissions of nitric oxide and VOCs increase as traffic flows increase. As sunlight increases, nitric oxide rapidly converts to nitrogen dioxide. The decrease of nitric oxide and the increase of nitrogen dioxide is crucial to ozone formation since nitric oxide destroys ozone. Around 09:00 h, VOCs peak and the VOCs, nitrogen dioxide and sunlight begin to work together to create ozone. The chemistry is aided by carbon monoxide, which acts as a catalyst. As ozone levels increase, VOCs and nitrogen dioxide decrease. Ozone formation ceases with the exhaustion of nitrogen dioxide. Ozone peaks around midday and early afternoon. Depending on the city and the atmospheric situation, ozone levels may remain high during the afternoon, drifting away from the city, and only beginning to diminish after dark (Bridgman, 1997). Ozone concentrations tend to be higher in the suburbs and over rural areas downwind of large

conurbations as it takes time for this secondary pollutant to form and because emissions of nitric oxide from traffic deplete ozone in traffic-congested city centers. Ozone and other photochemical oxidants such as peroxyacetyl nitrate (PAN) cause eye and nose irritation, respiratory illness and damage to materials (e.g., rubber, paint) and some plants.

MOTOR VEHICLE SOURCES

In urban areas, road transport is becoming the dominant source of many of the key pollutants affecting the health of urban residents. In recent decades there has been a phenomenal surge in the number and usage of motor vehicles, which reached a world total of 800 million in 1998. For example, the number of vehicles in Sao Paulo, Brazil is increasing at a rate of nearly 300 000 vehicles a year, having already reached a total of 5.7 million.

Emissions from individual vehicles depend on the constituents of the fuel, the design and size of the engine, the external conditions in which it is being driven (road surface, air temperature), the speed (and whether the car is accelerating/decelerating or under stress due to load or road gradient), its age and level of maintenance. Emissions from motor vehicles can be reduced by improvements in fuel and vehicle technologies and by transport and traffic management measures. Economic instruments (e.g., fines, charges, taxes and subsidies) can be used to increase the effectiveness, shorten the time taken to become effective, or help fund all or part of the cost of such measures.

Reformulated fuels can reduce emissions of certain pollutants by changing the fuel constituents. The introduction of unleaded petrol and the reduction of the lead content of leaded petrol has resulted in a marked lowering of airborne lead concentrations in many countries. In 1997, around 80% of all petrol sold worldwide was unleaded. Low-sulfur diesel fuel has helped reduce emissions of sulfur dioxide and fine particulates. Alternative vehicle fuels such as compressed natural gas (CNG) offer significant emission reductions in many pollutants. Electric battery-powered vehicles offer the potential for zero emissions in cities (but they produce pollution at the power stations where the electricity is generated to charge the batteries) as do vehicles powered by hydrogen fuel cells. Vehicle-targeted measures include governments setting emission limits for new and used vehicles, which are then tightened periodically. This can lead to marked improvements in engine design and a requirement for the fitting of pollution control equipment (e.g., catalytic converters and diesel particulate traps). Regular vehicle inspection and maintenance programs help encourage motorists to comply with the standards. Random roadside inspections are useful in identifying the worst polluting vehicles (e.g., poorly maintained) which make a disproportionate contribution to total vehicle emissions.

Transport and traffic management measures aim to reduce the number of private vehicles, their frequency of use, and the distances they are driven. In particular they attempt to encourage a modal switch from private cars to public transport, walking and cycling. Some traffic management measures are designed to create situations where vehicle engines operate efficiently, consuming less fuel and keeping pollutant emissions as low as possible. Measures include vehicle access restrictions, parking controls, traffic calming and smoothing, urban traffic control, park-and-ride facilities, road pricing, parking controls and priority lanes for public transport and high occupancy vehicles.

The problem of vehicle emissions may be made worse in developing countries because of the use of low quality fuels, a dominance of old cars characterized by poor fuel efficiency, poor vehicle maintenance and overloading of vehicles, leading to frequent breakdowns and traffic congestion, limited use of vehicle emission controls (e.g., catalytic converters), weak emission standards and lax enforcement, limited off-street parking facilities leading to on-street parking and congestion, and an inadequate public transport system (Onursal and Gautam, 1997; Wijetilleke and Karunaratne, 1995). The situation is often made worse by narrow canyon-like streets in the city center not designed for high traffic flows. Growth of cities may be largely uncontrolled as squatter settlements and shanty towns proliferate and the urban area expands. In many cities it is difficult to implement land use policies that locate new residential and commercial developments close to existing public transport facilities. Consequently there is a large increase in the number and length of journeys made by private cars, worsening congestion and increasing vehicle emissions. Curitiba (2.5 million population) in southeast Brazil has avoided the worst of these transport problems by ensuring urban growth takes place along radial axes and providing a dense network of prioritized express bus services along the axes and the concentric roads linking them. Three-quarters of all commuters use this service (Rabinovitch and Leitman, 1996).

INDUSTRIAL SOURCES

Emissions from electricity-generating stations and industrial plants can cause serious problems locally, as well as contribute to acid deposition farther afield. Measures to reduce emissions from these sources include increasing efficiency in energy production and consumption, using cleaner fuels and ensuring more widespread installation of effective pollution control equipment such as electrostatic precipitators (which use electrically charged wires to attract dust particles) to remove particulates, and flue gas desulfurization systems (scrubbers) to reduce sulfur dioxide emissions. Most industrialized countries have implemented legislation which specifies emission and technological standards. This

is enforced by requiring businesses to obtain a license before beginning operation, which has to be renewed annually subject to confirmation that the legislative requirements are being fulfilled. The stringency of pollution control in Europe and the United States contrasts markedly with that of many developing countries. In cities in some rapidly industrializing countries, industries processing and manufacturing chemicals, petroleum, metal and paper as well as electricity-generating stations lack even basic pollution controls. Extensive construction activities and unpaved roads give rise to a high particulate loading of the urban atmosphere. The authorities may well be aware of these problems and wish to improve air quality but simply lack the resources to do so effectively. Financial support from international bodies (e.g., the World Bank) will be needed.

RESIDENTIAL EMISSIONS

Much of the world s population relies on poor quality fuels such as biomass (*see* Biomass Use for Urban Fuels in Developing Countries, Volume 3), kerosene, low-grade coals and lignite for cooking and heating purposes. These can create high levels of ambient (outdoor) particulate and sulfur dioxide concentrations as well as poor indoor air quality adding to the pollution caused by other sources such as tobacco smoking. The shanty and squatter settlements of expanding cities in developing countries pose particular problems. People living in such poverty have no choice but to use cheap and polluting fuels. Air quality improvements can be achieved by increasing the efficiency of cooking stoves and heating appliances and shifting to fuels such as anthracite, oil, electricity and natural gas but this requires significant financial investment. Measures to reduce emissions from new residential areas, notably in parts of Europe, include installation of district heating systems using waste heat from nearby power stations. Ultimately, improved building insulation, energy conservation measures and more energy-efficient household appliances can reduce energy consumption and consequently reduce pollutant emissions.

AIR QUALITY STANDARDS

Governments of most countries as well as the World Health Organization have set health-based environmental air quality standards; threshold pollutant concentrations above which adverse effects are believed to occur (Table 1). Health-based standards (criteria) are derived from epidemiological studies of community groups and from laboratory toxicological experiments using human volunteers or animals. They are set to protect the health of the population, especially sensitive groups such as those with preexisting heart and lung diseases, the elderly, young children and pregnant women and their unborn babies. Such groups may form one-fifth of a national population. To such groups at risk may be added people taking vigorous physical exercise (e.g., participants in outdoor sports, cyclists and joggers).

Table 1 World Health Organization health-based guideline values for selected pollutants

Pollutant	Guideline value	Averaging time
Carbon monoxide	100 mg m^{-3} (86 ppm)	15 min
	60 mg m^{-3} (52 ppm)	30 min
	30 mg m^{-3} (26 ppm)	1 hour
	10 mg m^{-3} (9 ppm)	8 hour
Ozone	120 μg m^{-3} (60 ppb)	8 hour
Nitrogen dioxide	200 μg m^{-3} (105 ppb)	1 hour
	40 μg m^{-3} (21 ppb)	Annual
Sulfur dioxide	500 μg m^{-3} (188 ppb)	10 min
	125 μg m^{-3} (47 ppb)	24 hour
	50 μg m^{-3} (19 ppb)	Annual

SUMMER AND WINTER SMOG

A period of a few hours or a few days during which the concentrations of one or more pollutants greatly exceed health-based standards is called a *pollution episode* or *smog* (derived from the words SMoke and fOG). It occurs during stagnant meteorological conditions when atmospheric processes provide only limited dispersal and dilution of the pollutant emissions. A short-term increase in emissions can add to the problem such as from traffic emissions during rush hours or heating of homes during a cold spell. An anticyclone (high air pressure synoptic system) is usually present, characterized by light winds and the capping of the lower atmosphere by an intense temperature inversion which limits vertical mixing. Some cities such as Athens, Los Angeles and Santiago experience a subtropical (Mediterranean) type of climate, characterized by stagnant weather conditions for an entire season which creates the potential for almost continuous high pollutant concentrations lasting several months (Elsom, 1996; Turco, 1997).

Typically, smog occurs either during warm and sunny stable weather or during cold and foggy stable conditions. These are sometimes described as summer and winter smog types, respectively. However, such descriptions are more appropriate to mid- and high-latitude climates than to the tropics, where it is the dry season that triggers the smog. It should be stressed that although stable weather conditions result in pollution concentrations rising above health-based air quality standards, smog would not occur if pollutant emissions were not high to begin with. In other words, human activities are the fundamental cause of smog rather than the weather conditions. Topography and altitude can worsen smog. When a city lies in a basin or valley, the

slopes act like the sides of a box and a temperature inversion may form over the lid of the box, so trapping the pollutants. Oxygen levels are reduced at high altitude so combustion is less efficient in cities such as Mexico City (2250 m) while photochemical activity may be enhanced. Land and sea breezes can play a part in aggravating coastal city pollution problems such as in Athens, Los Angeles, Melbourne and Sydney. During the night an offshore land breeze sweeps the pollutants out to sea, but then an onshore sea breeze brings them back the next day.

URBAN AIR QUALITY MANAGEMENT

The ultimate aim of urban air quality management is to keep air pollution concentrations below levels (*air quality standards*) that pose a threat to people or the environment and, in areas where such levels are exceeded already, to implement a plan to return pollution concentrations to below air quality standards as soon as is practicable (Elsom, 1996; Longhurst *et al.*, 2000).

Air quality management first requires an assessment of whether pollutant concentrations exceed air quality standards, or may do so in the future, as well as an understanding of the nature and relative importance of the various pollutant sources. This involves monitoring current levels of air pollution, identifying and compiling an inventory of sources of the pollutants, using air quality models to calculate pollution levels where monitoring results are not available, and using the models to predict changes in concentrations over time, both short-term (hours, days) and long-term (years, decades). It is then necessary to develop, test and implement a plan to ensure that a healthy and environmentally acceptable air quality is achieved and then sustained in the future. That plan will need continually updating and modifying as the nature and sources of air pollution problems change (Box 1).

SMOG ALERT SYSTEMS

Reducing pollutant emissions to a minimal level will eliminate smog eventually. However, smog poses a serious risk to public health and because it may take many years before improved technologies and pollution control legislation take effect, short-term emergency emission reduction measures

Box 1 London: from sulfur smog to photochemical smog

From the mid-19th century through to the early 1960s London and other UK cities such as Glasgow, Manchester and Sheffield experienced frequent winter smog, commonly called peasoupers, during which levels of particulates (black smoke) and sulfur dioxide were so high that pollution caused hundreds and sometimes thousands of premature deaths amongst the elderly, infants and the sick (e.g., nearly 4000 excess deaths were attributed to the December 1952 smog in London) and left a legacy of chronic bronchitis sufferers amongst residents. The main sources contributing to these winter smogs were emissions from household open fires, industrial plants, power plants and railway steam engines. Inefficient combustion technology, the reliance on coal as the dominant fuel and relatively weak legislation all helped to ensure Britain suffered many decades of winter smog.

Following the notorious 1952 smog, the situation began to change and the frequency and severity of smog were reduced as emissions of pollutants were reduced dramatically. This was achieved through improvements in technology (especially with respect to improving fuel combustion efficiency), the availability of cleaner fuels (oil, natural gas and electricity replaced coal increasingly), urban redevelopment (much terraced housing with inefficient heating systems was replaced by high-rise dwellings with efficient systems), power station replacement (electricity became generated nationally by a smaller number of larger, efficient power stations located outside urban areas), the replacement of steam locomotives by diesel and electric powered engines, social changes (growing affluence resulting in a desire for more efficient and convenient home heating systems to replace open coal fires), public and media pressure for a cleaner environment, and landmark legislation in the form of the Clean Air Acts of 1956 and 1968. The Clean Air Act of 1956 enabled local authorities to introduce smoke control areas, requiring heating and cooking appliances in homes to run on smokeless fuels (some of which, such as natural gas, were sulfur free too). Minimum heights for industrial stacks were set and improved industrial pollution control was specified.

The marked reduction of suspended particulates, which had contributed to fog formation and persistence, resulted in local climate change. The frequency of dense fogs decreased and the number of hours of bright sunshine in November in central London nearly doubled from an average of 38 hours during 1921–1950 to reach 70 hours on average during 1961–1990. For comparison sunshine hours in the surrounding countryside over the same period increased by just eight hours.

Although London no longer experiences sulphurous smog, these episodes have now been replaced by smog caused by motor vehicle pollutants. This was evident during the London episode of 12–15 December 1991 when a period of cold, stable and foggy weather resulted in one-hour nitrogen dioxide levels peaking at 423 ppb (809 $\mu g\, m^{-3}$) while levels of fine particulates (PM_{10}) and benzene increased markedly too. Smog in and around London is no longer restricted to the winter and has become a year-round problem. As the cocktail of urban generated pollutants drift away from the cities, photochemical reactions on warm sunny days create ozone so spreading the smog problem across the country. European pollutants ignore national boundaries so Dutch, French and German emissions add to the ozone and PM_{10} pollution problems of Southeast England.

Table 2 Air pollution episode alert levels in Ile de France (Paris)[a]

Level	Sulfur dioxide	Nitrogen dioxide	Ozone
1 Information only	200(75)	200(105)	130(65)
2 Information and measures	350(130)	300(155)	180(90)
3 Alert and stringent measures	600(225)	400(210)	360(180)

[a] Pollution values are measured as hourly means in $\mu g\,m^{-3}$ (ppb) and at least two monitoring stations must register exceedances for declaration of a level.

may be implemented in the meantime. Most episodic management or smog alert schemes implement traffic restraint measures and place curbs on industry but also make some attempt to tackle residential emission sources. The measures are intended to reduce the severity and duration of smog. The ultimate objective would be to implement measures in advance of, and during, a period of stagnant meteorological conditions in order to prevent pollution concentrations ever reaching unacceptable levels.

Two or sometimes three pollutant threshold concentrations (smog alert levels) are commonly employed to alert the public to periods when air quality may pose an increasing risk to their health (Table 2). The first stage usually involves the issuing of a health advisory warning, especially to sensitive groups within the community. Advice is given on what actions they can take to minimize risks to their health, such as to stay indoors and avoid vigorous exercise. Requests are made for the public to take voluntary action to reduce emissions such as asking them not to undertake inessential car journeys. Subsequent smog alert stages introduce mandatory pollution control measures.

MEASURES TO TACKLE SMOG

Several major cities (Athens, Mexico City, Milan, Paris, Rome, Tehran) have introduced a scheme banning the use of half the cars in the city center during smog, the restriction being determined by the license-plate number, cars with odd-numbered plates being banned on odd-numbered dates (Box 2). Banning vehicles according to their level of emissions may be more effective but would require vehicles to display exemption permits. An experiment at Heilbronn, Germany, was conducted in June 1994 when it was closed for four days to all vehicles, except those fitted with three-way catalytic converters and emission diesel engines meeting the most stringent limits, as an experiment to measure the air quality impacts. The result was a 40% reduction in road traffic and a 50% increase in public transport use resulting in nitrogen dioxide concentrations falling by 40% and benzene concentrations being halved. Moving traffic is less polluting than congested stationary traffic (at least below about $88\,km\,h^{-1}$), so during gridlock conditions Madrid introduces short-term bans on parking along the main thoroughfares. In Mexico City, road repairs are halted to minimize traffic congestion, the use of government vehicles are halved, and schools are closed so there is no need to use vehicles to take children to school.

Some cities are planning to link their traffic light coordination system with pollution monitoring networks. This would enable an area within the city experiencing, or forecast to experience, poor air quality to be protected from further traffic emissions by redirecting vehicles along alternative routes and/or discouraging motorists from entering that area by charging them for entry. Effective

Box 2 Paris smog restrictions

Traffic restrictions were introduced in Paris on 1 October 1997 after the previous day's pollution levels reached smog alert level 3 (NO_2 one-hour threshold of $400\,\mu g\,m^{-3}$) for the first time since legislation empowering the authorities to restrict vehicle movement came into force. Around three million vehicles enter or leave the city each day and 1.1 million use the ring road around Paris. On this date only vehicles with an odd-numbered license plate were allowed access into the city. Public transport was free (being subsidized by the government), speed limits were reduced (from 80 to $60\,km\,h^{-1}$) on the Paris ring road, residential parking was free to try to persuade commuters to leave their cars behind, only priority vehicles were used by Parisian authorities, sports were stopped in schools, tourist buses were banned and industrial activities had to decrease emissions (the largest of three power stations near Paris ceased operation). Vehicles with three or more passengers, delivery vans and emergency vehicles were allowed to enter the city as well as electric and gas powered vehicles. In the future, exemptions (green stickers) will be given to less polluting vehicles, such as those fitted with a three-way catalytic converter. Around 1000 police officers were deployed to enforce the restrictions but, as this was the first time the alert procedure had been implemented, drivers breaking the ban were not fined Fr 900 ($150) but were asked to park their cars and walk or use public transport. The number of passengers on buses increased by 15% and on the Metro and trains by 10%. Traffic levels in central Paris fell by 17%, on the ring road by 6%, and around Paris by 14%. Emissions of nitric oxide and carbon monoxide were reduced and nitrogen dioxide levels fell and remained below alert level 1 (one-hour of $200\,\mu g\,m^{-3}$).

ways will be required to communicate to car drivers what actions they should take and to inform them of any charge that will be made. Communication may be via roadside variable-message signs and in-vehicle units (containing a smart card for any charge to be deducted). Schemes exploring this approach are being developed in Athens, Bangkok, Bristol, Helsinki, Gothenburg, Kanagawa and Leicester, while Singapore already has a sophisticated road pricing system. Its electronic scheme began in late 1998. Cars are charged $2 per pass during the congested 08:00 09:00 h period but this drops to $1 during the half an hour before and after this period. This is intended to smooth the peak morning traffic flow and reduce peak hourly pollutant concentrations but the charges could be raised and extended to other times of the day during smog to discourage even more motorists.

Emissions from residential areas, businesses and public buildings can be decreased during smog by urging people to reduce the level of heating during winter and air conditioning in summer as well as to reduce energy consumption in general. Use of garden incinerators and the lighting of bonfires can be curtailed. During summer smog episodes, the use of barbecues may be discouraged as well as that of certain household and decorating products (e.g., solvent-based paints) which release VOCs.

Industry may be required to reduce emissions by 30%, by half or even cease production completely. Exceptions may apply to industrial activities providing essential community services such as electricity generating stations unless a national grid system of electricity generation allows local stations to close. Reductions in industrial emissions can be achieved by switching to, say, low-sulfur fuels, which have been stocked in readiness for such an occasion. During a photochemical smog, closure of businesses emitting large amounts of VOCs (e.g., petrol stations not fitted with vapor recovery systems on the pumps, paint-spraying shops and dry cleaning stores) may be considered because of their contribution to ozone formation. Pollutants emitted from a very tall stack may penetrate a capping temperature inversion. In such a situation, the emissions may not contribute to the local smog problem if the emissions drift away from the area. On the other hand, some industries with low stacks may be required to cease production altogether or to switch their emissions from shorter stacks to taller ones, if such an option is available. However, if upper winds are light, pollutants emitted by tall stacks above a nocturnal capping inversion may remain there overnight and be brought back down rapidly to the surface the next morning when the sun warms the ground and convection develops (a process called *fumigation*).

The effectiveness of various episodic management measures depends upon many factors. Current smog alert schemes indicate that traffic restraint measures may have a significant effect on carbon monoxide levels within the area in which the restriction is imposed, and nitrogen dioxide levels to a lesser extent. High concentrations of PM_{10} are associated with regional transfer into the city as well as local sources so reductions in traffic and industrial emissions locally can influence only the latter component. Levels of ozone are more likely to be reduced if the restrictions on vehicles and industry apply over a wide regional area, not simply the city center. Reduction of sulfur dioxide levels may be achieved by reducing emissions from coal-fired electricity generating stations and industrial plants with low stacks in the vicinity as well as diesel engine vehicles but, as in many developing countries, where the major cause of high levels of sulfur dioxide is public transport diesel engine buses, then the problem may be harder to resolve.

URBAN AIR POLLUTION AND GLOBAL CLIMATE CHANGE

Ultimately, the solution to the smog problem and poor air quality in general is to reduce pollutant emissions within an urban area to a very low level. As the baseline or average pollution level in an urban area declines, so the severity and frequency of smog ought to decrease (Tables 3 and 4).

Table 3 Number of days exceeding the one-hour federal ozone standard (exceeding 0.12 ppm or 240 $\mu g\, m^{-3}$) and Stage 1 ozone episodes (exceeding 0.20 ppm or 400 $\mu g\, m^{-3}$) in the South Coast Air Basin (includes Los Angeles), 1976–1999[a]

Year	Federal standard	Stage 1 episode
1976	194	102
1977	208	121
1978	187	116
1979	191	120
1980	167	101
1981	180	99

1989	157	54
1990	130	41
1991	130	47
1992	143	41
1993	124	24
1994	118	23
1995	98	14
1996	90	7
1997	68	1
1998	62	12
1999	41	0

[a] Several decades of pioneering and increasingly stringent control legislation have begun to show the benefits.

Table 4 Number of days exceeding specified levels of the air pollution index (IMECA) for ozone in Mexico City, 1988–1997. The one-hour national health-based standard for ozone is 0.11 ppm (216 μg m^{-3}) which is represented by an IMECA index of 100[a]

Year	• 100	• 150	• 200	• 250	• 300
1988	330	232	69	11	1
1989	331	136	15	3	0
1990	338	235	94	28	4
1991	350	284	162	56	7
1992	329	264	125	39	12
1993	324	240	85	14	1
1994	346	263	100	4	0
1995	325	263	94	7	0
1996	327	235	71	5	0
1997	322	219	55	3	0

[a] Emission-reduction measures have reduced the ozone peaks but not the length of time of exceedances of the standard (typically 11 months each year).

In situations where pollution is imported from outside a city s boundaries, emissions will need to be reduced on a regional, national and even international scale too.

Urban air pollution problems will be affected by global environmental changes. Stratospheric ozone depletion has permitted increased penetration of ultraviolet radiation and this may enhance photochemical activity, resulting in increased ground level ozone concentrations. Global warming, due to the greenhouse effect, may lead to a worsening of pollution problems. For example a region may experience more frequent and intense anticyclones and rising temperatures may increase evaporative emissions of VOCs. Clearly there is a need to monitor air quality changes and to model the likely effects of changing environmental factors that may affect pollutant emissions and ambient concentrations.

Urban Wastes

Stephen T Washburn and Cheryl A Doyle
ENVIRON Corporation, Princeton, NJ, USA

It has become increasingly dif cult to safely handle the enormous amounts of waste produced by urban societies, as cities throughout the world continue to grow. Over the past 50 years, when the average population of the world's 100 largest cities more than doubled, the demand for waste disposal in urban areas has strained (and sometime overwhelmed) municipal resources. For example, Tokyo has grown so quickly, quadrupling its population since 1950, that municipal authorities have devised ways to build islands of waste in Tokyo Bay (United Nations Publications, 1997). In Bombay, at least two million residents have no sanitary facilities at all, and most sewage that is collected is discharged into local waterways (United Nations Publications, 1997).

The waste disposal challenges facing urban areas vary widely from one region to another, re ecting important

differences between cities in developing and industrialized countries. In poorer, less industrialized cities, concerns regarding waste disposal frequently focus on very local, immediate effects, including disease spread by untreated human waste and uncollected garbage, as well as pollution of surface and groundwater resources.

Richer, industrially developed cities, on the other hand, generally have the resources to process sewage and collect garbage, but higher rates of consumption and lower rates of recycling can create more widespread, even global, environmental effects. For example, according to the World Resources Institute, the resources consumed and greenhouse gases emitted to support cities in developed countries are much greater than those needed to support poorer cities in developing regions, on a per capita basis (EPA, 1992).

COMPONENTS OF THE URBAN WASTE STREAM

By volume, municipal solid waste (MSW) is by far the largest component of the overall urban waste stream. MSW generally consists of household garbage, commercial waste (i.e., waste from businesses, including stores and restaurants), and non-hazardous industrial waste.

The volume of MSW generated per person is generally much higher in wealthy, industrially developed urban areas than in poorer, rural areas. For example, high-income countries generate 300 1000 kg per person each year, while low-income countries generate between 100 and 200 kg per person each year (United Nations Publications, 1997). Wealthy cities also produce a higher percentage of wastes requiring final disposal, largely because the higher-income societies do not have as great a motivation to recover and recycle, and often no tradition of doing so.

In industrially developed countries, MSW consists primarily of food wastes, garden trimmings, paper and paperboard, glass, metals, and plastics; in the US, paper and paperboard represents the largest fraction (about 40% by weight) (Corbitt, 1999). By contrast, MSW in developing countries tends to have a much greater percentage of organic wastes, and much less plastic, paper, and other manufactured goods. For example, the organic content of MSW in Africa may exceed 70%; and plastics, glass and metals constituted less than 10% of MSW in four African cities studied (UNEP, 1999).

Although MSW is often considered non-hazardous, it may also include a variety of potentially toxic substances, such as oil-based paint, paint thinners, cleaning chemicals, used oil, batteries, and pesticides. Estimates of the percentage of such household hazardous waste in MSW range from 0.5 to 5% in industrialized countries. Because of their potential to cause environmental contamination, the impact of disposing of such wastes may be considerably greater than these low percentages may suggest.

Although MSW is produced in the greatest volumes, each of the following types of waste can also pose challenges to urban waste disposal systems:

- *Sewage and sewage sludge*: In the wealthiest countries, effective sewage systems have been developed to safely dispose of human biological waste. In developing countries, however, especially those undergoing rapid urban growth, sewage collection, disposal, and treatment present major problems. Inadequate sewage disposal can increase risk of disease resulting from exposure to pathogens in the waste, and cause ecological damage, particularly to rivers, lakes, and streams. In Shanghai, China, for example, serious water pollution and supply problems have been reportedly caused by the release of about four million $m^3\ day^{\bullet\ 1}$ of untreated human waste into the Huangpu River (United Nations Publications, 1997). Disposal of sludge from sewage treatment plants is also becoming a greater issue, particularly in more industrialized cities. This sludge can contain high concentrations of metals and other potentially toxic substances, and as a result some jurisdictions are placing increasingly stringent restrictions on traditional disposal options such as application to agricultural lands and ocean dumping.
- *Industrial waste (liquid and solid)*: Developing and transition countries, as well as some industrialized countries, have only recently begun to address the environmental effects of industrial waste disposal. Liquid and solid wastes from industrial processes are most frequently disposed of in dumps or simple landfills, although some types may also be burned. In economic terms, the environmental legacy of improper industrial waste disposal is perhaps clearest in the United States, where it has been estimated that approximately $1 trillion will ultimately be spent on the cleanup of former waste disposal sites (EPA, 1992) (*see* Love Canal, Volume 5).
- *Hospital/medical waste*: Hospital and medical wastes typically consist of common waste (office and kitchen waste), pathogenic or infectious waste (including sharps), and hazardous wastes (mainly from laboratories). While many types of common hospital/medical waste can be handled with regular MSW if proper separation can be achieved, infectious and hazardous wastes should receive special handling to prevent the spread of disease and other environmental problems.
- *Construction and demolition (C&D) debris*: C&D waste consists of cement, bricks, asphalt, wood, and other typically inert materials. In industrial countries, C&D waste can represent a significant fraction of the overall waste stream, and may contain asbestos, polychlorinated biphenyls (PCBs) and other potentially toxic substances (*see* Geomorphological Change for Urbanization and Industry, Volume 3).

METHODS OF WASTE DISPOSAL

Land Disposal

Land disposal ranges from open dumping, which may pose a serious risk of pollution and disease (UNEP, 1999), to sanitary landfills, which incorporate engineering features (such as liners and methane gas management) to reduce the potential for releases to the environment. Sanitary landfills are generally more common in developed countries, especially near urban areas where population densities are highest. For example, in Africa and Central America, most of the MSW that is not recycled is sent to open dumps; there are few, if any, sanitary landfills. In Latin America, where land disposal is used for about 60% of the MSW, open dumping is most common, although some large cities have state-of-the-art landfills. In North America, land disposal is used for 65 to 70% of MSW (down from more than 80% in the 1980s), and sanitary landfills are required by legislation in most areas (UNEP, 1999) (*see* Wastes: Land ll and Land Raising, Volume 3).

Local environmental effects of land disposal can include ground and surface water pollution, as well as the spread of disease if waste is not properly covered. At some landfill sites, methane gas can also accumulate and create an explosion hazard. Regional and global environmental effects of land disposal are less obvious, perhaps, but may represent a long-term threat to the global climate. For example, carbon dioxide and methane, which have been identified as greenhouse gases capable of contributing to global warming, are both generated by landfilling. It is likely that carbon dioxide emissions from landfills represent only a minor contributor to global loadings to the atmosphere; for example, fossil fuel combustion accounts for 99% of total carbon dioxide emissions in the US (US Department of State, 1997; US Environmental Protection Agency, 1998). For methane, however, landfills may represent a more significant percentage of total emissions, and landfill liners and covers can increase methane production by producing anaerobic conditions. In the US, which has many covered sanitary landfills fostering anaerobic conditions, approximately 35% of all methane emissions have been attributed to land disposal. In Venezuela, on the other hand, where open dumping under aerobic conditions is common, land disposal reportedly contributes less than 10% of all methane emissions (US Department of State, 1997; US Environmental Protection Agency, 1998).

Composting

Composting is the practice of promoting biodegradation of the organic constituents in solid wastes and sludges, thus reducing the volume and potential hazard of the waste. When compost is used as a soil conditioner, fertilizer, or growth medium, it benefits the environment by reducing the need for artificial fertilizers and by reducing the amount of waste to be landfilled. Although composting results in emissions of carbon dioxide, a greenhouse gas, aeration of compost piles prevents the generation of methane, a considerably more potent greenhouse gas that is produced in large quantities by landfilling, as discussed above (US Environmental Protection Agency, 1998).

In order for composting to be a sustainable component of any MSW management system, it is necessary to have a market for the compost. Many Asian countries have a long history of compost production and use. In northern Europe, centralized composting is a major component of MSW management, but most attempts at centralized composting have been unsuccessful in Latin America and the Caribbean. In Africa, despite the high organic content of the waste stream, composting is a little used waste management practice. In North America, bans on landfilling of garden trimmings in some areas have resulted in an increase in backyard composting, although it has generally been found that compost can be given away but not sold (UNEP, 1999).

Source Reduction, Materials Recovery, Reuse and Recycling

It is often possible to reduce the amount of materials requiring final disposal by simply reducing the amount discarded, or retrieving reusable or recyclable items from the waste stream. In addition to reducing the potential for adverse local effects, studies have shown that source reduction and recycling also represent good ways of reducing greenhouse gas emissions (US Environmental Protection Agency, 1998). Agenda 21, an agreement reached at the United Nations Conference on Environment and Development in Rio de Janeiro in 1992, noted that waste reduction and environmentally sound reuse and recycling should be the primary target in the waste management hierarchy (UNEP, 1999).

While some poorer societies have strong traditions of waste recovery and reuse, it is only relatively recently that most industrialized countries have begun to focus on reducing waste at its source, or recycling used materials instead of discarding them. The primary reason for this difference is economic: poorer societies often reuse and recycle in order to save the cost of new items and conserve resources. In richer societies, on the other hand, there may even be economic disincentives to reuse and recycling; for example, in Europe, almost 15% of the workforce are engaged in the production of packaging (European Commission, 1996). This potential loss of jobs could represent a hurdle to accomplishing source reduction through a switch to reusable packaging. Further, in industrialized countries, packaging is an important component of marketing for many products.

In some developing countries, more than half of the urban waste may be recycled or reused. For example, Bangalore,

a large Indian city, produces 3000 tonnes of waste a day; 2700 tonnes of which is recycled or reused, leaving only 300 tonnes for disposal (United Nations Publications, 1997). Countries such as India, Vietnam and China reuse most of their municipal wastes; in South and West Asia, food wastes are sold to farmers for use as compost, with some large hotels even auctioning them off (UNEP, 1999).

In the industrialized countries, source reduction and recycling efforts typically increase only when the cost of landfilling or other forms of disposal becomes excessive (for example, as a result of more stringent environmental controls), or if natural resources are significantly depleted. In the past several decades, however, some industrialized countries have begun to reduce the amount of urban waste requiring final disposal. For example, in North America, approximately 20 25% of the solid waste stream is currently recycled, compared to 10% recycled in 1975 (UNEP, 1999).

Incineration/Open Burning

Open burning or incineration of MSW can reduce the weight of the waste requiring land disposal by up to 75%, and the volume by up to 90%. While the solid residues of incineration still require disposal, and may be considered hazardous, they can sometimes be used in construction, reducing the amount to be landfilled.

In North America, the use of incineration varies from region to region, due in part to differences in local regulations and in the availability of landfill space. In the more densely populated northeastern US, for example, 40% of solid waste is incinerated, while a total of only about 2% of the MSW is incinerated over the rest of the country. There are fewer incinerators in Canada than in the US, and the province of Ontario has banned construction of any new facilities.

In Europe, incineration is relatively common, in part because of the shortage of land in many areas. Northern European countries rely greatly on incineration: 35% to 80% of residential waste stream in Western Europe is incinerated, with state-of-the-art pollution control and energy recovery. Incinerators in Eastern Europe are often older, with less sophisticated environmental controls.

Incineration is not common in developing countries because the cost is high relative to land disposal, and because wastes in such areas are difficult to incinerate due to high moisture and low energy content. Some former developing countries now incinerate waste, however; for example, Singapore incinerates 90% of its MSW (UNEP, 1999).

Potentially hazardous air emissions are usually a key issue in evaluating waste disposal through incineration. For example, there are concerns regarding the potential human health and ecological effects of polychlorinated dibenzo-p-dioxins and polychlorinated dibenzofurans (dioxins) emitted from MSW and hospital waste incinerators, even with increased use of air pollution controls. The effects of dioxins may not be limited to the immediate vicinity of the source; studies have shown that environmentally persistent chemicals such as dioxins can be transported globally. Waste incineration in industrialized countries has been identified as a major source of dioxins; according to one study, almost 40% of the global total dioxin emissions from identified sources have been attributed to waste incinerators in Japan (UNEP, 1999).

Incineration produces emissions of carbon dioxide and nitrogen oxides; the latter is a greenhouse gas with particularly strong global-warming potential (*see* Global Warming Potential (GWP), Volume 1). However, properly controlled combustion with energy recovery may actually reduce net greenhouse gas emissions by cutting emissions from burning fossil fuels for energy production, as well as emissions from landfills (US Environmental Protection Agency, 1998). Energy produced by incineration is generally converted to either electricity or steam; in the US, 90% of the MSW incinerators with energy recovery produce electricity. Steam generation is more common in Europe, due to a ready market for steam created by a widespread reliance on district heating (UNEP, 1999).

Several innovative incineration technologies have been proposed to reduce toxic emissions. For example, plasma systems operating at extremely high temperatures (e.g., 2000 °C or more) have been developed to provide more complete destruction of waste and minimize emissions of dioxin and other organic compounds. Such systems are more typically used for hazardous waste than for MSW, and have had limited commercial applicability to date.

Surface Water Disposal

Untreated or partially treated sewage is commonly discharged to waterways, leading to the potential spread of disease, particularly if the water is also used as a source of drinking water. Dumping of other types of solid and liquid wastes into rivers, lakes and oceans is also relatively common, since most urban areas are situated near major bodies of surface water. In rapidly developing countries that have limited environmental controls, bacterial contamination of surface water is widespread; in industrialized countries, concerns often focus on discharges of potentially toxic substances in wastewater.

LOOKING FORWARD

The population growth experienced in our cities over the past several decades is not expected to abate in the near future. In fact, according to data published by the United Nations and the World Resources Institute, it is projected that by 2025, the global urban population will be 5 billion

(or about 60% of the world population), compared to 2.5 billion in 1995 (United Nations Publications, 1997; World Resources Institute, 1997). This continuing population growth in the cities of the world will create increasingly difficult waste management and disposal challenges. These challenges will require a combination of local, regional, and global initiatives to reduce the amount of waste generated, and better manage the waste that cannot be eliminated.

A number of international bodies, including the United Nations Environment Programme (UNEP) are actively involved in supporting worldwide waste management efforts. Many cities and countries, whether they have a long history of industrialization or are experiencing recent and rapid development, are also recognizing the need for integrated planning and policy making. While some issues, such as reducing greenhouse gases, may be more global in nature, many decisions must be made regionally or locally.

In order for waste management efforts to be successful, they must be sustainable, both culturally and economically. As cities grow, cultural and economic conditions can change dramatically, affecting the sustainability of different waste management strategies. However, it appears clear that virtually all urban areas will need to develop a waste management hierarchy consisting of waste minimization; resource recovery; recycling; treatment (including incineration); and final disposal.

V

VEI (Volcanic Explosivity Index)

VEI is a logarithmic measure of the explosiveness of volcanic eruptions, which is used for the classification of types of eruption and method of comparison of past and present eruptions. As well as the direct effects of an erupting volcano, there is also a climate impact caused by stratospheric aerosol clouds, which may be produced by powerful eruptions. These clouds contain contaminant sulfuric acid aerosol layers that block out the rays of the sun and produce global cooling. Every year there are about 60 volcanic eruptions that may be quantified. In 1982, Newhall and Self proposed that it was the volume of dust injected into the stratosphere which determined the climatic effectiveness of an eruption and they developed a measure to determine a value of energy release for volcanoes using the volume of material erupted, height of the ash plume and duration of the eruptive phase as well as additional observations. VEI is dependent on the following five parameters.

1. Magnitude: determined from the volcanic ejecta volume.
2. Intensity: determined by the volume of ejecta per unit time calculated from column height and velocity.
3. Dispersive power: determined from column height.
4. Eruption violence: comparable to intensity for spontaneous eruptions.
5. Destructive potential: determined by the devastation extent caused by an eruption.

VEI is based on volcanologically derived data that removes the circularity of argument built into the application of Rdmax and Emax in estimating the value of the dust veil index (DVI) (*see* DVI (Dust Veil Index), Volume 3). In calculating VEI, an open-ended index was assigned to known eruptions on a scale of zero to eight ranging from zero for non-explosive eruptions to eight for the largest explosive eruption in history to characterize and evaluate volcanic eruptions follows (see Table 1).

An eruption with a VEI of zero such as Mauna Loa in Hawaii will have less than 10 000 m^3 of ejecta including lava and ash that will not reach a height above 0.1 km. Durations of eruptions from VEI zero to one will have up to one hour of continuous blasting. With a VEI of four at least 108 m^3 of ejecta is produced from a column height of 10 25 km but will not have any significant climatic effects. A VEI of eight has not been recorded in the last 10 000 years; however, in the past two decades there have been many volcanoes like Mount Pinatubo and El Chichon with high VEIs that have had a significant global cooling effect. A volcano with a VEI of six such as Mount Pinatubo is a highly explosive volcano in comparison to most other volcanoes. Mount Pinatubo located in the Philippines erupted in June of 1991 with a VEI of six. It ejected

Table 1 VEI criteria[a]

	Descriptive	Volume of ejecta (m^3)	Eruption column height (km)
0	Non-explosive	• 104	• 0.1
1	Small	104–106	0.1–1
2	Moderate	106–107	1–5
3	Moderate–large	107–108	3–15
4	Large	108–109	10–25

[a] *Source:* http://volcano.und.nodak.edu/vwdocs/eruption. scale.html.

20 Mt of sulfur dioxide (SO_2) into the stratosphere that produced a measured cooling effect in the tropics of 2 °C and a reported global decrease of 0.5 °C. The global cooling effects reached their peak in 1993, more then two years after the eruption. Similarly, El Chichon in Mexico erupted in April, 1982, with a VEI of five. It ejected 74 Mt of SO_2 into the stratosphere that had a comparable effect that caused a global cooling of 0.2 °C. Studies showed that estimates of magnitude are climatically independent and different latitude locations have no effect.

Table 2 identifies various VEIs defined in terms of plume height and consistency of occurrence.

As documented, the most powerful volcanic eruption in recent history occurred in Indonesia in 1815. The Tambora eruption with a VEI of seven ejected more than 150 km^3 of material into the atmosphere to heights of about 30 km. The expelled debris cut sunlight by approximately 30% and the average global temperature was reduced by 1.5 °C. The year of 1816 is often referred to as the year without a summer.

The VEI can also be used to classify the type of eruption. The five different types of eruptions recognized are: Hawaiian (the smallest), Strombolian, Volcanian, Plinian and Ultra-Plinian (the largest). An example of a Hawaiian eruption, a non-explosive volcanic eruption with a VEI of zero, is Mauna Loa compared to Yellowstone, a mega-colossal eruption with a VEI of eight, that is an Ultra-Plinian.

Additional scales for measuring the size of a volcano are the DVI and the ice-core volcanic index (IVI), which quantifies widespread ice acidity.

Viral Diseases and the Influence of Climate Change

Charles Guest
Australian National University, Canberra, Australia

This article outlines the range of in uences on the occurrence of viral diseases, a group of major and dynamic problems in public health. The nature of selected conditions most probably associated with climate variation, and therefore presumably with long-term climate change, is described. Human viral diseases include dengue fever, encephalitis syndromes borne by mosquitoes and ticks, Rift Valley fever, Ross River virus disease and yellow fever. In animals, increased arboviral disease activity of akabane, bluetongue and bovine ephemeral fever is expected. Prevention and mitigation of these problems, with epidemiological and other research prospects, are considered.

INTRODUCTION

Environmental factors are critical to the occurrence of disease. The idea is not new: links between climate and human health were proposed in Hippocrates treatise *Airs, waters and places*, in the fifth century BC. For the study of medicine, Hippocrates first recommended an understanding of the seasons, with investigation of how the various winds, waters, site, soil and other local environmental characteristics might influence the occurrence of disease. Environmental influences on health continued to receive attention up to the 17th and 18th centuries.

This focus changed in the late 19th century, with the germ theory of disease. The concept that a specific microbe reaches a susceptible host to cause distinctive patterns of morbidity and mortality came to dominate Western medicine. More recently, it has become clear that susceptibility and resistance to disease involve a wide range of factors, including physical environmental phenomena such as climate.

Global environmental change may have profound effects on many forms of life, including the cellular microorganisms and viruses (McMichael *et al.*, 1996). Viruses are not cells, but are completely dependent on cellular hosts for the production of energy. Consequently, with very few exceptions, viral diseases lack sensitivity to antibiotics, and are therefore of great public health concern.

The microbiological agents of vector-borne communicable disease are carried by animals. These diseases include arthropod-borne viral (arboviral) diseases, the primary focus here. First, to illustrate the ecological principles that relate global environmental change and human health, consider climatic influences on viruses in general.

CLIMATIC VARIABILITY AND VIRAL DISEASES

The epidemiological indicators of links between long-term variation in climate and the occurrence of viral disease have a range of time-scales. They come from more immediate (and sometimes venerable) observations on annual changes, through to more speculative, theoretical studies which depend on computer models of the long-term climate change that is now underway (Patz *et al.*, 2000).

Annual Cycles

In temperate and subtropical countries, death rates are highest in winter (Guest *et al.*, 1999). Viral diseases contribute to these rates, but even this relationship is partly obscured by social and behavioural adaptations to cold. Some adaptations prevent an unknown proportion of winter deaths, especially in countries at higher latitudes and altitudes, but more indoor living during colder periods increases the opportunities for transmission of communicable disease.

Interannual Variability

The El Nino/southern oscillation (ENSO) determines, in part, global climate anomalies with altered rainfall and other climatic patterns that are particularly relevant to vector-borne diseases. For example, the incidence of mosquito-borne Rift Valley fever (see in the following sections) has been associated with El Nino-driven flooding in Kenya (Linthicum *et al.*, 1999).

Long-term Climate Change

The frequency of extreme weather events is expected to increase in the coming century. This is more likely to be important to variations in disease patterns than the small changes in the averages of temperature and other climatic variables. It is difficult to predict changing incidence of viral diseases in relation to changing rainfall patterns, as higher temperatures may also increase evaporation. However, one effect of increased flooding and stagnation of water may be greater prevalence of vector-borne diseases. An increase in droughts could increase the incidence of gastrointestinal infections.

VECTOR-BORNE DISEASES

Vector-borne diseases prevail in ecological cycles that include the arthropod vector (mosquitoes, ticks, etc.), with human and other animal hosts. The survival of vectors is sensitive to climatic and other environmental influence, so that the distribution of some of these diseases may expand, while others may contract in future. The geographical range of the vectors may change, but it does not necessarily follow that the incidence of disease will reflect these changes.

For aeons, shifts in insect populations across latitudes may have taken place in response to fluctuating minimum temperatures or other phenomena. At present, many additional factors, such as land clearing, the movement of peoples into bush and jungle areas, and increasing irrigation are influencing the breeding habits of disease vectors and bringing humans into closer proximity with them.

With their short generation time, insects are sensitive biological indicators of terrestrial ecosystems. For example, temperature, humidity and wind may determine whether or not vectors are able to transmit disease in a given location. Rodent populations are another group that both may transmit disease to humans and respond rapidly to environmental change.

Two human diseases that are caused by microorganisms that are more complex than viruses should be mentioned. Malaria, of pre-eminent world importance as a

communicable disease, results from a protozoan parasitic infection of blood cells. Malaria is clearly sensitive to changes in climate, so changes in the territory of this disease, according to altitude and latitude, are expected in future (*see* Malnutrition, Infectious Diseases and Global Environmental Change, Volume 3). Lyme disease (vector-borne, but bacterial) has assumed major public health importance, particularly in the United States in recent years. It is possible that milder winters may increase the range of this disease. Third, consider red tide (discolouration of seawater, caused by toxic dinoflagellates (Halstead, 1982; Humpage *et al.*, 1993). This example of non-human disease suggests that the ecological niche of shellfish is highly sensitive to changing climatic conditions.

The remainder of this article is devoted to the possible climatic influences on arboviral diseases. It is also necessary to appreciate the possible contribution of factors other than climate to the emergence or reemergence of disease (Shope, 1994):

1. The pathogen may have been introduced from afar into an area where transmission could be amplified if vectors and reservoir hosts are present;
2. The vector may have been transported artificially or by natural means into the area;
3. Susceptible hosts may have migrated into the area, e.g., during conflict;
4. Environmental change in an enzootic site (where a disease is usually prevalent in animals) may increase the force of transmission of a pathogen; or
5. The pathogen may have evolved.

ARBOVIRAL DISEASES

Generally, arboviral disease is seasonal, depending on the period during which the arthropod takes its blood meals. Many factors influence the prevalence and season of disease, including climate (rainfall, temperature), vector competence, density of vectors, transport of virus to distant places, level of immunity in the vertebrate populations, the length of *extrinsic incubation period* (the interval between acquisition of the infectious blood meal and the time when the arthropod becomes capable of transmitting the agent), and the length of *intrinsic incubation period* (the interval between invasion of the body by the virus and the appearance of clinical disease in the human host), density of vectors, transport of virus to distant places, and level of immunity in the vertebrate populations.

Dengue

Dengue fever, a mosquito-borne viral disease, has become a widespread tropical urban health problem (Gubler, 1998). Of vector-borne diseases, only malaria affects more people world wide. WHO estimates that 2500 3000 million people in over 100 countries are at risk of both dengue and dengue haemorrhagic fever a serious and often fatal variant of the disease resulting from a second infection by another of the four strains of the virus. Millions of clinical cases occur each year, including up to 500 000 cases of the more severe form of the disease.

Dengue s highest incidence occurs during periods of high rainfall and humidity. Increased temperature may increase dengue transmission in coming decades, but many factors under more direct human control (such as patterns of urbanisation or the effectiveness of mosquito-control programs) may be more critical.

Increases in the latitudinal and altitudinal range of dengue have been projected with climate change. As the survival of *Aedes aegypti* mosquitoes is reduced when the temperature increases to above 42 °C, however, the incidence of dengue may eventually decline in the hottest parts of its current range (Chan *et al.*, 1999).

Increased transmission intensity could lead to a lowering of the average ages of primary and secondary infections (Jetten and Focks, 1997). As infants and adolescents appear most vulnerable to the more dangerous form of dengue, it is possible that with climate change, the morbidity and mortality associated with this disease could increase significantly.

With detailed information on local weather patterns, breeding sites for mosquitoes and the immunity status of the population, it may become possible to predict dengue outbreaks.

Encephalitis

Several viral infections of the brain, frequently fatal, may be influenced by global environmental change. In the Americas, these include Eastern Equine, Western Equine and Venezuelan Equine encephalitis. While their range and prevalence may change, again the importance of environmental changes other than climate should also be considered. Take, for example, the emergence of Eastern Equine encephalitis in Massachusetts. Centuries of farming, with the draining of swamps and deforestation, could have reduced the prevalence of the mosquito vector by the early twentieth century but also lowered immunity in the human host, leading to outbreaks in 1938 and subsequently.

Warm wet winters followed by dry summers have favoured the occurrence of St Louis Encephalitis, the most common form of arboviral encephalitis in the United States. With climate change, a northward extension of its current range is possible.

In Australia, since 1917, there have been seven major epidemics of Murray Valley Encephalitis. Epidemics have followed summers with high rainfall in the major catchment

areas of central and eastern Australia. The breeding cycle of the main mosquito vector, *Culex annulirostris*, is critical to the seasonal occurrence of this disease, which has peaked in the late summer-early autumn. Why epidemics have not occurred in southeastern Australia since 1974 remains unclear. With climate change, however, an increase in this disease is predicted, as variations of summer rainfall may promote the breeding of waterbirds and mosquitoes.

European tick-borne encephalitis is seen in temperate zones in the Northern Hemisphere. Its distribution may expand with global warming. In Sweden, for example, increased incidence of tick-borne encephalitis has been reported in association with milder winters (Lindgren, 1998).

Related syndromes in animals include the North American encephalitides, viral diseases occurring episodically in horses (and less frequently in humans). Weather variables have been used to develop predictive models for equine encephalomyelitis in the United States (Francy *et al.*, 1992).

Hantaviruses

Hantavirus pulmonary syndrome and haemorrhagic fever with renal syndrome have been recognised to be associated with changes in rodent populations, in turn related to variation of season and land use.

Rift Valley Fever

First described in 1930, epizootics of Rift Valley fever, sometimes accompanied by epidemic human disease, have occurred throughout sub-Saharan Africa. The acute viral infection may produce subclinical or mild disease in adult sheep and cattle, but is often fatal to young animals. High fever, severe headache, myalgia, and exhaustion comprise the acute syndrome in humans, while some develop fatal encephalitis and ocular disease.

Wilson (1994) traced the roles of environmental change (especially unusual rainfall), migration of ungulates, economic development, including the presence of dams and irrigation systems, human demography, behaviour and travel on the dynamics of the *Aedes* and *Culex* mosquito vectors, resulting in changes in endemic prevalence, and the frequency and intensity of epidemics.

Ross River Virus Disease

This syndrome of epidemic polyarthritis normally lasts a few days to several weeks, causing high morbidity. Widespread in Australia, the attack rates for Ross River virus disease are higher, for example, than rates associated with the vector-borne disease of greatest profile in North America (Lyme disease).

The greatest incidence of Ross River virus disease occurs in the wet season in northern Australia, and in the summer to mid-autumn period in southern Australia, a seasonal pattern that depends on the life cycle and habits of the mosquito vectors. Temperature, humidity and rainfall affect the incidence of this disease, while human activity (such as the development of irrigation) is also clearly important (Curson, 1996).

Climate change is expected to alter the incidence and distribution of Ross River virus disease. In coastal areas, sea level rise may enhance the penetration of tidal saline waters into estuarine and tidal river habitats, by consequence extending the breeding grounds of the mosquito vectors (e.g., two saltmarsh-breeding species, *Aedes camptorhynchus* and *vigilax*). Moreover, greater numbers of humans, particularly along the eastern seaboard, are expected to become exposed.

Yellow Fever

Yellow fever is a mosquito-borne disease occurring in tropical Africa and America. With the potential for urban outbreaks, the range of yellow fever may also be changing.

FUTURE CHALLENGES

Controlling these viral and other diseases will require improvements in both surveillance and risk communication. Future disease surveillance activity should examine how changing climate could influence both the environmental sources of pathogens and human behaviour (Patz *et al.*, 2000). Public health experts should become more familiar with the work of urban planners and *vice versa*.

Climate change will be important for these diseases and probably many others (such as Japanese Encephalitis) for which the climate-disease relationship has not yet been researched adequately. So far, research has principally been undertaken from centres in developed countries, but more detailed analyses from other regions are now underway (Githeko *et al.*, 2000). In animals, other possible examples of increasing arboviral disease activity include akabane, bluetongue and bovine ephemeral fever.

As this work goes to press, the outbreak of foot and mouth disease in the UK in the year 2001 has illustrated graphically some of the global forces additional to climate that must be considered in the changing environment. These forces included the de-regulation of the economy, with pressure on farmers. The decline of state veterinary services may also have contributed. Spread of this virus was promoted by the long-distance (and sometimes illegal) movement of animals, humans and vehicles, at vast economic and social cost. The effectiveness of intervention by vaccination as opposed to the policy of mass animal slaughter

was debated intensely. The panic moved to the centre-stage of politics. (See also Woolhouse and Donaldson, 2001).

Climate and disease should not be investigated separately from the behaviour of human populations or the practice of public health. Research priorities include the analysis of disease patterns in relation to climatic variables, but not restricted to them. The development of predictive models is needed to inform public policy in health and other sectors (Woodruff *et al.*, 2000). Research on preventive responses (including but not limited to the development of vaccines) is required. Adaptation to changing patterns of disease also needs research. To wait and see, an alternative preferred by some governments, could add an avoidable future burden of morbidity and mortality.

Volcanic Eruptions: Mt Merapi, Indonesia

Sutikno

Gadjah Mada University, Yogyakarta, Indonesia

Merapi volcano is one of the 26 most active volcanoes in Indonesia (Kusumadinata, 1979), and is one of about a dozen volcanoes in the world which are in a state of persistent eruptive activity (Tazieff, 1983). The Merapi volcano is located in Central Java, Yogyakarta Special Region Province, Republic of Indonesia; the 2911 m high peak is located at 7° 32′ 30″ S, 110° 26′ 30″ E, or about 25 km north of the Yogyakarta urban area.

The earliest record of Merapi activity was in 1006. Since then historical records show that big eruptions occur every 9- 16 years, while smaller eruptions occur at about 2- 3 year intervals. This activity is associated with two intersecting faults under the volcano. The consequences are:

eruption, lava ow, glowing cloud/nuée ardente (local term for the nuée ardente is wedus gembel - big white sheep), ash fall and lahar (mud) ow. Merapi eruptions are not explosive. The magma rises slowly and piles up above the active vent of the volcano to build a lava dome. The lava dome is unstable and partly slides down along the slope together with pyroclastic materials. If associated with heavy rain, a rain lahar occurs.

Living near an active volcano, such as the Merapi Volcano is full of danger and risk. Eruptions in 1930 and 1954 killed 1369 and 64 people, respectively (Kusumadinata, 1979). The Merapi activity with nuée ardente on November 22nd, 1994 killed 85 people, 22 people were seriously wounded, 17 of whom had to be hospitalised. Flora and fauna were destroyed, mostly caused by high temperature of the glowing cloud of 300 600 °C. From May to July 1998 Merapi was active again with nuée ardente and ash fall but without any loss of life. Archaeological remains show that the danger of the Merapi Volcano has been known for a very long time. Some Hindu temples (8 9th century) in the Merapi volcanic area were buried by volcanic material more than 2 m deep, and subsequently partly restored, such as the Sambisari Temple. In 1991, archaeological artefacts made from gold, supposedly from the Hindu period, were found in Wonoboyo village, in the eastern part of Yogyakarta town. Buried natural features, such as ancient rivers, palaeosols and charcoal were found everywhere in the sub-surface layers in the Merapi volcanic area.

In order to prevent deaths due to Merapi eruptions, the Volcanological Bureau has delimited four danger zones based on the magnitude of the danger:

1. *the prohibited zone*: an area located near the source of the danger, on the volcanic cone and the upper slope of the Merapi; this zone is not inhabited and naturally is not arable due to the pressure of very recent volcanic materials and lack of water;
2. *the level one danger zone*: an area where at any time a big eruption could cause danger, either by nuée ardente, bomb, lapilli, ash fall or their combination. This zone is located just below the prohibited zone, on the middle volcanic slope; this zone is inhabited and the land is utilised for settlement, dry fields and agroforestry;
3. *the level two danger zone*: an area located along the river banks flowing down from the volcanic slope of the Merapi Volcano; the main danger of this zone is rain lahar; there are eight main rivers flowing from the Merapi volcanic slope, i.e., Woro, Gendol, Kuning, Boyong, Krasak, Batang, Putih, Blongkeng and the Pabelan River; all of the rivers flowing through highly populated areas, and fertile and productive agricultural lands;
4. *the safe zone*: an area free from the threat of nuée ardente, lapilli, volcanic bombs, ash fall and rain lahar. Most of the urban areas of Yogyakarta are located in this zone (Kusumadinata, 1979).

People living in danger zones one and two should be prepared mentally and physically for volcanic activities, especially in an active period. Merapi volcano eruptions cause environmental changes physically, biologically and culturally. The physical environmental change is caused by volcanic deposits, such as lava flow, pyroclastic, nuée ardente, volcanic ash and lahar deposits. In an area covered by nuée ardente, the environmental changes are tremendous; dense and very hot masses of material that move rapidly are able to kill humans and animals, destroying and burning wooden material and vegetation, as shown by the tragedy of November 22nd, 1994 described earlier. All the trees facing in the direction of the nuée ardente flow were burnt, while the trees on the opposite side were still fresh. The ash fall deposit in a Merapi eruption varies in thickness while its spatial distribution depends on the position of the vent hole and the wind direction. In the eruption of May to July 1998, the thickness of the ash fall in the highest settlement was generally between 2 5 cm. The ash covered the agricultural land and most of the cash crops were damaged. The trees with wide and dense leaves fell down due to the weight of ash. Farmers had to wash grass in order to feed their cattle. Roofs of houses were also covered by volcanic ash, and the owners had extra work to do. The volumes of the volcanic deposits of the eruptions in 1969 and 1984 were estimated to be 5.5 million m^3 and 6.5 million m^3, respectively. The huge mass of volcanic materials covered the steep volcanic slopes, where precipitation is high (more than 3500 mm annually). In this saturated condition the material flowed down the slopes as rain lahar along the main stream, in some cases overflowing the banks and destroying settlement areas or agricultural land.

Even though living in an active volcanic area is dangerous, the area is still densely populated. Fertile soil, and plenty of water are magnets that attract people, who therefore refuse to migrate permanently to other locations. There are reasons why they do not like to move, such as:

1. Their forefathers have lived there for a very long time and historically they feel safe from the hazard; they believe that Merapi is their friend, and thus most of them are not afraid of Merapi activity and even believe that Merapi activity offers some advantages.
2. They believe that an accident can occur anywhere and anytime; and they believe the Merapi activity is only temporary, so they are willing to move temporarily if Merapi is active.
3. Most of them feel happy living in their settlement environment, because they have a piece of land with

fertile soil, water is available and they have enough foodstuff for their family.
4. Usually in the rural areas, they have a close relationship with their family and their neighbors, they do not want to lose this; they have a slogan in Javanese, mangan ora mangan waton kumpul which means whether we eat or not, the important thing is to live together ; they do not know whether a new place could bring certainty into their life.

Government policy with respect to people who do not want to leave the danger zone can be divided into three measures:

1. an early warning system; using detailed information from the Bureau of Volcanology and coordinated by the Governor and Regent; in some parts of the danger zone sirens were installed; in areas where the siren s sound is not heard, the local people use traditional tools, made from bamboo or wood (local term is kentongan) to indicate the danger of an eruption;
2. construction of physical structures to protect settlements from the lahar (mud) flow, such as the Sabo dam and embankment;
3. preparing evacuation and relocation of settlements.

Based on the accident on November 22nd, 1994 when the nuée ardente from Merapi rushed into Turgo village, the government prepared a relocation settlement area in the safe zone. The relocation settlement consists of single houses, public facilities and barns, such facilities are normal or even better than in other rural areas in mountainous areas in Java. Only a few people have stayed in the relocation settlements; the government regulation states that the people can work in their former fields, but do not allow them to stay permanently in the first danger zone; temporarily they obeyed the government regulation but after a few months they went back home again. The people who live along the rivers descending from the Merapi Volcano collect sand, gravel and stone to use as construction material. Formerly they collected the material manually, but when demand for materials increased rapidly due to development projects, private companies came with machines and trucks to collect and transport the materials to the urban area. After some time a conflict arose between the local people and the private companies. It meant that in a short time a lot of material was dug out from the land surface or from the river beds. Every day hundreds of trucks carry material out from the river beds mainly to the urban area. There are some impacts due to the withdrawal of the material from the river beds, i.e.:

1. most of the roads for transportation of surficial material are damaged by heavy trucks; in the dry season the air along the road becomes dusty;
2. along the river courses there are some intakes on the riverbank for irrigation purposes. Due to the lowering of the riverbed caused by withdrawal of the material, the irrigation channel offtakes cannot obtain enough water. This lack of water reduces the production of rice in the field fed by the channel. In the dry season most of the rice fields cannot be supplied by irrigation water;
3. as their income from the rice field decreases, farmers seek other sources of income to meet their daily needs. Some of them work collecting surficial material, which means that the area of sand and gravel exploration increases rapidly. In the rainy season the river course sometimes changes and vertical erosion becomes more active.

The Merapi volcano thus brings both benefits and problems. Constant vigilance and preparedness is required by everyone seeking to exploit the benefits by taking the risk of living in the areas likely to be affected by eruptions and the associated nuée ardentes and lahars.

Volcanic Explosivity Index (VEI)

see VEI (Volcanic Explosivity Index) (**Volume 3**)

Volcanoes and Cities

Grant Heiken

Los Alamos National Laboratory, Los Alamos, NM, USA

A volcanic eruption near a metropolitan area is capable of major destruction of property and loss of life. Globally, there are 60 large cities located near or on historically active volcanoes; including two megacities (Manila and Mexico City) and the population at risk is over 40 million people (1990 census estimates).

THE HAZARDS (SEE FIGURE 1)

- The greatest risks to life and property are posed by the fast-moving volcanic density currents called *pyroclastic ows* or surges. These rapidly moving, hot mixtures of volcanic ash, pumice, and gas possess energies capable of destroying stone buildings. During the 1902 eruption of Mont Pelée, Martinique, 29 000 lives were lost when volcanic density currents destroyed the town of St. Pierre. Infrequent but large volcanic density currents from the Philippines Taal Volcano once swept across the area now occupied by Manila.
- Although less dangerous than volcanic density currents, ash and pumice fallout can cover large areas, and damage the regional electrical and water infrastructure. Fallout also causes respiratory ailments, smothers plants and insects, and creates enormous clean-up problems (like a snowfall that fails to melt). In 1997, a light ashfall from Popocatépetl slowed down life in Mexico City, with respiratory irritation, slick roadways, and closure of the International Airport. Kagoshima City, Japan is regularly showered with ash from the nearby Sakurajima volcano, and ash cleanup is a part of the public works department s regular duties.
- Volcanic mudflows are generated after water and volcanic ash mix on the volcano, or ashfall deposits on hillsides are saturated by heavy rains. Prehistoric mudflows swept across the valleys of Mexico and Puebla with severe effects on Preclassic cultures. In 1985, volcanic mudflows from Nevado del Ruiz, Colombia, flowed through the town of Armero, located on the Río Lagunillas 70 km from the crater, killing 25 000 people. Mudflows from Mount Rainier, Washington are the most worrisome potential hazard for the lowlands near Seattle and Tacoma.
- Lava flows are a part of history for Catania, Sicily, where lava flows from an eruption of Mt Etna in 1669 traveled 17 km and destroyed the western part of the city. Lava flows have erupted intermittently from Mount Vesuvius during the last 370 years, damaging towns on the volcano s slopes.
- Gases are the least obvious but the most insidious of volcanic hazards. Volcanic gases, including carbon dioxide (CO_2), sulfur dioxide (SO_2), and hydrogen sulfate (H_2S), are heavier than air and can flow along valley bottoms and accumulate in closed areas such as craters, suffocating any breathing creatures. Effects near cities are mostly localized, but an eruption of CO_2 from a crater lake in the Cameroon highlands in 1986 flowed down two river valleys, suffocating 1700 people in five villages. It has been suggested that many of the deaths in Pompeii during the AD 79 eruption of Vesuvius were caused by CO_2 suffocation.
- Tsunamis generated by submarine caldera collapse, or by structural failure and collapse of a composite cone near the sea have damaged or destroyed coastal cities during historical time. The most famous eruption is that of Krakatau, Indonesia in 1883, when most of the 36 000 deaths in coastal towns along the Sunda Straits were caused by volcanogenic tsunamis. Most large cities with this potential hazard are located around the Pacific Rim, and especially around the coasts of Japan, the Philippines, Indonesia, and Papua-New Guinea.

THE GLOBAL ENVIRONMENT

The infrequent, large volcanic eruptions that have had global environmental effects, such as the 1815 eruption of Tambora, Indonesia, have also affected the world s cities (see Table 1). The 1815 eruption, responsible for the year without a summer, caused crop failures and famine in North America, eastern Europe, and China. In addition to stress related to food shortages, the gloomy, hazy days caused by the substantial sulfuric acid aerosol in the stratosphere that led to anxiety and civil unrest (*see* Volcanic Eruptions, Volume 1).

Because of the proximity of volcanoes such as Popocatépetl, Mexico (Mexico City and Puebla), Guagua Pichincha, Ecuador (Quito) and Taal, Philippines (Manila) to densely populated metropolitan areas, volcanologists are becoming involved in urban disaster mitigation planning, moving into the city. In a few cities, volcanic hazard studies are being added to integrated models of urban infrastructure (e.g., transportation, energy, civil defense, telecommunications, water distribution, and public health), and the social and political framework. Prevention of large-scale disasters in cities on or near volcanoes requires more than the traditional hazard mapping and volcano monitoring. The community has to be involved through extensive education and public awareness campaigns. Risk evaluation must rely heavily on modeling, and requires visualization of the physical processes involved, and their effects, in a manner that is easily grasped by emergency planners, the insurance industry, policy makers, and the public.

Volcanoes can catastrophically change environments in nearby towns and cities by simply destroying them. Widespread ash fallout and gases can also cause environmental catastrophes, with effects ranging from respiratory problems to seasons without bees for plant pollination. More indirect effects of large eruptions include global temperature decreases and possibly the enhancement of El Nino phenomena. In any case, with ever-increasing urban populations, volcanoes constitute a major environmental threat (*see* Volcanic Eruptions: Mt Merapi, Indonesia, Volume 3).

Volcanoes and the Environment

Susan L Donoghue
University of Hong Kong, Hong Kong

The surface of our Earth is studded with restless volcanoes, living reminders of the forces that have helped shape our world since its inception. The distribution of most of these volcanoes is governed by complex interactions between large mobile crustal plates that t together like pieces of a jigsaw to form the surface of the Earth. Some 50- 70 volcanoes erupt every year, but few of these have signi cant or lasting impacts. The greatest immediate dangers and possible changes to the global climate arise from volcanoes that erupt on time scales of hundreds to thousands of years. Several cataclysmic eruptions of the past few centuries have resulted in a volcanic forcing of climate and a temporary marked cooling of Earth's surface temperatures, with wide-ranging consequences.

It is no accident that many of the world's people live in the shadows of active and dormant volcanoes. This perilous existence is governed by our need for resources and because of this, people are prepared to risk their lives in return for the many bene ts that volcanism can bring. Although volcanoes are typically seen as agents of death and destruction, their ery breath also helps to sustain life by providing us with an essential resource - extensive regions of the most fertile soils in the world, capable of producing successive rich harvests to feed an ever increasing population.

THE FIRE MOUNTAINS

The theory of Plate Tectonics, a revolution in the earth sciences, holds that the rigid outer shell of the Earth is broken into a mosaic of plates that are in constant relative motion. These plates interact at their boundaries giving rise not only to the world s earthquakes but to the many diverse physical features of Earth s landscape including the myriad of volcanoes that lace Earth s surface (Figure 1).

Large concentrations of volcanoes occur above subduction zones, areas where lithospheric plates moving towards each other collide. The process of subduction of the underlying oceanic crust generates magma within the upper mantle, which rises beneath and intrudes into the overlying crustal layers. This magma eventually erupts at Earth s surface as lava, forming volcanoes.

Volcanoes formed above subduction zones occur as arcuate chains within the oceans where they are termed island arcs and along the margins of continents that lie above subduction zones, forming active continental margins. Subduction along the margins of the Pacific Plate

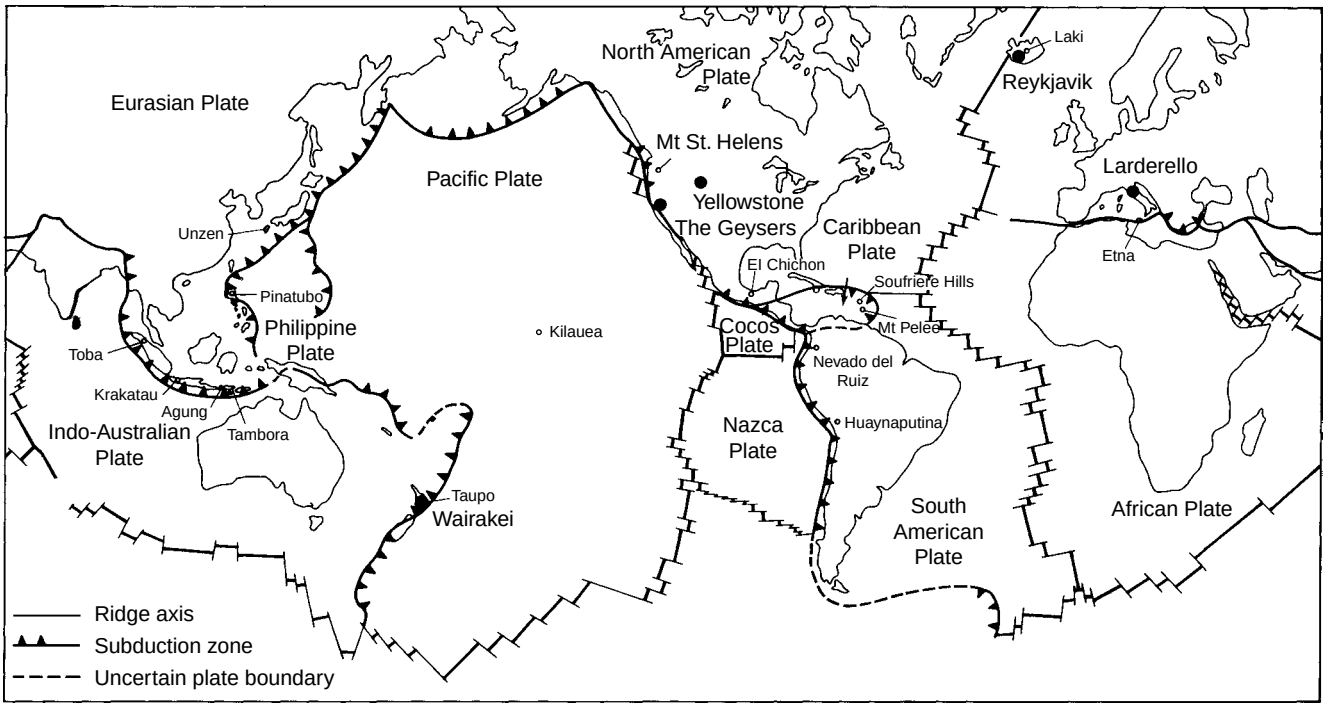

Figure 1 The location of some of the world's active volcanoes and developed geothermal fields in relation to the major tectonic plates of the Earth's surface. Subduction along the margins of the Pacific Plate has created a Ring of Fire where two-thirds of the world's active volcanoes are found

has created a spectacular belt of volcanism termed the Pacific Ring of Fire which is home to no less than 500 of the world s most active and explosive volcanoes.

Eruptions at subduction-related volcanoes are typically violent. Several to tens of cubic kilometers of tephra and gases may be explosively ejected into the atmosphere. Much of this tephra later falls back to ground, blanketing the landscape downwind of the vent. These eruptions are also known for their propensity to generate lahars (*see* Lahars, Volume 3) and pyroclastic flows, the latter being the most terrifying and certainly one of the deadliest of all volcanic phenomena. Lahars generated during the 1985 eruption of Nevado del Ruiz in Colombia overran the town of Armero, 50 km from the volcano, burying 23 000 citizens. Pyroclastic flows generated during the 1902 eruption of Mt Pelèe on the Lesser Antilles Island of Martinique incinerated the town of St Pierre, killing 27 000.

Not all of Earth s active volcanoes, however, occur at subduction zones. Thousands of active volcanoes dot the ocean floors in regions along mid-oceanic ridges, enormous fractures running the length of the ocean basins. These are areas where plates are being pulled away from one another at rates of 6 15 cm year^{-1}. Eruption of lava along the crests of these ridges generates new oceanic crust compensating for the destruction of oceanic crust at subduction zones. In Iceland, where a segment of the Mid-Atlantic ridge is exposed on land, birth of new crust is witnessed with great regularity. Icelandic eruptions are characterized by outpourings of enormous volumes of fluid basaltic lava and spectacular fire-fountaining episodes along the rift.

Active and extinct volcanoes are also found in seemingly anomalous locations away from plate boundaries. They occur where localized and relatively stationary upwellings of mantle material, termed hot spots or mantle plumes, sit beneath the crust, scorching the underside of the tectonic plate and eventually burning holes through it. Magma erupts to form volcanic islands in oceanic settings and isolated volcanic centers in continental settings. The Hawaiian islands, a chain of volcanoes formed as the overriding Pacific plate migrates over the hot spot, and Yellowstone volcanic center, are two such examples. Eruptions at hot spot volcanoes are more effusive than explosive in character, building broad shield volcanoes and lava plateaux.

Every year an estimated 50 70 volcanoes erupt somewhere on Earth. A few volcanoes, such as Kilauea (Hawaii) and Stromboli (Italy) are in more or less continuous eruption, but for most volcanoes, short-lived and often violent outbursts punctuate much longer periods of relative inactivity or dormancy. Dormant volcanoes, liable to awaken with very little warning, present the greatest threat to populations living in volcanic regions. Take, for example, the sudden awakenings of Washington State s Mount St. Helens in 1980 after a 600 year slumber, Mexico s El Chichón volcano in 1982 (which was thought to be extinct), and the recent 1995 1997 eruptions at Soufriére Hills Volcano on the Caribbean Island of Montserrat after a 400 year respite.

The potential loss of life from future eruptions is enormous. At risk are some 350 500 million people living on or near potentially active volcanoes, many of the people inhabiting towns that have been repeatedly rebuilt following previous disasters. Every century an estimated 100 000 people die as a result of volcanic activity. Twenty-seven volcanoes including Nevado del Ruiz (Colombia), Mt Unzen (Japan), El Chichón (Mexico), Tambora (Indonesia) and Laki (Iceland) have earned special distinction, each having killed more than 1000 people in the last 300 years.

In an effort to reduce the global loss from natural disasters, the United Nations declared the 1990s an International Decade for Natural Disaster Reduction (*see* IDNDR (The International Decade for Natural Disaster Reduction), Volume 4). The emphasis has been on cooperative international effort to mitigate disasters, especially in developing countries. In response to this, teams of scientists the world over have been busy establishing volcano surveillance networks and undertaking risk assessment studies at 16 of the world s most pernicious volcanoes, dubbed the decade volcanoes. Their aim has been to provide adequate warning of imminent activity to allow safe evacuation of populations living near volcanoes. By the close of this Decade program, their tremendous efforts will have meant the saving of hundreds of thousands of lives.

AGENTS OF CHAOS

Although immediate death and destruction are the most frequently described effects of volcanic eruptions, there may also be severe post-disaster social and economic effects. Historically, large magnitude eruptions and events of particularly long duration have resulted in widespread famine, disease and massive displacements of human populations. In recent years, the effects of famine and disease have been greatly reduced through international relief programs, but the problem of how to cope with mass human migration in the aftermath of disasters remains. This is a particularly pertinent issue for less developed Ring of Fire countries presently home to nearly half of the world s population and many of the largest growing cities. In the last two decades alone, eruptions in the Americas, Philippines and Indonesia have displaced in excess of one million people, with consequent hardship and economic distress. Such displacements of population occur when large areas of land engulfed by volcanic sediments are rendered temporarily or permanently uninhabitable. Recent eruptions at Mt Pinatubo (Philippines) and Soufriére Hills Volcano (Montserrat) are pointed illustrations of this problem.

Mt Pinatubo, one of a chain of volcanoes of the Luzon volcanic arc, had not erupted in 600 years. However, on

June 15, 1991, after several months of volcanic unrest, activity culminated in a climatic eruption described as the eruption of the century. Within one hour of the commencement of the eruption an enormous and vigorous eruption cloud developed which then spread laterally, at stratospheric levels, for 400 km. As the cloud expanded, tephra rained across 7500 km^2 of central and Western Luzon. At the same time, numerous pyroclastic flows roared down the slopes of the volcano in-filling and blocking major drainage systems with tens of meters of pyroclastic material. Rivers forced to flow unconfined across broad pyroclastic fans, mixed with loose debris generating voluminous debris flows that traveled down all major tributaries draining the volcano. Numerous lahars were also triggered by heavy rains associated with the untimely landfall of typhoon Yunya the same day (Figure 2).

The immediate effects of the eruption on local communities were disastrous. Several hundred lives were lost, millions of head of livestock killed, and an estimated 200 000 km^2 of farmland, the heart of Luzon s rice growing region, were lost beneath thick ash and lahar deposits. A staggering half a million people had been made homeless. In the longer term scientists projected that devastating lahars would likely occur for another 10 years as monsoon rains remobilize the 5 7 km^3 of loose pyroclastic material left resting on the slopes of the volcano. From June 1991 onwards literally hundreds of rain-generated lahars flowed down the main drainage pathways impacting communities up to 50 km away from the volcano and killing at least 850 people. In 1995, lahars breached hastily constructed dykes built to protect the heavily populated communities of Angeles City, San Fernando, Porac and Bacolor. Torrents of mud flooded prime agricultural lands and entombed Bacolor killing 100 people and leaving a further 100 000 homeless (Figure 3).

Much of the farmland around Pinatubo is now uninhabitable wastelands. This, together with the continued threat of lahars, has effectively prevented permanent resettlement of

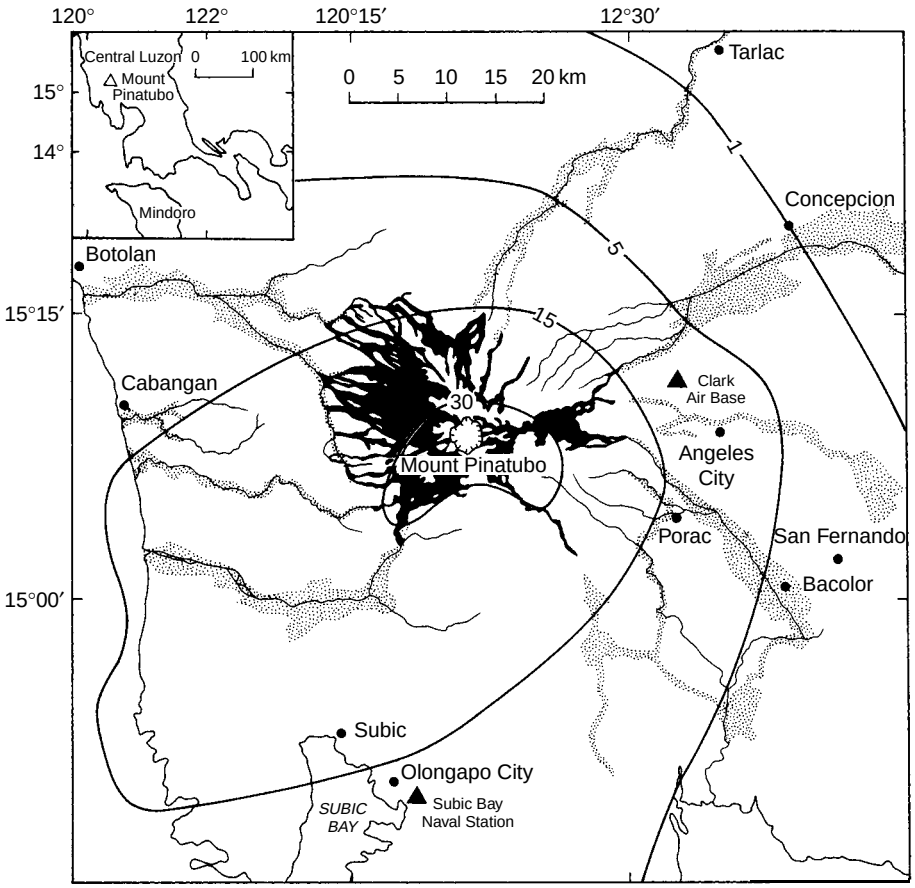

Figure 2 A composite map showing the distribution of tephra-fall deposits (isopachs are in centimeters) and pyroclastic flow deposits (in black) from the climatic June 15 1991 eruption at Mt Pinatubo. A thick blanket of tephra covered much of central and Western Luzon burying the heart of the rice bowl region. Also shown is the extent of deposition from hundreds of lahars (in stipple) that flowed down all major drainage systems between 1991 and 1993. the region and the resumption of vital economic activities. In fact, the physical landscape has been so transformed that today many of those who once lived on the slopes of Pinatubo are unable to locate their homelands, let alone return to them. The indigenous Aeta people, who prior to the eruption had farmed the slopes of the volcano, have lost not only their homelands but also their lifestyle, and presently face an uncertain future as they attempt to adjust to an urban existence.

Soufriére Hills Volcano located on the tiny island of Montserrat, in the Lesser Antilles volcanic chain, began erupting on July 18, 1995. The eruptions marked the beginning of an extended three year period of sporadic and at times violent activity, and the first eruption in recorded history for this peaceful Caribbean hideaway. Most affected were regions to the South, located downwind of the volcano. As eruptive activity escalated through 1995 1997 and towns were repeatedly showered with ash and threatened by pyroclastic flows, citizens in the South were progressively evacuated to designated safe zones in the North of the island. By August 1997, the volcano had claimed back two-thirds of the island, destroying in the process the capital of Plymouth. With continuing displacement of residents from the South, growing and intolerable pressure was exerted on the limited resources available in the North of the island, a situation made worse by ongoing eruptions which forced authorities to zone even more land as unsafe. The area occupied by safe zones was shrinking and conditions within them deteriorating. Hundreds of evacuees were living in cramped sub-standard shelters with little immediate prospect for improvement in living conditions. Eventually, with the threat of further activity and the growing realization that they may never be able to return to their homes in the South, two-thirds of the population left Montserrat in September 1997, accepting offers to be resettled on other Caribbean islands or in Britain.

FIRE AND ICE

The detrimental impacts of volcanism may also extend beyond these regional effects to influence the planet as a whole and specifically its climate. Our present understanding how volcanic eruptions affect climate derives from a much improved understanding of eruptive processes, revised interpretations of written accounts of famous historic eruptions, and new geologic and climate-proxy evidence of the effects of volcanism in prehistoric and historic times. These all lend support to the concept of volcano forcing as a mechanism of climate change.

Any sustained explosive eruption that generates a high-altitude (stratospheric) eruption plume has the potential to influence global climate. Such eruptions are termed Plinian and are characteristic of those at subduction-related volcanoes. Tephra, and hot gases released from the magma, are forcefully ejected into the atmosphere, forming a low-level eruption cloud above the vent. Initially, the momentum of this cloud allows it to propagate upward to heights of many hundreds of meters. However, in order for the cloud to reach higher stratospheric altitudes, its density must be reduced below that of the surrounding atmosphere. This will occur if sufficient atmospheric air is entrained into the cloud and heated. Buoyancy forces will then dominate and strong vertical convection will allow the cloud to continue to rise tens of kilometers until it reaches an altitude where its density becomes equal to that of the surrounding atmosphere. Here, the plume will begin to spread laterally forming a characteristic stratospheric umbrella cloud (Figure 4).

Volcanic ash carried to high altitudes in the convecting plume rains out from the base of the umbrella cloud over a period of several days to months, blanketing the landscape below it. Due to the short residence time of ash in the stratosphere, the effect of the particulate loading on Earth s global radiation budget is negligible. Rather, it is the gas content of the plume, specifically the sulfur dioxide loading, that is of importance. Once injected into the stratosphere, sulfur dioxide gradually reacts to form sulfuric acid aerosols, clouds of fine liquid droplets dispersed in air. These aerosols may persist for several years during which time they reduce the receipt of solar radiation at the Earth s surface by scattering and absorbing solar radiation. Their effect is to reduce tropospheric temperatures. The degree of cooling is a function of both the optical density (the extent to which aerosols scatter and absorb solar radiation) of the aerosol and its latitudinal distribution as it spreads with the atmospheric circulation. Eruptions at equatorial latitudes are

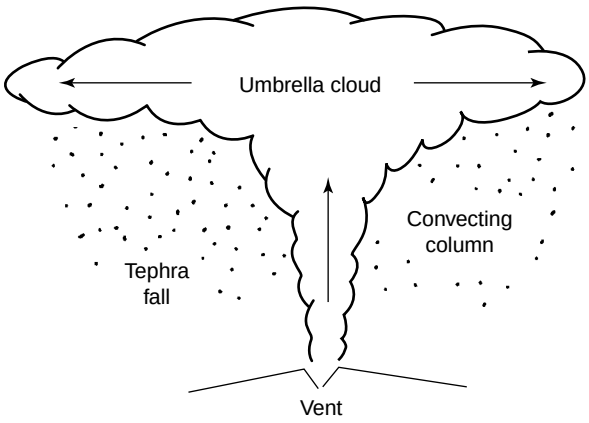

Figure 4 Schematic diagram showing a buoyant convective eruption column and stratospheric umbrella cloud. Tephra falls from the base of the umbrella cloud blanketing the landscape below. (Reproduced from Sparks *et al.*, 1997 by permission of John Wiley & Sons)

nicely positioned to disperse aerosols into both hemispheres and so have far greater potential to affect global climate.

In recent years, eruptions such as the 1982 El Chichón and 1991 Pinatubo eruptions have had small but measurable effects on global climate. Sulfuric acid aerosols from these eruptions encircled the Earth in less than three months, reducing mid-latitude Northern hemisphere temperatures by 0.3 0.5 °C (Figure 5).

The overall tendency of upper-atmospheric winds is to spiral towards the poles where downward movement of air masses aids sedimentation into the ice caps. As a result, sulfate concentrations in polar ice cores provide a direct measure of the deposition of volcanically produced sulfuric acid. Ice layers showing high sulfate concentrations correlate with well documented recent eruptions, and such acid spikes can be used to identify probable climate forcing volcanic events in early historic and prehistoric times. Identified are the eruptions of Taupo (New Zealand) in 181, Huaynaputina (Peru) in 1600, Tambora (Indonesia) in 1815, Krakatau (Indonesia) in 1883 and Gunung Agung (Indonesia) in 1963, amongst many others.

Historical accounts of some of these events describe volcanic winters, characterized by deteriorating climatic conditions and markedly cooler summer temperatures for up

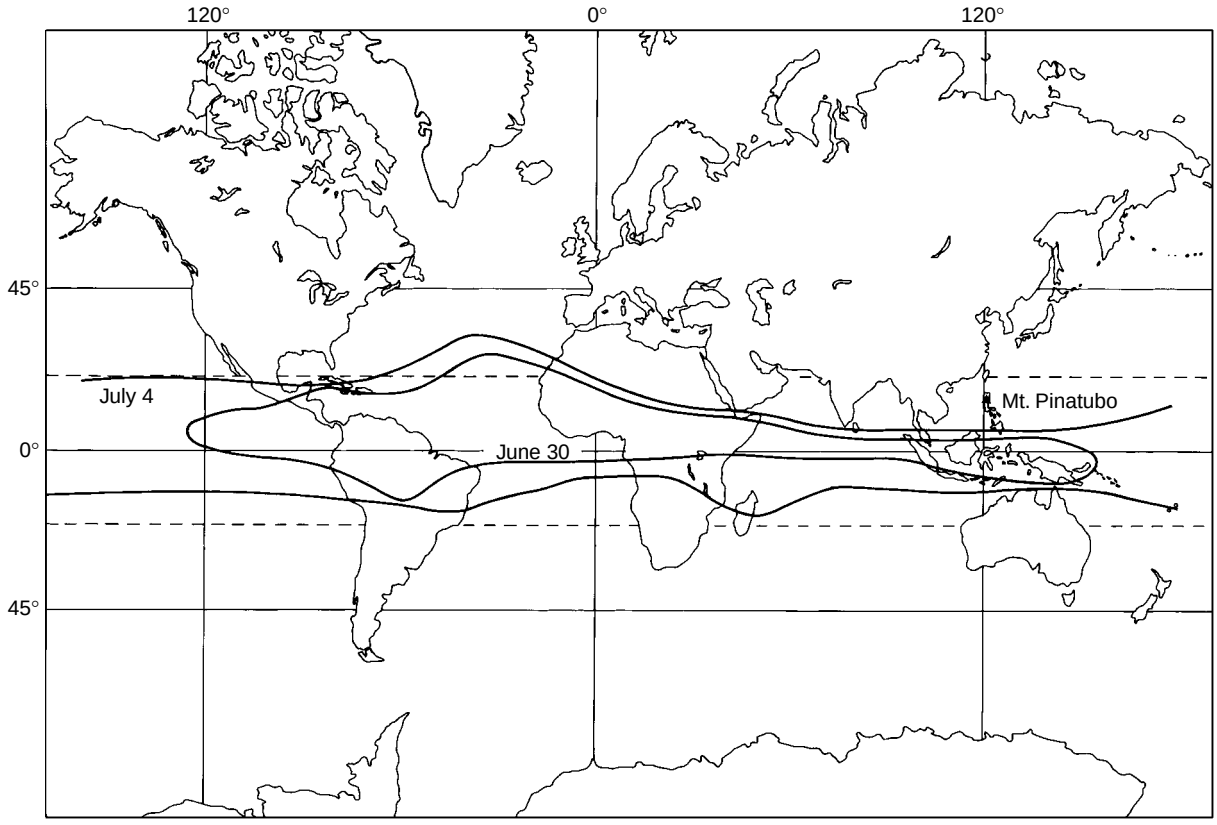

Figure 5 Stratospheric distribution of the aerosol cloud formed following the climatic June 15, 1991 eruption of Mt Pinatubo. The aerosol circled the Earth in 21 days and spread between 30 °N and 10 °S, causing measurable cooling (0.3–0.5 °C) of the troposphere. The distribution of the cloud was mapped by a TOMS (total ozone mapping spectrometer) carried aboard a satellite. (Reproduced with permission from Self *et al.*, 1995. Data courtesy of Gregg Bluth and Arlin Krueger, NASA Goddard Space Flight Center)

to 3 years following the eruption. The effects of a volcanic winter can be devastating, resulting in widespread crop and livestock losses, famine and deaths of thousands of people.

Some eruptions produce acid spikes at both poles, indicating widespread circulation of sulfur-rich aerosols. These eruptions are assumed to be of global importance and may be intimately linked with major climatic global perturbations. One such eruption occurred 74 000 years ago at Mt Toba in Indonesia, during a period of climate change associated with the last glacial cycle. The eruption produced a stratospheric sulfuric acid loading in excess of one billion tons resulting in an estimated 3 5 °C decrease in global surface temperatures for up to three years, but more importantly, a lowering of summer temperatures of • 10 °C in areas adjacent to those of established ice-cover. This temperature change would have been sufficient to tip the balance toward annual snow accumulation and the establishment of a snow albedo feedback mechanism. Dramatic increases in the planetary surface albedo would thus have triggered rapid glaciation and an acceleration of the global cooling already in progress.

The Toba eruption may itself have been triggered by a lowering of sea levels associated with the onset of glaciation. Throughout the Quaternary (the last 2 million years), periods of increased global volcanic activity, especially at volcanoes along coastlines, appear coincident with periods of rapidly fluctuating sea levels. During low sea levels, hydrostatic pressures acting to confine magma at depth are reduced, so allowing magma to ascend through new and reactivated crustal fractures caused by increased crustal tension. During periods of high sea level, the undermining of a volcanic edifice and periodic flank collapses may trigger decompression-related explosive eruptions. Indeed, studies at Mt Etna, on the coast of Sicily, suggest that past explosive eruptions are linked to rapidly changing sea levels in the Mediterranean area. Given that more than 90% of all active volcanoes are located within 20 km of the sea, the predicted rise in global sea levels attributable to global warming may have important implications for future eruptive activity, both in terms of eruption periodicity and impact on global climate.

CRUCIBLES OF CREATION

The scale of devastation wrought by volcanic eruptions in historic times has led us to view volcanoes primarily as agents of destruction and to overlook the immense tangible benefits that volcanism has presented to mankind, from extremely fertile agricultural soils to a source of renewable energy. These benefits derive from geologic processes that have acted over often very long periods of time measurable on geologic timescales and rarely within an individual s lifetime. Subtle as they are, they drive the economies of many developing nations, helping to sustain their typically dense populations. They may also be a source of additional wealth for many industrialized nations.

The most important of these benefits is the development and rejuvenation of soils. Of all the world s soils, those found in volcanic regions are probably the most fertile and have the highest potential for agricultural production, owing to the special nature of the parent material from which they develop. Termed *andisols*, these soils develop in tephra or pyroclastics, that is, from ejecta formed by the explosive disruption of magma. Pyroclasts are composed of minerals that crystallized within the magma and volcanic glass formed from the residual non-crystalline melt. They are classified according to their grain size, with material finer than 2 mm called *ash*. The constituent minerals and glass contain an abundance of elements such as potassium, magnesium and calcium which are essential plant nutrients, allowing plants to thrive. These nutrients become available to plants after many tens to hundreds of years of weathering in typically warm and wet tropical climates. In addition to their natural fertility, andisols also have excellent textural and structural characteristics providing for good natural moisture retention, drainage, and ease of tilling. Light dustings of ash from intermittent eruptions provide a means of rejuvenating heavily utilized soils or soils leached by monsoon rains by acting as a potent slow-release fertilizer. Thus, it is no accident that the densest populations of the world are found living on and around the slopes of active and dormant volcanoes. These are the rice bowl areas of developing nations such as Indonesia and the Philippines, which also support the world s best tea, coffee and sugar cane plantations.

Additional and economically important benefits include geothermal energy and ore deposits. Geothermal systems are found in areas of high regional heat flow where cooling intrusive magma bodies, at depths anywhere between several hundreds of meters to several kilometers, transfer heat and magmatic gases to subsurface groundwater reservoirs, hence their intimate association with young volcanic regions and the boundaries of Earth s tectonic plates.

The oil crisis in the 1970s and the subsequent concern over the finite nature of fossil fuel reserves saw great interest in the potential of geothermal systems as energy sources. Historically, those countries that successfully harnessed geothermal energy, principally for electrical energy generation, were wealthy and industrially developed. Italy s Larderello field began producing geothermal power in 1904, with plants in New Zealand, the USA, Japan and Iceland established shortly after. Developments in the 1980s and 1990s, however, have seen rapidly expanding capacity in the Ring of Fire countries and particularly within the Philippines and Indonesia. The Philippines is now the world s second largest producer next to the USA. Geothermal production is expected to continue in the Philippines to help meet industrial needs, part of an overall strategy to achieve

recognition as an industrialized nation. Today around 20 countries have significant contributions to their electrical supply from geothermal energy, and total global geothermal capacity is around 8000 MWe.

Iceland, situated above one of the world s hot spots and astride the mid-Atlantic oceanic ridge, is in an enviable situation of having potential geothermal reserves well in excess of the population s requirements. The very existence of this island as a developed nation is irrevocably entwined with the diverse and innovative development of its geothermal resources in overcoming the restrictions imposed by the harsh sub-arctic climate. Hot igneous intrusions beneath the 200 or more Icelandic volcanoes support numerous large high-temperature geothermal systems. Harnessing of geothermal energy began at Reykjavik in the 1930s, utilizing hot-water reservoirs for central heating of homes. Subsequent developments utilize geothermal waters and steam for electricity generation in concert with hydroelectric plants, for a range of commercial and industrial applications such as the heating of greenhouses and the drying of diatomaceous lake sediments used to manufacture high-quality industrial filters.

However, as with all energy sources, development of geothermal energy offers both advantages and disadvantages. Obvious advantages over the use of fossil fuels are the renewable nature of the reserves, and the lack of greenhouse gas emissions and consequent contribution to global warming. Disadvantages include resource management problems, potentially serious environmental pollution, and technological limitations to the exploitation of many geothermal fields.

Where geothermal reserves are extracted beyond their replenishment rates there is water depletion and pressure reduction. Excessive removal of geothermal water from the reserve can also result in surface subsidence. Water under the high temperatures and pressures associated with geothermal systems is capable of dissolving large amounts of solutes such as calcium carbonate and silica from the country rock[•]. On release of pressure and cooling, much of this solute can precipitate from solution. This effect is seen in areas where superheated waters vent naturally at the surface as hot springs or geysers and where spectacular formations such as the travertine terraces (composed of finely crystalline calcium carbonate) at Mammoth Hot Springs in Yellowstone may form. For the geothermal engineer, the formation of choking calcite and silica precipitates in pipes is a constant problem. Further, the residual brine left after the use of geothermal water and steam in electricity production is often a rich cocktail containing compounds of arsenic, mercury and boron which when discharged into surface waters can be a serious pollutant.

[•] *Country rock* is a general term for older rock (either sedimentary, metamorphic, or igneous) which has been intruded by magma or penetrated by mineral veins (Lapidus, 1987)

The future of geothermal energy development may not rely solely on superheated steam and pressurized hot water reservoirs presently harnessed, but on geopressurized zones and hot dry rocks. Geopressurized zones are areas where heat, water and methane are trapped under abnormally high pressures beneath thick layers of sedimentary rock, at depths of 3 km or more. These great depths prevent exploitation with current technologies. Hot dry rocks are areas where heated rocks exist near the surface, but where there are no associated reservoirs of water to carry away this heat. Experiments in harnessing this heat through the injection of cold surface waters and the recovery of the heated return water, though technically difficult, look promising. The potential energy resources of these reservoirs is enormous, but for the moment it is the dry steam reservoirs such as occur in the USA at the Geysers in California that are the most economically viable.

High-energy geothermal systems generated by volcanoes are among the most efficient natural concentrators of valuable ore minerals because factors critical for the creation of high temperature geothermal systems also favor formation of mineral deposits. Active volcanic systems are almost always too hot to mine and so ores are largely extracted from ancient or extinct volcanic complexes. Geothermal systems have the potential to deposit commercial concentrations of many elements including gold, silver, copper, lead, zinc, and sulfur. To illustrate the extraction of volcanic ores, we can consider the mining of sulfur from a chain of volcanoes along the crest of the Altiplano in the central Andes of South America. Here, economic deposits of particulate sulfur are found disseminated within the country rock and deposited around fumaroles. Sulfur extracted from no less than one hundred of the highest worked mines in the world (at around 6000 m above sea level) contributes to the global production of some 60 million tons per year which is destined for use in the manufacture of sulfuric acid, plastics, detergents, fertilizer, vulcanized rubber, and a host of other products.

DEFINITIONS

Pyroclasts are particles of volcanic origin expelled through volcanic vents. They are formed by fragmentation of magma and country rock surrounding the vent. They are classified according to their grain size as either blocks or bombs, lapilli or ash (Sparks *et al.*, 1997).

Tephra is synonymous with pyroclast and the terms tephra-fall and tephra-flow are used to indicate their mode of transport and deposition. Tephra-fall is used for all pyroclasts transported within and deposited from an eruption

column or cloud and tephra-flow is used for pyroclasts transported and deposited by pyroclastic flows (Sparks *et al.*, 1997).

Pyroclastic flows are hot, high-concentration, gas pyroclast dispersions that flow down the slopes of volcanoes. Their origins are from collapse of an eruption column that is unable to rise buoyantly (Sparks *et al.*, 1997).

A *lahar* is a rapidly flowing mixture of rock debris and water (other than stream flow) from a volcano. The term is restricted to sediment water flows of volcanic origin. In non-volcanic environments the term debris-flow is generally used (Smith and Fritz, 1989) (*see* Lahars, Volume 3).

Wadi

Wadi: an Arabic word for a watercourse that is dry for much of the time but which is subject to flash floods, sometimes catastrophic. Within the United Nations Educational, Scientific and Cultural Organization International Hydrological Program, there is a wadi hydrology network (Salih, 1999). The objectives of the network are:

- to enhance the knowledge and understanding of wadi systems;
- to develop the human and institutional capacities needed for the sustainable management of wadi systems;
- to develop the human and institutional capacities needed for the sustainable management of wadis and their water resources in arid and semi-arid areas.

Waste Dumps in Megacities: Case Study of Istanbul

Günay Kocasoy
Boğaziçi University, Istanbul, Turkey

Istanbul, with a population of 14 million, is located on two continents, Europe and Asia, acting as a bridge between them. Every day 6000 tons of solid waste is generated on the European side and 3000 tons on the Asian side. Wastes of Istanbul were dumped into the sea until 1953. Then the disposal of the solid wastes into open dumps became a common practice until the publication of the Solid Waste Regulation at 1992. Since then, the Municipality of the Metropolitan City of Istanbul has started construction of transfer stations and sanitary land lls. Currently there are six transfer stations and two sanitary land lls in Istanbul. Solid wastes are collected and transported to transfer stations and emptied into silos by the local district municipalities. After their volume has been reduced by 20%, they are transported in silos to the nal disposal areas and buried by the Municipality of the Metropolitan City of Istanbul.

Industrial solid waste is collected and transported to the nal disposal areas by industry itself. Medical wastes are handled in a special way and collected and transported separately to the medical waste incinerator of the Municipality. Construction of solid waste recovery and compost plants is included in the programme of the Municipality for the coming years.

One of the most significant problems of a city is the management of the solid waste generated. Handling the solid waste properly is very significant especially for cities like Istanbul, whose population is continuously increasing because of the migration from rural areas and other cities. Today, the population of Istanbul has reached 14 million and it is expected to reach 17 million by the year 2020. As a result of the increase in the population, 9000 tons of municipal solid waste is generated per day.

Istanbul, situated on two continents, is a bridge between Europe and Asia. Six thousand and 3000 tons of solid waste are generated on the European and Asian sides of Istanbul, respectively. The residential areas, hotels, offices, commercial areas, street cleanings, parks and recreational areas are the sources of solid wastes generated. The annual waste generation estimates for the future are given in Table 1.

According to Table 1, the solid waste production *per capita* is $0.66\,\mathrm{kg\,day^{-1}}$ on the European side while it is $0.56\,\mathrm{kg\,day^{-1}}$ on the Asian side; the average for the whole city is $0.63\,\mathrm{kg\,day^{-1}}$.

The physical and chemical properties of Istanbul s solid waste change from region to region and also from season to season. Therefore, the composition of the solid waste generated in Istanbul is estimated by dividing the city into five regions according to the socio-economic level of the inhabitants and the type of fuel used for heating in the district.

1. Commercial districts.
2. Low socio-economic level, shanty houses, using coal or wood for heating. Thirty percent of the population live in this region.
3. High socio-economical level, using solid fuel. Twenty percent of the population live in this region.
4. High socio-economical level, using liquid fuel. Twenty percent of the population are living in this region.
5. Normal average socio-economical level, using solid fuel. Thirty percent of the population live in this region.

Table 1 Annual solid waste production in Istanbul (millions of tonnes) (Curi *et al.*, 1998)

	Years			
Location	1990	2000	2010	2020
European	1.11	1.71	2.34	3.01
Asian	0.55	0.97	1.35	1.74
Total	1.66	2.68	3.69	4.75

Composition of the solid waste by year, in percentage, is given in Table 2. These percentages will change because of the increase in the use of natural gas and low-ash coal. As a result, the ash content is expected to decrease. Also, although the amount of organic materials is increasing, the percentage of it decreases because of the increase in the total amount of solid waste.

The most common method of disposal of solid waste used to be open dumps. Istanbul had five open dumping areas, named Kemerburgaz, Halkalı, Umraniye, Aydınlı and Yakacık. All of them, except Kemerburgaz and Halkalı, were legally closed but rehabilitation activities are still going on. These were the places where solid waste was simply dumped and left as it was. Wastes were neither compacted nor covered. Also, the dumping areas did not have any leachate or gas collection systems. Therefore, they were potential sources of very serious environmental problems.

With the publication of the Solid Waste Control Regulation in 1992, the Metropolitan Municipality started to construct transfer stations and sanitary landfills according to international standards. Six transfer stations and two sanitary landfills have been constructed since 1995.

The transfer stations at Halkalı, Baruthane and Yeni Bosna with 53, 65 and 50 silos, respectively, and a total capacity of $7500\,\mathrm{tons\,day^{-1}}$ are located on the Asian side. The other three transfer stations, Aydınlı, Hekimbası and Kucuk Bakkalkoy, having 55, 69 and 45 silos and a total capacity of $7500\,\mathrm{tons\,day^{-1}}$ are on the European side. The volumes of the silos are $32\,\mathrm{m^3}$. The distances from the transfer stations to the sanitary landfills are 38 51 km. Collected solid wastes are brought by truck to the transfer stations, emptied into the vertical silos and pressed, reducing the volume by 20%. Then the silos are carried to the final removal areas.

There have been two sanitary landfills in operation in Istanbul since 1995. One, called Odayeri, is located on the European side and the other one, named Komurcuada is on the Asian side. Odayeri sanitary landfill has an available area of 14 hectare (ha), but it has a projected area of 2000 ha for future developments. It has the capacity

Table 2 Change in solid waste composition according to year (%) (Curi, 1990; Kocasoy, 1996)

Content	1980	1981	1983	1984	1985	1986	1987	1992	1996
Organic material	60.8	60.60	59.00	51.8	43.25	42.70	44.62	45.00	48.00
Paper	10.15	18.80	13.12	10.73	11.72	10.20	11.92	14.50	8.40
Textile	3.22	31.00	1.40	3.21	4.87	3.10	4.28	5.60	2.90
Plastic	3.05	3.10	4.04	4.83	7.13	6.22	11.87	9.50	11.00
Glass	0.65	0.70	0.55	1.36	1.71	3.61	3.42	3.80	4.60
Metal	1.43	1.50	6.49	4.82	4.34	4.56	2.28	2.20	2.30
Ash	16.16	14.60	10.04	18.45	16.84	20.15	14.12	15.00	13.20
Miscellaneous	4.54	6.90	5.00	4.79	10.14	9.46	7.43	4.40	6.30

to store 4500 tons of solid waste per day. The area of the other sanitary landfill, Komurcuada, is 6 ha, but an additional 50 ha is reserved for the future. The target is 198 ha for the next 25 years. The base of the landfill areas was made impermeable (10^{-8}) by a layer of clay 60 cm thick and a high density polyethylene (HDPE) membrane 2 mm thick. Leachate collection pipes were installed above the impermeable layer and the collected leachate is transferred to treatment plants. Also gas collection chimneys were placed every 50 m. It is planned to convert the collected gas into electric energy in the future.

The local district municipalities are responsible for the collection and transportation of all municipality solid wastes to the transfer stations while the Metropolitan Municipality is responsible only for the collection of solid wastes from the main streets, public parks and then the management of all solid waste after it has been brought to the transfer stations. The Metropolitan Municipality is also responsible for the construction and operation of the final disposal areas.

The Municipality does not collect industrial solid waste. It is the responsibility of the industry itself to collect and transport domestic solid waste to the disposal sites and hazardous waste to the incineration plant located at Kocaeli. Health-care waste is collected and transferred to the incineration plant separately by the Municipality.

Silos of compacted wastes are transported from the transfer stations to the sanitary landfills by trucks and emptied onto specially built platforms; from there they are placed in prepared cells by bulldozers and pressed by compressors. At the end of the daily storage operation, the cells are covered with soil. Every day 4500 tons of waste is brought to Odayeri and 3000 tons of solid waste is brought to the Komurcuada sanitary landfill. The rest of the solid waste is dumped in open dumps.

There are no effective recycling and recovery programs in Instanbul although one recovery plant operates as a pilot plant. Construction of compost plants is also within the program of the Municipality.

Waste: the Global Mass and its Management

W S Fyfe
University of Western Ontario, London, Canada

There is no doubt that one of the major causes of recent global change is the increase in human population and the impact of the present life-support technologies for this population on the global environment. It is interesting to look at dictionary de nitions, of the word waste (vastos): to desolate, ravage, devastate, damage, ruinous, neglect, useless, spend uselessly, foolishly, squander, decay, exhaust, consume the livelihood.

We would not have six billion humans on the planet (soon eight to ten billion) without certain technological systems. These all involve waste production and waste management or mismanagement. The key components include:

1. *energy production;*
2. *water quality and quantity;*
3. *food related to soil quality and quantity, water and climate, biodiversity;*
4. *arti cial materials (steel, glass, concrete, etc.) all derived from the outer 5 km of the crust of the Earth by mining technologies;*
5. *the chemical industries, from plastics to pesticides, etc.;*
6. *the management of urban wastes; today most of the people of the world live in cities.*

ENERGY

There is no doubt that a major component determining the quality of life is the availability of energy. The present world is divided into those who waste energy, those who are trying to conserve and those who desperately need more energy. Thus in the US, energy consumption *per capita* is 317 gigajoules; Germany, 170, Japan, 141; China, 25; India, 10; Nigeria, 7 and Afghanistan, 1 (Fyfe, 1999).

Today, most energy is produced from fossil fuels (coal, oil, gas) which are not renewable on human time scales. Smaller sources of energy include nuclear energy, whose use has greatly increased over the past 30 years, hydroelectricity and solar energy (wind, waves, light), whose use is increasing (Table 1). All energy technologies are associated with the production of wastes.

First, with fossil carbon fuels the dominant waste is carbon dioxide. As the famous Swedish chemist Arrhenius stressed in 1896, if we continue to increase the carbon dioxide concentration of the atmosphere, the planet will

Table 1 World Energy Consumption (*Source:* Fyfe, 1999)

	Petajoules (1993)	Percent increase since 1973
Solid carbon fuels	92 000	36
Liquid carbon fuels	134 000	11
Gas carbon fuels	78 146	72
Geothermal and wind	1463	641
Hydro	8554	86
Nuclear	23 646	1365

become warmer, the greenhouse effect! Today, world data are clear. In the year 1800, atmospheric carbon dioxide was 280 parts per million (ppm) by volume, while today is over 350 ppm. Our energy industries have changed the air we breath and slowly, the impacts on human health are appearing (Haines and McMichael, 1999) (*see* Environmental Change and Human Health: Extending the Sustainability Agenda, Volume 3). *Per capita* emissions of carbon dioxide are 20.8 tonnes in the US, 10.2 Germany, 5.8 France, but if all people in the world produced carbon dioxide *per capita* as with North America, it would not be a greenhouse, it would be Venus!

But when one examines the chemistry of fossil carbon fuels, there are many other forms of atmospheric and environmental pollution. Thus atmospheric methane concentrations are increasing rapidly (*see* Methane: Industrial Sources, Volume 3). With high sulfur coals, which are common with up to 10% sulfur, acid rain is related to combustion. And some coals contain halogens at moderate concentrations, particularly, chlorine and fluorine, and during combustion acid gases and even organo-halogen components can be produced.

The chemical composition of coal, the major fuel of China and India, is highly variable. Coal can contain a host of trace elements like lead and arsenic. It is amazing that when a very large coal powered electric plant was recently built in Northern Thailand, the detailed chemistry of the coal had not been determined. Normally, engineers are interested in moisture, sulfur and ash only. We discovered that tones of the coal being used was very rich in arsenic, 1000 ppm. Arsenic pollution of soil and moisture is a huge world problem. A recent report by Pearce (2000) states: unless urgent action is taken, one in ten deaths in Southern Bangladesh could be due to arsenic poisoning . There are many sources of arsenic pollution but coal is one that must be carefully watched. It is interesting to note that India and China mine over 1.5 billion tonnes of coal per year. This implies moving something like 3 km^3 of rock per year!

The ash and waste produced from the coal industry is of the order of 1 km^3 per year. It is only recently that there have been detailed studies of the chemical composition of coal ash. Some coals are rich in uranium, and even gold. But more commonly, because of the bio-organic origin of coal, there may be significant concentrations of bio-essential elements (potassium, calcium, phosphorus, •••). Some coal ash can even be useful for soil remediation and as a fertilizer.

COMBUSTION GAS DISPOSAL

There is increasing interest in the possibility of controlling and using combustion gases (see Fyfe, 1999). And if combustion gases are pumped into appropriate rock formations, the acid rain problem can be reduced. The reactions also generate energy and there can be a bonus of warm water.

After fossil fuels, nuclear energy is the major producer of electrical energy. During the period 1985 1996 nuclear energy production increased 56%. In the 1940s and 1950s, most scientists saw a future for clean nuclear energy. Today, that view has changed. First, particularly since the Chernobyl disaster, one must be sure there are no accidents with nuclear power plants, an impossible guarantee.

Only recently have we become aware of the problems of nuclear waste management, isolation from the biosphere. And recent work has shown (see Pedersen, 1993) that complex communities of microorganisms are active to depths of several kilometers. The problem is urgent as stressed by Pease and Roberts (1996) who show that there is enough plutonium on the Earth s surface to make 200 000 nuclear bombs. Nuclear waste isolation is an urgent international responsibility (*see* Nuclear Waste: Geological Issues, Volume 3).

Is hazardous, toxic waste isolation from the biosphere possible? With nuclear waste, we are concerned with times of a few million years for decay of the most dangerous species. But there are wastes, as with arsenic, mercury and many other chemical elements and compounds, where there is no half-life. Fortunately geological and geochemical data show that long-term isolation is possible. We have many examples of materials formed more than a billion years ago, materials sensitive to corrosion and chemical transport, which are perfectly preserved. Such minerals include species like elemental copper, many types of metal sulfides, even massive deposits of oil, gas, and salt! But a problem with nuclear and other toxic wastes is that nations which have the nuclear reactors may not have the best host rocks for disposal. Also, recent work in Sweden has shown that events like an ice age can lead to disturbance of an underground site.

IS CLEAN ENERGY POSSIBLE?

Fortunately the answer to this critical question is positive. We have two vast energy resources on planet Earth. If we could collect and use about 12 hours of solar energy, it would provide all that is needed. Solar energy exists

in many forms, such as radiation, wind, tides and ocean currents (*see* Wave Power Development, Volume 3; Wind Power Development, Volume 3). The costs of wind, photovoltaic, energy are rapidly diminishing and the use expanding. As reported in the *New Scientist*, 16, October, 1999, Germany is planning the two largest wind energy systems in the world. These sites, farms, will produce power on the scale of 1000 MW (cf. nuclear plants), with minimal pollution.

The other great source of clean energy is from the thermal gradient in the rocks of our planet. In most situations, the temperature increases 30 °C per km depth. Near volcanic sites, rocks near the surface can be at temperatures over 1000 °C and are produced on and in the continents and on a massive scale in submarine environments. The rate of production of heat is sufficient to supply the energy needs in many nations. And as stressed by many, the land disturbance, and of wastes associated with solar and geothermal energy is minimal. It is interesting to note that as reported by the Worldwatch Institute (2000) the annual growth rate of wind power is 22%, solar electric, 16%, geothermal 4%, oil gas 2%, nuclear 1%, coal 0% in the period 1990 1998. There is hope for clean energy.

MATERIALS

Advanced societies use a very complex array of inorganic and organic materials. These include stone, concrete, brick, ceramics, glass, steel, copper, zinc, aluminum, plastics, paper and a huge array of chemicals. In advanced societies something like 20 tonnes of rock are used annually per person. The great demands are for construction purposes, buildings, roads, railways, etc. If all people in the world of 2050 were to use rock on this scale, it would approach a volume of 100 km^3 per year, more than all volcanism on land and ocean floors. Yes; Vernadsky (1986) was correct!

In our populated world the land surface becomes more precious and must not be wasted. Giant shallow, open cast, mining operations destroy the land surface. Almost all our inorganic resources come from the outer 5 km of the Earth s crust. Some very deep mines, mainly for gold, approach 5 km depth. It is interesting to look at world mining figures (World Resources Institute, 1999). For example, iron ore 554 million tonnes; aluminum ore 27 million tonnes; copper ore 10 million tonnes. An interesting example of mining and waste is provided by gold with total annual production over 2 million kg. In the rocks mined for gold, the normal concentration is about 3 g per tonne (3 ppm). Thus for the total production about 1 billion tonnes of rock is mined, ground to a powder and the gold extracted by mechanical methods or with chemicals like cyanide. Recently in one of our university classes, we weighed the gold rings of the young students. The average weight was 10 g so the student was wearing the product of processing about 3 tonnes of rock! (*see* Materials Flows for Mining and Quarrying, Volume 3).

Gold illustrates the general problem of quality control of all extraction processes. Gold ores are normally associated with iron sulfide minerals. And very frequently there is a moderate concentration of arsenic or lead. The wastes from gold mining and gold extraction can be highly toxic and environmental disasters occur frequently. For example in a recent report in *Harper's Magazine*, October, 1999, it is stated:

> Constrained by environmental and labor regulations at home, American, Canadian, Australian and European mining companies have turned increasingly to remote, developing countries, digging mines of unprecedented size and destructiveness in relative obscurity. Many of these projects have caused significant deforestation, forced migration, and the release of industrial waste (cyanide, arsenic, lead and copper) into nearby waterways, killing all life in several rivers

A recent study by Nriagu (1996) on the history of global metal pollution is alarming. Thus as metal production has increased so has atmospheric pollution which in turn leads to soil and water pollution. Thus for lead, annual production increased from about 5 million tonnes in 1850 to 30 million tonnes in 1990. Lead emission to the atmosphere changed from about 0.5 million tonnes to 4 million tonnes over the same period. In many regions today, children have high levels of lead in blood with serious health effects (World Resources Institute, 1999). However, in countries where only lead-free gasoline is sold, children s blood no longer shows elevated levels of lead.

The use of metals illustrates well the need for quality control at all stages in their production and the need for recycling. Birkett (2000) describes the new European Union proposal for massive reuse and recovery of all materials in automobiles. And these approaches are needed for all materials extracted from the Earth.

An elegant example of waste prevention is given by highway construction in Sweden. A new multilane highway was proposed to link major cities in Sweden. Normally, one would aim for the shortest distance. But when the geology, the nature of the surface (rocks, soil, water) was carefully studied, it was found that by using a slightly longer route, the costs were reduced by 50% and the environmental impact vastly reduced.

WASTE AND URBAN SYSTEMS

In 1950, the urban population of the world was about 1 billion, today about 3 billion and is projected to rise to 5 billion by 2030 (*see* Urban Population Change, Volume 3). In the world today 47% of people live in urban regions, in Europe 75%. North America, 77%, South America 80%, Africa 38%, Asia, 38% and all cities are projected to grow.

Urban wastes are massive and complex in their variety (*see* Urban Wastes, Volume 3). A typical example is provided by paper and paper products. Today, *per capita* use of paper is near 0.05 tonnes worldwide. The greatest waste of paper is in North America at a figure of 0.25 tonnes per person, compared with Europe 0.09 tonnes per person. Given quality control, paper can be recycled. In 1993 the lead nations were Austria and Spain with 78% recycling compare to the US at 34%. In many nations, paper products if carefully collected and separated can be recycled or even used as fuel for electricity production.

World data on total urban solid wastes per capita for 1993 (World Resources Institute, 1999) are impressive. For example, Lagos Nigeria, 0.3 kg per day, Paris, France 1.3 kg, Toronto, Canada 1.4 kg, New York, US 1.7 kg, Shanghai, China 0.8 kg, Dubai 2.3 kg. If one examines world data on urban wastes (see the *Economist*, 1999) the annual municipal wastes in the developed nations averages about 500 kg per person. If this was the average for a world with 10 billion humans, given that most wastes have a density near $1\,g\,cm^{-3}$, world production would be of the order of $5\,km^3$ per year, a figure comparable to the output of all annual continental volcanism.

But as well as typical urban domestic wastes, there are hazardous wastes and a variety of industrial wastes, which are produced on an even larger scale in industrial nations. These include wastes from the chemical industries, the metallurgical mining industries and the like. A dramatic example of industrial waste problems was the cyanide spills from Romanian mining.

A new initiative from the European Union will produce regulations that will require that in automobile manufacture, at least 85% of materials from used automobiles, including plastics, must be reused (Birkett, 2000)! This illustrates the general principle that quality control at the input determines the ease and economics of recycling the wastes.

It is interesting to examine the history of urban architecture and waste. Before electricity, before the large use of fossil fuels and before air conditioning, great attention was given to efficient construction. I was very impressed visiting some very old houses in Saudi Arabia during a very hot summer. The materials used were designed to reflect the sun, windows were placed to catch the night breezes. Today, with many of our massive modern buildings, such factors are rarely considered.

WATER

For many nations there is a growing crisis in the supply of clean water. Almost 40% of the average annual precipitation is manipulated by man. And after we use fresh water, its chemistry and biology are changed. The growth of urban populations has increased the problems and in many nations urban waste waters are discharged to the local rivers and oceans untreated. The world situation has been described by the World Resources Institute (1999) with particular attention to the situation in China. In most of Europe over 90% of wastewater is subject to some form of treatment. But for Lagos, Nigeria, only 2% is treated, Bombay 10%, Rio de Janeiro, 23%. We have recently been flooded by reports of the pollution on Copacabana Beach, Rio, with massive death of fish due to improper treatment and disposal. Normally the treatment involved some form of use of aerobic bacteria. With careful control, the sludges can be used for various compost, applications. Often, before the final fluid is discharged, low levels of chlorination are used (Baird, 1999).

SOIL

One of the most critical issues facing the present and future world is providing sufficient food of nutritional quality. As recently reported in *Nature* (Nov. 25, 1999, 341) to turn a blind eye to 40 000 people starving to death every day is a moral outrage . Many would say that 40 000 is a very conservative estimate. Food production in large part depends on soil quality, water and climate. As Brown and Wolf (1984) of the Worldwatch Institute wrote soil erosion: quiet crisis in the world economy (*see* Soil Deterioration and Loss of Topsoil, Volume 3). These authors show that over the past decades topsoil loss has approached 1% per year globally. We have shown in many places, that when soils are eroded by wind or water, the fine particulate clays are removed. These materials with large surface areas are vital to water retention and nutrient cycling between soil microorganisms and plants. Global satellite pictures dramatically show the patterns of soil erosion, an ultimate case of waste of a major component of our life support systems. Quality soil formation from rock materials takes times measured in 100s or 1000s of years. There are many examples of how wastes can be used for soil remediation (*see* Soil Amelioration, Volume 3).

Wastes: Landfill and Land Raising

Peter Jones
Biffa Waste Services Ltd., Buckinghamshire, UK

Land ll is the oldest and most obvious waste activity associated in the human mind with the management of discarded materials. Historically this position was shared with reuse but the growing sophistication of materials and the complexity of products in the waste stream result in steadily increasing global tonnages to this exit route. This article explores aspects of this process in terms of the sustainability challenge. Speci cally, we discuss land ll morphology, land ll economics, in uences on compositional shifts (demand and supply side), and future challenges.

The role and signi cance of land ll management systems in different national frameworks is subject to a complex interplay of factors involving geology, climate, input waste stream policies and engineering expertise. The unpredictability of these constantly changing variables by de nition results in a counsel of caution with regard to the use of land ll as a strategic element in end-life waste management. The key strategic issue is whether, at local, regional or national level, it is easier to manage the unpredictable gaseous and liquid impacts of land lls or to apply equivalent energy and nancial resources to front-end segregation and specialist processing systems. At its heart is the question: are centralized aggregated processes simpler to manage and measure than geographically dispersed and segregated processes?

LANDFILL MORPHOLOGY

There will always be a need for some form of long-term storage facility for waste products whether in combination or segregated (Figure 1). Technology is readily available to reduce the mass of a wide variety of waste streams but governmental and corporate choice is restricted by straight economics. As long as landfill remains considerably cheaper than alternative process routes, the greater the volume that will be entombed in this fashion. Even where via a framework of fiscal and budgetary pressures or market forces those cost differentials are narrow, landfill entombment remains a best practicable option for a wide range of difficult substances, the mass or toxicity of which renders alternative routes unviable. Prominent examples include bottom ashes from waste incineration plants, certain types of foundry sands and contaminated soils (Figure 2).

Engineering practice in landfills has accelerated in response to the complexity of waste stream mixing introduced with sites accepting wet/dry, organic/inorganic and industrial/domestic streams representing the greatest challenge for containment engineers. The basic prerequisite introduced by regulatory pressures is that externalities and pollution arising from the landfill activity proper (in gaseous, liquid or disamenity (dust, odors and windblown pollution)) are reduced to an absolute minimum (Figure 3). In practical terms, in a sector where measurement systems are still represented as emergent technologies, the challenge for landfill operators is to benchmark individual site performance on these factors against industry-wide norms or expectations of zero performance standards. Against this background, national governments have thus fluctuated between outright bans (Denmark) to higher regulatory and monitoring standards (UK) to flexible input strategies coupled to significant liability and legal exposure (USA).

Figure 3 Incineration versus landfill emissions of greenhouse gases

Each of these core policy frameworks produces a different emphasis in terms of engineering management and cost profiles.

Engineering Issues

Landfills are complex material processing mechanisms which operate within a fairly simple framework. In essence a chemical reaction is introduced by limited quantities of oxygen, moisture/fluids, organic materials, soluble metals and compounds and non-reactible materials. Over time scales varying from hours to decades, the result is a displacement of mass in this material into gaseous methane and carbon dioxide, liquids containing inorganic materials in solution, precipitates and stable, inert material. The reactions between each of these diverse materials do not occur in a consistent and controllable manner. They are driven by waste inputs related to material supply and demand in complex economic situations. Given the wide diversity of origin of wastes, coupled to the variable geology of their local position, it is feasible to produce a constant output stream only by careful attention to on-site engineering in respect to construction of working cells together with associated pipework and gas collection infrastructure.

Nevertheless, the broad range of combined outputs from landfill sites is often readily identifiable. Work has been undertaken on methane CO_2 compositional analysis and the factors influencing it as well as on similar factors affecting leachate composition and basicity. Mass balance evaluation of this nature for entire landfill sites is the most productive area of research. This is largely because, at the operational level, regulatory frameworks require the landfill site to be managed by phased development in units or cells. Such construction techniques are enforced by the need to concentrate releases of gas and liquids on a day by day basis throughout the working lifetime of the operation. Thus individual cells which often operate as mini-self-encapsulated landfills within the main body of the landfill are themselves subject to regular daily cover or capping by inert materials which further inhibit local disamenity on a day by day basis. The effect of such management practices, however, is to inhibit cross reactivity of materials within a site as well as the transboundary migration of gaseous and leachate liquid by-products in ways which are optimal to the operation of the site (Figure 4).

Much work continues to be done on the trade-offs between the avoidance of localized pollution during the construction phase of the landfill and maximizing the long-term productivity of the site for converting methane and other gases for power generation.

In turn this has triggered further debate on whether best engineering practice on landfills should encourage tight day to day containment (which often results in extensions to the active cycle of the site life) or accelerated biodegradation (which reduces whole-life activity cycles but may compromise localized disamenity during site operation). The choice between such options is often a function of location, geology and input streams; these points are evaluated in the section on future challenges.

LANDFILL ECONOMICS

As is common with most items of capital plant in any engineering application, one has to distinguish between operating and capital overhead costs. The assessment of landfill sites in financial accounting terms is often as complex as the variables involved in their physical operation. Historically, given an abundant supply of new landfills capable of meeting existing and future demands, it was perfectly acceptable in the UK for new landfills to be valued at their direct acquisition cost and depreciated on a straight-turn basis over their anticipated life cycle. In the UK, in common with other countries where the planning system allows public participation, the replacement of void on a like-for-like basis is often inhibited. In such circumstances the cost of replacement void in the UK trebled from £0.7 to £2 m^{-3} between 1990 and 1999.

Cost allocation strategies with regard to remediation and ongoing engineering thus vary between operators. This is a function of their approach in terms of the engineering process selected (see above) and the quality of leachate gas management retrieval systems. The most predictable cost factor relates to routine site operation in the form of compactor operation, *in situ* management and checking facilities. Nevertheless, additional variations creep in, given that different operators adopt different operating management systems in the form of ISO accreditation and other standards. Pricing strategy in such circumstances tends to be opportunist, marginal and designed to operate on the basis of charging what the market will bear (Figures 5 and 6).

For those landfills accepting multi-material inputs, pricing decisions may be even more erratic, often reflecting the degree of local monopoly control enjoyed by the operator. Where two or more operators exist within a 30 km radius, pricing tactics tend to reflect cash flow and profit expectations on a marginal basis. Where single operators have no immediate competition, gate fees tend to reflect the entry price of the next best available processing technology for specific material streams. Inputs of classes of material classified as hazardous or special, offer premium price options which contributes substantially to net margins. Volumes are restricted, however, in the UK by license conditions which prevent carryover of unused quotas from one week to the next (Figures 7 and 8).

INFLUENCES ON COMPOSITIONAL SHIFTS

Supply Side Factors

Supply side factors are those that influence variability in the composition of the waste coming to the landfill. As public consciousness is raised with regard to the management of end-life materials, such factors tend to be driven by governmental policy or strategy. The most significant of those which operate in Europe in 1999 are:

- Producer responsibility: whereby companies or industry sectors introducing particular products into the environment are responsible for the final disposal of these products at the end of their useful life. Such organizations may see landfill as a desirable objective but their thinking is often influenced by governmental policies involving targets or objectives which divert their material away from landfill. A Traded Pollution Permits framework designed to provide an incentive for choosing landfill diversion strategies may reinforce such tactics. In the UK landfill context, the most significant of these are the Packaging Directives relating to organic and inorganic inputs in the packaging supply chain.
- Landfill taxes are also a significant contribution to the process by which governments can raise the competitiveness of other forms of waste reprocessing. In the late 1990s, British waste stream charges for mixed waste arisings to landfill increased from around £5 $tonne^{-1}$ to £10^{-1}, yet even with landfill taxes of an additional £11^{-1} the incentive was still insufficient to encourage substantial diversion. Regarding customs data the moving annual total (MAT) tonnages to landfill have fallen 25% in 3 years to 70 million tonnes (latest data December 2000) (Figure 9). More important, the municipal contribution to overall total inputs has risen from 25% in January 1998 to 40%.
- Virgin input taxes such as on newly quarried aggregates may also encourage landfill diversion activity. Such mechanisms raise the cost of freshly mined material particularly aggregates and construction products thus encouraging the sorting and cleaning of materials such as construction and demolition waste which would otherwise have passed to landfill.
- Shifts in behavior of significant waste-generating sectors such as municipal and household arisings moving toward higher levels of source segregation in response to government-set targets or other factors can also impact on compositional profiles to landfill.
- Outright bans have an obvious and immediate effect depending on the time cycle over which they are phased. Examples in the UK include threats to the landfilling of liquid hazardous materials, tyres, clinical waste (incontinence pads), biodegradable materials and certain hazardous substances such as insecticides, pesticides and heavy metals. The key focus of EU

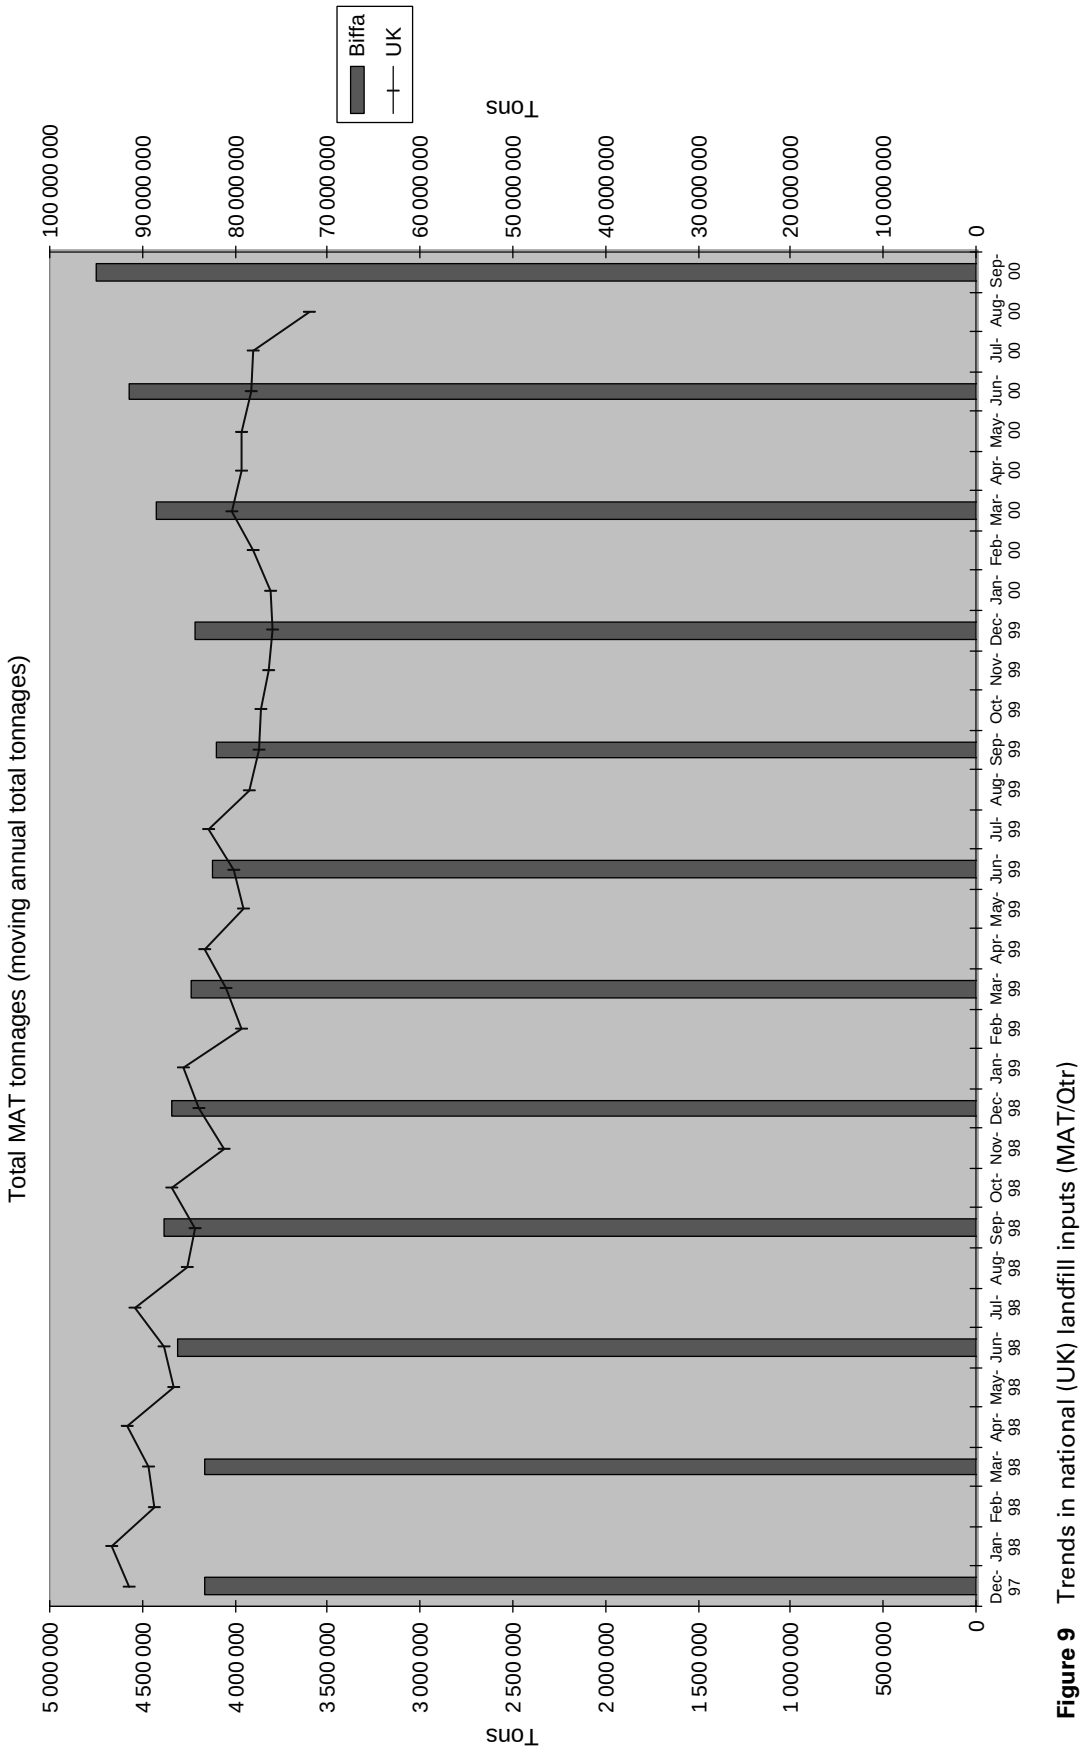

Figure 9 Trends in national (UK) landfill inputs (MAT/Qtr)

- By 2020 at latest, reduce biodegradable municipal waste (BMW) to landfill to 35% of total BMW in 1995. Intermediate targets of 75% by 2011 and 50% by 2013
- Ban on co-disposal
- Ban on tyres (by 2003 for whole tyres; by 2006 for shredded tyres)
- Ban on liquid wastes, infectious clinical waste, certain hazardous wastes by 2001

Figure 10 Landfill directive

strategy lies in reducing organic inputs to landfill with the consequence that the biodegradable activity in the landfill site is slowed and the active phase of the site thus extended. The most significant cumulative impact of this process is seen in the UK Landfill Directive which calls for a reduction of 65% in the tonnage of biodegradable municipal waste inputs by 2016 on 1995 levels (Figure 10).

FUTURE CHALLENGES

To Mono-dispose or Co-mingle

The persistent fundamental question on the true function of landfills remains as to whether they are ongoing chemical bioreactors with the specific purpose of neutralizing their content or whether they are long-term surrogate storage units for segregated, mono-material pollutant streams which can be held in the best practicable environmental medium until such time as innovative technologies permit them to be mined and exploited at some point in the future?

Dry Versus Wet Entombment and Management

As bioreactor units, landfill sites can biodegrade over an extended life cycle, major sites with organic materials often having a life expectancy in excess of 30 years. That life cycle can be reduced by absolute bans on all liquid inputs or pre-preparation of waste streams prior to burial. Conversely it can be accelerated significantly by the active introduction of liquid or aquatic waste streams along the concept of the flushing bioreactor. In this scenario, landfill sites are flushed on an accelerated basis of precipitates, heavy metal compounds and sulfides which may otherwise contribute to longer-term risk and management costs. The effect of the latter process is to foreshorten the active biodegrading phase of the landfill life cycle so that the site can be capped and sealed within a more manageable time frame.

Added Value Options

Different operators and sites follow different strategies in terms of income generation. Landfill gas may be engineered as a product of landfill sites to maximize income streams from power generation. Such initiatives often depend on innovative kick-start funding mechanisms from government to offer subsidies for energy production from renewable sources. One such has been the UK government s non-fossil fuel obligation that offered entry fees of 6.5 pence per kilowatt hour against a mean coal-fired power station baseline of 2.2 pence in the early 1990s. As the scheme expanded, economies of scale were identified and levels of knowledge on installation and exploitation increased significantly to the point that power generation costs from landfill gas now match those from gas-fired combined heat and power plants without the need for support subsidies.

Landfills as Material Management Operations

Given the range of uncertainties and the challenges to input streams which arise from a mix of external market and government-inspired regulations in different countries, many landfills are now becoming final resting places for materials. However, more importantly, many are now beginning to attach more significance to their role as material presorting and quality control centers. As taxes for disposal increase, landfill operators find it attractive to install primary processing capacity to sort specific elements of their captive waste stream. This is clearly profitable where average segregation costs are less than or equal to the prevailing level of tax. Their marketing and logistics infrastructure put them in a preferential position to attract such waste streams. In addition, both rail and road connections can add to their operational and economic flexibility. Such operations may also bring about a re-appraisal in the basic advantages of landfill as a last resort provided it meets scientifically quantifiable targets as a genuinely best practicable environmental option.

Water Resources: Baltic

Erkki Leppäkoski
Åbo Akademi University, Turku, Finland

The Baltic is a brackish water epicontinental sea, a fjord-type super estuary common to about 250 rivers. It is non-tidal, small (415 000 km^2, water volume 21 700 km^3, i.e., covering 0.1% of the area and 0.002% of the volume of the world's seas) and shallow (maximum depth 459 m, mean depth 56 m; 17% of bottom areas • 10 m deep). It is long (1400 km from 54 °N to 66 °N), isolated from the North Sea by both geographical (sill depth 18 m, total opening circa 25 km) and ecological (coldness and less than one- fth of the salinity of the oceans) barriers. The annual in ow of salt water corresponds to about 2% of its total volume. Surplus water passes through the Danish sounds, resulting in a positive water balance. The residence time of water in the Baltic proper is estimated at 25- 40 years.

Seasonal variations are distinct, increasing in proportion to the distance from the entrance area. The northernmost parts are covered by ice 140 days year^{-1}.

The Baltic is a young, unstable sea. After the latest deglaciation, a freshwater lake was formed, followed by a short marine period lasting until about 9000 before present (BP). Gradual crustal uplift cut off the oceanic connection, and the Baltic changed into a fresh-water lake again. Around 7500 BP, it became brackish. Consequently, all animal and plant species living in the Baltic regions (including humans) are immigrants. Few survive in brackish water. Living close to their tolerance limits, even slight salinity and temperature changes may seriously affect distribution and dominance relationships. Increasing rainfall and river run-off have reduced salinity in recent decades. The ecosystem is thus increasingly fueled by waterborne inputs of organic matter produced outside the marine ecosystem. The oxygen periodically decreases to zero in the bottom water; poisonous hydrogen sulfide is formed, killing all bottom-living animals. These lifeless bottoms, Europe s largest deserts , periodically comprise 100 000 km^2 (25% of the total area). In the southern Baltic, postglacial Arctic relict species are threatened: their populations have poor resilience to catastrophic events like oxygen deficiency. Since the 1950s, Arctic and Arctic-boreal fauna have decreased. Atlantic-boreal and cosmopolitan species are now dominant.

Eutrophication is a major environmental concern in the Baltic region. The drainage basin (population 85 million) is shared by 14 industrialized countries. It is also subject to atmospheric fallout of nitrogen and harmful substances such as heavy metals. The initially oligotrophic (or slightly mesotrophic) Baltic ecosystem is becoming eutrophic. Inputs from multiple sources of nitrogen have increased about four times, and those of phosphorous, eight times. Most of this increase has taken place since 1955, particularly during the 1970s and early 1980s. Recently, the phosphorous inputs have decreased, but the concentrations continuously fluctuate at high levels.

During the 20th century, water transparency in the coastal and open Baltic decreased by 2 5 m. The macroalgal community, especially bladder-wrack (the main community-forming macroalga), has suffered from eutrophication (reduced light penetration, substrate changes, overgrowth by epiphytic algae, and increased grazing pressure). Perennial brown and red algae have been replaced by annual filamentous green and brown algae.

Massive phytoplankton blooms, mainly of cyanobacteria (some of which are toxic) are common in the Baltic proper; in late summer, one-sixth of the sea may be affected.

On deeper oxygen-poor bottoms devoid of bioturbating animals, laminated sediments with distinct winter and summer layers are formed. Some 25% of recent sediments in the Baltic proper are laminated. Since the 1960s, they have expanded over 2000 km^2 annually. In shallower areas, the biomass of soft bottom fauna has increased 3 5-fold, which is related to an almost 2-fold increase in the deposition of organic matter in sediments since the 1920s.

Since the early 1700s, the maximum annual extent of ice cover of the Baltic has decreased from an average of 240 190 $\times 10^2$ km with the ice in some rivers breaking up 15 days earlier. The expected sea level rise resulting from global warming will be compensated by the parallel land uplift that has been occuring since the last glaciation (maximum 0.9 m per 100 years) in the northern parts. However, in the south, rising waters will aggravate the inundation threats in low-lying coastal regions.

Three fish species (cod, sprat, and herring) account for 80 90% of the landings. Cod is the most sensitive to eutrophication requiring a salinity of • 11 parts per trillion (ppt), and an oxygen content of • 2 ml l^{-1} to breed. Increasing eutrophication increases the risks of oxygen deficiency in the saline near-bottom waters.

The following factors have caused annual fish catches to rise from 100 000 to 1 000 000 tons since the 1950s: intensified fishing, eutrophication and decreased numbers of seals (down from several hundred thousand in 1900 to 10 000 by the mid 1970s). Consequently, man has become the top consumer in the food webs of the Baltic ecosystem.

River-spawning stocks of Baltic salmon are at risk. They are found in less than 40 rivers instead of almost 100 rivers a century ago. Almost 90% of salmon stocks result

from farmed smolts implying serious genetic depletion risks.

The accidental introduction of non-native species spread with ballast water or via canals, or intentionally introduced into adjacent fresh water bodies, is an indicator of global change. Over 100 non-indigenous aquatic species have been recorded in the Baltic. They become common members of the fouling community in shallow waters, especially at river mouths and coastal inlets. Most of them originate from warmer areas. Global warming is expected to increase future introductions with devastating impact.

Water Resources: Great Lakes Case Study

Henry Regier
University of Toronto, Toronto, Canada

North America's chain of ve Great Lakes are headwaters within the St Lawrence River Basin. The Basin is shared by Canada, the United States and many tiny nations of Aboriginals of two major language groups. The two lakes lowest in the watershed, Ontario and Erie, have the highest densities of humans, and were severely degraded ecologically by 1960. Shallow southerly parts of the two middle lakes, Huron and Michigan, were equally degraded. Superior, the most northerly lake, was less degraded. All this degradation was due to careless industrialization, strong urbanization and poor land use practices. Many of the environmental abuses that were generated within the Basin have been partially corrected or remediated since 1960, at a direct cost of many billions of dollars. While this has been happening, researchers have shown that this Basin is also part of a global pattern of biospheric degradation. It is caught in: hemispheric processes of atmospheric transport of hazardous contaminants northward and eastward; worldwide shipping practices that involve transport in ballast water of exotic species, which then are released in Great Lakes ports; growing demands for export of water to drier areas of the continent with growing political pressure by entrepreneurs that the water be declared a commodity for purposes of international free trade; and migration of people into the Basin. Of course, the Basin has been contributing vast amounts of greenhouse gases and ozone-destroying chemicals to the biosphere, but its people are committed to reducing these atmospheric loadings gradually.

Fortunately, there has never been a major war in the Great Lakes Basin and not even minor wars for nearly two centuries. The Aboriginal Anishinabek and Haudenaushaunee peoples were generally considerate of European invaders, who usually did not reciprocate such consideration.

Throughout the 19th and 20th centuries, Americans and Canadians have cooperated implicitly or explicitly in the processes that led eventually to the intense ecosystemic debasement of the more southerly waters that are downstream in the Basin. Since about 1950 these two countries have collaborated in processes of remediation that have led to partial rehabilitation of the Basin s lands and waters. The programs under the numerous inter-governmental agreements undertaken to correct the environmental abuses are being celebrated for innovation with respect to participatory governance in the context of an ecosystem/bioregion approach (*see* Ecosystem Stability, Volume 2). The many enclaves of Aboriginal people each has a treaty with one of the two larger nations; gradually they have been empowering themselves to participate in correcting the ecological ills of the Basin for which they themselves can seldom be blamed.

Some kinds of regional abuses are still largely uncontrolled, e.g., intense smog events due, in part, to transboundary atmospheric flows in a northerly and easterly direction, e.g., from Chicago to Detroit to Hamilton/Toronto

to Montreal to Quebec City. Each conurbation is in both a downwind and an upwind position with respect to such massive fumigations. Not surprisingly, each is more agitated about being the downwind victim of smog fumigations rather than the upwind abuser that is contributing smog substances to be wafted downwind.

The current set of inter-jurisdictional Basin-wide programs and agreements does not suffice with respect to a need to correct the processes of biospheric degradation, as became evident in the 1990s.

The waters of the Great Lakes, as any other waters, act as temporary storage places for hazardous contaminants such as organohalides and polycyclic aromatic hydrocarbons. In water, these substances have strong tendencies to become complexed with weak chemical linkages to suspended clay or organic substances, and especially to living things. While temporarily in free form, such chemicals may escape into the air and then be transported downwind on particulates, to be washed out again by atmospheric precipitation.

In the 1990s it was found that pesticides that were used recently to the south and west of the Basin, notably Toxaphene and dichlorodiphenyltrichloroethane, were being transported into the lakes. Some of this new material then cycles harmfully among the biota through food webs, causing cancer and endocrine-related developmental handicaps, before being destroyed naturally, being buried naturally in sediments, or escaping again to the atmosphere to be transported farther east and north. Under some reasonable scenarios of reductions in the loadings of such contaminants to the regional and global environment, quantitative models predict that contamination of waters of the Great Lakes may fall to non-detectable levels sometime within the 21st century, depending on the particular chemical contaminant. Meanwhile generations of humans and other creatures will suffer harm.

Some of the threats posed by exotic creatures, e.g., the zebra mussel, transported into Great Lakes with ballast water of ocean-going ships, were perceived by researchers in 1980. Efforts in the mid-1980s by two binational commissions to stop such introductions to the Great Lakes had little effect on the shipping industry, in part because the designs of ballast systems in ships make retrofitting for purposes of preventing release of live exotic organisms almost impossible. Also, the leaders of the shipping industry appeared to have little if any concern about ecological phenomena, and could hide behind foreign registries of their vessels. The abundance of exotics released by ocean-going vessels was reduced somewhat by the late 1990s, but still to an inadequate extent. Meanwhile, the ecological associations of these lakes have been forever changed because of these exotics, most of which are found to be undesirable. Thus it is now unknown what the ecological outcome will be of ecosystemic rehabilitation programs which have cost many billions of dollars, in part because the exotic species are participating in unpredictable ecological reorganization.

The Great Lakes drain northeastward into the Gulf of St Lawrence and the northwest Atlantic Ocean. The mixing of the fresh and saline waters generates ecosystemic phenomena such as plankton blooms that are important for the reproduction of some valued migratory fish and other marine species. Thus the water that flows down the St Lawrence River is not wasted as is presupposed by some proponents of diversion of Great Lakes southward and westward to drier lands outside the Basin.

Economic studies of the various notions to divert Great Lakes waters have all shown that governmental subsidies would be necessary, i.e., that free market processes would not justify such expenditures over an alternative, say, of more efficient and less costly conservation of available water in those drier lands. Nevertheless, attempts to have any and all water of the Great Lakes Basin declared a commodity under current conventions of international free trade persist. Presumably the entrepreneurs expect to receive governmental subsidies for any ventures to divert or ship the water to drier lands. Aboriginals and naturalists, among others, object to such commodification, since they take the water to be part of the habitat of countless species of living things. The abundance, and even survival, of some of these aquatic creatures would likely be threatened by major withdrawals of water.

A fourth global process important to the Great Lakes Basin is the migration of people. In the 1990s about 40 million people lived in the Basin. Current assessments of climate warming in coming decades do not indicate catastrophic adverse effects, and might even imply that the Basin could generally become more attractive climatologically to mobile people. However, the current rate of urbanization is cause for concern. Further, the extant infrastructure of public utilities related to water, sewage, heating and cooling of buildings, etc., is largely obsolescent in the older parts of the Basin s cities. Hence, rapid population growth due to immigration into the Basin combined with postponement of replacement of obsolete infrastructure will likely exacerbate urban environmental problems.

The Great Lakes Basin was richly endowed with many kinds of resources that were developed and abused during the 19th and 20th centuries. As corrective measures were undertaken regionally late in the 20th century, toward a better but unpredictable ecosystemic state, it became apparent that the Basin was contributing and receiving massive abuses to and from other parts of the biosphere. No doubt, that will be a major challenge for all of the 21st century.

Water Resources: Río de la Plata

Gustavo J Nagy[1], M Gómez-Erache[1], and A C Perdomo[2]

[1]*Facultad de Ciencias, Montevideo, Uruguay*
[2]*SOHMA, Montevideo, Uruguay*

The R´o de la Plata in South America is one of the world's largest and oceanographically most signi cant river and estuarine systems. Its economic value for transportation, sheries, and tourism is enormous, and its sustainable development an imperative (Wells and Daborn, 1997). Its basin, the most important in Latin America in terms of population and economic development, is changing as a result of both El Niño/Southern Oscillation (ENSO) related variability and such human driven activities as soil erosion and fertilizer application. As a consequence of continuing demographic and economic growth in the basin, environmental deterioration will be dif cult to arrest.

STUDY SITE

The Río de la Plata is a large, river-dominated, microtidal, wind driven, nutrient rich, stratified, and plankton-based coastal system (Figure 1) fed by the rivers Paraná and Uruguay (freshwater inflow into the estuary $\sim 7\ \ 12 \times 10^{11}\,m^3\,y^{-1}$). River flow typically varies on both seasonal and interannual timescales between 22 000 and 28 000 $m^3\,s^{-1}$, with extreme values, i.e., more than 30 000 $m^3\,s^{-1}$ and less than 20 000 $m^3\,s^{-1}$ during El Nino and La Nina, respectively (Nagy *et al.*, 2001, in press).

Wind and water discharge rate control the seasonal variability of the salinity field in the upper layer of the river. The lowest wind influence and a maximum in river runoff result in a lower salinity regime, whereas onshore winds and a minimum of riverine runoff induce a high salinity condition (Guerrero *et al.*, 1997).

ENVIRONMENTAL VARIABILITY AND CHANGE

The main global environmental change processes in the Río de la Plata are:

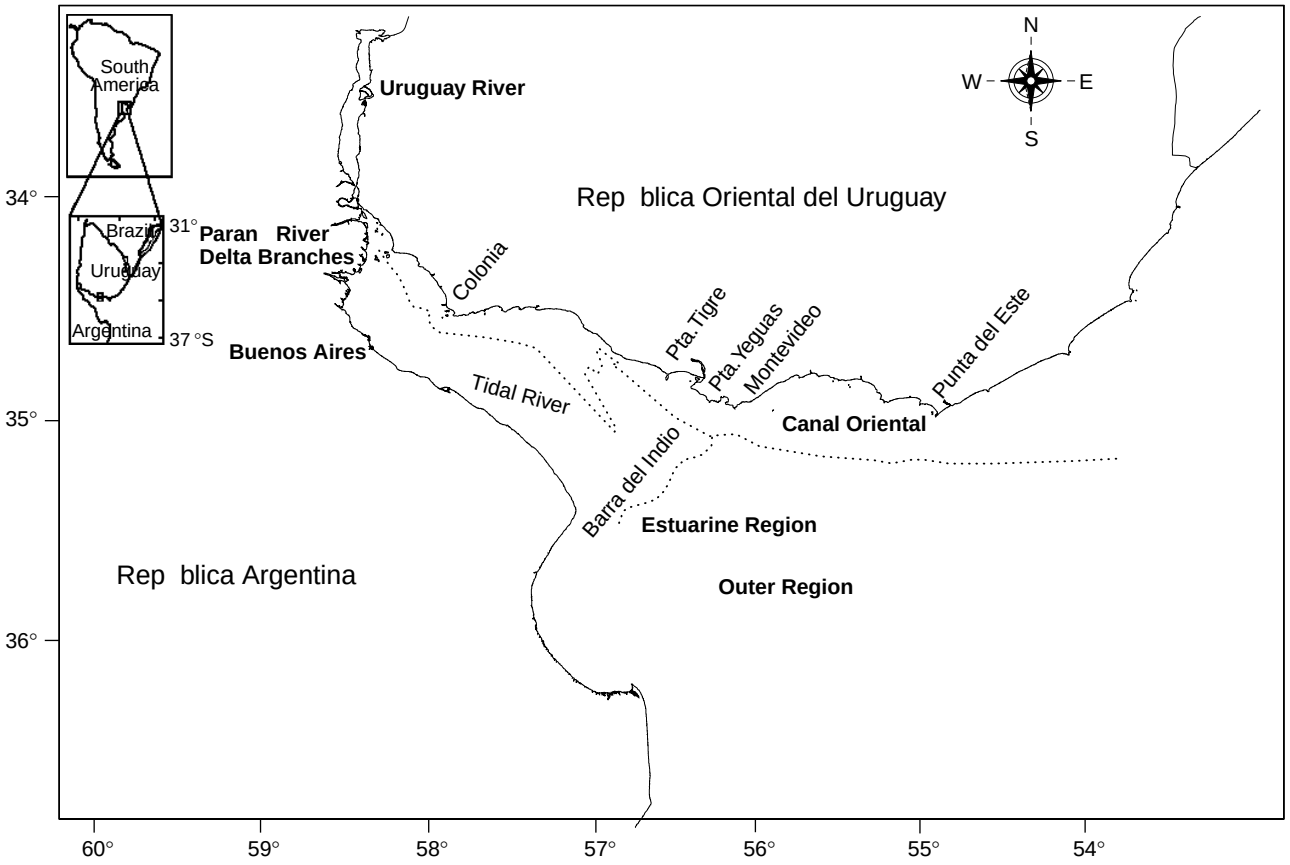

Figure 1 Río de la Plata system location and regions. The Uruguayan coast (Canal Oriental) is deeper at each cross-section and consequently is more stratified (greater bottom-surface salinity difference)

1. *Hydroclimatic variability and change*: a shift occurred in the Río de la Plata basin freshwater inflow in the early 1970s (García and Vargas, 1998). The variability and total volume of river discharge have both increased by about 25% in the last 30 years. Most of these fluctuations and part of this trend are associated with ENSO-related variability (Nagy *et al.*, 1996, 1997). Since 1972, four strong El Nino events (1972, 1983, 1992, 1997) and two strong La Nina events (1988, 1998) strongly affected the Río de la Plata basin and coastal system. Over the long term, river discharge fluctuations control yearly salinity variability (Figure 2) and induce sea level changes (± 10 cm) at Montevideo (Nagy *et al.*, 1996, 1997).
2. *Eutrophication*: The Río de la Plata receives primary treated urban wastewater and fertilizers from the basin. Point sources from the Buenos Aires metropolitan area account for about 25% of the total nutrient load to the river (Pizarro and Orlando, 1985), estimated to be about $3{\bullet}5 \times 10^6$ mol dissolved inorganic phase (DIP) d^{-1} and 64×10^6 mol dissolved inorganic nitrogen (DIN) d^{-1} (Nagy, 2000). Because of *in situ* sink processes like organic matter production and denitrification (Nagy, 2000), nutrient values in the estuarine region are within the range considered by Nixon (1995) as typical for most subtropical coastal zones with low human-induced eutrophication (Gómez-Erache *et al.*, 2000). Direct atmospheric deposition of nitrogen (N) has been estimated to be to the order of 1 2% of the total nitrogen load (Nagy, 2000). This value is consistent with the estuarine area/watershed area ratio $\simeq$1.2%, suggesting low deposition (Ocean Studies Board, 2000).

ENVIRONMENTAL CHANGES RELATED TO HYDROCLIMATIC CHANGE AND NUTRIFICATION

Such changes include:

- Decrease of mean yearly salinity (Figure 2) at Montevideo (Nagy *et al.*, 1997).
- Increase of vertical saline stratification (Nagy *et al.*, 2000).
- Increase of diffuse nitrates load. After the El Nino flood in 1983, when the water discharge increased by about 50%, the nitrate concentrations rose by 25%, whereas phosphate concentrations were 50% lower; therefore, the nitrate load and the N/P ratio increased by about 75%.
- Low dissolved oxygen values (• 50% saturation) in the bottom layer (Nagy *et al.*, 1997, 2000).
- Downward displacement of the estuarine front, affecting the fish spawning zone and the catchment.
- High nitrogen flux per unit land area (Nixon, 1995); the livestock wastes reported by the author seem to be too high.
- High diffuse and point source phosphorus inputs from the Uruguayan coast to the Río de la Plata via fertilizers and detergents (Sommaruga *et al.*, 1995).

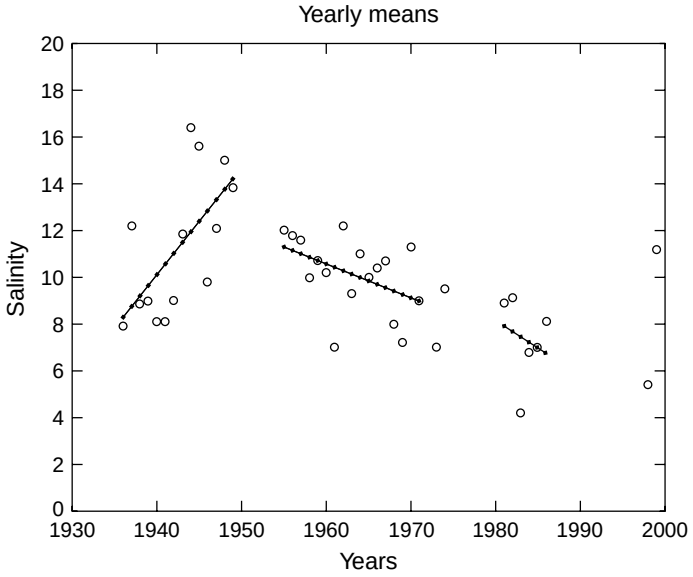

Figure 2 Yearly mean salinities at Montevideo. The series is discontinuous because of the lack of data for several periods. The means are highly correlated with total yearly river flow into the estuary, especially with the river Uruguay discharge. Note the great variation between 1998 (strong El Niño) and 1999 (strong La Niña). The long-term trend and extreme values of salinity match the river inflow trend and fluctuations

Figure 3 Turbidity front image (November 17th, 1999) during the peak of La Niña signal in the Río de la Plata. The front was displaced three to five tens km up-river of its average location because of very low river flow. Consequently, both residence time within the system and biological activity increased, and algal pigment concentrations reached eutrophic values (up to 38 μg chlorophyll-a l^{-1})

- Freshwater cianobacteriae blooms (coming from the river Uruguay) and nitrogen fixation (De León and Yunes, 2001).
- Harmful and toxic algal blooms (Méndez *et al.*, 1996).
- A slight increase of water level (+3 cm) at Montevideo; most yearly fluctuations are correlated with freshwater inflow (Nagy *et al.*, 1997), and therefore, with the ENSO signal.
- Eutrophic values of algal biomass (• 25 μg chlorophyll-a l^{-1}) have been found:

    1. close to the emissions of urban waste waters, i.e., in Montevideo bay (Gómez-Erache *et al.*, 2000); and
    2. seaward of the turbidity front during La Nina low river flows in November 1999 (Figure 3).

GLOBAL CHANGE PERSPECTIVES

Stratified systems, like the Río de la Plata along the Uruguayan coast, are highly susceptible to oxygen stress in the bottom layer as a response to nutrient over-enrichment and the consequent increase of productivity and organic matter respiration (Rabalais *et al.*, 1999). Excess nitrogen (a limiting nutrient), stimulates primary production. However, as anoxia does not occur in the Río de la Plata because of mixing by the wind, denitrification is also stimulated by excess nitrogen, acting as a feedback on both carbon dioxide (CO_2) and nitrogen (N_2) nitrous oxide (N_2O). If river flow increases, as in 1998, vertical stratification, allochtonous organic matter, and oxygen stress would also increase. If anoxia develops, it could act as a positive feedback: both available nitrogen for organic matter production and oxygen deficit increase. If this is coupled with increased human-driven nutrification, in the long-term the system could become heterotrophic (net carbon dioxide emission).

Waterlogging

Waterlogging occurs when water is near, at, or above the surface of the land, resulting in the total saturation of the soil. It can be permanent or intermittent, the latter due to seasonal or other conditions. It has a number of causes, all of which are associated with inadequate or impeded drainage, including over-irrigation, rising groundwater levels, and seepage, as well as periods of high rainfall and flooding. The effects of waterlogging depend in large part on how long it lasts. While a soil is waterlogged, there is no energy for plant growth, nutrient uptake stops, plant roots are drowned and die (except for those of hydrophytes, plants that grow in water, either submerged, emergent or floating), soil microbes and other organisms die, and there is increased likelihood of plant and animal diseases. As a result, plants are damaged, their productivity reduced, and they may eventually die. Waterlogging affects a significant proportion of the world s irrigated lands, the result of inadequate or non-existent drainage; a 1977 United Nations study estimating the area affected at some 22 million ha. The costs are substantial. For example, in the late 1980s, it was estimated that farm production from irrigated dairy pastures in northern Victoria (Australia) could be increased by over $AUD50 million per year if waterlogging problems could be eliminated. Where waterlogging is more or less permanent, the anaerobic conditions reduce the ability of bacteria to break down the dead plant materials. The accumulation and only partial decomposition of plant materials can result in the formation of peat, especially in temperate humid conditions. Waterlogging also destroys soil structure and leads to the formation of gley soils (characterized by the reduction of iron and other elements producing their blue-gray mottling). Waterlogging is often a precursor to salinization.

Wave Power Development

Les Duckers
Coventry University, Coventry, UK

Wave power technologies are being developed to generate electricity, heat or mechanical power from ocean waves.

Wind, passing over the surface of water, gradually transfers some of its energy into the water to create waves. If the wind has a reasonable velocity and persists for a significant time across a long stretch of water, then the resulting waves will be large and powerful. This is why certain locations around the World enjoy favorable wave climates for electricity generation: for them the predominant winds have traveled across several thousand kilometers of ocean and in so doing have generated annual average wave power levels of around 50 kW m^{-1} of wave front.

The exploitable World wave power resource is estimated at 2000 GW, largely to be found in offshore locations where the water is deeper than 40 m. The shoreline resource, although easier to exploit, has lower power density (typically around 20 kW m^{-1}) since some of the energy content of the waves is dissipated as the waves approach the shore.

Concern for the security of energy supply during the oil crisis of the 1970s prompted modern research and development in wave power. Shore-mounted oscillating water column (OWC) and the offshore Edinburgh Duck were among the rst concepts to provoke interest and both continue to be developed.

Now, though, the motivation comes from the low environmental impact of electricity generated from wave power, which emits about 11 g of carbon dioxide (CO_2) kW h^{-1} compared to 730 g CO_2 kW h^{-1} for average UK electricity generation.

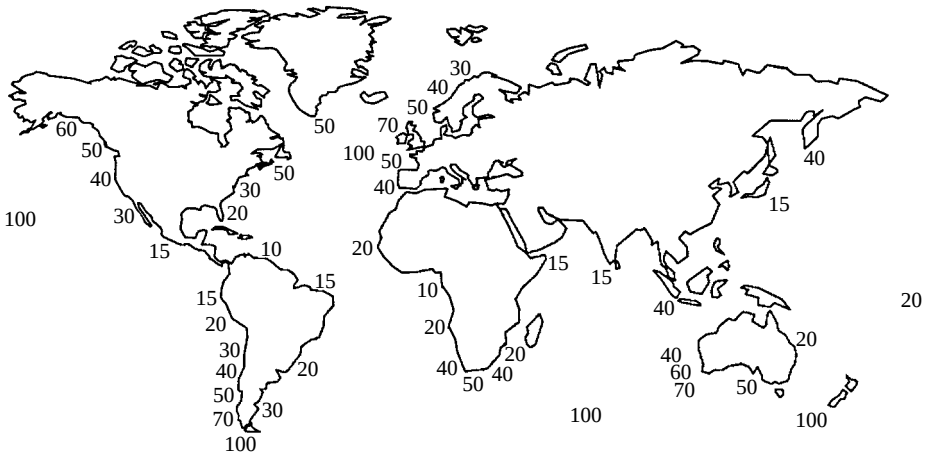

Figure 1 Estimated world potential of wave technologies. The shoreline unit (1–50 GW): fixed to shore in wave power densities of about 20 kW m^{-1}. The offshore unit (200–5000 GW): probably floating in deep water, with wave power densities of about 50 kW m^{-1}. The figures are the author's estimates of the technically achievable powers. Approximate wave powers are given as kW m^{-1} of wave front

SHORE-MOUNTED TECHNOLOGIES

Many of the prototype schemes are shore mounted and incorporate an OWC (oscillating water column) driving a self-rectifying air turbine. These schemes have few moving parts, and with judicious choice of structural size and geometry, overall performance can be impressive. Micro-OWCs are deployed in huge numbers to power navigation buoys with a few kilowatt, a 600 kW shore mounted scheme was built in Norway in 1985 and 1 MW scheme is installed in Scotland. India, Japan, China, Portugal are some other countries which are piloting OWCs.

Tapchan (Tapered channel) is also a shore-mounted device but has the advantage of some inherent energy storage. As waves approach the mouth of the Tapchan they become compressed in width and so build up in height. It is the design of this Tapchan, which enables the scheme to harvest energy from the ocean waves arriving at the mouth of the channel. The 350 kW prototype, built in 1985 in Norway, had a 40 m wide horn shaped collector capable of accepting energy from waves with a range of frequencies and directions. A 1.1 MW plant is under construction in Indonesia.

OFFSHORE TECHNOLOGIES

Large-scale offshore devices like the Duck and Clam will be deployed in deep water and so can exploit the higher wave power densities to found there. The numbers plotted on the World map in Figure 1 are the average deep water wave power density in kW m^{-1} of wave front. Since these offshore systems will have to float, they are designed to be large enough to span several wave crests. In this way the wave force on the structure is averaged at an acceptably low value permitting the structure to survive and moreover to provide a reasonably stable frame of reference. Arrays of hundreds of such devices could form wave farms and could transmit substantial amounts of electricity to the Irish, UK and Norwegian grids. The collective output from an array will be smoother than from individual devices. Offshore devices would transmit electricity via subsea cables. Modular construction methods should permit minimization of capital costs and ensure rapid deployment and early operation of each unit.

The Edinburgh Duck was originally envisaged as many cam-shaped bodies linked together on a long flexible floating spine, which was to span several kilometers of the sea. Individual ducks respond to incident waves by rotating with respect to the common spine.

The SEA-Coventry Clam is an 80 m diameter rigid toroid, rated at 3 MW, delivering an average of 1 MW, and floating in deep water. Twelve air cells are arranged around the circumference of the toroid and these cells are coupled together by an air ducting, which contains 12 air turbines.

POINT ABSORBER TECHNOLOGIES

Float systems, with a body floating on the surface but moored to the seabed via a pump are attracting some attention. These can act as point absorbers, which draw in energy from a greater width of water than their own physical diameter (i.e., they have capture width ratios greater than one).

The hose pump wave energy converter has been developed in Sweden and is intended to pump sea water from an array of devices fixed to the seabed to an elevated reservoir on land. A Pelton wheel extracts energy from the water as it is released from an upper reservoir back to the

sea. A hose-pump lightbuoy is undergoing pre-production tests, and evaluation of wave power plants in Ireland, Spain, Sweden and the USA have been carried out.

Variations on the systems mentioned above or new ideas are being developed in Denmark, the Netherlands, Norway, USA, Korea and Australia.

PREDICTED WAVE ENERGY COSTS

The predicted cost of electricity generated from wave power schemes is dropping as designs improve and as construction techniques are refined. To illustrate this, one of the OWC designs had a cost of US\$0.3 $kW\,h^{-1}$ in 1982. By 1993, OWC designs were costed at US\$0.11 $kW\,h^{-1}$ and projections suggest that costs will fall to US\$0.06 $kW\,h^{-1}$ by 2005 and lower still by 2010.

Weather Extremes and Climate Impacts: a Case Study for the United States

Roger A Pielke, Jr

National Center for Atmospheric Research, Boulder, CO, USA

Weather events are among the most pervasive in uences on human affairs. Good weather can enhance society's efforts, bad weather often reveals vulnerabilities and sometimes leads to human and environmental disasters. The degree to which society exploits good weather and reduces its vulnerabilities to bad weather is a function of how society organizes and informs itself and its decision processes in the face of various typical and extreme weather events. This essay provides a perspective on the manner in which researchers acquire information about extreme weather impacts and how societies cope (and do not cope) with extreme weather. Such information and coping strategies are increasingly important as societies around the world see their economic and human vulnerabilities change and grow with increasing population and wealth.

What are weather impacts?

In the 1970s, climate became of increasing interest to many societies around the world. Events included the failed Peruvian anchovy harvests in 1971 and 1973; the 1972 1974 drought in the African Sahel; a severe 1972 winter freeze in the Soviet Union; and in 1974, floods, drought, and early frost in the US Midwest. The 1977 winter in the eastern US was the coldest ever recorded and summer was one of the three hottest in a century. As a consequence of these extreme events and their impacts, decision makers in influential national and international settings began paying significant attention to the relation of weather, climate, and human affairs (*see* Climatic Extremes, Volume 3).

The concept of weather impacts and related societal problems includes:

- extreme events, including droughts, hurricanes, floods, blizzards, tornadoes, thunderstorms (including hail), etc.;
- the benefits of good weather, meaning favorable conditions for a particular activity;
- routinely disruptive weather, defined as not extreme, but significant enough to warrant behavioral adjustments.

Most public and political attention focuses on disasters and extreme events, but the other types of weather are likely to have significant impacts on society as well. This essay focuses on extreme events.

THE CHALLENGE OF ASSESSING DAMAGES OF EXTREME WEATHER AND STORMS

In the aftermath of any extreme event such as a hurricane, there are many considerations in measuring its costs (of impacts). Any assessment of impacts resulting in an estimate of total damages associated with a disaster must pay explicit attention to assumptions guiding the analysis in order to facilitate interpretation of the estimate. The analyst needs to pay attention to five factors that can complicate damage assessment: contingency, quantification, attribution, aggregation, and comparison.

Contingency: The Problem of Multiple-order Impacts

When an extreme event strikes a community, it leaves an obvious path of destruction. For example, following a hurricane, as a result of high winds and water from a storm surge, homes, businesses, and crops may be destroyed or damaged, public infrastructure may also be compromised, and people may suffer injuries or loss of life. Such obvious impacts can be called direct impacts because of the close connection between event and damages. The costs associated with direct impacts are generally easiest to assess because they come in discrete quantities. In the US, federal insurance payouts are one measure of direct impacts, as are federal aid, public infrastructure reconstruction, and debris removal.

Secondary impacts are related to direct impacts. Generally, secondary impacts occur in the days and weeks following an event. For example, a flood may destroy a water treatment plant. The direct impact is the cost associated with rebuilding the plant; secondary impacts include the costs associated with providing fresh water for local citizens. In general, such secondary impacts are more difficult to assess because they require estimation and are part of an existing social process; e.g., estimating the costs of providing fresh water in lieu of the costs of normal operation of the plant without the disaster.

Other impacts on time scales of months and years occur and can easily be imagined but can be hard to quantify. For example, a flood may destroy a number of businesses in a community resulting in a decrease in tourist visits, which in turn leads to a shortfall in sales tax collection. As a result, community services that had been funded from sales tax revenues may suffer, leading to further social disruption and thus additional impacts. Estimation of the costs associated with such impacts is difficult because of numerous confounding factors. In short, an extreme event causes various impacts that reverberate through the social system for short and long periods. Separating the signal from the noise of ongoing social processes becomes increasingly difficult as the impact becomes further removed in time and in causation from the event s direct impacts.

Attribution: The Problem of Causation

Related to contingency is attribution. In the aftermath of a natural disaster, people are quick to place blame on nature, e.g., the flood caused billions of dollars in damages. However, it is often the case that natural disasters are a consequence of human failures. Damage is often a result of poor decisions of the past and inadequate preparation, rather than simply the overwhelming forces of nature. It is often at the intersection of extreme events and poor preparation that a disaster occurs. An important aspect of learning from a disaster is to understand what damages and casualties might have been preventable and which were not. Gross tabulations of damages neglect the question of why damage occurred, and often implicitly blame nature rather than society.

Quantification: The Problem of Measurement

How much is a life worth? Or put in practical terms, how much public money are people willing to pay to save one more life in the face of an environmental hazard? According to one review, the public assigns between $2.0 million and $10.9 million as the value of a human life. The difficulty associated with assigning an economic value to a human life is representative of the more general problem of assessing many of the costs associated with weather impacts. Similar questions might include: what is the value of a lost ecosystem, park, or unrecoverable time in school, etc.? What are the costs associated with psychological trauma?

Often, an extreme event impacts many aspects of society that are not explicitly associated with an economic measure (e.g., well-being). As a consequence, any comprehensive economic measurement of an extreme event s impact necessitates the quantification of costs associated with subjective losses. Therefore, the assumptions that one brings to assessment of value can affect the bottom line. Care must be taken to make such assumptions explicit in the analysis.

Aggregation: The Problem of Benefits and Spatial Scale

Estimates of impacts from disasters rarely consider benefits. Consider the following example: following a hurricane that severely damages agricultural productivity in a region, commodity prices rise nationwide. Thus, while farmers in the affected region may lose money, farmers outside of the region may actually incur significant benefits. At a national level the hurricane may thus lead to net economic benefits. Even in the immediate vicinity of the storm track, the rainfall may be beneficial in replenishing depleted reservoirs and groundwater.

The above example points to two sorts of issues: benefits and spatial scale. Arguably, following every disaster some individuals and groups realize benefits in some way from the event. Should such benefits be subtracted from a hurricane s total impact? Further, the picture of damages depends upon the scale of the analysis. For the same event a county may experience complete devastation, the state only moderate impacts, and the nation positive benefits. Transfers of wealth through disaster aid further complicate the picture. Since there are multiple valid spatial scales from which to view a hurricane s impacts, careful attention must be paid to the purposes of loss estimates. Furthermore, it is important to remember that impacts go beyond those things

that can be expressed in dollars suffering and hardship are losses independent of scale.

Comparison: The Problem of Demographic Change

As a consequence of the challenges facing meaningful impact assessment, comparing impacts across time and space is problematic. In many settings, past extreme events would certainly leave a greater legacy had they occurred in more recent years. Yet, damage statistics often go into the historical record noting only the event and economic damage (usually adjusted only for inflation). Such statistics can lead to mistaken conclusions about the significance of damage trends. Since population and property at risk to extremes have changed dramatically in recent decades, such statistics may grossly underestimate vulnerability. Therefore, care must be taken in the use of bottom-line damage estimates to reach policy conclusions.

The Bottom Line: Apples with Apples, Oranges with Oranges

There are many ways to measure the costs associated with a weather or climate impact. There is no one right way. The method chosen for measurement of the costs of damages depends upon the purposes for which the measurement is made, and therefore must be determined on a case-by-case basis. No matter what method is employed when assessing or using the costs associated with an impact, the analyst needs to ensure at least two things. First, the analyst needs to explicitly describe the assumptions that guide the assessment: what is being measured, how, and why. Second, apples should be compared with apples and oranges with oranges. If the purpose is to compare the impacts of a recent event with one in the past or a weather disaster with an earthquake, the methods employed ought to result in conclusions that are meaningful in a comparative setting.

IMPACTS TREND DATA

Following the discussion above, a three-tiered sequence is useful for assessing weather and climate impacts. Direct impacts are those most closely related to the event, such as property losses associated with wind damage. Secondary impacts are those resulting later from the direct impacts. For example, an increase in medical problems or disease following a hurricane would be a secondary impact. Tertiary impacts are those that follow long after the storm has passed. A change in property tax revenues collected in the years following a storm is an example of a tertiary impact. The impacts discussed below are direct impacts.

Hurricanes

In the US, after adjusting only for inflation, hurricanes were responsible for an annual average of $1.6 billion for the period 1950 1989, $2.2 billion over 1950 1995, and $6.2 billion over 1989 1995. For comparison, China suffered an average of $1.3 billion (unadjusted) in damage related to typhoons over the period 1986 1994. Significant tropical cyclone damage is also experienced by other countries including those in south-east Asia, along the Indian Ocean (including Australia), islands of the Caribbean and Pacific, and in Central America (including Mexico). While a full accounting of these damages has yet to be documented and made accessible, it is surely in the billions of dollars, with a reasonable estimate of about $10 20 billion annually (1995 $).

In the US, 196 people lost their lives as a result of hurricanes over the period 1986 1995. Experts have estimated that world wide, tropical cyclones result in approximately 12 000 23 000 deaths. Tropical cyclones have been responsible for the largest losses of life due to a natural disaster. For instance, in April 1991, a cyclone made landfall in Bangladesh resulting in the loss of more than 140 000 lives and disrupting more than 10 million people (and leading to $2 billion in damages). A similar storm resulted in the loss of more than 250 000 lives in November 1970. Similarly, thousands of lives have been lost in China, India, Thailand, Honduras, and the Philippines in recent years.

Society has become more vulnerable to hurricane impacts. The trend of increasing losses during a relatively quiet period of hurricane frequencies should be taken as an important warning. When hurricane frequencies and intensities return to levels observed earlier in the 20th century, then losses are likely to increase to record levels unless actions are taken to reduce vulnerability.

Inhabitants along the US Atlantic and Gulf Coasts are fortunate in that hurricane watches and warnings are readily available, as are shelters and well-conceived evacuation routes. However, this should not give reason for complacency the hurricane problem cannot be said to be solved. Disaster planners have developed a number of scenarios that might result in a large loss of life in the US. For instance, imagine a situation of gridlock as evacuees seek to flee the Florida Keys on the only available road. Or imagine New Orleans, with much of the city below sea level, suffering the brunt of a powerful storm, resulting in tremendous flooding. Scenarios such as these highlight the need for constant attention to saving lives. Since the nature of the hurricane problem is constantly changing as society changes, the hurricane problem can never be said to be solved.

Floods

By any measure, floods have a significant impact on society. The Red Cross estimates that, worldwide, more than

1.5 billion people over the 25-year period ending in 1995 have felt the impact of floods. Of that total, they estimate that more than 318 000 people were killed and more than 81 million were made homeless. In addition, over the period 1991 1995 flood-related damages totaled more than US$200 billion (not inflation adjusted) worldwide, representing close to 40% of all economic damages attributed to natural disasters in this 5-year period. In the 1990s, significant flood damage occurred in eastern Europe (1997, damages totaling US$4 6 billion), US and Canada (1997, US$1.75 billion), China (1996, US$26.5 billion), central Europe (1993 and 1995, US$4 billion), and the US Midwest (1993, US$16 billion).

Reliable and accurate knowledge of flood impacts is important because decision makers allocate scarce resources to flood-related concerns based on their interpretation of past trends in and expectations for the future of the magnitude and causes of flood impacts. In addition, local actions taken to reduce vulnerability to floods are based on public and decision-makers perceptions of the past and expectations for the future. Regrettably, implementation of policies in response to floods is hampered by a lack of specific knowledge of past trends in flood impacts on society and, more importantly, the factors that underlie those trends. Indeed, the International Federation of Red Cross and Red Crescent Societies has written:

> The lack of systematic and standardized data collection from disasters, man-made or natural, in the past is now revealing itself as a major weakness for any developmental planning. Cost benefit analysis, impact analysis of disasters or rationalization of preventative actions are severely compromised by unavailability and inaccuracy of data or even field methods for such data collection.

Some have speculated that the steady increase in the average annual economic damages related to floods in the US indicates a change in climate; some blame population growth and development; others place the blame on federal policies; and still others suggest that the trend distracts from the larger success of the nation s flood policies. Empirical evidence from a number of cases clearly shows that climate, population growth and development, and flawed policy all play a role in trends in the costs of flooding in the US, but the state of knowledge is such that the relative contribution of each factor is poorly understood. The US case seems typical: policy makers face difficulties in assessing the magnitudes and causes of floods and in evaluating the effectiveness of past responses.

A consequence of the lack of data on the spatial extent of floodplains in the US is the difficulty in assessing trends in flood frequencies and current levels of population at risk to floods. Trends in population at risk to flood events are important in any determination as to whether societal vulnerability to floods is decreasing, increasing, or remaining relatively constant. One can easily hypothesize that increasing population and urbanization in the US has led to a commensurate increase in population at risk. Yet, one can also hypothesize that the various societal responses to floods may have more than compensated for population growth and, in fact, fewer people are today at risk to flood events. Currently, reliable data to assess trends in populations at risk from flood events are lacking.

Accurate determination of property at risk to flooding faces many of the same obstacles. Differences in estimates of people and property at risk to floods are attributable to actual demographic changes, but also to differences in floodplain definitions, and to the lack of reliable data. The data that do exist allow for only gross generalizations.

CONCLUSIONS

The information presented above is consistent with the findings of the Intergovernmental Panel on Climate Change (IPCC). Even on a global scale it is difficult for scientists to discern trends in extreme events. As the IPCC (1996, 173) notes:

> Overall, there is no evidence that extreme weather events, or climate variability, have increased, in a global sense, through the 20th century, although data and analyses are poor and not comprehensive. On regional scales there is clear evidence of changes in some extremes and climate variability indicators. Some of these changes have been toward greater variability; some have been toward lower variability.

For many years, decision-makers have assumed that climate remains constant, at least over the relevant period of record. So it was possible to estimate statistical return periods from historical time series. In recent years, however, scientists and policy makers have come to realize that we live in a climate that is changing in ways that are difficult to assess and predict. In other words, both the distribution of events and the central tendency may be changing. A consequence is that climate change or variability may be responsible for some of the variance in weather-related deaths and damages.

However, it is difficult to attribute the documented recent increases in economic impacts in the US to fluctuations in climate. This is primarily due to the fact that the strongest signal in the impacts record is increased societal vulnerability.

In this context, studies of extreme events have often called for greater emphasis to be placed on the following areas:

Vulnerability Mapping

Communities would benefit from a greater understanding of exposure and risk. Many countries, particularly developing countries, lack the resources to undertake such studies. Even some US communities have never been evaluated for

flood risk. In addition to mapping where natural hazards could occur, community planners could map the neighborhoods where highly vulnerable groups such as the disabled, poor, and elderly reside. This information can provide a tool for targeting education and other mitigation programs, evacuation plans, distribution of relief supplies, and other response services to where they are most needed.

Land Use

Much development around the world occurs in the most vulnerable locations, including low-lying shorelines and inland flood-prone areas. Land use planning is typically in a rudimentary stage in those regions. For example, coastal areas of parts of the southeastern US have experienced explosive growth over recent years. In 1990, Dade and Broward Counties in south Florida had larger populations than all 109 counties from Texas through Virginia on the Gulf and Atlantic coasts in 1930. Some policies for managing land in vulnerable areas include zoning, regulation, taxing, creating special property districts in which governments may exercise eminent domain, and public acquisition of land at risk.

Promulgation and Effective Enforcement of Building Codes

Building codes are an important component in strengthening housing stock and reducing vulnerability. In disaster-prone areas, effective building codes should address factors such as the ability of structures to withstand high wind velocities. For example, South Florida s building code requires structures to be able to withstand wind velocities not less than 120 mph (53.2 m s^{-1}) at a height of 10 m above the ground. Many engineers maintain that using steel or composite fasteners to hold on a roof would save homes. However, even the best codes will not reduce vulnerability without adequate enforcement. One study comparing damage from two hurricanes of roughly equal size and intensity found that building code enforcement was a primary factor in reducing structural damage to buildings during hurricanes. Other strategies are necessary in those parts of the developing world where much of the construction of homes occurs informally and does not go through a code review and inspection process.

Improved Forecasts, Warnings, and Evacuations

While major improvements in weather forecast accuracy have been made, thanks to advances in technology, considerable opportunity exists for further improvement in both the technical production of forecasts and their use by decision-makers. In addition, some countries need better national communications systems to disseminate warnings. Dissemination of effective warnings can be a challenge in countries such as India where warnings need to be translated into several languages. It is likely that those who suffered the greatest impacts of Hurricane Mitch in Central America had little or no warning of its approach and little opportunity to evacuate even if warned.

For evacuation to be effective, communities must develop data banks on various factors including: what areas need to be evacuated, how many people need to be evacuated, how will the public respond to an evacuation, what roads will be used, and where will evacuees be sheltered? Improvements to the evacuation process can range from widening roads, to building new causeways, to limiting population growth in areas most at risk.

Reduce Environmental Degradation

Deforestation is occurring at alarming rates in some parts of the world. Loss of natural vegetation reduces the soil s ability to absorb rainwater, and contributes to the instability of hill slopes. These factors can lead to highly dangerous landslides that result in hundreds of deaths. Development of wetlands and beaches interferes with the ability of these natural environmental features to absorb floodwaters and act as seawalls. Poor land use and natural resource management, while a reflection of poverty, is also caused by government policies that subsidize unsustainable activities and practices. These policies often result from conscious decisions and trade-offs made by government officials. If the decision-making processes are opaque and corrupt, there is little that people can do to exert pressure to correct these environmentally harmful practices.

Addressing Poverty and Poor Health

Many factors that increase societal vulnerability to extreme weather, particularly in the developing world, will not be solved without a concurrent focus on alleviating poverty, improving public health and provision of secure land tenure in safe sites. Poor people frequently build homes through the informal housing sector, making building codes and land use restrictions meaningless. They often settle on marginal lands such as steep slopes and flood-prone areas. Poverty is also a factor in environmental degradation practices such as deforestation. Vulnerability reduction has clear links with economic development and public health.

Wind Power Development

Derek Taylor
Open University, Milton Keynes, UK

Harnessing winds for mechanical power purposes is thought to have originated in China or Persia in ancient times. Windmills became a key form of mechanical power in Europe; the number peaked at over 300 000 two centuries ago. Denmark began the rst tentative steps towards using wind power to generate electricity in the last decade of the 19th century. There were periodic attempts to develop wind power in the early part of the 20th century, but it was not until the 1970s and 1980s that wind power began to be used seriously (Taylor, 1996). By the end of the 1990s, wind turbines had become a successful mature technology capable, in suf ciently windy areas, of generating clean electricity at a cost approaching that of electricity from conventional power stations.

Most of the technical issues have been addressed, and clusters of wind turbines known as wind farms have become established as types of power stations (Figure 1). Most wind farms have used wind turbines rated between 300 and 600 kW but commercial wind turbines are increasing in size and are now available with ratings of 1 MW, 1.5 MW, 2 MW and 2.5 MW. Over 1001 MW class machines have been installed in Europe (Taylor, 1999).

Figure 1 Typical wind farm. (*Source:* photograph by Dr Derek Taylor 1998)

The global potential for electricity production from land based wind power has been estimated to be approximately 20 000 terawatt-hours year^{-1} (Van Wijk *et al.*, 1991) or about twice the 1987 global electricity consumption of 9000 TWh. If this level of generation was achieved and displaced electricity from coal fired power stations, emission of about 17 billion tons of carbon dioxide (CO_2) per year would be avoided. The European Wind Energy Association proposed ambitious new targets for wind power development in Europe in 21st century of 8000 MW by 2000, 40 000 MW by 2010 and 100 000 MW by 2020.

Because wind turbines do not emit any pollutants, the environmental impacts are generally positive and when substituted for fossil fuelled electricity power plants, wind turbines will result in major reductions in air pollution, thus benefiting the local environment. There are also reductions in acid rain and in emissions of CO_2 the major greenhouse gas. Each kWh produced by a wind turbine will avoid 860 1000 g of CO_2 if substituting for a coal fired power station. Wind power is a rapid and cost effective means of achieving cuts in greenhouse gas emissions; it can be installed quickly and economically and is a key technology for combating climate change.

As well as improving the quality of forest and water ecosystems by offsetting the use of power stations producing acid rain, it is possible that wind turbines can actually help to enhance their immediate local ecosystems and environments and may help to increase the biodiversity at their location sites (Percival, 1998) and offshore wind turbine platforms appear to be able to increase fish stocks by acting as reefs. Wind power development may also be able to protect wilderness areas or valued landscapes because landowners of such areas will be able to receive a sustainable income from wind turbines on their land, while leaving 99% of it unused, thus reducing the need to develop or plough up the land for economic benefit. A land use activity capable of generating a sustainable form of revenue is likely to be of growing economic, environmental, social and employment importance.

In operation, inland conventional steam thermal power stations lose substantial amounts of water in their cooling systems by evaporation, so substituting wind turbines will help to reduce this water use and thus be able to assist strategies for water conservation.

It is these environmental benefits, coupled with progressively reducing costs, which is helping to drive the industry which generated sales approaching some 2 billion US dollars in 1998, and is considered to be the fastest growing energy source world wide with a 35% increase in the installation rate achieved in 1998 compared to 1997 (Flavin, 1998). By the end of 1998, the estimated world wide installed capacity of wind power plants had exceeded 9600 MW (capable of generating approximately 21 TWh year^{-1}) and Germany had the largest capacity of

over 2800 MW in place. It was estimated that by the end of 1999, Germany would have a wind power capacity of over 4000 MW (Hinsch, 1999).

There are no major negative environmental impacts resulting from wind energy development but there are subjective public acceptability factors that may limit the extent of their use. The acceptability factors are not strictly environmental but are dependent on how many of the public that feel that wind turbines are attractive and/or prefer the cleaner generation characteristics of wind energy to the impacts of other methods of electricity generation, compared to the number of people that feel them to be unattractive. Unlike the environmental impacts of other technologies, the effects of wind turbines are readily reversible as they can be easily removed at a later date.

Noise from turbines was considered intrusive in some projects in the early days of wind power development, but it is becoming less of problem today as the major manufacturers are taking great care to avoid generating noise. The regulatory authorities of the countries where wind energy is becoming established impose maximum noise levels permitted to be audible at certain distances from a wind turbine.

The next big opportunity for wind energy is offshore development. Two successful wind farms are operating in the seas around Denmark and are providing valuable practical experience in offshore wind energy development, so much so that the Danish government plans to develop 750 MW of offshore wind power by 2008 and 4000 MW by 2030. Offshore projects are also operating in Sweden and the Netherlands and are planned for the UK. The offshore wind energy resource around Europe is substantial, and major energy and marine companies appear to be seriously interested in developing potential projects.

A further development underway in a number of countries (notably the UK and the USA) is that of so-called *green electricity distribution*. In the liberalized electricity supply markets in these countries, a number of companies are offering to supply electricity from assured renewable energy sources. Wind power is expected to play a key role in providing pollution free electricity to these schemes.

World Energy Consumption Trends

Ian Douglas
University of Manchester, Manchester, UK

Energy is necessary for all human activities. The most important energy types are:

1. *biomass;*
2. *solid fuels (coal, lignite and peat);*
3. *petroleum products and natural gas;*
4. *electricity generated from running water and wind;*
5. *nuclear power.*

*Other sources of energy such as the tides, waves, solar energy and geothermal heat are less common, but becoming more signi cant in special situations (*see *Wave Power Development, Volume 3).*

World annual energy consumption rose from 363.74 Billion Megajoules (10^{15} J) in 1990 to 384•83 $\times$ 10^{15} J in 1995 and was predicted to rise by 2015, in a high economic growth scenario to 685•93 $\times$ 10^{15} J and to 508•22 $\times$ 10^{15} J under low growth conditions. Developed countries consume a disproportionate share of the energy supply. The US uses 25% of the world's energy output for only 5% of the world's population. The developing (non-Organization for Economic Cooperation and Development (OECD)) countries with 85% of the world's population use less than 50% of the world's energy output. However as the populations and economies of the non-OECD countries grow, their energy use is beginning to catch up to that of the industrialized (OECD) countries (Figure 1).

Projected future expansion in energy use under a high growth scenario sees coal rich countries such as India and China increasing coal production and use, while everywhere else use of natural gas would grow even faster than coal (Figure 2). High growth would lead to particularly rapid increase in oil use in countries like China (Figure 3). A

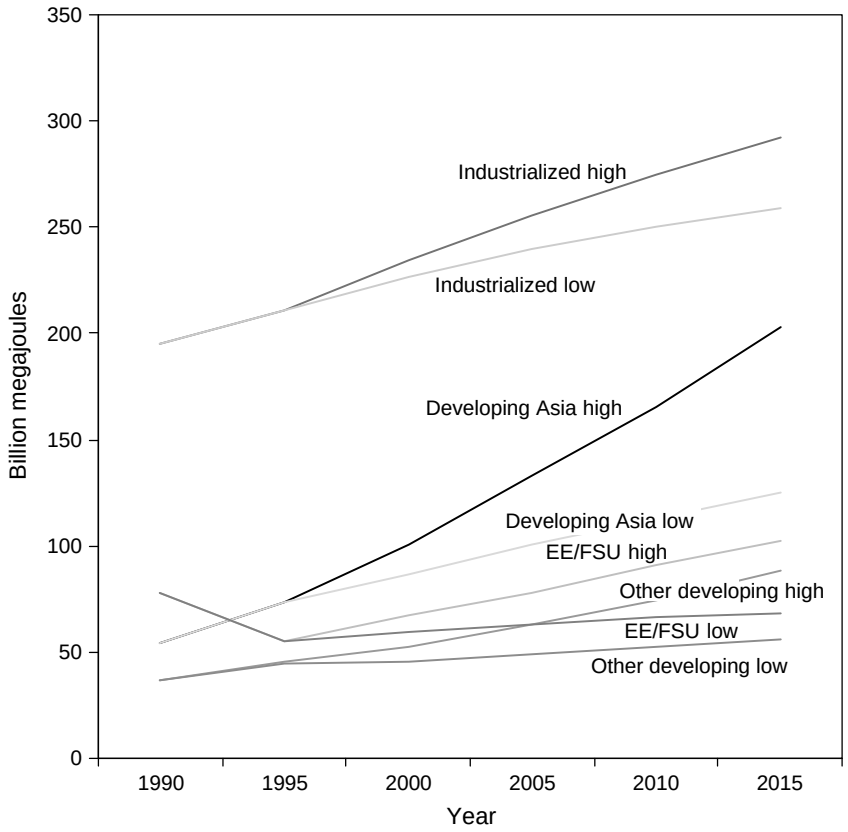

Figure 1 World total energy past and projected future use by region (based on data from International Energy Outlook, 1997) (EE/FSU denotes Eastern Europe and the Former Soviet Union)

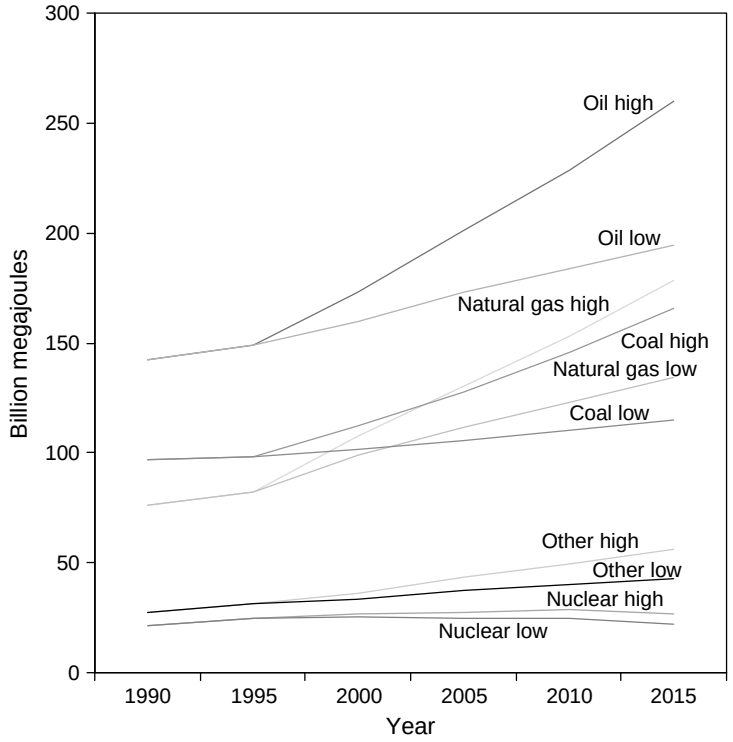

Figure 2 Past and projected future trends in global annual use of different sources of energy (based on data from International Energy Outlook, 1997)

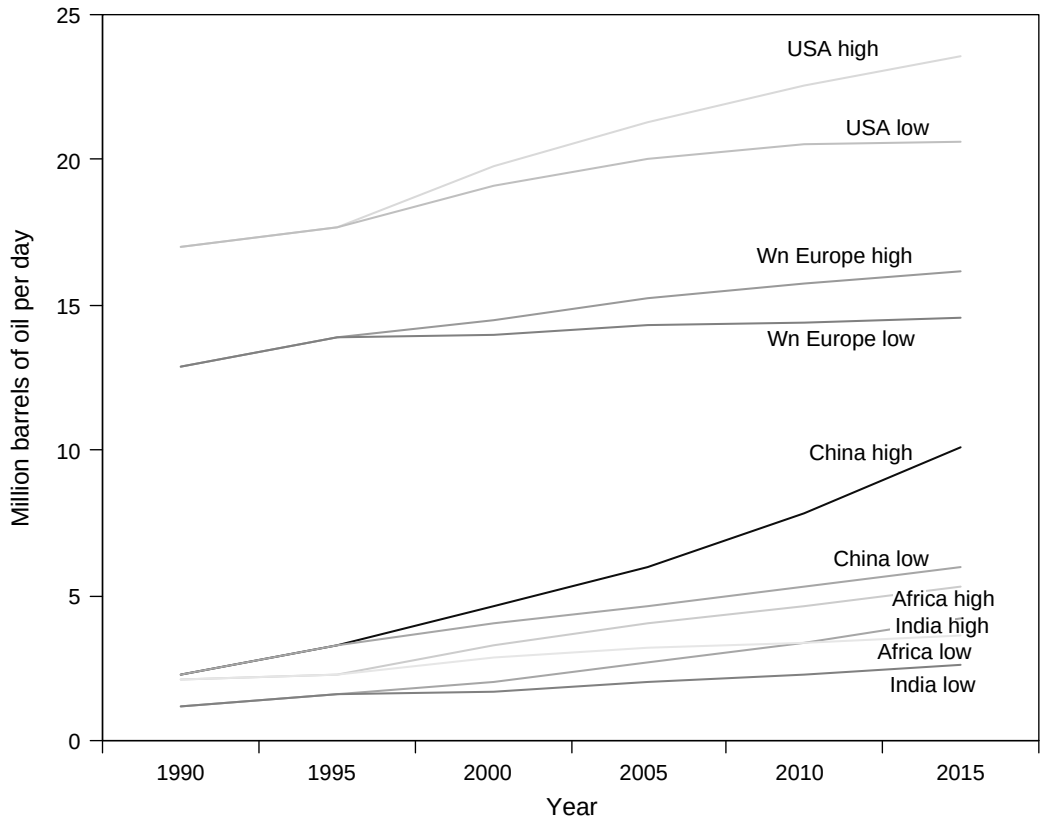

Figure 3 Past trends and future predictions of oil consumption in different part of the world (based on data from International Energy Outlook, 1997)

low growth scenario would still see a 3.4% annual growth in energy use in India and 3.1% in Mexico, compared with 0.4 in the Middle East, 0.7% in the US and 0.9% in Australasia.

PRESENT ENERGY USE

Present patterns of energy use show that the rich, industrial countries generally import energy. One extreme example is Japan, which has no oil and only a little coal and imports virtually all of its energy. Singapore, a much smaller country, is even more completely dependent on imported energy to maintain its high standard of living, yet it has a major petrochemical industry. At the other extreme are the countries of sub-Saharan Africa which have the lowest per capita fuel use rates in the world, little commercially produced energy, and a high dependence on wood fuel in rural areas and charcoal and wood in cities and towns. These countries are highly vulnerable to future shortages of biomass fuel due to the present high rate of deforestation.

Many major energy exporting countries, such as Mexico, Iran, Nigeria, South Africa, China and Indonesia, do not have particularly high per capita rates of fuel use. The wealth gained from fuel exports is not always redistributed equitably within such countries. Industrial countries use a variety of sources of energy, especially from coal, oil, natural gas, hydropower and nuclear energy. Most other countries depend on one source of fuel, China at present getting about 75% of its energy from coal, and accounting for some 25% of the world s coal production. South Africa similarly has high dependence on coal, while most countries in the Middle East and North Africa rely on oil (Rogers and Feiss, 1998).

FUTURE ENERGY USE

Projections of future energy use are difficult and there are variations in the predictions made. For example the World Energy Council s reference case shows demand rising more than 50% from 1995 2020, while those of the International Energy Agency and the US Department of Energy suggest a 34 44% rise in demand by 2010 (World Resources Institute, 1996). All three models suggest that growth in demand will be highest in Asia and Latin America. Demand will increase most markedly in developing Asia, largely as a result of rapid economic growth in India, China and Southeast Asia. The proportion of the

total world energy production used by the industrialized countries will gradually fall, but their per capita energy use will remain well above that of other countries for several decades.

A major factor in future energy demand will be the expansion in motor vehicle transport. The world currently has just over 500 million private cars, but is projected to have over 1 billion by 2020. Most of the growth in motor vehicle numbers will occur in urban areas in developing countries, although per capita vehicle ownership will remain highest in the industrialized countries for many decades. For example, there are already 4.5 million vehicles in Sao Paulo, Brazil, compared to 2.1 million in New York. The number of cars in Sao Paulo is increasing by 1000 per day. China is undergoing an unprecedented increase in motor vehicle numbers.

Petroleum is thus expected to remain the largest energy source, but the rapid expansion in natural gas powered electricity generation means that under high economic growth, world use of natural gas will begin to exceed that of coal before 2005. The exact mix of energy sources depends on the particular scenarios in each predictive model and on whether governments are assumed to have introduced measures to promote energy efficiency and the use of renewable fuels.

Practically all projections envisage that renewable energy sources (included under other in Figure 2) will play a small but growing role in the total energy supply in the next three decades. Already biomass fuels supply over 10% of global energy needs and a much higher proportion in developing countries, but with low efficiency of use. Hydroelectricity could be greatly expanded but large projects, such as the Three Gorge Dam in China, are highly controversial and schemes such a series of hydropower stations along the Mekong River in Southeast Asia, are unlikely to materialize.

Table 1 Energy related environmental degradation (after Gupta and Asher, 1998)

	Environmental degradation related to each stage of production and use			
Type	Accession and processing	Transportation	Utilization	Disposal of residuals
Petroleum	Seepage, burning of gas in oilfields, Subsidence due to withdrawal of fluids	Pipeline leakages, oceanic oil spills, permafrost pipeline problems	Air pollution, particulates from diesel fuel, emission of greenhouse gases	Management of oil wastes, risks of groundwater contamination
Solid fuels (coal, lignite, peat)	Opencast pits, landform destruction (e.g., ridge top excavations) lignite workings, destruction of wetlands through peat extraction	Coal dust	Air pollution, emission of sulfur dioxide and carbon dioxide particulates, local smog, regional acid rain, global warming	Restoration of mined land, subsidence over old coal workings, power station fly ash, mine waste dumps
Nuclear power	Uranium tailings, release of radioactive matter and heat	Risk of accidents during transport of nuclear materials and spent fuel rods	Problems of secure radioactive waste collection	High level nuclear waste disposal, restoration of areas mined for uranium; decommissioning of old nuclear reactors
Hydroelectricity	Dam and reservoir related problems			
Biomass Burning	Deforestation, soil erosion, modification of river regimes, release of air pollutants during charcoal manufacture		Household air pollution: health risks from smoke; air pollution, release of carbon dioxide and particulates; global warming	Disposal of ash, restoration of deforested areas

Projections suggest a faster rate of increase, in energy supply from renewable sources than from fossil fuels in areas like Western Europe. Here increased use of wind, solar energy and farm produced biomass is in part encouraged by government policies, such as the UK s non-fossil fuel obligation imposed on its privatized electricity distribution companies. Nevertheless, it is unlikely that such sources will account for more than 5% of world energy supplies by 2020 unless much stronger encouragement is given to their adoption.

The World Energy Council projections under an ecologically driven scenario assume deliberate fiscal and regulatory measures, as well as strong energy conservation incentives, to promote the use of renewable energy sources. With such actions and the development of new technologies, the percentage of the supply coming from renewable sources could grow to 12% of the global total by 2020. Even so, the 21st century will still be predominantly powered by fossil fuels with severe implications for future emissions of greenhouse gases.

ENERGY AND THE ENVIRONMENT

Serious environmental degradation at the local, regional and global scales is produced by the consumption of all types of non-renewable energy (Table 1). Use of renewable energy, in hydroelectricity production and biomass burning, also produces severe impacts on the environment. Dams and reservoirs may cause deterioration of river channels and of the immediately adjacent physical environment (*see* River Regulation, Volume 3). The barrages and water bodies disrupt freshwater ecosystems and movement of migratory fish. The mass of water in the largest reservoirs may place such pressure on the earth s crust that they cause earth tremors (*see* Earthquakes Triggered by Human Activities, Volume 3). Biomass burning may destroy forests and woodlands and release carbon dioxide, smoke and particulate matter to the atmosphere (*see* Low Concentration Methane Bearing Gases, Volume 3 and Biomass Fuel Power Development, Volume 3). However, the majority of the severe environmental problems caused by energy use, stem from the use of fossil fuels at all stages of the production consumption and waste disposal train. Problems arise during mining, preparation, transportation, use and residue disposal (Table 1) (*see also* Oil and the Arctic Environment, Volume 3). Normally nuclear power should only release emissions to the atmosphere in the expenditure of energy to manufacture components and to construct the reactors and generators. However, in the event of leak at a nuclear reactor, the consequences are extremely serious. Major environmental issues arise when radioactive waste has to be dealt with (*see* Nuclear Waste: Geological Issues, Volume 3).

Global fossil fuel burning was expected to grow by 32% (low growth) to 78% (high growth) between 1995 and 2015 (International Energy Outlook, 1997) and would create increases in global energy related carbon dioxide emissions of the order of 40 80%, depending on the growth scenario adopted. A considerable part of the growth in emissions would come from the accelerating growth in energy use in countries like India and China (Figure 3). However, even with that rapid growth, per capita emissions from developing countries will remain well below those of the industrialized countries (*see* National Responsibilities for Greenhouse Gas Emissions, Volume 3). If the world per capita fossil fuel burning related emissions were at the level of the average industrialized countries, world carbon dioxide emissions would be three times those already projected by 2010. The problem of emissions is extremely serious, for even if global emissions could be held at current levels, the concentrations of carbon dioxide in the atmosphere would be unlikely to stabilize for several hundred years.

World Energy Council

The 75-year-old World Energy Council (WEC) is the world s leading multi-energy organization, with member committees in over 90 countries, including most of the largest energy-producing and energy consuming countries. The United Nations-accredited, non-governmental, non-commercial and non-aligned organization covers all types of energy, including coal, oil, natural gas, nuclear, hydro, and renewables, and is a UK-registered charity based in London. WEC s mission is to promote the sustainable supply and use of energy for the greatest benefit of all.

WEC offers a wide variety of services, programs and activities to its members, the energy industry at large and the general public. WEC is well known for its authoritative reports, analyses, research, case studies, medium and long-term energy projections, and policy and strategy

recommendations. The work of the organization spans the entire energy spectrum, focusing on such topics as market restructuring; energy efficiency; energy and the environment; financing energy systems; energy pricing and subsidies; energy poverty; ethics; benchmarking and standards; use of new technologies; and energy issues in developed, transitional, developing countries.

WEC maintains a world energy information data base for its members and has issued four seminal reports: *World Energy: Looking Ahead to 2020* in 1978; *Global Energy Perspectives 2000- 2020* in 1989; *Energy for Tomorrow's World: Realities, Real Options, The Agenda for Achievement* in 1993 and *Energy for Tomorrow's World - Acting Now!* in 2000 (World Energy Council, 2000).

WEC, which counts some of the world s major energy suppliers and power generation equipment manufacturers among its patrons, gives special attention to the need to bring reliable power supplies to the world s two billion people who still lack them. The executive assembly chairman, Jima Adam, has urged WEC to have a global conscience: we must price energy appropriately to help the poor gain access without subsidizing the wealthy, and we need to foster financing partnerships between developed and developing countries linked to environmental goals (Adam, 2000a).

Commenting on responses to the international agreements to reduce greenhouse gases and alleviate the trends towards global climate change, WEC has said:

1. developed countries, with few exceptions, have not done enough by way of domestic actions or through transfer of technology, finance and know-how to fulfill the commitments they have entered into;
2. the developed countries that achieved the aim of returning their emissions to 1990 levels by the year 2000, by a substantial margin, did so for reasons largely unconnected with steps taken to mitigate climate change;
3. developing countries, while understandably pointing to failures of developed countries to meet their commitments, have sometimes acted in ways which obstruct relevant projects and financing being undertaken jointly with investors from developed countries (World Energy Council, 2000).

In addition, WEC has advocated careful attention to the future expansion of nuclear energy and hydropower.

> Our commitment to reduce greenhouse gas emissions requires that we grow the world s nuclear power capacity as one element of our strategy. Instead of opposing nuclear power at every opportunity, the industrial world should step up development of advanced, high efficiency nuclear power plants ••• Just as with nuclear power, the world s hydro-electric capacity needs to be greatly expanded and this means developing large projects as well as small projects.
>
> (Adam, 2000b)

WEC sees these measures as an essential part of meeting its three goals of energy accessibility to all at reasonable prices, energy availability in terms of reliable uninterrupted supplies and energy acceptability in terms of the social and environmental impact of types of supply and source.

The WEC is located on the 5th Floor, Regency House, 1-4 Warwick Street, London, W1B 5LT, UK. Tel: +44 (20) 7734 5996; Fax: +44 (20) 7734 5926; Website: http://www.worldenergy.org/wec-geis/.

Yellow River, China: a Case Study in Water Resources

Changming Liu
Chinese Academy of Sciences, Beijing, China

The Yellow River is the second largest river in China (between 96- 119°E and 32- 42°N). The length of its main course is 5464 km from its headwater in Qinghai province to the Bo Sea in Shandong province with a drainage area of 752 443 km^2. The population is 107 million (1997) with an average population density of about 143 per km^2. The area of farmland totals 12.6 million hectare (ha), of which about 40% is under irrigation using the Yellow River's water resources. Per capita *grain production reached 352 kg in 1997. About 70% of the grain yield was produced on irrigated lands. The urban population of about 25.06 million comprises 23.4% of the total.* Per capita *gross domestic product (GDP) was 4530 Yuan equivalent to about US$550. Water resources in the basin total 71.9 billion m^3 including annual average runoff of 58 billion m^3 and groundwater of 13.9 billion m^3 while the Yangtze River has an annual average runoff of around 1000 billion m^3. The Yellow River is characterized by its hyper-concentrated sediment load. The measured annual sediment runoff during 1919- 1996 averaged 1.69 billion tonnes, which mainly comes from the Loess Plateau of the Yellow River's middle reaches.*

MAJOR PROBLEMS IN WATER EXPLOITATION

The Yellow River faces severe water shortages, as well as an increasing threat of floods and deterioration of the ecology and environment in the basin. The main channels of the lower Yellow River have dried up in 22 of the 28 years of records from 1972 to 1999, causing water shortages. In the 1990s, such events occurred every year as never before. The most severe situation was in 1997 and the duration of the dry riverbed totaled 226 and 330 days without water flowing through the river estuary outlet into the Bo Sea. The maximum length of a dry river bed in 1997 reached 704 km, about 90% of the length of the lower Yellow River (786 km), so the Yellow can be called an ephemeral stream or temporary river nowadays. Moreover, at the same time, the drying of the river has also been occurring in the main tributaries of the mid-upper reaches of the Yellow River (see Figure 1).

MAJOR IMPACTS OF THE DRYING UP CHANNEL UPON THE ENVIRONMENT

Ecologically, frequent drying up of water courses would cause a number of eco-environmental problems. The most critical one would be found in wetlands along the Yellow River s estuary and delta areas where the national wetland protected area lies with an extent of 150 000 hectare (ha), which would be influenced by the depletion of water. Obviously, this damages the biodiversity of the wetlands. Disastrously, under successively drying up courses the lower Yellow River would reduce its carrying capacity in transporting the hyper-concentrated sediment loads resulting in channel aggradation, consequently in a decrease of channeling water flows. This implies an increasing threat of floods in the areas along the lower Yellow River in the case of heavy rainstorms.

THE MAIN REASONS FOR THE DRYING-UP OF THE RIVER'S DOWNSTREAM COURSES

1. Climatically, most of the river basin lies in semiarid and arid regions. Its water balance features high evaporation and low runoff. The annual precipitation of the river basin averages only 475.9 mm while the mean annual evapotranspiration is 388.3 mm. The annual runoff is only 87.6 mm, equivalent to just 18.5% of the precipitation. Moreover, the runoff varies greatly in space and time, being highest in summer but fluctuating greatly from year to year. The lowest recorded annual

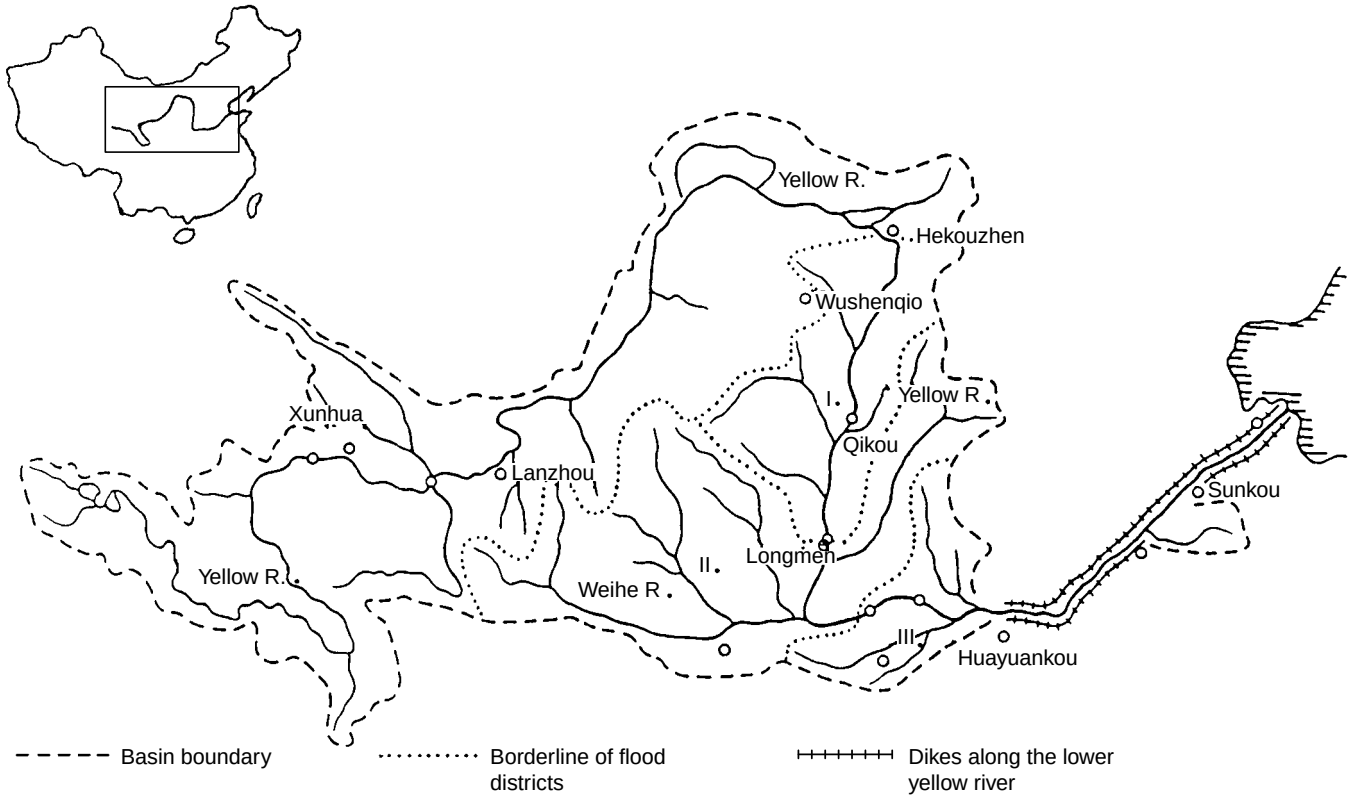

Figure 1 The Yellow River

runoff between 1919 and 1997 was only 27.5 billion m^3 in 1928, while the highest yearly runoff, in 1964, reached 93.3 billion m^3. In particular, there were successive low-water years in 1922 1932, 1969 1974 and 1990 1997. Of course, the dry years in the 1990s were the reason for the successive drying up of the river courses.

2. With intensive socio-economic development, water consumption has increased year by year, from 12.2 billion m^3 in the 1950s to about 30 billion m^3 in the 1990s, an increase of about 2.5 times. Most river water withdrawal goes to the agricultural sector, which takes about 92% of all the water used in the basin. The total installed withdrawal in the whole basin has reached 6000 $m^3 s^{-1}$ of which 4000 $m^3 s^{-1}$ is in the lower reaches, much exceeding the availability of the river s natural runoff (1840 $m^3 s^{-1}$).
3. Institutionally, water resource management is inadequate in terms of poor control of water withdrawals among the provincial authorities along the river courses. Administrative bodies control water rights; and water allocation is not adjusted in accordance with water regimes. For instance, each province takes the same amount of water from the river in both dry and wet years.

PROJECTION OF THE YELLOW RIVER'S WATER RESOURCES DEVELOPMENT IN THE 21ST CENTURY

Average annual runoff and exploitable groundwater in the basin totals 71.9 billion m^3. *Per capita* water volume in 1993 was 543 m^3 and is estimated to be 459 m^3 in 2010 and 402 m^3 in 2050. With rapid socio-economic growth, water consumption will continue to increase. Water demand in the river basin is expected to be 53 billion m^3 in 2010, 58 billion m^3 in 2030, and 60.7 billion m^3 in 2050. Accordingly, a water deficit would last till the middle of the century, when water demand will approach zero growth. The situation will become even worse if climate change brings warmer and drier conditions to the region.

MAJOR STRATEGIC CONSIDERATIONS

Based on the principle of sustainable development, three countermeasures are critical:

1. The establishment of a unified management system and formulation of a unified river basin management commission under the leadership of the state council and the setting up of an executive authority

implementing unified management, thus coordinating local administrations and water users.

2. Development of a water-saving policy incorporating water demand management as a countermeasure against wasting of water (implementation of a marketing policy including water fee regulation to protect water resources against pollution, thus maintaining the ecological equilibrium of the river basin).
3. Formulation of a special law for managing the Yellow River basin which is an extremely large unit covering nine administrative bodies of eight provinces and one autonomous region; and two administrative bodies of Hebei province and Tianjing City outside the basin. The 11 administrations have their own rights to obtain water from the Yellow River. Such water allocation was made by the state council in 1987. In addition, there are several hydro-power stations and watershed administrations with their own operational rights in the river basin. Therefore the formulation of a law to manage the Yellow River is highly advisable.

Preface to the Encyclopedia of Global Environmental Change

THE ENVIRONMENT

The word *environment*, whose dictionary meaning is simply that which surrounds, has in the last few decades become a buzzword , encompassing an exceedingly diverse array of elements and social issues. Taking the original meaning as a point of departure, it is clear that we humans depend totally on the environment provided by planet Earth for the food we eat, the water we drink, and the air we breathe. Thus changes in this environment must be of vital concern. Will Earth continue to sustain humans in a way that also encourages the ourishing of the other living things with whom we share the planet? This question has loomed ever larger as it has become more evident that human activities have been inducing major changes in all of the compartments of the global environment. We have converted forests and savannas to farms and cities; we have exhumed ancient treasures of fuels and minerals; we have used the rivers and winds as convenient sewers; and we have released entirely new chemical compounds and organisms into the environment. In the 1960s, the scientific community began to use the word *environment* in this new non-specialist sense. Soon too, Departments of the Environment were created by many governments, and new scientific journals began publication while others were re-named. For example, the *International Journal of Air Pollution* became *Atmospheric Environment*! In the ensuing decades, the world community has come to see the environment in many different ways, as a life-support system, as a fragile sphere hanging in space, as a problem, a threat and a home.

GLOBAL ENVIRONMENTAL CHANGE

A broader and deeper understanding of the global aspects of environmental concerns emerged in the 1970s and 1980s, and a new phrase *global environmental change* acquired popular currency. Paleoresearch had revealed that environmental change was far from new, and by no means the sole result of the actions of heedless humans. Since the planet's formation, virtually every element of its environment has been undergoing massive changes on all space and time scales. Oxygen waxed and carbon dioxide waned in the atmosphere. Continents moved about the planet's surface like scum on a soup kettle. Great ice sheets grew and shrank. Above all, the force of life (the biosphere) emerged as a dominant driver of planetary change.

However, another vital insight began to emerge about 1980: the inescapably interlinked nature of these many environmental changes. On the very longest time scales, continental drift moved lands into different climates – but also changed the climate of the globe itself. Photosynthetic life changed the atmosphere – but also made possible more advanced life forms that could take advantage of the new environment. On shorter time scales, atmosphere and ocean often interact to produce the massive changes in the Southern Pacific that we term El Nino and La Nina, whose consequences extend across the planet, and profoundly affect even our socioeconomic systems. Indeed, we have come to realize that human-induced perturbations in the environment are becoming increasingly large, and are potentially coming to dominate the natural workings of the complex and interdependent global system that sustains life on Earth. Humans and their global environment are no longer independent; they are ever-increasingly becoming interdependent components of a single global system.

Thus, the term *global environmental change* has come to encompass a full range of globally significant issues relating to both natural and human-induced changes in Earth's environment, as well as their socioeconomic drivers. This implicitly includes concerns for the capacity of the Earth to sustain life that have motivated the development of studies of global change and sustainable development in the last few decades. Analyses of global environmental change therefore demand input from the social sciences as well as the natural sciences (and indeed also from the engineering and health sciences) – necessitating an inescapably interdisciplinary approach.

Scientists from many disciplines have been attracted to this growing field of global environmental change. This is particularly noticeable in the biological sciences through the encouragement of IGBP (International Geosphere–Biosphere Programme), which invites ecologists to expand their field of vision from the plot and landscape scales to the regional, continental and global ones, and to interact with scientists from other disciplines in exploring environmental change at these larger scales. Indeed this trend has encouraged publishers and scientific societies to introduce new journal titles, and these publications from all accounts appear to be ourishing.

At the same time, human social, economic, and cultural systems are rapidly changing under the in uence of growing globalization. In the economic sphere, for example, today's discourse centers on multinational corporations, the Global

Economy, and the Globalization of Trade. Thus, the agendas of most of the physical, life, and social sciences increasingly focus on global-scale changes.

THE EVER-CHANGING ENVIRONMENT

Since the launching of Earth-viewing satellites, we have been able to see a constantly updated moving picture of our planet. Great weather systems sweep around the globe, waves of green and brown ebb and ow over the continents with the seasons, as do white waves of ice and snow. Nevertheless, a remarkable feature of the Earth system has been its relative stability. Since the dawn of life, the planet's environment has remained within a range of conditions that has supported life. Moreover, with some notable and perhaps cautionary exceptions, changes from year to year, decade to decade, millennium to millennium, have been modest, particularly during the last 10 000 years. Many features of human society exhibit similar behavior. Civilizations and cultures evolve slowly for the most part in response to environmental, economic, and social driving forces over their long lives. Great cities like Rome endure through the ages. A citizen of ancient Babylon probably would have little difficulty understanding the politics of modern Toronto.

But today we appear to be entering an era of change unprecedented since Babylon was a cluster of mud huts. There are many reasons to believe that changes greater than humankind has experienced in its history are in progress and are likely to accelerate.

Virtually every measure of human society – numbers of people and automobiles, airplanes, energy consumption, generation of waste – is increasing exponentially. While the values of a few indicators are leveling off, the magnitudes of annual increases of others remain immense.

Major changes are becoming evident in many critical elements of the environment – increasing carbon dioxide concentrations, stratospheric ozone depletion (not to mention the stratospheric Antarctic ozone hole and the possibility of a similar Arctic event), rising sea level, declining productivity of soils, widespread collapses of fisheries, dramatic declines in biodiversity, destruction of tropical forests, etc. Within living memory, the countryside around large cities has been swallowed up by suburban developments and highways. Humans are stepping on the gas pedal of the planet's environment, and perhaps recklessly breaking the survivable speed limit of global change.

Paleoclimatological studies have shown that the stable environment that we take for granted has not always prevailed. Indeed, the relatively brief period in which human civilization has developed is somewhat unusual in its equable stability. Neolithic hunters in Europe some 13 000 years ago saw their climate shift from temperate to glacial in a single short lifetime. The evolution of human society is punctuated by wars, pestilence, and technological revolutions. Major – perhaps even catastrophic – change could occur in the future, because we know it has occurred in the past.

Rapidly advancing understanding of both natural and human systems – and above all the ability to translate that understanding into quantitative models – has enabled us to explore the future of our global society and its global climate with unprecedented realism. Although prediction of the single future path that we will follow is inherently unpredictable, it is possible to map a broad range of future environmental trajectories that we might take, each completely consistent with our understanding of how the system works. Such scenario-building exercises amply confirm our concerns that the changes of the 21st Century could be far greater than experienced in the last several millennia. Business-as-usual for human society appears to imply business-as-highly-unusual for the global environment.

THE INTERLOCKING BIOGEOPHYSICAL – SOCIOECONOMIC SYSTEMS

Recognition came in the 1970s that many of the environmental issues are inter-connected through the biogeochemical cycling of trace substances, especially carbon, sulfur, nitrogen and phosphorus. In fact, in a prescient statement on the main environmental research priority of the 1980s, Mostafa Tolba (then Executive Director of the United Nations Environment Programme) and Gilbert White (then President of the Scientific Committee on Problems of the Environment) drew the attention of both the scientific and the science-policy communities to the need to understand the major global biogeochemical cycles in order to maintain the global life support systems in a healthy state (Tolba and White, 1979). Quoting from that statement,

> We draw attention to the fundamental scientific importance of understanding the biogeochemical cycles which link and unify the major chemical and biological processes of the Earth's surface and atmosphere. The results will have practical significance for all of us who inhabit an Earth with limited resources and who, by our actions, increasingly affect the quality of the human environment.

So it is that many of the global environmental issues – acid rain, stratospheric ozone depletion, climate change, nitrogen over-fertilization – are inter-related through the global biogeochemical cycles.

One of the interesting results of the study of the Earth's history has been the discovery of the global teleconnections of the Earth system, with some major climatic shifts occurring simultaneously in the two hemispheres. In an analogous way, there has been recognition for a long time that human social, economic, and cultural systems are globally inter-related. That these are connected in turn to the

Earth system was implicitly recognized as early as the 1972 Stockholm Conference on the Human Environment.

To manage the human responses to this enormously varied but at least moderately coupled world system in an era of increasing global change through the diverse array of local, national and international organizations is indeed a daunting challenge. An essential first step is to describe past and present states, then to explain the various phenomena observed, and finally to develop predictive models (or at least a range of scenarios) describing the future behavior of this total Socioeconomic–Cultural–Environmental system. In this process, environmental scientists must learn how to assimilate better the new information constantly being received, although uncertainties, often large, will continue to exist. Within this mix, rational and effective policies must be developed that will balance the risks and costs of global environmental change in an adaptive way. Only then will we be able to even formulate, much less start to implement, rational and effective policies that cope effectively with global change. The prospect of change tempts us to think in terms of winners and losers. However, such analyses often do not play out in simple ways. For example, a modest increase in rainfall would cause farmers to rejoice while vacationers would despair. However, greater farm production can lead to lower commodity prices, thereby reducing farm incomes while making vacation food purchases less expensive. Human society is pretty well adapted to the present environment, so change is necessarily a challenge.

In the longer-term, much depends on the ability of societies to respond, to adapt. Societies will differ in the resources – natural, human, and technological – that are available to them. They will also differ in terms of the values and priorities they attach to physical, social, and environmental goals, and in the social and political mechanisms that they employ to seek these goals. These differences in the human world of generations yet unborn may be as great – and as significant – as the changes in the global environment. A major challenge for our times is to develop frameworks for understanding complex interdisciplinary issues of this complexity.

No discussion of change and the future can be complete without consideration of risk. Projections of the future, however imaginative or soundly based, necessarily center on plausible, surprise-free scenarios – population will increase, economies will advance, climate will change – all typically slowly and smoothly. However, such projections made at the beginning of the 20th Century would have missed two World Wars, the automobile, aviation, space travel, television, and McDonald's in Beijing. By definition, genuine surprises cannot be predicted. However, an understanding of the impacts of past surprises may help us to make our society and our world somewhat more robust in the face of the unknown surprises that await us.

THE HUMAN DIMENSIONS OF GLOBAL ENVIRONMENTAL CHANGE

The human dimension of global change has been defined as the ways in which individuals and societies contribute to global environmental change, are in uenced by it, and adapt to it. Many empirical studies have been undertaken that describe human activities in physical terms, based on various kinds of indicators. Rates of deforestation, urbanization, and changing levels of emissions of greenhouse gases are only some measurable contributors to environmental change. But the dynamics of human activities and global change are much more complex, and they re ect the complexities of the human–nature relationship.

While the sheer burden of human activity on the planet is important, we know that the major forces at work are human beings operating together through political systems, corporations, interest groups, and beliefs that sway whole peoples. These raise questions about the nature of choice, about the hopes, dreams, and frustrations that impel people forward, or block them. At the moment, for instance, the dream of the good life – which has been a critical element of every religious tradition in the world – is increasingly being defined in terms of material possessions and powerful images that are shown on global media. Can this particular version of human happiness be sustained on a limited planet? Some people say that it can; others say that it cannot.

The central questions about the role of human beings in global environmental change revolve around social, cultural, economic, ethical, and even religious issues. These are becoming more and more pressing, and more and more foundational as human beings deliberately or inadvertently modify more and more of the planet. It is also obvious that in this generation the modification of organisms and ecosystems may well extend to the modification of human beings themselves. Among the fundamental questions are: What motivates us towards saving or harming the environment? How do we see ourselves with regard to nature? What is our responsibility to this and future generations? Who do we think we are, and who would we like to become? Appropriately enough, Volume Five of this Encyclopedia wrestles, in many different voices, with these ultimate questions that remain intimately linked with the sweep of physical, chemical, biological, geographical, and institutional changes documented and discussed throughout the earlier four volumes.

The Brundtland philosophy urges us not to reduce options for future generations. Implementation of this idea is, however, difficult. For example, it often seems more compelling to alleviate current poverty than to protect the environment and renewable resources for future generations. Many scientists agree that new approaches are needed to meld the social with the natural sciences in the policy arena. Some of the new methodologies that go beyond the physical sciences

are described in Volumes Four and Five of this Encyclopedia, e.g., post-normal science, integrated environmental assessment, and the precautionary principle.

In a commentary in which he described the 21st Century as the century of the environment, Edward O. Wilson began by referring to the growing *consilience* (the interlocking of causal explanations across disciplines) so that the interfaces between disciplines become as important as the disciplines themselves. He then stated that this interlocking amongst the natural sciences will in the 21st Century also touch the borders of the social sciences and humanities. In the environmental context, environmental scientists in diverse specialities, including human ecology, are more precisely defining the arena in which that species arose, and those parts that must be sustained for human survival (Wilson, 1998).

This is a major challenge for environmental scientists. Already through DNA techniques, for example, it is possible to trace back connections amongst prehistoric peoples through the last Ice Age to modern times.

THIS *ENCYCLOPEDIA OF GLOBAL ENVIRONMENTAL CHANGE*

More than two million papers are published every year in science and medicine, a twentyfold increase since 1940 that taxes the resources of concerned citizens, scientists, university departments, research institutes and libraries. At the same time, many policy-motivated organizations find it difficult to draw together the necessary expertise for resolving the newly emerging environmental issues. The scientific literature relating to the environment is burgeoning. However, research syntheses are in general still scattered across a broad spectrum of journals and books, and information on global environmental change is not readily available in an inter-related way. In particular, it is quite uncommon for contributions from the natural sciences to appear in the same journal or workshop proceedings as contributions from the social sciences and the humanities.

This *Encyclopedia of Global Environmental Change* is a comprehensive and integrated reference in the broad area of global environmental change that will be conveniently accessible and productively usable by students, managers, administrators, legislators, and concerned citizens. The Encyclopedia consists of five volumes of interrelated material:

Volume 1 The Earth system: physical and chemical dimensions of global environmental change (Michael C MacCracken and John S Perry, editors)

Volume 2 The Earth system: biological and ecological dimensions of global environmental change (Harold A Mooney and Josep G Canadell, editors)

Volume 3 Causes and consequences of global environmental change (Ian Douglas, editor)

Volume 4 Responding to global environmental change (Mostafa K Tolba, editor)

Volume 5 Social and economic dimensions of global environmental change (Peter Timmerman, editor)

The first four volumes cover the broad issues of the science and politics of global environmental change. Volume Five adds an often understated but extremely important aspect, linking as it does, global environmental change to the socioeconomic, cultural and ethical dimensions of human societies. Here will be found a rich panoply of writings by people who are not natural scientists but who have thought deeply about the environment. It places global environmental change in a refreshing historical, sociological and cultural context. In many contributions, the time horizons of most interest are the last hundred and the next hundred years. However, some contributions dip backward millions of years. Throughout, the emphasis is upon the dynamics of the various processes discussed – how and why did they change? A second recurrent theme is the interconnection of processes and changes – What produces change? What is impacted by change? Finally, we attempt to deal even-handedly with natural and human-induced change, and with impacts on both the natural world and human society. From the numerous diverse articles in the Encyclopedia, we believe that the user can obtain a coherent picture of this complex and dynamic system of which we all are a part.

To assist in promoting this coherence, each volume begins with a group of extended essays on major topics that embrace the field covered in that volume. These are intended to provide an introduction to the topic, a convenient road map through cross-references for exploring the Encyclopedia. Then there follows, in alphabetical order, shorter articles on a variety of scientific topics, descriptions of scientific programs, definitions, acronyms, and biographies of leading contributors to the field – from Charles Darwin, through the Russian ecologist Vernadski, to the three most recent environmental Nobel Laureates – Crutzen, Rowland and Molina. Indeed, these definitions, biographies and acronym definitions are, we believe, a uniquely valuable feature of the Encyclopedia. In the case of acronyms of international organizations and programs, it is no exaggeration to state that a young environmental scientist requires not only a good understanding of science, but also a good knowledge of acronyms, if they are to follow the discussions taking place at many international meetings! Also included in the alphabetic listings are abundant cross-references to related topics in the same or other volumes.

The substantive scientific articles that comprise the meat of the Encyclopedia are original contributions by active scientists from around the world, and thus

represent authoritative and up-to-date summaries of the state of current knowledge, direct from the producers of this knowledge. A number of these articles break new ground in synthesizing and summarizing our understanding from novel viewpoints and in unconventional ways. Thus, readers will find a wide variety of styles and approaches within the articles, re ecting in a unique way the rich diversity of today's world science. The articles have also had the benefit of careful reviews, particularly by our Editors.

The scientific essays and some of the program descriptions begin with a few italicized paragraphs written for non-specialists. These are not intended to be abstracts of the paper to follow, but rather are aimed at providing the reader with an introduction into why the topic is important and where it fits into the broader aspects of global change – a kind of encouragement to read on. Reading on should not be too difficult a task, since most of the scientific essays are written at the level of journals such as *Scienti c American* and *AMBIO* that are intended for the non-specialist. The Encyclopedia will be a valuable source of information for everyone with a general interest or a need-to-know in the various environmental fields (the natural sciences, socio-economics, engineering, the health sciences, and policy analyses) particularly as they relate to global-scale environmental change, its drivers, and its consequences. It is also expected that among the audiences for each volume will be practitioners and researchers in the fields covered by the other four volumes. We believe that this rather unusual – indeed unique – Encyclopedia will be used in a variety of ways.

1. Some people will employ it simply as a convenient source of information on specific topics – What has been happening recently to the sea ice in the Arctic Ocean? Who was Roger Revelle? What is soil mineralization? What is ICSU or IGBP? What is the Kyoto Protocol? What is deep ecology?
2. Serious students in the environmental sciences may begin by reading one or all of the introductory essays, which present highly compressed crash courses in a range of central topics.
3. We believe that the substantive specialized articles that constitute the bodies of the volumes are productively and enjoyably readable in their own right.
4. Finally, a case has been made by one of the volume editors (Peter Timmerman) for encyclopedia browsing as an enjoyable and productive pastime (*see* Encyclopedias: Compendia of Global Knowledge, Volume 5).

We believe that these five volumes are in the tradition of the human aspiration towards the compilation of global knowledge that sparked the preparation of the first encyclopedias in the 18th Century.

Our Editors have had the benefit of a marvellous postgraduate education in the course of the Encyclopedia's evolution! We are immensely grateful to the many, many authors in our virtual university who have contributed their wisdom to this project.

ACKNOWLEDGMENT

Many helpful comments and draft paragraphs were received from the Volume Editors during the preparation of this Preface.

Preface to Volume Four

Volume Four deals with human responses to global environmental change. The opening essays discuss actions that have been taken, or are contemplated, to deal with global environmental change – separately by the public, by governmental and intergovernmental bodies, by engineers in search of technological solutions, by business and industry, by the scientific community and by various sectoral interests such as the fishing, forestry and tourist industries. There follow about 100 shorter articles that elaborate on these themes. Topics covered include strategies for adapting to global change, tradable emission permits, the Biodiversity Convention, the Montreal Protocol, various tools that assist in the development of better long-term environmental policies (environmental assessment methods, environmental dispute resolution, the design of early warning monitoring systems, indicators of sustainability, etc.), the precautionary principle, and Agenda 21.

Over the past three decades, the pace of global environmental change has been increasing, and there are warning signals that this trend may accelerate. This has triggered much re ection (and action) within the environmental policy community, and there is not enough space in the Encyclopedia, let alone in this volume, to describe all of the important developments that have taken place. So we have had to be selective, while at the same time trying not to miss any of the major responses. Thus the volume covers:

1. Policies that have been developed with a view to achieving sustainability (of energy, transport, fisheries, cities, tourism, development, •••);
2. Intergovernmental and other environmental meetings that have had significant impacts on progress being made in environmental policy formulation (particularly the Stockholm Conference; the UNCED Rio Summit; Kyoto and the various world conferences organized by the UN and its Specialized Agencies);
3. The main principles agreed during the past three decades (polluter pays; common but differentiated responsibilities; no regrets principle; precautionary principle, •••);
4. Concepts (cleaner production; eco-efficiency; dematerialization; adaptive environmental monitoring strategies, •••);
5. Tools for assessing the state of the environment and dealing with environmental problems (environmental and social assessments; material ow accounting; tradable permits; eco-labelling; adaptation strategies; capacity building, •••);
6. The major International Environmental Conventions (Ozone; Climate Change; Hazardous Wastes; Biodiversity; Basel Convention; CITES; Desertification; LRTAP; Vienna Convention and Montreal Protocol, •••);
7. Examples of Actions taken to deal with regional environmental problems (Mediterranean; Black Sea; Baltic; Great Lakes; Caspian Sea; Aral Sea; Lake Victoria, RAINS, MINK). For convenience, these regional cases have been grouped together at the end of the volume, preceded by an introductory article written by Osama El-Kholy);
8. Short descriptions of organizations that have contributed significantly to the development of long-term environmental policy formulation (Club of Rome; IPCC; Commission on Sustainable Development; WBCSD; European Environmental Agency; ICSU; IPCS; Worldwatch Institute; UNEP; World Resource Institute, •••);
9. Short biographies of people who have played significant roles in the environmental response field (Gro Brundtland; James Dooge; Maurice Strong; Mostafa Tolba; Gilbert White; Anil Agarwal; Barbara Ward; José Goldemberg, •••).

We believe that in spite of space limitations, this volume provides ample information on the progress that has been made in the last 30 years in the field of human responses to global environmental change – by institutions, academia, governments, lawyers, economists and the whole array of people around the world involved in this noble task.

Mostafa K Tolba
Editor of Volume Four

Environmental Responses: an Overview

MOSTAFA K TOLBA

International Center for Environment and Development, Cairo, Egypt

Over two million or so papers are published every year in various disciplines of science, including medicine. Assessing such a massive output, is quite impossible. However, there is no doubt that understanding in all branches of science has deepened tremendously in recent decades. This is particularly true in the environmental field (Tolba *et al.*, 1992).

Once consequence of these developments has been the increasing attention given to long term futures (50 or even 100 years ahead). During the 1970s and 1980s, much was learned about the global nature of environmental systems. Particularly impressive are the insights gained into the biogeochemical cycling of elements essential for life, notably carbon, nitrogen, oxygen, phosphorus and sulfur, called the environmental life-support system by Tolba and White (1979), who have emphasized that many large-scale environmental issues – climate warming, stratospheric ozone depletion, acid rain and soil degradation – are inter-related through disruptions in the global cycles of these elements.

The last two decades have seen considerable advances in understanding the behavior of geophysical systems, and of plant and animal populations, and in the development of a capacity to model them mathematically. If changes within a system are sufficiently small for it to be expected to remain close to the range of previous experience, it is possible to develop rational environmental management plans by applying the ideas of carrying capacity of a region, sustainable yield of a renewable resource, and assimilative capacity of a watershed or airshed. These tools have developed considerably in the last 20 years. Holling introduced the idea of resilience of an ecosystem, which means that although most ecosystems can withstand environmental stresses within certain limits, they may not survive a major shock.

A related idea that has been much popularized in recent years is that of *chaos*, which is a measure of the sensitivity of a system to initial conditions. It was first studied in the context of weather forecasts by Lorenz (1963) who demonstrated that the atmosphere quickly loses its predictability.

These and other concepts have been drawn together in the development of new approaches to environmental management. The ecological insights into the dynamics of ecosystems and the critical conditions governing stability or change have led in turn to analyses of how far it is practicable to use certain systems sustainably. The concept of sustainable development embraces economic, social and ethical elements as well as ecological ones, but it is clear that development is sustainable only if it is ecologically sound (IUCN/UNEP/WWF, 1991). The intellectual challenge for ecologists is that sustainability must be achieved not simply under conditions of slow change, but also under the rapid environmental and socio-economic transformations expected in coming decades. Studies that attempt to evaluate these changes and to manage the resulting impacts are, therefore, becoming increasingly important. In this connection, the scientific problem of how to achieve re-development of degraded ecosystems has been given increased attention in the last decade.

There have of course, been major advances in many other branches of both basic and applied science, which have contributed in important ways to the intellectual context within which environmental understanding has evolved. Physics, chemistry, mathematics and geophysics have all contributed much. Within the engineering sciences, the idea of industrial metabolism and material ows has been pursued by many. Major advances in medical science have contributed considerably to human quality of life. Smallpox has been eradicated and there is now a much better understanding of other major infections and about the causes of cancer. On the other hand, the appearance of many new kinds of industrial chemicals, and rapid advances in measurement techniques have led to the appearance of a suite of new health issues relating to toxic substances such as PCBs (Polychlorinated Biphenyls) and pesticides. In fact, a new scientific discipline, environmental toxicology (or ecotoicology) has been born.

Although social scientists are making increasingly important contributions to our understanding of the environment, progress has not been as spectacular as in the natural sciences. This imbalance is gradually being corrected as the roles of human population growth, resource consumption and life-styles are increasingly recognized as major factors transforming the biosphere. It is now appreciated that it is impossible to draw up plans and strategies for environmental management without understanding the sociology and economics of the people involved. Resource planning requires models of demographic trends and resource consumption patterns. The role of special groups – women, children and the aged – are being closely analyzed. The traditional wisdom of indigenous people is also being evaluated for the insights it can provide into sustainable resource use. Developments in social science research have led in turn to the development of new techniques to promote environmental management. These range from evaluations of the environmental impacts of new policies and industrial developments, examined through environmental impact assessment (which increasingly considers economic and social factors) to combinations of regulatory and economic instruments to promote optimal resource use and minimal pollution. Such principles as the Precautionary Principle, the Polluter Pays Principle and the User Pays Principle have originated at least as much from the social sciences as from the world of pollution-control technologies.

Environmental ethics' is a term that has recently come into use to describe the principles that should guide humanity's relationship to the environment. The history of environmental ethics under other names is long, encompassing the whole range of humanity's experience and use of nature. However, the current global environmental situation has given fresh impetus to the exploration of the values underpinning modern society. Some of this is being carried out in the philosophical community, some in religious groups, and some simply among ordinary people who want to know what they ought to be doing to think globally, and act locally.

There are two different kinds of ethical approach to the environment. The less radical kind suggests that we can apply standard ethical understandings derived from philosophy or theology. This is the approach used by the International Union for Conservation of Nature and Natural Resources (IUCN), the United Nations Environmental Programme (UNEP) and the World Wildlife Fund (WWF) in their publication *Caring for the Earth: a Strategy for Sustainable Living* (1991). The second kind is more radical, and argues that a complete rethinking of our relationship to the environment is required, and that by doing that, we shall inevitably by forced to change many things we take for granted, including what we mean by ethics. These two kinds of environmental ethics have been referred to as shallow ecology and deep ecology, although both use the term ecology in a sense somewhat removed from its scientific meaning (*see* Deep Ecology, Volume 5).

RESPONSES TO ENVIRONMENTAL PROBLEMS

At the National Level

In the development of human societies, interactions with the environment were predominantly at local, and especially village, level. This is still the case in most of the world. In the 1970s, 75% of the population of developing countries was rural, although by 1980 this figure had fallen to 71%, and 63% by 1990. Agriculture continues to provide over two-thirds of total employment in many of the lower-income countries, and to provide over three-quarters of their exports (MacNeil *et al.*, 1991). However, the development process has in most countries been accompanied by the progressive expansion of the industrial sector, and urbanization has brought the growth of municipal utilities and aggregated many human impacts on the environment.

Local policies governing human interactions with the environment are as ancient as history. Technical ways of apportioning hunting rights, and controlling how land and water are used, or livestock managed, unquestionably began long before we had written records. National policies for the apportionment of land, protection of forests and control of hunting and fisheries are also ancient. This is not surprising, for there is nothing more fundamental to a nation than its land and water; and the rights to the use of such resources must inevitably have been among the first to be guarded by the central organization of a state.

Environmental policy has become increasingly cross-sectoral and integrated. While it is necessary to have specific environmental policy objectives for each of the many sectors of a modern complex state, it is also necessary to have a broad over-view and system of guidance, designed to optimize the use of the natural capital which the environment represents.

Environmental policy is developed by institutions at many levels, including local authorities, citizens' groups, environment and development non-government organizations (NGOs), religious groups and industry. All have their place and importance alongside national governmental institutions.

Another trend of the past 20 years has been the recognition of the interdependence of nations and the need for this to be expressed in regional policies and institutions that span broad areas of the environment, and for whose management a number of sovereign states need to come together. The most obvious examples are large river basins (40% of the world's population live in the catchment area of a river shared by several states), and areas of sea whose ecosystems are interlinked, and which need managing as units.

The diversity observed in policies and institutions is both inevitable and adaptive. The world's environment is

Box 1 Major international agreements

EARLY INITIATIVES

1906 Convention concerning the Equitable Distribution of the Waters of the Rio Grande for Irrigation (US–Mexico water treaty)
1909 Boundary Waters Treaty concluded between Great Britain (on behalf of Canada) and the United States
1911 Convention for the Protection and Preservation of Fur Seals
1923 Convention for the Preservation of the Halibut fishery of the Northern Pacific Ocean and the Bering Sea
1931 Convention on the Regulation of Whaling
1940 Convention on Nature Protection and Wildlife Preservation in the Western Hemisphere
1946 International Convention for the Regulation of Whaling
1951 International Plant Protection Convention
1954 Convention for the Prevention of Pollution of the Sea by Oil
1958 Convention on Fishing and Conservation of the Living Resources of the High Seas
1959 Antarctic Treaty
1964 Agreed Measures on the Conservation of Antarctic Fauna and Flora
1963 Treaty Banning Nuclear Weapon Tests in the Atmosphere, in Outer Space and Under Water
1967 Treaty on Principles Governing the Activities of States in the Exploration and Use of Outer Space, including the Moon and other Celestial Bodies

LATER INTERNATIONAL AGREEMENTS

Species and Habitat

1971 Convention on Wetlands of International Importance Especially as Waterfowl Habitat (Ramsar Convention) IUCN/International Waterfowl and Wetlands (IWRB)
1972 Convention Concerning the Protection of the World Cultural and Natural Heritage (World Heritage Convention) UNESCO
1973 Convention on International Trade in Endangered Species (CITES) UNEP
1979 Convention on the Conservation of Migratory Species of Wild Animals (Bonn Convention) UNEP
1992 Biodiversity Convention (UNEP)
1994 UN Convention on Control of Desertification
1980 Convention on the Conservation of Antarctic Marine Living Resources (CCAMLR) – CCAMLR Secretariat
1991 Protocol to the Antarctic Treaty on Conservation

Marine Pollution

1972 Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter (London Dumping Convention) (IMO)
1973 International Convention for the Prevention of Pollution from Ships and the Protocol of 1978 Relating Thereto with Annexes (MARPOL 73/78) (IMO)
1982 UN Convention on the Law of the Sea (LOS Convention) – UN Office of Ocean Affairs and Law of the Sea (OALOS)
1990 International Convention on Oil Pollution Preparedness, Response and Cooperation (IMO)

Hazardous Substances

1986 Convention on Early Notification of a Nuclear Accident (International Atomic Energy Agency (IAEA))
1986 Convention on Assistance in the Case of a Nuclear Accident or Radiological Emergency (IAEA)
1989 Convention on the Control of Transboundary Movements of Hazardous Wastes and their Disposal (Basel Convention) (UNEP)

Pollution of the Atmosphere

1979 Convention on Long-Range Transboundary Air Pollution (LRTAP) United Nations Economic Commission for Europe (UN/ECE)
1985 Helsinki Protocol on the Reduction of Sulphur Emissions or Their Transboundary Fluxes by at least 30%
1988 Sofia Protocol Concerning the Control of Emissions of Nitrogen Oxides or Their Transboundary Fluxes
1985 Vienna Convention for the Protection of the Ozone Layer (Vienna Convention) (UNEP)
1987 Montreal Protocol on Substances that Deplete the Ozone Layer (Montreal Protocol) (UNEP)
1992 UN Framework Convention on Climate Change

International organizations depend for their effectiveness on the commitment of governments (and in a few cases a wider membership) to support them. All have governing bodies representative of their members, in which policies are laid down. Many have national committees or institutions with which they have forged close links. The international and national institutional structures have thus evolved together.

diverse: peoples have adapted to it culturally and have adopted environmental policies that are an expression of sustainable living under local conditions.

The depletion of natural resources led belatedly to the adoption of international agreements and regulations in the shape of regional fisheries agreements and the International Whaling Convention. The other parallel trend has been the extension of controls by coastal states outward to sea so that strict national jurisdictional rules could be applied, thus restricting open access to the resource. This has been a classic pattern for fisheries in most parts of the world, with the extension of territorial waters from the original 3 mile (5 km) limit to 12 miles (19 km) and the more recent establishment of exclusive economic zones (EEZs) extending 200 miles (320 km) from land. In parallel, there have been developments of controls in the shape of net sizes and other regulations on fishing gear, together with seasonal regulation and the establishment of sanctuary areas.

On land, resource utilization has largely been regulated by grants of land ownership, either to individuals or to groups. Where there was communal ownership, elaborate policies backed by enforceable rules evolved early in history. Water management in arid regions has been subject to tight codes of practice from very early times, for reasons that are obvious given the limiting role of water in agriculture in such locations. In parts of Northwestern Europe, grazing rights in common pasturage have often been apportioned in terms of a right to particular farms within a village to graze a specified number of animals on the shared pasture, a particular unit of grazing carrying the right (for example) to graze one horse or one cow or three sheep. In Africa, pastoral practices have also been subject to unwritten, but elaborate, traditions.

These traditional resource-use policies were both adaptive and sustainable as long as the number of people seeking to exploit the resource did not rise dramatically. Many of the policies, however, have broken down under the combined pressures of population growth, the development of technologies that have permitted more intensive use of the resource, or the superimposition of alien systems, often in conjunction with colonial expansion.

The evolution of environmental policies up to 1970 was sectoral, reactive and uneven. In many countries, it was intimately linked to the granting of rights to certain sections of the population, often to the exclusion of others. Sometimes the rights of one sector to damage the environment in the pursuit of personal land had pre-eminence over the general interest of the community to be provided with clean air, safe water supplies and a productive environment. In many countries, industrial development and urban growth assumed priority over the protection of air, water and land and the safeguarding of agricultural interests. Many cities were permitted to expand over prime farmland, and the cash value of land approved for urban and industrial development was commonly much greater than that for agricultural use, re ecting the increased potential earnings from the land under the new pattern of use rather than its intrinsic worth to the community. The need for systems of economic evaluation that truly re ected the service to the community provided by wild land and agricultural land had not been recognized, and economic cost-benefit equations and the judgement process behind permission for land conversion tended to favor the urban and industrial sectors and the short-term over the long-term.

Institutions for environmental management also grew sectorally and sporadically. By 1970, many developed countries had departments of government that were concerned with aspects of environmental management notably agriculture, fisheries, forestry, town and country planning, industrial development, transport policy and central government's responsibilities for local and municipal affairs. At local level, there was commonly devolved responsibility for land management and development control within the area of the authority's interests, and for the control of local sources of pollution. In developing countries, a number of Ministers of Health had responsibilities that included environmental matters. However, coherent environmental policies based on monitoring and with guiding strategies generally did not exist in any country.

There was a burst of activity just prior to the 1972 Stockholm United Nations (UN) Conference on the Human Environment. Sweden established a National Environmental Protection Board in 1969, while the United States established its Council on Environmental Quality and its Environmental Protection Agency (EPA) in 1970, under a National Environment Policy Act (NEPA). The United Kingdom established a Royal Commission on Environmental Pollution and a Department of the Environment in 1970, and Canada established its Department of Environment in the same period. In 1971, Japan established its Environmental Agency and France established a Ministry for the Environment and the Protection of Nature. It was not, however, until after the Stockholm Conference that Departments of Environment and cross-sectoral coordinating machinery for environmental affairs were established in many countries. The same pattern also characterized national law. Among the Organization for Economic Cooperation and Development (OECD) nations, only four major national environmental laws were passed in the five years 1956–1960, 10 in 1961–1965 and 18 in 1966–1970, but between 1971 and 1975, 31 such measures were adopted (Holdgate *et al.*, 1982).

The period up to 1970 was also characterized by a widening in uence of what can broadly be termed *ecological thinking* on national policies, laws and institutions and a growth in citizens' groups concerned with environmental issues. These private organizations – the ancestors of

today's worldwide non-governmental environmental movement – were founded to focus on very specific issues such as the protection of birds and the safeguarding of sites of outstanding importance for their natural beauty and wildlife. The vast proliferation of environmental NGOs, many of them with wide cross-sectoral interests, and their expansion to cover international affairs, has been a post 1970 phenomenon.

These trends were undoubtedly stimulated by increasing concern in developed countries over the adequacy of the world's environmental systems to support mounting human populations, and the recognition in the 1960s of the unforeseen environmental impacts of modern industry, and especially pesticides (Carson, 1962). However, at the time of the Stockholm Conference, these concerns were only beginning to reach developing countries, which had their own preoccupations, especially with the pollution of poverty.

In 1972, therefore, the national situation around the world was one of extreme unevenness in policy, law and institution. While there was worldwide recognition of the need for productive agriculture and forestry and the protection of fisheries, in most countries these had not been given an environmental label. Environmental protection and pollution control were largely a concern of northern developed countries. A few of the latter had established Departments of the Environment and national environment protection agencies, backed by special councils to establish national targets across the whole environmental field but these countries were in the minority. The scientific base for environmental policy was fragmented, and there were few national reports on the state of the environment and few national monitoring systems. Indeed, the first real urry of such national reports was provoked by the Stockholm Conference itself, which received 80 such documents (McCormick, 1989).

Trends in the Industrialized Countries

The emergence of environmental policy in the industrialized countries over the past 25 years has been characterized by the following main features.

- *A recognition of the need for sectoral policies to take a greater account of environmental impacts and constraints*. Agricultural policies for example, have been broadened to include much tighter controls over pesticides, fertilizers and farm wastes. Energy, industry and transport policies have all devoted increasing attention to reduction in emissions to air and water, and to the handling of hazardous wastes. Environmental impact assessment has been a feature of development control in most developed countries.
- *An increasing recognition of the need for cross-sectoral policies*. Links between environment, energy, and transport policies have been strengthened. Pollution control policies have become cross-sectoral, seeking the best practicable environmental option.
- *Replacement of a largely reactive approach to pollution control by an anticipatory and preventive one*. There has been an increasing focus on pollution abatement at source. The precautionary principle and the polluter pays principle are more and more widely recognized. Screening of potentially hazardous substances before their introduction to the general market has become more stringent partly as a reaction to the unforeseen impacts of persistent organochlorine pesticides and chloro uorocarbons. The concept of *critical loads* (defined as the maximum amount of pollutant an ecosystem can withstand without stress) has increasingly come to guide policy.
- *Increasing interest in economic instruments as an incentive to energy and pollution control*. This development recognizes that while strict regulation remains necessary, within a market economy such instruments are often the most efficient way of bringing about the necessary environmental improvement.
- *Increasing promotion of energy ef ciency, energy conservation, and environmentally sound processes in industry, transport and domestic environments*.
- *Recognition of the international, and often regional, nature of many environmental problems*.
- *Increased attention to public information and participation*. It has become evident that the most effective way of ensuring the success of environmental policies is to involve all sectors of the community in the discussion of their objectives, and to inform the public about the state of their environment and the success of the actions being taken to protect it.
- *Better environmental science and monitoring*. These are the foundations of sound policy and public understanding. Through them, the loop between policy, implementation and effect can be closed. Due to the international dimension of many environmental problems, monitoring is increasingly subject to international coordination, and linked into global programmes.

During the 1970s and 1980s, as in the preceding decades, unforeseen accidents continued to force sudden adjustments in policy. These were one cause of the action early in the 1970s to prevent the pollution of the sea from the dumping of toxic materials and through accidents involving large oil tankers. In the 1960s and 1970s, there had been a prevailing view of the ocean as an effectively limitless disposal system, but it was clear by the time of the Stockholm Conference that this was not a resource that should be relied on. Since that date a whole series of national and international

Table 1 Investment in environmental protection in OECD member countries, 1970–1985

	As percentage of GNP	As percentage of all investment
Public sector	0.13–1.17	0.24–2.87
Public sector	0.08–0.86	0.28–1.62
Total	0.82–1.52	1.28–3.15

measures curbing marine pollution have been implemented. Many of the latter are regional in scope.

Disasters at Flixborough, Bhopal, Seveso, Basel and Chernobyl led in turn to the demand for more stringent action on the safety of industrial plants, better protection and higher health standards for workers in industry, more certain containment of hazards, close controls over the movement of hazardous waste and improvements in the safety of nuclear reactors, all of which were re ected in both national and international responses. These events were a salutary reminder of the fact that risk is inherent in many complex industrial operations and there was, therefore, a need for commitment to improving risk assessment and to the judgement of new policy on the basis of its results.

As a result of these evolutions in policy, there has been increased investment in the developed countries in three particular spheres: environmental protection itself (Table 1), governmental investment in environmental research (Figure 1), and public information.

The volume of public information has increased enormously. Most developed countries have published government policy statements about the state of the nation's environment, and the intentions of the national authorities in this field.

A number of countries have established independent bodies to act as evaluators of the state of the environment or of particular environmental problems, publishing their reports for the information of the community at large.

A final important development in policy has been the requirement in many OECD countries that there should be public access to information on the environment held by public authorities, especially including the results of monitoring imposed by government. The difficulty has lain in striking an appropriate balance between the public interest and the need for industry to maintain commercial confidentially over technical advances that secure market advantages. The main categories of information released into the public domain have been the quantities and nature of hazardous materials held by particular industrial plants, and the quantities of discharge to the environment of specified substances (Tolba *et al.*, 1992).

Public concern, expressed through the Green Consumer Movement regarding the environmental friendliness of products, has led to a further policy of requiring the labeling

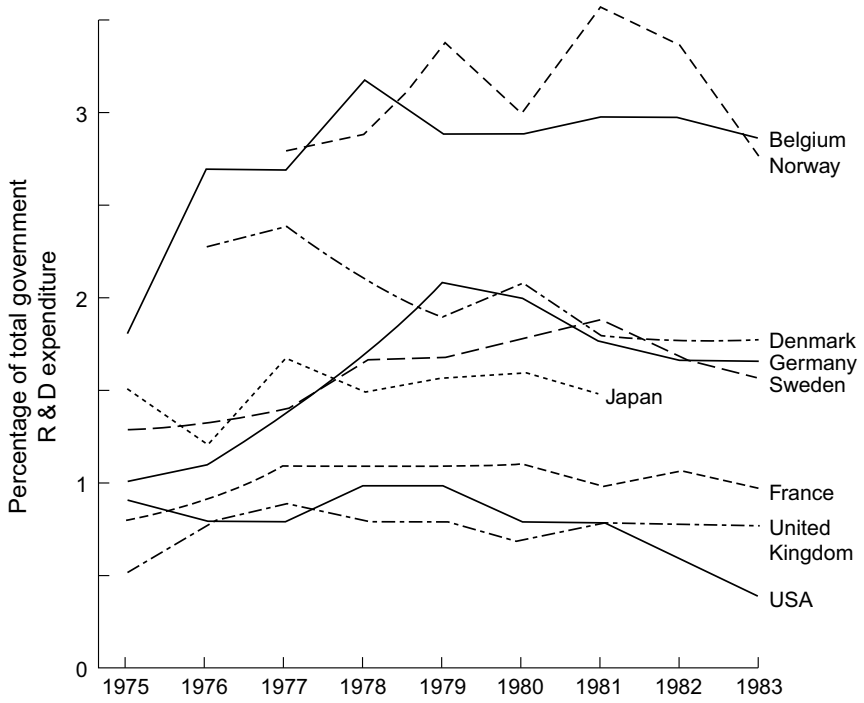

Figure 1 Government expenditure on environmental research and development in selected countries, 1975–1983. These expenditures refer to pollution abatement, but do not include expenditures concerning pollution through changes in production processes themselves. (Data were obtained from OECD, 1985)

of consumer goods to include information that will allow a prospective purchaser to judge whether or not they meet criteria of environmental acceptability. Labeling schemes, pioneered in Germany and extended in Canada and Japan, are now being adopted in the Nordic countries, Australia, New Zealand, the European Community and elsewhere (*see* Environmental (Eco) Labeling, Volume 4).

Laws and Instruments

There has been a major evolution of environmental law in the industrialized countries between 1970 and 1990. Table 2 gives some general statistics. The surge in environmental legislation between 1950 and 1970 appears to have been followed by a more measured process from 1970 onwards. The character of the legislation has changed to bring about a more integrated and cross-sectoral series of policies, and increasingly to apply within the territory of individual countries' international obligations entered into on a regional or global basis.

The emergence of an increasing body of law and regulation has been paralleled by changes in the way in which legal instruments are interpreted and enforced in a number of countries. The public has acquired an increasing right to challenge the way in which government departments and official agencies carry out their functions. This move to make public authorities accountable to the public at large, through the courts, for the achievement of national policy goals in the environmental field is a development that has clear implications for the future.

During the 1960s and 1970s increasing numbers of countries have recognized that economic instruments can, within market economies, be an effective means of improving the environment and then maintaining high environmental quality. By 1988, 153 different economic instruments were reported to be in use in the OECD countries, and 31 were of other kinds. User and administrative charges were commonest, and included fees for waste collection and sewerage services, while administrative charges were usually for licences to release substances to the environment. Not all of these charges covered the full economic cost of the activity in question, some simply recovering the costs of the administrative activities of the licensing authority. Among the other economic instruments in use were charges added to the cost of projects in order to encourage recycling, for example of oil, batteries and containers (OECD, 1991). Differential taxes, though not a direct charge, have been found useful in in uencing consumer behavior at an individual and household level. For example, Denmark, Finland, Germany, The Netherlands, New Zealand, Sweden, Switzerland and the United Kingdom impose different levels of taxation on leaded and unleaded gasoline, while the Netherlands, Sweden, Japan and Germany use taxation as an instrument to promote low pollution vehicles.

The evolution of natural *resource accounting* as a base for economic instruments that will in turn promote sound use of natural resources, was an active phenomenon in many industrialized countries in the late 1980s. This new development has been a re ection of the fact that gross national product and related aggregate economic accounts do not include the degradation of natural resources.

Table 2 Environmental laws adopted by OECD member countries, 1950–1984

Type of legislation	1950–1959	1960–1969	1970–1979	1980–1984
General	0	2	8	7
Water	3	6	16	4
Wastes	0	1	13	2
Air	1	6	8	4
EIA	0	2	8	1
Others	0	3	11	5

Institutions

Institutional responsibility for the environment in industrialized countries is commonly divided between the national and the state/district/municipal/local authority levels. Moreover, there are commonly divisions, at both these levels, between departments with overall responsibility for policy and agencies that have operational responsibility for setting technical standards, granting operational consents, levying charges, monitoring performance and prosecuting infringements.

The governmental sector has no monopoly of institutions concerned with the national environment. During the last three decades there has been an increasing emergence of self-regulation institutions within industry, linked to the development of new and environmentally compatible technologies in which sectors of industry have commonly cooperated. A third institutional development has been the massive growth in NGOs, usually in the form of groups whose business it is to demand high standards of environmental performance, protect particular regions or interests, or draw attention to inadequacies of performance.

Toward the end of the 1980s there was increasing concern within governments over the inadequacy of having sectoral Departments of Environment established alongside others, when it was apparent that the environment was actually the natural capital of nations, and the foundation of quality of life and prosperity (WCED, 1987).

Many governments have, therefore, established new machinery to better coordinate the activity of the sectoral departments.

In the industrial field, Chambers of Commerce, national business councils and specialized industrial organizations are playing an increasing part in developing environmental policy. Some such organizations are concerned with promoting products perceived to be superior in energy use

or environmental impact, while others seek to represent industrial sectors in dialogue with government.

Trends in Developing Countries

The database on national action within the developing countries is far less extensive than for the developed countries. However, as a broad generalization the developing world follows a pattern similar to that of the developed countries, but with a different range of concerns and on a different time-scale.

The primary environmental concern in the developing world is obviously the management of land and fresh waters in order to maintain the production of food and other essential resources, and the exports which are the mainstay of these economies. Development is clearly essential in order to improve the quality of life, eliminate poverty and support the infrastructure needed in order to deliver the health care, education and other institutions essential to the national future. It is, however, increasingly recognized that development processes must be based on care for the environment, and this is well illustrated by the large number of developing countries that have prepared substantial national conservation strategies (in the form of national environmental plans for the sustainable use of their resources). Many such countries have also provided reports on the state of the environment, statements of environmental policy, and in some cases considerable volumes of statistics (Tolba *et al.*, 1992).

In most countries in the Asia–Pacific region, the primary thrust of environmental policy is mostly the maintenance of agricultural and forest productivity, often in the face of pressures from mounting population growth and a con ict between the requirement for maximum revenue in the short-term and the protection of interests of the future. However, a number of countries have enunciated very broad statements of environmental policy and several are becoming increasingly preoccupied with managing industrial growth. For example, the integrated national planning of the economy, including environmental planning, its development through national land-use planning and the associated planning of environmental pollution control, have all been stressed as policy goals in China.

Similarly, Indonesia has stated its commitment to development based on the sustainable use of the country's resources, with improved planning and management of the environment, better use of human resources and natural resources such as land and water, and more attention to the environmental dimension in land and resource-use practices. Similar broad policy statements are evident in, e.g., national reports from the region to the UN Conference on Environment and Development.

Environmental laws in this region are diverse. Some countries have a relatively wide-ranging and sophisticated series of laws (e.g., India, Malaysia, The Philippines and Sri Lanka) while others (e.g., Brunei, Maldives and the Pacific Island nations) have rather less developed environmental legislation. Institutions in the region are similarly diverse.

However, as a general summary, ministerial and departmental authority for environmental interests now exists in most of the states of the region. A considerable number have national environmental protection agencies which are increasingly concerned with the overall planning of the management of natural resources. Few, if any, of these existed in the early 1970s. The cross-sectoral integration of these interests is, however, far from easy, especially given the complexities of the environmental situation in the region. The rural level, and especially the village communities, are often the key entities in environmental management, and yet it is not easy to involve them in overall policy strategies to develop land and water use systems that are built on local resource availability, people's own knowledge and traditions, local skills and needs and ecological circumstances are, however, now being developed.

A corresponding increase can be seen in the number, membership and effectiveness of NGOs concerned with environment in this region. Asia, and South Asia in particular, has the largest number of NGOs in the developing world. It also has a more active NGO involvement in policy making than other regions.

Environmental policy in the African countries has been especially concerned with agricultural development, the management of the publicly-owned forest estate, the management of wildlife resources, especially for tourism and above all the acceleration of the development process.

Africa is an immensely diverse continent, with a wide range of human traditions, climates and vegetation types. A number of African countries have developed national conservation strategies or national environmental plans. However, overall national conservation strategies and environmental plans are relatively few and far between. Those that do exist display a strongly sectoral structure within government, with very little cross-sectoral machinery yet established, despite the call for integration in many conservation strategies and environmental plans. This is a challenge for the future, which a number of governments are beginning to address.

Environmental law in Africa generally follows the same sectoral pattern. In a number of countries, however, separate laws put in place by sectoral ministries have been linked together in over-arching legislation, and some new laws have been introduced.

In many African countries environmental institutions also take the form of sectoral departments, though this too is changing. By the mid 1990s, 37 out of 51 countries on the continent had established Ministries of Environment, Natural Resources or Nature Conservation/Protection. In the remainder, responsibility for environment and natural

resource management remained with other, usually sectorally based, ministries or agencies. Most of these are concerned with agricultural, forestry, lands and natural resources, tourism and wildlife or variants on these themes.

During the last three decades there has also been a rapid growth in NGOs and citizens' groups dealing with environmental issues. An umbrella organization for African NGOs working in the environment, the African NGOs Environment Network (ANEN), was formed in 1982 with a membership of 21 organizations. This number increased more than 10-fold in the first six years of its existence, and more than doubled again in the next two years. In 1990, the membership was 530 organizations in 45 countries. The ANEN database of NGOs working in the field of environment and development in Africa in 1990 listed over 3700 NGOs. Although African NGOs are involved in the same range of activities – from advocacy and policy development to grass-roots conservation and development efforts – a higher proportion is involved in practical environment and development work than among their counterparts in other regions. A 1989 list produced by ANEN names 39 nationally organized indigenous NGOs undertaking conservation and rehabilitation work in respect of one or more of the following areas: deserts and arid land; rivers and lake basins; forests and woodlands.

Many countries in Latin America and the Caribbean have published national development strategies during the past three decades, although few (apart from Costa Rica) have produced national conservation strategies and environmental plans.

Environmental profiles have been produced by five English-speaking countries as a first step in resource assessment, and as a base on which full environmental strategies might be developed. The process of establishing cross-sectoral policies, in countries where environmental damage has occasionally been caused by the pursuit of sectoral goals, remains an urgent need. These reviews and reappraisals have already led to some extremely striking changes in national policy.

There is a considerable diversity of legal instruments bearing on environmental resources in the Latin America and Caribbean region, but this tends to be fragmented and sectoral, and there are few overall national bodies of environmental law which come together to provide an integrated framework for the protection of the environment and the sustainable management of its resources. Specific legislation has, however, dealt with the protection of forests, the safeguarding of National Parks and other protected areas, the regulation of settlements, and the protection of air and water from pollution.

Many countries in Latin America have a decentralized system, each with a Regional Council on Economic and Social Planning (CORPES). Each of these bodies formulates regional plans, prepares investment programs and coordinates and supervises the activity of various sectoral agencies. This structure was developed following an extensive discussion of a national environmental profile, which recognized the need for coordination of national activities, with an appropriate balance between central and regional administrations, and with the creation of a national environmental system in which the Administrative Department of Natural Resources and Environment would have a leading role in the formulation of overall strategy.

The number of NGOs and citizens' groups in the region dealing with the environment has also grown rapidly It is estimated that there are currently more than 6000 NGOs in the Latin American and Caribbean region that have goals related to environmental protection, most of them having been formed within the last 20 years.

INTERNATIONAL RESPONSES

Before World War II, few international environmental agreements existed. There were also few institutions, with the distinguished exception of the World (originally International) Meteorological Organization, founded in 1873 to coordinate world weather observations and promote the understanding of climate, and the International Council of Science which, founded in 1919 as the International Research Council, began to promote and coordinate international science. Most of the environmental agreements concentrated on protecting migratory birds and animals, managing transfrontier river basins and boundary waters, and conserving marine fish and mammals.

However, from 1944 onwards there was a surge of institution building, the Food and Agriculture Organization (FAO), the World Health Organization (WHO) and the United Nations Educational, Scientific and Cultural Organization (UNESCO) were all established between 1945 and 1948. Within a few years new agreements were concluded protecting the oceans and living marine species, governing Antarctica, and banning nuclear tests under water, in the atmosphere and outer space, and in Antarctica. In addition, the Treaty on Principles Governing the Activities of States in the Exploration and Use of Outer Space, including the Moon and Other Celestial Bodies, signed on 27 January 1967, obliged states engaged in studying or exploring outer space to avoid harmful contamination and adverse changes in the environment of the Earth.

World War II highlighted the importance of consultation and dialogue to identify potential sources of friction early on, and so avoid future con icts. The UN Charter not only established the UN itself in 1945, but contemplated that specialized agencies in economic, social, cultural, educational, health and related fields would be linked to it with a view to the conditions of stability and well-being which are necessary for peaceful and friendly relations among nations .

The Charter also called for the establishment of regional agreements to further these ends.

As this network of international institutions evolved, it was inevitable that specialized organizations and programmes would be founded to promote the cooperation that is essential if transboundary resources and the global commons are to be preserved. The IUCN, founded in 1948 with both state and non-governmental members, was charged with protecting natural areas and species. Others, including the International Maritime Organization (IMO), the International Labor Organization (ILO), and the WHO stemmed from efforts to protect the human environment by ensuring human health and safety.

These institutional developments have proceeded in parallel and in close association with the evolution of international policy and philosophy on environmental issues. One of the most striking aspects of this evolution has been the way in which environmental concepts and terms have entered the language of international policies and diplomacy. One possible reason for this growth may have been the perceived political neutrality of the environment, allowing environmental actions to be promoted as a bridge across doctrinal divides.

THE DEVELOPMENT OF INTERNATIONAL ENVIRONMENTAL INSTITUTIONS

The UN Conference on the Human Environment, held at Stockholm in 1972, is commonly thought to be the event where international debate on the environment began, but it was, in reality, the culmination of a considerable process of discussion. It was also a presentation of rather different points of view. The industrialized world came to discuss international solutions to pollution problems, which resulted from the growth of industrial activity. Their emphasis was on regulation and pollution control. They were also concerned with nature conservation and especially with threats to particular species (such as whales) and habitats (such as rain forests). The developing countries expressed little interest in these problems as compared with the pollution of poverty and the inefficiency of resource use caused by underdevelopment.

This divergence became a serious issue in the months leading up to the Stockholm Conference, and at one point seemed to endanger it. An important meeting that began to bridge the gap in perception was held at Founex, Switzerland, in June 1971. The report of this meeting clearly and cogently defined many of the issues that were to confront governments from both developed and developing countries. At Founex it became clear that development and environment were two sides of the same coin.

The breadth of activity within the UN system was familiar to the governmental delegations at Stockholm, many of whom were also members of non-UN institutions such as the OECD and IUCN, who were playing an active part in evaluating and responding to emerging environmental concerns. There were three main thrusts behind the Stockholm agenda:

1. The recognition that the developing nations faced massive environmental problems – especially linked to poverty – that needed to be overcome by development, while the developed countries had problems because their development had followed the wrong course.
2. The growing scientific understanding of the interrelatedness of natural systems.
3. Growing public concern over the cumulative impacts of human activities on global environments. This had been stimulated by disasters such as the 1967 wreck of the Torrey Canyon (the world's first supertanker accident) and reports of damage to wildlife through persistent contamination by DDT, mercury and other substances.

In addition there was the increasing recognition that neither individual nations, nor the North or the South acting alone, could adequately protect the global environment.

The UN family was hardly in a position to respond coherently to the Stockholm agenda. Those agencies with programmes directly relevant to the environment, such as FAO, UNESCO and WHO, presented points of view that were naturally linked closely to their formal mandates. Forest depletion was seen through the eyes of foresters, soil loss by agronomists and soil scientists, and so on. Stockholm came before the period when all applicable natural sciences became grouped as environmental science. The holistic, or systems, approach was still something being studied by a few academics. Moreover, social scientists hardly ever participated in the debate. Economic questions were discussed largely in relation to development and natural resource depletion. Government organizations were similarly sectoral (and there were, as yet, hardly any Departments of Environment). The overall approach was compartmentalized, and the diplomatic community did not regard environment as a central concern at all.

The Stockholm Conference was the culmination of a two-year preparatory process and the beginning of a new and intensified programmme. In the preparatory process, an Intergovernmental Working Group drew up plans, later endorsed by the conference and put into operation by the UNEP, for a global environmental monitoring system (GEMS), and an International Referral System for Sources of Environmental Information (INFOTERRA). Concern over marine pollution led to the negotiation of the Convention on the Prevention of the Pollution of the Sea by the Dumping of Wastes and Other Matter, finalized in London in October 1972. In parallel, conventions on wetland conservation (Ramsar), world heritage sites (Paris), and the control of trade in endangered species (CITES) (Washington) were stimulated and pressed forward.

Given the background, it is remarkable that the Stockholm Conference in fact decided on a system of environmental coordination for the UN that took 15 years for many governments to adopt for themselves. Although the resolutions were not systematically organized, and were truly global or even regional in scope, they nonetheless covered a wide spectrum of issues. The need for global information (as manifest through the establishment of *Earthwatch*) led towards global standard setting. The establishment of the UNEP, with its voluntary fund, was a major advance, and a spur both to the development of the UN system and to the adoption of a more integrated approach by governments, slowly though this proceeded. The limiting factor in the success of the UNEP machinery may well, in fact, have been the slowness in the adoption of similarly inter-sectoral approaches at the national level.

The Stockholm Conference was also a success because it created tremendous public interest in the environment and provided directives for international and national action. It began a process that linked environment inseparably with development, an issue explored further at the UN Conference on Environment and Development (UNCED or as commonly known, the *Earth Summit*) held in Rio de Janeiro, Brazil, 1992.

A comparable approach was adopted but with less success in response to mounting concern over desertification. As the Stockholm Conference closed, the 1968–1973 Sahel drought was at its height. Widespread crop failure and livestock deaths brought great hardship to people living in arid areas in five African countries. A UN Conference on Desertification, held in Nairobi in 1977, adopted a Plan of Action with 28 recommendations. Unfortunately, the subsequent response was slow and limited. Some training programmes were initiated, and a few national action plans were prepared (although even fewer were implemented). The call for contributions to a UN Special Account to support action against desertification was also disappointing. The 1977 Conference calculated that US 2.4 billion should be spent annually. However, because of opposition by a number of developed countries to the principle of special funds, only eight governments actually contributed to the account. The special account was ultimately closed, as decided by UN General Assembly (December 1989) at the recommendation of UNEP's Governing Council.

THE ENVIRONMENT PROGRAMS OF THE UN AGENCIES

Over 70 UN programs and agencies are listed in directories of the UN system. The vast majority carries out functions relevant to national economic and social development and to managing the global commons. These functions may be grouped roughly into data collection and research, policy formulation (including international treaties and soft law codes and standards), and development cooperation activities, such as training and education, technical assistance and project funding. Virtually all of these agencies and programs also contribute to global awareness by making available to the public, information describing the issues and objectives of their programs.

As the interconnections between avoiding environmental degradation, alleviating poverty and developing the human potential are more clearly understood, it has become increasingly apparent that virtually every organization in the UN system has some bearing on the environment and sustainable development. The Stockholm Conference prompted many agencies and programmes to examine their activities and highlight environmental components. Many of the major global conferences following Stockholm which explored in depth issues related to food and fresh water, science and technology, population, women, climate, renewable energy sources, desertification and other topics, led to the establishment of additional inter-governmental and secretariat organs within the UN system. Yet, in a perverse manner, the proliferation of environmental components and narrow, issue-oriented organs has increased the isolation of each, instead of enhancing an integrated, multisectoral approach to problem solving.

The Report of the World Commission on Environment and Development (WCED, 1987) and the UNEP's report: *The Environmental Perspective to the Year 2000 and Beyond* (UNEP, 1988) were a major spur to new thinking and especially to a recognition that an integrated approach was essential. They have been complemented by several significant regional responses including *From Our Own Agenda*, for Latin America and the Caribbean, *Economic Policies for Sustainable Development*, prepared under the auspices of the Asian Development Bank (1990), and a long-term perspective study by the World Bank, *From Crisis to Sustainable Growth*, dealing with sub-Saharan Africa. While these three latter documents are not specifically about the environment, they demonstrate how environmental considerations are now deeply integrated into development planning.

ENVIRONMENTAL POLICY AND LAW

Many of the UN agencies provide guidance on environmentally-sound development, and prepare action plans, strategies, principles, codes and guidelines as well as legally binding international treaties. Some of these state objectives and principles, while others provide operational guidelines and practices. The more general ones are designed for review every five to ten years, while many of the more specific ones provide institutional mechanisms to evaluate and update their specifications (*see* International Environmental Law, Volume 5).

REGIONAL INSTITUTIONS AND ACTIONS

The numbers of regional political and economic organizations that in one way or another are concerned with environment and development questions have also increased greatly since 1972. They include the original regional security arrangements that came into being after World War II as contemplated in Chapter VII of the UN Charter; the five UN regional economic commissions established directly under the economic and social council (ECOSOC): numerous regional offices of global UN agencies and programs, the regional development banks, and several other organizations and conferences that bear no relationship to the UN system at all, such as the OECD and the South Pacific Forum. This list is further swelled by the increasing decentralization of bodies such as IUCN, WWF and the growth of NGOs on the regional scale.

A primary reason for the growth in regional environmental activities has been the recognition that many severe environmental questions – such as control of transboundary air pollution, shared river basin management, and the protection and use of regional seas and their coastal areas – span national frontiers, and cannot be dealt with unless the states that share them act together for mutual benefit. Many species of animal, and especially birds, migrate or move across frontiers. Animal-borne diseases, ranging from malaria to rabies, are carried by their vectors from country to country and demand coordinated preventative measures. Cargoes of potentially hazardous substances are carried through regional seas, necessitating cooperative arrangements to guard against, and deal with, accidents.

At the regional level, policy, law and institutions have commonly evolved together. A problem, once admitted, leads to bilateral or multilateral regional discussion. Agreements then reached define the policies it has been agreed to pursue, and these require translation into national legal instruments and administrative practices, which in turn affect the nature of national institutions.

International institutions are commonly set up as a framework for the onward development of policy, for monitoring its effectiveness, and for sharing expertise and resources.

The United Nations Conference on Environment and Development (1992)

As stated earlier there has been a series of global conferences convened by the UN on various development issues, which dealt in detail with the environmental aspects related to the conference subject.

At the 20th Anniversary of the Stockholm Conference, the UN convened another major conference on environment and development in Rio de Janeiro, Brazil, 1992. The Conference squarely cemented the close relationships between environment and development and addressed clearly the issue of poverty and the role of major groups in society. The Conference was attended by the highest number of Heads of State and Government ever to attend a UN Conference.

The Conference adopted the carefully worded and agonisingly negotiated Rio Declaration. It adopted a plan of Action for the 21st century called Agenda 21, which synthesized and updated the outcome of all previous conferences and meetings. Commitments were made at the conference to work effectively towards the implementation of Agenda 21 and particularly to assist developing countries in this regard.

Five years later the UN General Assembly convened a Special Session to review the implementation of Agenda 21. The Special Session concluded that while there were positive steps towards achieving sustainable development, the situation in 1997 was worse than in 1992. Th Special Session adopted a Programme for the Further Implementation of Agenda 21 hoping to rectify the situation.

THE CENTRAL CHALLENGE

The complexity and magnitude of the environment/development *problematique* was recognized during the preparatory process for the Stockholm Conference. Twenty years later, at Rio, the level of political interest in the environment was very different. Yet, ironically, many of the essential points recognized by the participants in the Founex meeting in 1991 are still almost 30 years later, being raised in debate.

The major problem of underdevelopment is back on the agenda of the developing countries in a major way. The debate over the over-consumptive, wasteful life-styles in the developed countries has, if anything, intensified. Many people are again asking the kinds of questions posed in *Limits to Growth*, e.g., concerning the possibility, let alone the desirability, of unabated growth in energy demand and the private transport sector. In the 1970s, these questions generally related to energy resources running out. Today they focus on the limits of the environment as a sink or provider of services, but the central issue of nature's capacity to tolerate human impact remains.

The massive expansion of national and international institutions that has occurred during the past 30 years or so has produced as much sectoralization and fragmentation as synthesis. Only now is the world community really beginning to come to grip with the underlying economic and demographic forces that impede sustainable development.

It is now clear that development strategies need substantial adjustment, and that this must go far beyond the technology of environmental management to incorporate trade debt, and social infrastructure. It is also evident that environmental costs and benefits must be incorporated into the technologies and processes of development from the

initial planning stages. There is now much talk of a greater reliance on market mechanisms as a mode of environmental control. The use of economic instruments and full environmental cost accounting, largely unexplored until the mid-1980s, is the new fashion in environmental governance. Many governments are insisting that the costs of natural resources depletion must be accounted for and that those who generate pollution and waste must pay the price. Many of the 1972 Stockholm Conference recommendations were about reducing uncertainty through new research and monitoring and waiting for the resulting clarification. Now, when there are far more answers, the precautionary principle is gaining general acceptance.

What has been particularly lacking is an appreciation of the complex linkages between sectoral activities, macroeconomic policies and sustainable development and how to internalize them in policies and development strategies. This next step will require far greater collaboration among all concerned agencies, and a far greater effort to ensure that best use is made of all available resources for the promotion of sustainable development. It will also require better procedures to review and evaluate the effectiveness of on-going programs.

One can safely say that despite manifest failures and inadequacies, there have been important advances in international cooperation during the past decades. The trends toward closer cooperation in program planning, specific activities, funding and regional action are a heartening sign that the world's institutions can function as a community, while retaining the distinctive strengths of each. We now possess institutions and infrastructure for dealing with virtually every conceivable kind of environmental issue.

Trends in Environmental Management in the Last 40 Years

OSAMA A EL-KHOLY

Arabian Gulf University, Manama, Bahrain

One of the oft-repeated slogans in management textbooks is that what cannot be measured, cannot be managed. This seems to lead – at least at a first glance – to the conclusion that the management of environmental affairs should be a straightforward business. Once we have regulations of one sort or the other, specifying desirable properties of ambient conditions, on the one hand, and discharges to the environment, on the other, this should provide a conceptual framework for environmental management. This is of course true, except that it is much easier said than done!

Here is a preliminary list of reasons why this is the case: (a) How do we define the environmentally desirable? (b) What are the boundaries of the system we are managing? (c) What are the scientific-technical and socio-economic constraints that bound the choice of management tools, and specify, in the final analysis, the optimum mix of such options? And last, and certainly not least (d) What are the feasible objectives of the management exercise?

Looking back over the path we have trodden over the last three decades in environmental management, we can see that we have been grappling, with different degrees of success and wisdom, with one or more of these questions. With hindsight, we can identify today a few significant signposts along the road, each leading to an interesting change of course, as well as to a new destination. We are still doing this and will most probably continue to do so for some time to come.

Each stretch of this tortuous road had its buzz word. Four such stages can be distinguished and these are reviewed brie y.

When Rachel Carson's book *Silent Spring*, was published in 1962, it shocked American society, and eventually the industrialized world at large (Carson, 1962). It argued that pollution, caused by harmful chemicals and radiation, was the major threat to the environment and life on the planet.

In the second chapter of the book entitled *The Obligation to Endure*, she declares that the

> ••• most alarming of all man's assaults upon the environment is the contamination of air, earth, rivers and sea with dangerous and even lethal materials. This pollution is for the most part irreversible••• To adjust to these chemicals would require time on the scale that is nature's••• And even this, were it by some miracle possible, would be futile, for the new chemicals come from our laboratories in an endless stream.

Towards the end of the chapter, she cries out

> ••• why should we tolerate a diet of weak poisons, a home in insipid surroundings, a circle of acquaintances who are not quite our enemies, the noise of motors with just enough relief to prevent insanity? Who would want to live in a world which is just not quite fatal?

A dire warning indeed and a powerful expression of agony and despair.

The chemical industry was up in arms. It went on the war path claiming that the book was based on bad science leading to wrong conclusions. A massive media campaign was organized nationwide extolling the benefits brought about by the chemical industry since World War II. The counter claim was that without these huge benefits mankind would be plunged into a dark era of pestilence and hunger. It was the public pronouncement of support by the president of the United States himself that finally upheld her warning, putting pollution at the top of the environmental agenda, at least in the industrialized countries.

Pollution was, in fact, the initial thrust of the 1972 Stockholm Conference on the Human Environment. Yet in gearing up for the world gathering, two significant developments changed the course of events, both before and during the conference itself. First, the Founex meeting (UNEP, 1981) brought into the argument an entirely new gamut of thorny problems and objectives. The environmental agenda,

i.e., the management objectives, now had to embrace such issues as poverty (dubbed the worst polluter), technology transfer and even world trade patterns. Next, came the Swedish case study blaming the severe pollution of Swedish lakes on sulfur emissions from chimneys hundreds of kilometers away, in Norway, Finland, Poland, Czechoslovakia, Germany, the Benelux countries, France and the UK. Suddenly, the boundaries of the system acquired global dimensions rather than Carson's local one. These made the deliberations of the conference quite difficult. Apart from changes in the system boundaries, the con ict between development objectives and those of environmental stewardship came out in the open. The Chinese delegation led the movement that did not consider pollution as the main problem for developing countries. Turning the argument on its head, it declared that it was prepared to live with some pollution in its fight against disease! We can see traces of this con ict in the Stockholm Declaration itself. In almost every one of the items in the preamble listing the environmental agenda, pollution comes first, followed by issues such as disturbing the ecological balance, or depletion of resources. While distinguishing between the priorities and objectives of developing and developed countries, it acknowledges the existence of a growing class of environmental problems of regional or global dimensions that require extensive cooperation among nations. However, the principle recognizing the sovereign right of states to follow their environmental policies while calling upon them to ensure that they do not cause damage to the environment of other states is number 21 in a list of 26 principles. Even in calling for the development of international law regarding liability and compensation for the victims of environmental damage in areas beyond their jurisdiction, pollution is again singled out and mentioned by name. The objectives of Stockholm were indeed a tall order. It is obvious that such diverse objectives could not have been all addressed at once. There had to be priorities.

COMMAND AND CONTROL MANAGEMENT

It comes as no surprise that pollution abatement was at the top of the agenda. Emphasis was on the treatment of emissions and ef uents to comply with certain permissible qualities. The main environmental management tool was command and control. The state now acted as the guardian of public interest, deciding on standards for permissible releases into the environment, keeping a watchful eye on compliance, and punishing the wayward for their misdeeds.

Limits set on discharges became more stringent and extended in scope to cover more types of discharges. Around the mid-1970s, a new generation of chemicals management legislation emerged calling for pre-marketing or pre-manufacturing assessments of new industrial chemicals. This proved to be practically impossible and many chemicals were in actual use while still awaiting satisfactory assessments. No wonder that relations between the regulating agencies and the regulated community became progressively adversarial and socially destructive.

In most developing countries the command and control approach failed ignominiously for obvious reasons. Ludicrously inappropriate standards copied from more developed communities were adopted. In Egypt, the first clean air legislation specified no less than 93 properties of emissions to be monitored! Government machinery was totally ill-equipped to monitor compliance or enact enforcement. By the end of the 1970s, it became obvious that not only was this approach socially expensive, but also remarkably ineffective and inefficient.

THE NEW SOCIAL DIMENSION IN THE ENVIRONMENTAL AGENDA

Pollution abatement may have been at the top of the environmental agenda at the operational level in the 1970s, but it would be misleading to leave the impression that this was the only item on the agenda. In fact there were many other initiatives, action programs, strategies, declarations and conventions, both at the regional and the international levels. One or two initiatives that went almost unnoticed, only to come back with a vengeance later on are worth noting. United Nations Environment Program (UNEP), which had just taken shape and started operating, called for eco-development and development without destruction. But these were still very much at the conceptual rather than the operational level. In 1974, the Cocoyoc symposium, organized jointly by UNEP and United Nations Conference on Trade and Development (UNCTAD), looked into the economic and social factors inherent in environmental degradation. In examining the increasing scarcity of resources it raised the issue of consumption patterns in the developed nations, relating them to environmental degradation in the developing countries. This came soon after the first Club of Rome report, *Limits to Growth*, and its almost total rejection by nearly everybody: the business community, the modeling community, and the developing countries. The business community emphasized that resource availability responds to scarcity through the price mechanism and technological innovation. The modeling community was alarmed by the crudity of the model. The Third World abhorred the notion that economic growth should be limited while two-thirds of the world lived in poverty, responding with its own, the Bariloche model. However, the model's major impact was to set many people seriously thinking about a conserver society, perhaps for the first time. Towards the end of the decade, the concept

of environmental ethics was again revived. It gave fresh impetus to the exploration of values underpinning modern society. By 1980, the debate now encompassed, amongst other things, the issue of the responsibility for future generations (Partridge, 1980). The discussion finally culminated, in the Brundtland report of 1987, as the concept of *sustainable development*.

However, these and other efforts at understanding the environment-development problematique were at the conceptual level. They had little impact on the operational aspects of environmental management, which had reached a dead end in its concentration on pollution abatement. A change of course was obviously in the offing.

FROM ABATEMENT TO PREVENTION

During the latter half of the 1970s, the concept of low and non-waste technologies (LNWT) emerged, shifting emphasis to pollution prevention rather than pollution abatement. With the benefit of hindsight, we could well wonder how it had taken us so long to remember the old adage that prevention is better than cure . But let us remember that tinkering with the innards of a functioning system is not welcome. Attention now came to be focused more and more on so-called clean technologies. However, a number of complicating considerations soon became apparent. First, there is no clear-cut distinction between the clean and the dirty. Furthermore, the issue should logically extend to the products themselves, their design, the materials used in making them, and their disposal, i.e., the assessment should encompass the whole life cycle of a product from cradle to grave (or cradle to cradle as the Wuppertal school preached later on). Finally, the very premises on which products or services are provided, and the value systems behind them, were questioned. Although this was well articulated in what UNEP labeled *cleaner production* (*see* Cleaner Production, Volume 4), the emphasis in the 1980s at the operational level was on pollution prevention, and mainly on production technologies and processes. It did not extend, at first, to addressing this hierarchy of issues. Almost every day new examples of remarkable combinations of pollution reduction and economic benefit were publicized, both in the industrialized and the industrializing countries. Almost one-third of these examples were mainly good housekeeping measures. Payback periods for their adoption were remarkably short and capital expenditure upfront was quite small and almost negligible in many cases. The European Preventive Environmental Protection Approaches in Europe (PREPARE) added an extra dimension, viz. catalyzing industry/government cooperation and the transfer of information on pollution prevention. In the USA, prevention teams helped small businesses in adopting pollution prevention technologies.

This new trend of the regulator joining hands with the regulated, rather than commanding and controlling, was a healthy development initiated by the Dutch. Covenants were concluded between the two parties, specifying what needs doing and what it takes to do it. This resulted in a welcome change in relations and in confidence-building measures. Transnational corporations (TNCs) now committed themselves publicly to quantitative reductions in polluting discharges over specific time horizons. The Triple P now stood for Pollution Prevention Pays, rather than the 1975 Polluter Pays Principle of the OECD (*see* PPP (Polluter Pay Principle), Volume 4). This came to be regarded as a win-win situation. Win-win came to be an article of faith accepted worldwide, heralding a new phase in environmental management.

Gradually, the law of diminishing returns dampened this euphoria. The idea became more and more difficult to sell; once the easier options resulting in substantial savings were exhausted, win-win became more problematic and its limitations became gradually clearer. DuPont came up with their version of the 80/20 principle – 80% of all possible environmental benefit came from the first 20% of costs. Sophisticated methods for identifying these 20% cost measures were being developed. Other social complications arose, sometimes preventing the implementation of some corporate priorities.

THE SOCIAL RESPONSIBILITY OF BUSINESS

But before we move on to the next phase we need to take note of a particular class of events and the reactions they triggered, namely, industrial accidents causing serious damage to the environment.

Bhopal, in particular, will always remain as a very significant watershed in environmental history. The accident occurred in a plant belonging to a well-known TNC in a developing country. The extent of damage and human suffering was horrendous. It suddenly became clear that response to previous accidents in industrialized countries (Flixborough or Seveso; *see* Seveso, Volume 5) had to move to a much higher level, and to take a global dimension, and also at the social, rather than just at the technical front (SCOPE, 1989).

Industry woke up to the need to improve its public image. The Community Awareness and Emergency Response (CAER) program was initiated by the Chemical Manufacturers Association (CMA) in the USA. The public was now kept informed about business operations, the hazards and risks involved, and plans for dealing effectively with emergencies. Similar programs were also initiated in Europe by the European Chemical Industry Council (CEFIC). Industry was now seriously seeking closer relations with society. The Responsible Care program, started in Canada in the mid-1980s, became adopted worldwide.

This declared the *moral responsibility* of business towards the safety and well-being of people and the environment, throughout the life cycle of its products. The chemical industry has indeed come a long way since it denounced Rachel Carson three decades earlier.

Furthermore, the International Chamber of Commerce (ICC) Second World Industry Conference on Environmental Management (WICEMII) of 1991 confirmed business commitment to the new concept of sustainable development, now receiving the hallmark of world acceptance in the Brundtland report. The ICC enshrined its commitment in a new business charter. A World Business Council for Sustainable Development (WBCSD), and even local councils, were formed.

FROM POLLUTION PREVENTION TO ECO-EFFICIENCY

Enter the third phase, that of *eco-ef ciency* (*see also* Eco-efficiency, Volume 4). This moved upstream from the tail end of pollution control to the very beginning: to better resource utilization. The conceptual forays towards the end of the 1980s, whether Ayres' *industrial metabolism* (Ayres, 1989) or, later on, Frosch's *industrial ecosystems* (Frosch and Gallopoulos, 1991) emphasized the need for dealing with all material ows in interconnected industrial systems that form part of the larger environmental system. It emphasized the importance of minimizing inputs of energy and raw materials, on the one hand, and utilizing wastes as inputs to new processes, on the other.

Business was now moving beyond compliance to a more aggressive commitment to exceeding regulatory requirements. It was now venturing into a vast arena of continuous improvement. The new buzz word was *eco-ef ciency*. Unlike pollution prevention, which focuses on reducing harmful discharges, eco-efficiency is concerned now also with material inputs. Reductions in these inputs by factors of four were being demonstrated as feasible targets through an increasing number of examples in many walks of life. A factor of 10 was now set as the target for sustainable development worldwide. Dematerialization, first mentioned in the late 1980s came out of the cold to become the new moving target to be pursued indefinitely by business (*see* Dematerialization and Sustainable Development, Volume 4). Eco-efficiency now replaced pollution prevention as the route to benefiting both the bottom line and the environment.

While eco-efficiency was clearly desirable environmentally, it was less obviously so economically. In this brave new world, the environment became more and more a cost center. The challenge was to build a business case for its implementation. Public image in an atmosphere of more vocal public opinion and aggressive environmental non-government organizations had to be factored in, as well as the impact on market acceptance and penetration measured in new ways. Environmental reports by enterprises were published, using a variety of approaches and measures of eco-efficiency. In the absence of a standard methodology and performance indicators, there was confusion often leading to skepticism. Analysis of these reports showed that eco-efficiency was not really being measured.

In 1994, an article in the *Harvard Business Review* argued against adopting this approach as the foundation of corporate environmental strategy, pointing out the danger of environmental planning being guided by wishful thinking and comforting buzz words. Greening could no longer be regarded as a win-win strategy for all corporations, all the time. It was time for a change of course.

THE AGE OF SUSTAINABLE DEVELOPMENT

By the time the Rio Earth summit was held in 1992, the tiny stream of ideas and approaches forming the environmental agenda had become a major river fed by a multitude of tributaries of new ideas and experiences, that certainly exceed in their number, and significance, the rather eclectic review given here. No wonder that Agenda 21, in its attempt to acknowledge each one of these, came out to be such a thick volume providing a rather forbidding checklist of what needs doing, together with rather dubious estimates of the cost of doing it.

Be that as it may, UNCED was particularly significant in two respects. First, the signing of two new global environmental conventions, emphasizing the urgency of the global dimension of environmental problems. It is worth noting here, in passing, that the principle of ensuring that activities within the jurisdiction and control of states do not cause damage to the environment of other states has now jumped from number 21 on the list of principles in the Stockholm Declaration to the very top of that in the Rio Declaration (*see* Sustainable Development, Volume 4).

The second was enshrining the concept of *sustainable development* firmly and squarely at the global level. No one would henceforth discuss environmental issues without at least paying lip service to sustainable development.

The question now is: how has this affected environmental management, particularly in the business community that had already committed itself to the concept in a charter and set up its own council, the World Business Council for Sustainable Development (WBCSD), even before Rio (*see* WBCSD (World Business Council for Sustainable Development), Volume 4)? Governments and the public have long been concerned with the environment. Business has now entered the field as a third and responsible player. Here are a few examples:

- Before 1992 was over, a book was published by Stephan Schmidheiny on behalf of the WBCSD

(Schmidheiny, 1992). Schmidheiny is a unique phenomenon – a successful businessman who does not mince words when advocating the responsibilities of business towards society, particularly in environmental stewardship. The book calls for profound changes in the goals and assumptions that drive corporate activities and change in the daily practices and tools used to reach them. This, for the author, means a break with business-as-usual mentalities and conventional wisdom that sidelines environmental and human concerns. He goes on to say: the painful truth is that the present is a relatively comfortable place for those who have reached positions of mainstream political or business leadership. This is the crux of the problem of sustainable development, and perhaps the main reason there has been great acceptance of it in principle, but less concrete actions to put it into practice.

Strong fiery words indeed, but how do they translate into actions?

- At the level of WBCSD, its working groups produced a plethora of reports on many topics, such as eco-efficiency, sustainable production and consumption. It now remains to see this converted into tangible operating practices on which new generations of business personnel will be trained. Corporate social responsibility (CSR) is the new buzz word that strengthens the voluntary approach, and the involvement of all stakeholders, away once and for all, from command and control. Working groups are busy thrashing this out in an attempt to formulate a working model combining everyday business activities with the well-being of society, and accepting accountability to different stakeholders. In a sense, business is taking over some of the traditional responsibilities of governments. This is a dangerous and slippery path. The WBCSD is particularly, and quite rightly, concerned about the role of each party in a new business–government–civil society partnership.

Let us first admit in all honesty, that there is as yet no worldwide consensus as to what sustainable development means. All the more reason that we do not quite know yet what it means operationally. The jury is still out and we must not be too severe in judging current efforts to interpret the term and be guided by it.

- The trouble with sustainable development is that it is abstract, complex and subversive. Business is uncomfortable with such qualities. Pollution prevention, eco-efficiency and other strategies are useful; but they in fact dodge the issue for a simple reason. They are local, straightforward issues amenable to relatively simple and fairly clear analysis and quantification of some sort or the other. Sustainable development, on the other hand, is a global and fiendishly complex issue calling for much deeper and broader involvement – something business shuns for obvious reasons. It had to bring sustainable development to a clearer and more manageable size and form. The way business has done this so far seems to have been essentially to equate sustainable development to eco-efficiency.

Stated bluntly this means that we will be less worse off tomorrow then we are today. In doing this we are in a sense doing our best within the constraints of the *status quo*. This is a far cry from what Schmidheiny is calling for.

TAKING STOCK, LOOKING AHEAD

To re ect on our experience so far will help us to clarify our understanding of how and why we arrived where we are today, to take stock of our past experience, and to base our future plans on the lessons we have learnt:

1. One striking feature is that the ideas that happen to be the fashion at any time are seldom new. We have heard them before but failed to grasp their significance. Reading today the Founex report, or even the first Meadows report, or the Cocoyoc declaration, or revising the recurrent warnings over decades of possible dramatic climate change brought about by mankind, or reminding ourselves that responsibility for future generations is much older than the Brundtland report, to cite but a few examples, recalls, as Victor Hugo once remarked, that their time had not come when they were first enunciated.
2. One reason is – and will continue to be – our incomplete knowledge of the complex natural and social issues we are grappling with. This is hardly a confidence-inspiring foundation for policy-making. We only act – or rather react – when the environment springs a surprise on us. Such extraordinary events end up improving our knowledge; but the next emergency when it comes will, more often than not, be somewhere else. No profound global change can be predicted on the basis of recognizing one specific hazard, or through one scientific discipline. We are still unable to encompass all imaginable effects or to predict all possible interactions in time and space, in order to plan meaningful interference. We now realize that environmental effects are time bombs – they are very slow and could go on practically unnoticed for decades before they explode into irreversible change.
3. Scientific discovery is not in itself a social force. We need a credible consensus amongst scientists before

the politicians start acting. Science has not always managed to establish, beyond reasonable doubt, a clear cause–effect relation. While scientific uncertainty is the driving force of scientific progress, it also paralyses decision-making. Unfortunately, some scientists become advocates, confusing the decision-making process even more.

4. Faced with this daunting challenge we have not been standing idle. If we still do not quite know the dynamics of environmental change, we have at least come up with some new ideas, e.g., the precautionary principle, environmental economics, the need to correct market deficiencies, the necessity for all stakeholders to cooperate sincerely and consistently. We will no doubt continue to improvise new approaches.

What we must never do is to forget that this is a long and hard struggle that calls for sustainability of effort as we seek to achieve the ultimate goal of economic, social and environmental sustainability.

Global environmental change (GEC) is directly related to the general public. On the one hand, GEC is ultimately shaped by the activities of people, be it energy- and material-intensive lifestyles in industrialized countries or poverty-driven deforestation and other land use changes in developing countries. On the other hand, it is the public which is directly affected by GEC and which suffers from living conditions changing for the worse.

Conventional wisdom suggests that two elements lead to public support of a development towards sustainability: setting the right prices for energy and other resources, and increasing public awareness of the dangers of GEC by information and education. In this opening essay, we argue that this approach by itself is not suf cient. Not only have newspaper articles like " Double the Price Without Pain: What Happened to Oil Shocks?" (International Herald Tribune, 2000) publicly put a question mark on how much the mechanisms of today's economies are in uenced by energy prices. But, more importantly, recent research on public responses to GEC discussed in this essay shows that citizens are not supportive of strongly increasing energy prices by scal measures. This is not caused by any lack of environmental awareness. The same research nds that citizens around the globe are very concerned with prospects of GEC, and strongly support preventive action. But they expect solutions to be found without hard-hitting price increases. Technological change in combination with related lifestyle changes will be essential in nding solutions to GEC problems that are supported by the public. Opportunities for such processes can only evolve in a complex network of actors in science, business, and politics together with the general public. Figure 1 illustrates this system of different actors, which is complex due to many interactions and feedback-loops (not shown in detail). The nature of complex systems suggests that new solutions, e.g., for less polluting transportation, can emerge but cannot be planned by any unique agent. Our essay focuses on the dynamics of the response to GEC evolving from the complex interplay between the public, politics, business, and science. Studying this complex system in more depth will require a combination of natural and social sciences, of quantitative and qualitative methods, and of modeling and empirical research.

In our essay, we will discuss this complex system as follows. In the section on studying public reactions to global environmental change, we highlight the importance of understanding public reactions for the formulation of sustainable development policies. We will discuss recent research on public response to GEC mainly on the basis of three major studies. These are, first the global Health of the Planet survey, second a study of US residents' views on global climate change, and third the European research project, Urban Lifestyles, Sustainability and Integrated Environmental Assessment (ULYSSES) focusing on citizen views on climate change and policy options. These three projects and their different methodologies will be discussed in order to explore the responses to GEC of citizens with different cultural backgrounds. Results of these studies indicate that most citizens, both in industrialized and developing countries, are concerned about GEC and do not accept the lack of absolute scientific proof as a reason to delay preventive action. On the other hand, they are not willing to support a major increase of energy prices to induce a reduction of greenhouse gas emissions. This implies an essential role for technological change fostered

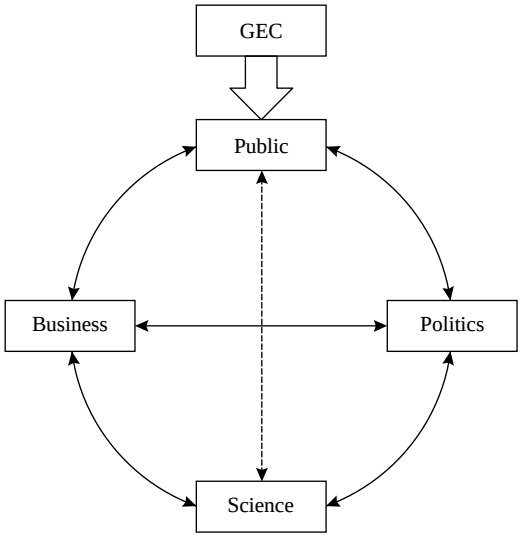

Figure 1 Response to GEC results from a complex interplay between the public and actors in business, politics, and science

by science and business, which are often perceived to have responsibility here. Their interaction with citizens and policy makers in complex social systems will be crucial for shaping technological change combined with lifestyle changes as an effective response to global environmental change.

In the section on perceptions of technological opportunities, we follow the pathway paved of the results of public opinion studies and discuss possibilities and problems of technological change and related lifestyle changes in response to GEC. We focus on questions related to development towards a sustainable energy system, which requires the application of technological innovations in both energy production and energy consumption. The emerging picture for the global energy requirements in the next hundred years clearly shows that drastic action is needed which consists not only in the development of new technologies and their implementation but also of behavioral attitudes of consumers. This can be illustrated best in the context of transportation, which has been the fastest growing energy sector during the last two decades. Urbanization, rationalization and globalization have changed living conditions dramatically leading to a fast growing demand for transportation of people and goods. Technological innovations towards more energy-efficient transport are of great importance but must be accepted by the public. This underlines the importance of investigating the dynamics of the whole system constituting the public in its double role of citizens and consumers and the other main players? politics, business and science.

In the section on complex dynamics: innovation and lifestyle changes, we discuss new approaches essential for analyzing such systems. We argue from the viewpoint of the interdisciplinary science of complex systems. This novel perception of natural systems, developed during the last three decades, has revealed basic misconceptions and misbeliefs of traditional natural scientists and bears the potential to reconcile natural with human sciences. The combination of non-linearity and feedback-loops in complex systems leads to a variety of possible dynamics which often differ from common expectations based on linear extrapolation from the present state. We will make clear that seemingly impossible but important changes in socio-economic systems, if they occur, often happen abruptly and without warning. These changes are unpredictable surprises that can be in uenced by different factors only within narrow time intervals or *windows of opportunity*. This view leaves room for hope for innovation and lifestyle changes inducing development of a sustainable future, but at the same time, sets clear limits to our possibilities to create it according to our own design. Appropriate action can only be developed in a common effort involving all actors in Figure 1. Finally, we discuss the application of some principles of the science of non-linear dynamics to an innovative process, describing the substitution of conventional, by innovative cars.

In the final section we re ect on implications of recent research on public responses to GEC on the interplay between the public, politics, business and science and we discuss how *social learning* (*see* Social Learning in the Management of Global Atmospheric Risks, Volume 5) in this complex system could be both studied and supported by future research, as an interdisciplinary effort including close dialogue between the public and other stakeholders.

STUDYING PUBLIC REACTIONS TO GLOBAL ENVIRONMENTAL CHANGE

The Importance of Public Reactions

Effective responses to GEC will have to include major changes in our socio-economic system. While some simpler environmental problems could be tackled by reducing some toxic byproducts of certain production processes, responses to climate change require large shifts right at the heart of our industrialized cultures. Referring to reduction scenarios discussed in the Intergovernmental Panel on Climate Change (IPCC) context, (Kempton, 1991) has stressed that if world leaders decide to reduce greenhouse gas emissions by two-thirds, such a large reduction will require consumer and worker cooperation as well as citizen consent that major societal changes are worth the effort . Public support is an essential requirement for any effective response to global environmental change.

This suggests that studying reactions of citizens concerning climate change and related policy options is a central element in developing effective response strategies.

Such studies can build upon a large body of research on environmental consciousness and behavior in general (see, e.g., the comprehensive overview by Brand, 1997). In the last decades, various studies have focused specifically on perceptions of climate change issues (see, e.g., the overview by Thompson and Rayner, 1998). Bearing in mind the scale of changes needed in the longer run for effective climate protection, the crucial research goal here is to understand the role of the public in supporting changes of a complex socio-economic system. This includes collective action by many players, and not just isolated individual reactions in an otherwise static social environment.

> Reducing carbon dioxide and taking further steps to curtail global warming will require collective action and institutional change (both intra- and internationally) and are unlikely to result primarily from people changing their consumption patterns on an individual basis. Indeed, one could argue that public support for environmental regulation and incentives, and for politicians who will implement them, is far more essential than voluntary change in individual consumer behaviour when it comes to achieving a global-level public good' like a (reasonably) stable climate.
>
> (Dunlap, 1998)

In this section we will thus discuss research on public responses to GEC from the perspective of what its findings imply for the complex interplay between the different actors in society. What does the public expect from science, politics and business, and what can be expected from the public? We will illustrate these questions on the basis of discussing three major studies which have recently targeted responses of the public to environmental issues, and to GEC in particular.

1. Global Responses: Health of the Planet Survey

The international Health of the Planet' survey on environmental attitudes aimed to give voice to individual citizens around the world concerning the environment and economic development issues affecting their lives (Dunlap *et al.*, 1993a,b). This large questionnaire study was carried out in 24 nations both in developed and in developing regions around the world, with sample sizes between 770 (for Finland) and nearly 5000 (for India). Overall, nearly 30 000 questionnaire responses were collected and analyzed. The questionnaires were completed in face-to-face meetings with survey researchers, thus minimizing problems, e.g., of illiteracy.

A highly interesting result of the Health of the Planet survey concerns the comparison of views on environmental issues between developed and developing countries. The researchers were surprised that the views expressed were much less polarized than has often been assumed. Citizens of both developed and developing nations were found to accept a share of responsibility for environmental problems. The most frequent response to the question who is more responsible for today's environmental problems in the world? was that industrialized and developing countries are both equally responsible (Dunlap *et al.*, 1993a). Respondents from developing nations were nearly as likely as their developed country counterparts to mention overpopulation as the major cause of environmental problems within developing countries themselves. And not much difference was found between residents of developed and developing countries concerning the degree of blame placed on consumption of the world's resources by industrialized countries (Dunlap *et al.*, 1993b). Major differences in international climate diplomacy between the two sets of countries can be expected to persist related to the question whether long-term emission rights should be based on grandfathering (favoring developed countries with high current emissions) or on *per capita* emissions (favoring developing countries with low current *per capita* emissions). However, the results of the Health of the Planet survey suggest that citizens in developing and developed countries are basically not pointing the finger of blame at each other. This should encourage policy makers in both sets of countries to look for a consensus on dealing with GEC problems.

Furthermore, a striking finding of the Health of the Planet survey was that careful analysis of the data did not support the post-materialist hypothesis that higher economic security in developed countries would generate post-materialist values leading to higher environmental concern compared to developing countries. Indeed, national wealth and environmental concern seemed to be negatively rather than positively correlated. Even if the level of environmental concern is comparable in developed and developing regions, one might have assumed that citizens in developed countries worry more about GEC than their counterparts in developing countries, which face severe local environmental degradation. However, the survey found that this is not the case. While citizens in poor nations were indeed much more likely to rate local community problems as serious than were residents of wealthy nations, they rated global environmental problems nearly as serious as did those in the wealthy nations (Dunlap *et al.*, 1993a). Concerning actions that developed countries could take to support developing countries in protecting the environment, technological assistance was often mentioned, next to providing educational information. However, the role of technology was perceived ambiguously. Respondents often saw technology both as a cause of environmental problems, and as a part of the solution. Also, the survey overall found willingness to pay somewhat higher prices if this supports environmental protection.

The Health of the Planet survey also found issues where the views of developing and developed country respondents differed from each other. This was the case, for example, concerning the questions: Which group within

a given country was mainly responsible for environmental protection? and; How much can citizens effectively contribute to solving environmental problems? While most often government was felt to be primarily responsible for environmental protection, also individual citizens and citizen groups were often seen in this role. The response that citizens should have primary responsibility for environmental protection

> is somewhat more likely in the developing than in the industrialized nations and is especially pronounced among Latin American nations. This pattern would be more distinct were it not for the abnormally low level of responsibility assigned to citizens in Russia and Poland [which Dunlap *et al.* had included in the group of developing nations], which could re ect the low levels of citizen efficacy in these formerly totalitarian nations . (Dunlap *et al.*, 1993b)

Also with regard to the question, How much effect do citizens (both individually and as citizens groups) have on solving environmental problems? respondents from developing countries were more likely than those of developed countries to think citizens can play an effective role in solving environmental problems. Again, the Eastern European nations included in the survey (Russia, Poland and Hungary) were striking exceptions in that here, citizen action was seldom seen as very effective. Overall, these findings mean that in many nations (especially in developing countries) citizens do not simply delegate responsibility to policy makers but also assume a share of responsibility for environmental protection themselves.

In a subset of the Health of the Planet survey, citizens in six nations (Canada, the US, Mexico, Brazil, Portugal, and the Republic of Russia) were asked specifically about global warming (Dunlap, 1998). While other aspects of GEC like ozone depletion, loss of rain forests and jungles, and large-scale water pollution were perceived as even more worrying, global warming was in general seen as very serious. Challenging again the post-materialist hypothesis, respondents from Brazil, Mexico and Portugal were overall more likely to see global warming as having very harmful effects than their counterparts from Canada, the US or Russia. Overall, the respondents saw global warming effects on natural systems (either by creating various ecological problems or by changing weather patterns) as more worrying than effects on social systems. Choices that people have of where to live and economic well-being are the least likely realms to be seen as being harmed – suggesting that economists' emphasis on economic impacts [•••] ignores the public's crucial concerns ••• (Dunlap, 1998).

2. US Residents' Views

In contrast to the Health of the Planet survey, a series of studies of US residents' views on global climate change has combined questionnaire survey methods with semi-structured interviews of a small but diverse sample of citizens. A first study has been based on the analysis of just fourteen ethnographic interviews (Kempton, 1991). In a further step, 43 interviews were conducted together with the collection and analysis of 142 questionnaire responses from US residents with a wide range of different backgrounds (Kempton, 1997). The semi-structured interviews were based on open-ended questions, follow-up probes for unexpected topics raised by the informants, and paraphrases for verification. Kempton suggests that such interview techniques, originally developed by anthropologists to study foreign cultures, are recommended when the interviewer initially has little understanding of the native concepts. Such methods contrast with survey research, in which the questions and range of possible answers are already known and precise answer frequencies are measured (Kempton, 1991). Such interviews are often taped and selectively or fully transcribed, so that exact quotations can illustrate the *mental models* of the interviewees as directly as possible. Thus, interview studies usually provide more in-depth insights into the perceptions of a smaller number of respondents than surveys. In the case of this study, the small number of interviews was backed up by a questionnaire study with at least a medium-sized sample.

One set of findings of this study concerns lay conceptualizations of the greenhouse effect. These were found to be rather different from scientists' descriptions. The research team reports, e.g., that lay people often confused the greenhouse effect with ozone depletion or tropospheric air pollution. In general, Kempton concludes that citizens fit new information on global warming into prior concepts or cultural models easily accessible to them, instead of receiving the information as it was meant by the scientific authors. Different conclusions have been drawn from this mismatch between citizens' and analysts' conceptualizations of global climate change. The leading researcher of this study sees the current mismatch as evidence for the difficulties in putting a new concept [i.e., climate change] on the lay person's cognitive map (Kempton, 1991). He suggests that it is vital to change this situation by continuing media coverage and education, because citizen knowledge is needed to keep leaders on the right track .

In contrast to that, Dunlap remains skeptical that public support for environmental protection will hinge upon laypersons becoming highly informed about technical aspects of global warming (Dunlap, 1998). He sees it as no surprise that lay people try to make sense of global climate change by associating it with existing and more accessible mental models like air pollution, ozone depletion, or ecological problems in general. Instead of worrying about the mismatches with expert concepts, he thinks that public concern over global climate change is unlikely to disappear in the foreseeable future precisely because it is woven into the fabric of the ecological problematique' that seems

firmly (if not deeply) embedded in public consciousness . A similar interpretation is given by Thompson and Rayner, who argue that

> For many lay people, the climate change issue is perceived as part of a wider problem concerning humankind's disturbed relationship with nature. In this sense, climate change and ozone depletion are the same thing: they are members of the category of environmental insults deriving from industrial society. If industrial society is the problem, and if climate change and ozone depletion are interchangeable symbols or prototypes of the problem, then the specific etiology of each simply may not be relevant to the respondents of these surveys.
>
> (Thompson and Rayner, 1998)

It may well be, this debate suggests to re ect on the question: To what extent are technical details of GEC relevant for citizens, or To what extent does Dunlap's analysis apply that in an era of re exive modernization, it may well be more crucial for the public to know which experts to trust and distrust than to understand the details of their respective arguments (Dunlap, 1998).

A second set of findings from Kempton's studies concerns environmental values. In agreement with the overall results of the Health of the Planet survey, Kempton and his colleagues report that US residents express strong support for protecting the environment in general and preventing global climate change in particular (Kempton, 1997). This seems based on ethical values which include the perceived intrinsic value of nature, in addition to religious reasons or the human use aspects of ecological systems. The strongest environmental value to emerge was a desire to preserve the environment for one's descendants, sometimes including concern for more than one coming generation. Also, the weather seems to be a natural system with a special cultural meaning, and people seem to have a tendency even in our technology-based society, to feel that it is wrong for humans to tamper with it (Kempton, 1991). Kempton suggests that an important part of citizen support for environmental protection is local, e.g., the desire to preserve local recreational and scenic places and to protect one's own health .

Concerning specific climate change impacts, Kempton's findings suggest that species preservation is not highly valued in the abstract by the majority of the US public. Rather, e.g., rising food costs were perceived as more worrying than species extinction, and most informants justified species preservation in anthropocentric terms. While weather patterns were seen as becoming more unpredictable, with storms and violent weather more common, most respondents connected the greenhouse effect primarily to higher temperatures rather than to the more complex climate effects expected by scientists.

Regarding policy options, Kempton found that there often was a lack of connection between the greenhouse effect and energy efficiency. He finds that people do not really understand what energy efficiency is, and when analysts talk about reducing energy use, lay people [in the US] tend to interpret it as decreasing energy services . US residents were found often to see energy taxes as negative, although not very strongly so. However, a policy of adaptation without prevention was not supported by the interview partners. He interprets that in the children/descendants reference frame, informants did not acknowledge discounting of future costs . Average Americans are aware that measurable environmental disturbance is now global in scale, ••• and they want decisions to be based not only on cost and benefits but also on our responsibility to leave a healthy planet for our descendants (Kempton, 1991).

3. European Perspectives: the ULYSSES Project

Instead of using individual interview methods, the European ULYSSES project has developed a specific form of *focus group* procedures (called *integrated assessment* (IA) (*see* Integrated Assessment, Definition of, Volume 4; Integrated Assessment Models of Global Change, Volume 4) focus groups) to study views of citizens and other stakeholders on global change issues as part of IA processes (Kasemir *et al.*, 2000). IA strives to provide more useful information to decision-makers than can be achieved with traditional disciplinary research (for more on IA concepts, see Weyant *et al.*, 1996). The IA focus group method allows exploration of spontaneous associations by the participants (e.g., in collage work) as well as the interaction with current research findings (usually by the use of computer models in the focus groups), before the participants themselves summarize their views on the focal topic. Within ULYSSES, IA focus groups were conducted in seven metropolitan areas across Europe in order to study views of ordinary European citizens on climate and energy issues. Approximately 600 European citizens participated in these groups.

The IA focus group method as developed by ULYSSES tries to avoid both extremes mentioned above concerning the role of expert knowledge in citizen debates on global environmental change. Scientific findings on GEC issues are seen as an important reference point, in that the groups of citizens are confronted in a series of meetings with current expert assessments of global change issues. But it is not the goal of the exercise to study to what extent the citizens in the IA focus groups assimilate these expert views. Rather, the aim is to understand what views on climate change and climate policy options emerge in the confrontation with scientific findings and with other citizens' points of view.

IA focus groups are not designed to elicit individual consumer preferences (which are better studied by observing actual consumption behavior). Rather, in line with the contention by Dunlap (quoted at the start of this section) that collective action is essential for any effective response

to global change, these focus groups are intended to show how ordinary citizens develop preferences about public choices and how these preferences evolve and are expressed in a dynamic social setting. Because the principal purpose of ULYSSES was to study views emerging in discussions between different types of participants (thought to be more indicative of public opinion dynamics than a study of the views of isolated segments of the population), it was important that the focus groups be diverse with respect to age, gender, income, educational level, and attitudes toward the environment. To that end, the potential participants were carefully screened, with quotas established for manual workers and college graduates; those who felt that environmental problems were important and those who did not; and those who favored environmental regulation and those who did not.

In agreement with findings of Dunlap's global and Kempton's US study, European citizens who participated in ULYSSES focus groups often saw the prospect of climate change as very frightening. In general, the ethical aspects of global change, such as the duty to preserve nature or responsibility toward future generations, were important to participants. Worries about the frightening aspects of climate change were not restricted to the impacts in the regions where the participants lived. Impacts in other parts of the world, especially in developing countries, mattered to the European focus group members. Somewhat in contrast to Kempton's findings that higher temperatures rather than more complex climate effects were of major concern to US citizens, the European ULYSSES study found that, while rising temperatures were often mentioned, other consequences (notably a rise in sea-level and the increased frequency of extreme weather events) were seen as more worrying. Significantly, the impacts of climate change were usually not perceived in economic terms but rather in terms of the deterioration of basic living conditions. This supports Dunlap's finding that economic impacts are not at the center of citizens' worries about climate change.

One of the aspects stressed in the ULYSSES study was the role of uncertainties surrounding climate change and its impacts. The ULYSSES researchers took care to confront the participants with the uncertainties in global change science, and not just with some *best guess* scenario. As a result, the focus group participants were often disappointed that science cannot be more definitive about these issues. However, in most cases uncertainty about future climate change was not seen as a reason for not taking preventive measures. Expectations of the deterioration of basic living conditions around the world, ecological destruction, and danger to future generations made a wait-and-see policy unacceptable to the participants.

While participants usually did not frame climate impacts in economic terms, economic arguments were readily offered in discussing response options. In line with Dunlap's finding that globally there is some willingness to pay higher prices for environmental protection, a certain increase in energy prices was often seen as a useful measure by the European citizens participating in the ULYSSES study. However, in the focus group discussions it became clear that not many participants supported hard-hitting increases in energy prices. The reasons for rejecting very-high energy prices included fairness. For example, it was generally not seen as fair if only the rich could afford to continue using their cars. However, some participants thought that slow and steady increases in energy prices would induce technological change towards greater energy efficiency, and most believed that more investment in research and development was necessary.

Overall, and in contrast to the findings of Kempton for US residents discussed above, the European participants in the focus groups often saw a society with much lower energy use than today as being very desirable. Many of the people participating in the focus groups wanted to reach this goal without excessive increases in energy prices. They tended to feel that the development of innovative, energy efficient products is crucial for making this goal feasible and also thought that researchers and firms have the responsibility for it. For example, it was felt that much more energy efficient cars could already be produced, but that industry was delaying the release of such innovations. From the point of view of many European citizens, what seems required in the climate policy debate is an ethical discussion concerning which climate impacts are unacceptable, together with a discussion of how to attain large reductions in energy use at low cost. Fostering related technological change will be essential for this.

PERCEPTIONS OF TECHNOLOGICAL OPPORTUNITIES

The research on public responses discussed above implies considerable responsibility for politics, business, and science to share in the exploration of low-cost options for global change mitigation by supporting major processes of technological change. According to traditional views of technological change, science would come up with different technological options for a well-defined problem, politics would support the technology option being selected based on independent scientific information, and business would develop, produce, and sell the corresponding technology to consumers or industry if profit results. In reality, technological change is often a very time-consuming process which is dominated by a series of coincidences rather than planning, and, finally, leads sometimes to results very different from the initial expectations (Grubler, 1998, and references therein). It is the complex network between business, politics and science, which makes the difference. Because some links between business, politics and science

dominate the system and other possibly important links are missing, information and financial resources, most often, are not accessible to some key actors in innovation processes. Technological innovation might not lead to expected results, if promising technological solutions cannot be communicated by science, politics relies on particular interest groups, and business is focused on short-term profit only. It seems reasonable that well organized and continuous information exchange and support between politics, science and business can improve the chances that even visionary long-term goals can be achieved (still success is not guaranteed, see section on complex dynamics: innovation and lifestyle changes). In addition, public acceptance is often the key element: numerous examples exist of technological options with great potential which have not been accepted by the public for various reasons. Thus, the traditional approach (especially promoted by scientists), that technology just has to be developed and transferred, is hardly a successful way to induce technological change towards sustainable development.

In this article, technological change refers to a concept of technology which is not only defined by both hardware and knowledge for production and use but includes technology diffusion, resulting from the spread of technological innovation via different communication channels in time and space based on acceptance among members of a social system (Grubler, 1998). The various actors in science, business, politics, and the public shape the different stages of the technological life cycle consisting of invention, innovation, and, finally, diffusion. Concerning technological change as a response to GEC, various processes like introduction, substitution, and cut-off processes of complete technological systems or even technology clusters as well as efficiency and end-of-pipe measures on already existing technological systems are of fundamental importance. Developing countries with strong economic growth could profit from the introduction of new technological systems (such as power plants or transport systems) to increase their productivity and close the gap to with industrialized countries without making the same mistakes in wasting resources. In the industrialized countries, substitution (e.g., innovative fuel cell cars for conventional cars) and increasing efficiency (e.g., more efficient fuel consumption by conventional cars) of technological systems are needed to maintain (and increase) the productivity but decrease the consumption of resources and the production of waste. Cutback processes are necessary to restrict production of dangerous products (e.g., chloro u-orocarbons (CFC)) whereas end-of-pipe processes reduce the environmental impact by filtering out (e.g., sulfur-based components) or transforming (e.g., by catalysors in car engines) wastes or emission components. Technological changes involving large capital-intensive facilities (such as power plants) are often crucial since the environmental impact is most significant. However, the long time scales for introduction or substitution processes have to be taken into account, huge investments in (basic) research and development, as well as public acceptance have to be guaranteed. Recently, the concept of an efficiency revolution involving decentralized and smaller as well as highly adaptable technological systems has been renewed (von Weizsacker *et al.*, 1997). It is argued that investment in technological change of this kind has several advantages like short time scales for development and implementation, high payback rates for profit-oriented business and improved living quality for people.

In the following section, we will focus our discussion on technological change involving energy systems since the world consumption of primary energy, which increased by a factor of more than four during the last 50 years, is directly related to one major element of GEC, climate change. The primary energy consumption *per capita* measured in kilowatts (kW) is an interesting indicator of the present situation. A kW is a thousand watts, and a watt is a rate of using energy. The present worldwide average of 2 kW *per capita* results from a very broad distribution including developing countries such as Ethiopia with 0.29 kW, Europe with 4.8 kW and the United States with more than 10 kW *per capita* (World Resource Institute, 1997; Imboden and Jaeger, 1999). Two simple scenarios outline potential limit cases for future development. If, on the one hand, an increased world population of 10 billion people head for the specific energy consumption of the US, a global energy consumption level ten times larger than in 1990 would result. If, on the other hand, the global average of 2 kW *per capita* was kept constant, the global energy consumption would only increase due to growth of the population, e.g., double with respect to 1990 in case of 10 billion people. Considering the strongly increasing energy demand of developing countries, it is obvious that the ambitious approach of keeping the average at 2 kW could only result from a less heterogeneous distribution of the energy consumption *per capita*. For example, if the industrialized countries could reduce their energy consumption *per capita* by a factor $2-5$ due to a huge efficiency increase, and the economically growing developing countries could restrict their energy consumption *per capita* to 2 kW by establishing efficient energy use. We refer to this scenario as the *global 2 kW society*.

An energy system satisfying the consumption of an energy efficient global 2 kW society but based on fossil resources would, however, still lead to an increase of the atmospheric carbon dioxide (CO_2) concentration exceeding double its pre-industrial value before the year 2100 which is generally considered as a level inducing significant climate changes. Thus, technological change affecting the energy production side plays a key role in reducing CO_2 emissions as well. The Intergovernmental Panel on Climate Change

(Houghton *et al.*, 1995) suggests that the overall emissions have to be decreased from the present 8 Gt C (Giga-tons carbon) per year (including 6 Gt C due to consumption of fossil energy and 2 Gt C due to deforestation) to a level of 40% (3 Gt C per year) within the next 100 years. To achieve this goal, the burning of forests has to be stopped and the contribution of fossil energy has to be reduced from currently approx. 77% (World Energy Council and International Institute for Applied System Analysis, 1995) to 25–30% in 2100 (taking increasing efficiencies into account). The rest of 70–75% must be contributed by different technologies without producing CO_2 emissions. A global 2 kW society of 10 billion people which satisfies the requirements of the IPCC could have the following contributions of energy resources in the year 2100 (Wokaun, 1999a): wind energy 5–10%, geothermal energy 5–10%, solar energy 10–15%, biomass 25%, hydropower 10%, nuclear energy 10%, fossil energy 25–30%. Massive introduction and substitution processes have to be undertaken to build a sustainable energy production system of this kind. Technological change on the energy production side involves large facilities and the above mentioned problems have to be taken into account.

The global final energy consumption can be divided into the following energy sectors (International Energy Agency and Organization for Economic Cooperation and Development, 2000) industry 35%, transportation 28%, residential/commercial 33%, and non-energy use 4%. More than 50% of the global final energy consumption (major part of the transportation and residential sectors) directly results from activities of the public and, therefore, depends on the behavior and decision-making of the consumers. In many countries, the transportation sector has been the fastest growing energy sector and has overtaken the industrial sector. In the following section, we focus on technological change in the sector referred to as the transportation of people looking at some of the key problems on the way to a 2 kW society. The transportation sector, in particular, is very interesting from the point of view of the science of complexity (see section on complex dynamics: innovation and lifestyle changes) since technological change within this sector is connected with a large variety of processes, including all actors of Figure 1 whose strategies underlie numerous environmental, economical, and social criteria.

Passenger travel demand and mode choice follow regular patterns rooted in regularities in time and money expenditures (Schafer and Victor, 2000). At highly aggregate (world-regional) levels, humans spend a roughly constant fraction of their income and time on transportation. A roughly constant fraction of travel money expenditures implies that travel demand rises approximately in proportion to income, while a roughly constant travel time budget (1–1.5 hours *per capita* and day) requires the rising travel demand to be satisfied with higher-speed modes. Walking is replaced by public transport, then private cars, and finally modes which involve high-speed trains and airplanes. Based on these regularities in time and money expenditures, land-use constraints, and projected growth in world economy and population, the volume of passenger traffic world-wide might increase from 23.4 trillion Pkm (passenger kilometer) in 1990 to about 100 trillion Pkm in 2050, and worldwide shares will change dramatically in the coming decades. High-speed traffic might gain a market share of about one third of the world passenger traffic volume by 2050 compared to 9% in 1990 whereas car traffic might supply about 40% in 2050 compared to 53% in 1990. These results suggest that changes in the transportation sector will have a tremendous in uence on GEC. We discuss some aspects of technological changes in the most important traffic modes for the transportation of people-high-speed trains and cars.

Aviation is the least environmentally sustainable of all transport modes at present and shows the least promise of becoming sustainable. Largely because commercial aircraft are usually better occupied than cars, fuel-use per passenger kilometer is, on average, only slightly higher than for cars. However, in the most recent report of the IPCC (Penner *et al.*, 1999) it is concluded that burning a given amount of fuel in an airplane appears to be equivalent to burning about three times as much fuel in a car because exhaust gases seem to have a much more potent greenhouse effect 10–11 kilometers above ground than at sea level (mainly due to the increased production of the greenhouse gas ozone, which is the transformation product of exhausted NO_x). Thus, one return Trans-Atlantic trip by airplane has an equivalent global warming impact as about two years of automobile travel of an average European or North American. The globalized economy, resulting in growing demand for business trips, and modern lifestyle, with travel-intensive leisure activities, has led to an annual rate of increase of air travel of about 6% in the 80's and 90's with a slightly reduced increase of 4–5% until 2000 (Air Transport Action Group, 2000). This dramatically increasing demand has exceeded the technological improvements needed for energy efficiency, although aircraft are about 70% more fuel efficient per passenger-km than 40 years ago. It is projected (Penner *et al.*, 1999) that future engine and airframe design improvements will result in a 20% improvement of fuel efficiency by 2015 and a 40–50% improvement by 2050 relative to aircraft produced today. However, the realization of such improvements in the form of substitution processes takes a long time since typical life expectancies of aircraft are 25 to 30 years. Alternatives to kerosene-based fuels are promising but long-term options, such as hydrogen fuel, which would reduce CO_2 and NO_x emissions from aircraft, require new approaches to aircraft design and supply infrastructure. Technological changes on a shorter time scale will affect air traffic management with a reduction potential for fuel consumption in

the range between 8–18%. Smart techniques for guidance, separation, coordination, and control of aircraft movements are promising since they have the potential to improve security and energy efficiency at the same time.

The public is a key player for the further development of aviation. The outcome is uncertain since contrary aspects ranging from the lifestyle-driven demand for high-speed travel to public opposition against expanding airport activities characterize the present situation. Complex decision-making processes in uenced by public opinion have a high impact on the realization of the potential technological improvements since, first, safety considerations have priority and, second, there is a considerable trade-off between energy efficiency and noise protection measures (quieter airplanes use more fuel). Regulatory and economic options in the form of increasing fuel prices or aviation taxes (Penner *et al.*, 1999) could successfully reduce the explosive growth of air traffic but public opposition (see section on public reactions to global environmental change) has to be taken into account. Thus, technological alternatives combined with changes in travel behavior that aim for the substitution of aircraft travel are the most interesting options. Most aircraft ights over land are still in a short-distance range and could be substituted by ecologically more efficient high-speed trains, which could eventually offer mobility at comparable speed and/or superior travel comfort. Intercontinental travel by airplane is, of course, much harder to replace since travel by sea is much more time-consuming and needs to be combined with leisure or working activities to be attractive for a certain sector of travelers.

In the railway sector, a relatively large variety of technological options exist. The conventional steel-wheel-on-steel rail technology still dominates and ongoing technological progress ranges from improved electric and diesel power trains, reduction of train weight and improved aerodynamics to new design concepts for conventional trains, like the successful Italian Pendolino tilt-technology, which enables up to 35% increased velocities on curves and increased travel comfort for passengers. The next stage comprises innovative rail concepts including modifications in track infrastructure. High-speed trains like the French TGV and the German ICE are compatible with the existing track system but profit from high-speed tracks with reduced curve radii, which enables top speeds greater than 300 km h^{-1} in regular service. Introduced about one decade ago, they are widely accepted by consumers in many countries. However, their potential for further progress in speed and, thus, competition on a time basis with ights of up to 1000 km is limited. Thus, several concepts for new high-speed railway systems based on magnetic levitation or jet-powered hover trains, like the Japanese MLU and the German Transrapid , with velocities from 350 km h^{-1} up to more than 500 km h^{-1}, are being developed. Another new technology, the Eurometro , would operate below ground in partially evacuated tunnels running on magnetic propulsion, levitating, and guiding systems. It is argued (National Research Program NRP 41, 2000) that such a system would be much more resource- and energy-efficient than other transport modes (about 5–10 times compared to short-distance aircraft, 6 times compared to cars, and about 3 times compared to conventional trains). However, such large-scale technological change would have to rely on high and long-term investment, broad political and public acceptance as well as international cooperation. Critics of such high-speed systems (von Weizsacker *et al.*, 1997) argue that these systems are not compatible with existing infrastructures and the needed high investments, which should instead be used to improve either conventional technology combined with much increased travel comfort or, if new infrastructures are desired, to build more exible, consumer-oriented train systems that could increasingly compete with car traffic. The Cyber-Tran system (National Center for Advanced Transportation Technology, University of Idaho), for example, would be based on large numbers of small, light, and therefore energy-efficient vehicles operating on elevated guide-ways at speeds of up to 240 km h^{-1}. Flexible operation would be based on consumer call options and a high number of small vehicles.

Apart from technological considerations concerning travel speed, railway systems have a huge potential to improve their travel comfort and, thus, compete increasingly with car or air traffic. Simplified booking and ticketing procedures, improved home computer and internet access, and, most importantly, novel on-board-entertainment concepts for families or groups would improve travel comfort significantly. In addition, railway traffic could be much better synchronized with other traffic modes, in particular, public transport and cars. The implementation of car sharing, which operates from railway stations, can be very attractive for consumers in terms of travel comfort as well as costs. In the end, public acceptance of novel train travel forms is as important as technological criteria for selecting appropriate train systems and for replacing air and car traffic by train traffic.

At present, car traffic is the backbone of transportation of people in many countries. The worldwide success story of the car is strongly connected to the fact that it enables a high degree of individual mobility which is an important feature of modern lifestyles. However, the huge increases in car traffic during recent decades has led to a situation where people in most cities all over the world suffer from car emissions, noise and daily traffic gridlocks. Furthermore, the contribution of the car segment to global warming is very significant. Considerable effort is being undertaken by regional, national, and international actors to reduce environmental impacts. The strategy consists, most often, of

measures in three categories. Modern city planning applies concepts seeking to avoid car traffic or enabling a shift towards more efficient public transport. For car traffic that cannot be avoided or shifted, smoothing measures have a large potential. Smoothing measures comprise improvements in car operation and technology. With regard to car operation;

1. occupancy of cars is low, in Switzerland, for example, 1.1 persons per car for work trips, and about 2 persons per car for leisure trips. It is a considerable challenge to integrate efficient forms of car sharing in consumer-accepted travel habits;
2. fuel consumption of cars depends heavily on their technical operation. An efficient driving style, which consists of defensive driving in high gears, results in a reduction of fuel consumption of about 10–25%.

A major shift in the behavior of consumers can only result if concerned stakeholders including manufacturers develop new lifestyle priorities in car driving based on security and efficiency. In some European countries, for example, EcoDrive is an established ecolabel which is supported by authorities in the form of lessons on eco-efficient driving and even efficiency competitions (*see* Environmental (Eco) Labeling, Volume 4).

Long-term improvements in car technology will have a decisive impact to the contribution of car traffic on global warming. Besides the improvement of air and rolling resistance of a car, two aspects of technological development predominate. A reduction of car weight is a necessary prerequisite for any drastic reduction of fuel consumption. At present, we are confronted with the general tendency towards even heavier and more powerful cars, which results from increasing demands for security and comfort as well as lifestyle-driven desires. Several approaches for weight reduction exist which relate to very different design concepts. The automobile in its present form is a vehicle optimized for a broad range of travel patterns, in particular for medium to long-distance travel. A comprehensive lightweight-strategy for the large variety of conventional cars is not realized yet, although some manufacturers refer to first successes in producing cars with an increasing amount of lightweight components and significantly decreased fuel consumption. Manufacturers, in general, argue that production costs increase significantly because of still expensive lightweight components. They leave it to future research and development to make possible the use of alternatives to steel without serious drawbacks in costs, security or comfort. A lightweight-strategy can also be developed in a very different way in the form of a car that would be optimized for city or low-distance use at lower velocities and, thus, could be built with radically reduced weight in the range between 200 and 500 kg. The use of such vehicles could be combined with public transport or railway systems and could therefore substitute most of the city or short-distance car traffic based on heavy vehicles. However, a major shift of consumers' habits would be part of this more radical lightweight-strategy. The second starting point for improved fuel efficiency is the innovation of power train systems. There exist a couple of options apart from conventional combustion engines, including battery-driven electric cars, hybrid cars combining elements of electric and combustion engines as well as fuel cell cars (Adler, 1996). The car industry seems to follow a two-sided strategy: on the one hand, the conventional combustion engine is constantly improved and, on the other hand, considerable effort is undertaken to develop fuel cell cars which are driven by hydrogen fuel. Fuel cell cars are of considerable interest since there exist several short- to long-term options to produce hydrogen fuel in a sustainable way ranging from on-board reformation of methanol gained from biomass gasification to solar production of hydrogen (Wokaun, 1999b). A fuel cell car package based on solar hydrogen could be one of the major challenges in the transportation sector in the coming decades. Large-scale technological change, involving the introduction of a new fuel supply infrastructure as well as changes towards public acceptance of new car concepts, are necessary prerequisites for this transition process.

The technological options for the worldwide fast-growing transportation sector would make an important contribution to possible solutions of pressing environmental problems, but technology is only one element in the process of change. Several other aspects have to be considered. First, transformations in all sectors have to be compatible with each other. Second, technological change has to be accepted by people living in very different societies with different histories, various norm and value systems, divergent ethical-philosophical backgrounds, with different priorities for basic needs and possibilities to cope with them. It is important that political and public acceptance is considered in the early stage of technological research (in the form of stakeholder-dialogues including e.g., IA focus groups) to support decision-making in the context of, for example, the selection of appropriate car concepts or train systems. In general, it has to be taken into account that some technological options, if not supported by lifestyle-changes, might drive the system as a whole into an even less sustainable direction. In spite of the widely held conviction that large-scale technological change, including behavior changes, are impossible and that developing-country imitation of the unsustainable lifestyle of industrialized countries is unavoidable, the evolving science of complex systems adds reasons to believe that a large-scale transition process is more than a mere esoteric dream.

COMPLEX DYNAMICS: INNOVATION AND LIFESTYLE CHANGES

During the last three decades, a major paradigm change induced by novel concepts arising in the natural sciences and associated with the notions of *chaos* and *self-organization* has lead to the development of a new science of complexity (Mainzer, 1997; Strogatz, 1998). This approach tries to circumvent important limitations encountered by traditional reductionistic methods when dealing with complex systems such as ecosystems, the global climate system, living organisms, the immune system, socio-economic systems or the human brain (Gallagher and Appenzeller, 1999). An important contribution of the developing new science is the insight that some central conceptions and beliefs of traditional natural scientists are wrong. So is the seemingly logical idea that a deterministic system can be predicted for an extended period of time. When computers began to transform science in the 1960s, the idea of P S Laplace (1749–1827), often referred to as the *demon of Laplace*, let scientists believe that e.g., weather forecasts could be extended over any desired period, if only enough computing power and observations would be available. Though computing power as well as memory size has grown a billion-fold in the meantime, weather forecast periods could be extended by a modest factor of about 10 only. Another old misconception probably dates back to Aristoteles (384–322 BC) who believed in the continuity of natural development. The idea was assimilated by the classical Romans and put into the well-known expression *natura non facit saltum* (nature does not make leaps) which found its way into the heads of today's scientists. New observations indicate that, even the largest system on our planet, the global climate system, can be subject to abrupt transitions (Greenland Ice-core Project (GRIP) Members, 1993) which could hardly contrast more with the idea of a gradual development.

These two basic characteristics of complex systems, limited predictability and prevalence of abrupt transitions, share common roots: *non-linearity* and *circular causality*. Both are ubiquitous in natural systems, where the same causes can produce different effects depending on the state of the system (non-linearity) and long chains of interlinked cause-effect relationships can lead to closed feedback loops (circular causality). An example for non-linearity is the relation between carbon dioxide concentration in the atmosphere and the resulting warming force, pushing the global climate towards another state. The already raised atmospheric CO_2 concentration increase of 32% above pre-industrial level exerts a larger climate changing force than an equivalent future increase will do. Because of the existence of many feedbacks in the climate system (circular causality), however, this saturation effect does not necessarily mean that the measured global mean temperature increase of 0.4–0.8 °C since the end of the 19th century will be an upper bound for the effect of a further anthropogenic CO_2 concentration increase of another 32%. Feedbacks including e.g., changes of the Earth's vegetation cover could induce abrupt climate change involving a large temperature increase not directly related to CO_2 growth (Houghton *et al.*, 1995). Such abrupt climate change could be induced, as soon as a yet unknown critical CO_2 concentration will be exceeded.

The most important outcome of complexity science, is probably the identification of common traits of spatio-temporal evolution for very different systems: abrupt climate change and an epilepsy episode are, from the complex systems point of view, related phenomena and their basic dynamics can be understood with rather simple mathematical models. Applied to the social phenomenon of lifestyle changes, complexity science leads us to expect the following characteristics:

The Seemingly Impossible Happens Abruptly

Looking at a given socio-economic system with its intricate interactions and interdependencies, its couplings to the existing infrastructure, to the complicated network of trade relations within itself and with other but perhaps different socio-economic systems, its correlation with the value system, beliefs and behavior of people, we are astonished by the near perfect match of the myriad of components which support each other. The classical explanation for this outcome is that the system was intentionally designed and created by the people involved. On the grounds of this explanation, it seems plausible that an intelligent dictator could make an even better design. However, why did the great historical experiments with planned economies fail? Complexity science gives an answer by suggesting a more dynamic and process-oriented view, in which small random events help a system find one of its *multiple* equilibrium states. These stable states are emergent properties of the system naturally evolving by self-organization processes. External planning efforts would act on the system as additional implied forces driving it along another path into a different state not necessarily being characterized by the efficiency and stability typical for the natural equilibria. Such a forced state is unstable in the sense that the system relaxes to one of its natural states as soon as the force is removed. Free market economies, subject to moderate planning forces only, have the possibility to evolve through their internal dynamics into one of their natural equilibria, explaining their superior stability and efficiency (Waldrop, 1992; Arthur, 1999). Because every equilibrium state shows the above mentioned astonishing match of all subsystems, another equilibrium cannot be understood on the basis of the present one and therefore seems to us impossible: today's lifestyle may not be a good reference for anticipating tomorrow's lifestyle (and e.g., its matching transport system).

From this point of view, the prominent trait of complex systems to jump from one to another equilibrium rather than changing gradually and slowly is plausible. As the components cannot be changed one by one (they would not match any more the whole system), a lot of them have to be transformed simultaneously. Due to strong couplings and feedbacks, this transition phase is short and therefore changes are *abrupt*. However, if some components almost instantaneously react to the ever-changing situation during a state transition, a new match cannot easily be established: an irregular *chaotic* phase is the system's answer. As chaos always looms in the backyard of transitions, the intuitive hesitation of politicians against changes is well founded.

Important Changes are Unpredictable, and Irreversible Surprises

Everyday life experience tells us that complex systems can slowly be brought to a critical point, where their reaction is very intense. Due to our incomplete knowledge of the internal dynamics of complex systems, we do not know of the exact location of such critical boundaries and sometimes not even that they exist. A system forced slowly in a certain direction might exceed such an invisible and so far unknown threshold and its sudden movement towards another equilibrium is a *surprise*. An abrupt global climate change at a so far unknown critical CO_2 concentration is in the same way unpredictable as a sudden change in lifestyle at critical levels of civilization, environmental damage, education, wealth, etc. In addition, an abrupt change modifies the system in such a way that a direct return to the original state is not possible. A hypothetical jump of the global climate to a warmer state beyond a critical CO_2 concentration would be *irreversible* in the sense that the system might return to the original cooler state only after a considerable reduction of CO_2 concentrations, perhaps even to below its current value (Gassmann, 1998). Because such a reduction would be impossible or at least take an excessive length of time, an abrupt climate change would have to be considered as a practically irreversible development.

Be At The Right Place In Exactly The Right Moment

Recent stability investigations reveal that e.g., complex hydrodynamic systems are almost always rather insensitive to external disturbances, even if they are in a chaotic state. So, the legendary butter y has to disturb the weather system at the right place at exactly the right moment to be effective. Computer simulations show transitory and localized sensitive hot spots, reminiscent of windows of opportunity in business or of the phenomenon called *kairos* in psychology. This Greek term for weather or time is used there to describe the narrow time window when a psychiatric treatment would be effective. In addition, this insight into the dynamics of complex systems could explain the significance of historical moments and gives us hope that the development of human history could be in uenced. At the same time, it indicates to us that we should adopt a rather modest attitude, realizing that important changes cannot be programmed to occur at the moment of our choice, but can only be induced when the system is ripe to react. This view questions versions of neo-classical economic theories that were inspired by the successful classical physical theories (applicable for rather simple and artificial systems only) and led, e.g., to the development of general equilibrium models with unique equilibrium states and poor dynamics. The science of complexity offers radically different and hopefully more realistic paradigms exhibiting *multistability* and *path-dependency*. But contrary to neo-classical theory, this dynamic rather than static equilibrium is of temporary nature: The possibility of abrupt changes to another state induced by external or internal uctuations is a permanent reality. This everlasting potential for change can be seen as a threat, but also as giving hope that our society can move towards a more sustainable future, with a better match between mankind and nature.

These concepts can be used to study very different complex systems. We concentrate on the example of a system of actors running a car eet and being affected by innovative car developments. The present car eet industry based on conventional fuels, which is run by a network of actors (customers, manufacturers, and the fuel supply industry) acting under economical, environmental, and political constraints, constitutes a complex system with many interlinked circular cause-effect relationships. The established norms and values, especially those developed in the industrialized nations, have led to a context supporting and stabilizing the traditional car types. In a first transition stage, an innovative car, e.g., powered by fuel cells, with low noise and CO_2 emissions would hardly match existing infrastructure, actual taste, and economical expectations of its potential customers. Every innovation process would be doomed to fail, if it does not take into account this initial situation.

In a social system, every individual contribution is integrated into a macroscopic pattern called *lifestyle* (*see* Life Style, Private Choice, and Environmental Governance, Volume 5), giving a context that guarantees stability of the system by circular causality (Kuppers, 1998). This relationship is analogous to the situation of an ecosystem modifying an initially hostile environment into one that tolerates a first variant of a new ecosystem. This pioneer-ecosystem pushes the environment further into a more favorable state, supporting a next step in its development. By this self-sustaining circular relationship, isolated ecosystems can survive and even expand in a general environment that, in the unmodified state, would not permit survival.

In the same sense, an innovative setup within the car industry dominated by conventional cars has to create its own environment supporting the ongoing innovation process. It can be catalyzed best, if some major concerns are part of an *innovation network* enabling strong cooperation. Not only technical aspects are optimized due to these interactions and in the course of the innovation process, but the system of norms and values changes which leads to a modified context with new opportunities for new car types. Reciprocally, the car type has to be modified until it finds a match within emerging new norms and values. As information on adverse aspects of conventional cars and prerequisites for public acceptance of the new car type have to be evaluated at the same time with the technical optimization, strong links between science, manufacturers and the public are absolutely necessary. Technical feasibility, economical success and social acceptability have to reproduce each other in a stable way, inducing an abrupt change in a carefully chosen innovation-friendly environment. For further information on the dynamics of complex systems, *see* Chaos and Predictability, Volume 1; Chaos and Cycles, Volume 2; Non-equilibrium Ecology, Volume 2; Monitoring in Support of Policy: an Adaptive Ecosystem Approach, Volume 4.

A new interaction could result if, for example, independent research institutes were to develop, with the help of IA focus groups and surveys, revolutionary car concepts that found broad acceptance among consumers. If such novel concepts, which might not be found in more interest-driven market research of car manufacturers, could be communicated to business, the at first isolated innovation region would be stabilized and in a late stage, a revolutionary car type could even be made. The links established during the innovation process would help to integrate characteristics of the operation of the new car type into the lifestyle of consumers: disadvantages of innovative cars according to today's norms and values would be turned into advantages by modifications of these norms and values. This cooperation of all involved actors would finally arrive at a point where traditional cars would be considered as old fashioned and would therefore be rejected. Today's ideals of car types with impressive power and size would lose their dominance and would give way to new values better matching the conditions for sustainable development.

CONCLUDING REMARKS

Conclusions on Citizens' Responses to GEC

What does the research on public responses to GEC discussed above imply for the interplay of the public with politics, business and science? First, the Health of the Planet survey indicates that concern about the environment in general and global environmental problems in particular seems to be on roughly the same level in developing and in developed countries. The finding that citizens of both sets of countries are not pointing the finger of blame at each other should encourage policy makers around the globe to look for a consensus on dealing with global environmental change. Often, not only government, but also individual citizens and citizen groups were seen as responsible and effective players in environmental protection. This means that citizens do not simply delegate responsibility to policy makers but are willing to assume responsibility themselves.

All three studies discussed indicate that citizens in different parts of the globe see climate change as a clear threat. Some aspects of this concern were found to be different in the three studies. While the study of Kempton *et al.*, stressed the importance placed by US residents on preserving the local environment, the ULYSSES study found that many European citizens are concerned with climate change impacts around the globe. While Kempton's results indicate, e.g., an anthropocentric justification of species preservation or its secondary importance compared to rising food costs for US residents, both the findings of the Health of the Planet survey and the ULYSSES project imply that impacts on social systems, phrased in economic terms, were not the main concern of the citizens participating in these two studies. However, Kempton's US study and the European ULYSSES project agree in the conclusion that ethical values, including a desire to preserve the environment for further generations, lead to clear citizen support for a preventive climate policy.

Concerning the role of climate change science, the studies came to different conclusions. It seems clear that there is a mismatch between expert and lay conceptualizations of climate change (see Bostrom *et al.*, 1994). However, recommendations range from increasing public education about climate science (favored by Kempton *et al.*) to considering the support by citizens for environmental protection based on a holistic fabric of the perceived ecological problematique' (implied by Dunlap). A mediating suggestion is to confront study respondents with scientific findings, but then to focus on what views on climate change and climate policy options emerge in this confrontation (as done in ULYSSES IA focus groups), rather than on how much of the expert assessments were assimilated by the participants.

Of major importance for the topic of this essay is a set of findings regarding energy prices and technology. Dunlap's survey results imply that globally there is some willingness to pay more for environmental protection. The more in-depth discussions with European citizens in the ULYSSES study support this willingness to pay somewhat more for the case of energy, but also show clearly that hard-hitting increases in energy prices could not be supported. This is in line with the finding by Kempton that energy taxes were often seen as negative by his US respondents. The ULYSSES study found clear positive associations with a

low-energy future by European citizens, who seem much more supportive of reducing overall energy use than their US counterparts participating in Kempton's study. But in both cases, while climate protection was clearly supported, high energy prices seem not to be perceived as the way to get there. This implies an essential role for technological change fostered by science and business. While technology was seen as one cause of environmental problems, Dunlap's findings also indicate as well citizens' hope that the right technological change can help to find a solution. The ULYSSES study found that (at least for the case of European citizens) the development of innovative energy-efficient products like low-energy cars is seen as crucial, and science and industry are perceived to have responsibility here. It will be their interaction with citizens and policy makers in complex social systems that will be crucial for shaping a combination of technological change and lifestyle changes as humankind's response to global environmental change.

Conclusions on Social Learning and Future Research

While technology plays a major role for a development towards a sustainable society, the technological imperative *can* implies *ought* , as widely accepted in the golden age of engineering, has to be replaced by more comprehensive approaches. Complex processes of *social learning* which result from a new quality of interaction between the public and science, business, and politics, will shape the chances for transition processes including combinations of technological change and lifestyle changes and, thus, the feasibility of effective GEC mitigation options in the future. *See* Social Learning in the Management of Global Atmospheric Risks, Volume 5.

Social learning (see, e.g., Social-learning-group, 2000) starts with the awareness of all of the actors in a complex system. Dialogues between all actors will unavoidably create new questions not confined to single areas and, therefore, open up new horizons for innovative solutions of pressing problems. According to the science of complexity, modified interaction patterns between different actors in such a network bear the potential to invoke a self-organization process leading to abrupt transitions or trend changes, which happen as a surprise to single actors in contrast to expectations of linear evolution.

In the following, we focus specifically on the interaction between the public and science, which represents, to our understanding, an especially weak link in the network of Figure 1. In principle, public and science interact in both directions. The more established interaction consists of scientists informing the public. Specifically in the last years, many research institutes all over the world have defined new programs to increase information to citizens and tax payers about their research activities. This important interaction, however, cannot compensate for the fact that there is as yet almost no direct reciprocal impact of the public on science.

The public does not just stand aside in innovation processes, profiting or suffering passively from the results of scientific discoveries and respective technical innovations. It is heavily involved in the process due to decision-making of consumers and voters. Public participation in early stages of research projects with relevance to GEC could not only make the techno-scientific enterprise more transparent but also more successful, as public acceptance would be considered from the very beginning. A dialogue between scientists and people, e.g., in form of IA focus groups, could help experts avoid linearly extrapolating their technical knowledge and neglecting important consequences of innovations. On the other hand, if lay people's creative fantasy exaggerates technological possibilities, integration of people in such a process can help to increase public acceptance for scientists' problems like, for example, the lack of simple solutions to complex problems.

New forms of interactions, e.g., between the general public and scientists, call for new tools to support communication. In this context, computer simulation and modeling could be very useful. We do not think that a future sustainable world can be designed on the basis of mathematical models; this would be reminiscent of the efforts to establish planned economies during the last century. However, we suggest that the communicative potential of models of complex systems should be exploited. Contrary to traditional scientific beliefs, adequate models will hardly be found as a by-product of disciplinary scientific research, but will require a highly interdisciplinary scientific enterprise of its own. And using such models effectively will require carefully prepared processes of model-stakeholder interactions. As a necessary prerequisite for such an endeavor, scientists have to adapt a more holistic view allowing them to see their own research field as a valuable contribution, rather than the only or at least the main part of the scientific adventure. We consider it as an exciting challenge that an adequate research agenda for the decades to come, when questions in the grey area between natural and social sciences arise, can only be addressed in a collaborative effort involving science, business, politics, *and* the public.

Scientific Responses in an Era of Global Environmental Change

PHILIPPE BOURDEAU

Université Libre de Bruxelles, Brussels, Belgium

" Panta rhei, oùden menei" (All is in ux, nothing is stationary), said Heracleitus 2600 years ago. What is new about global environmental change (GEC) is the increased rate and scale of change imposed on the environment by human activities. Science is playing a major role in detecting evidence of this new trend and in predicting its frequently negative consequences, as well as in devising responses to it. Its function remains essential but will also have to evolve. Early on scientists foresaw several of the large-scale environmental issues that subsequently developed, such as acidi cation and the impact on climate of the release of carbon dioxide (CO_2) in the atmosphere from coal combustion, but these warnings went initially unheeded. In the late 1960s the international scienti c community as a whole, represented, inter alia, by the International Council for Science (ICSU) and its Scienti c Committee on Problems of the Environment (SCOPE), or ICSU - SCOPE, became deeply concerned with the new environmental threats. SCOPE identi ed and assessed the main environmental problems of the time and made recommendations, which provided an important input to the 1972 UN (United Nations) Conference on the Human Environment. Thereafter, it kept a continuous watch to detect emerging issues, such as the depletion of the ozone layer or the loss in biodiversity. At about the same time, other international scienti c bodies planned and coordinated large research programs, such as GARP (Global Atmospheric Research Program), WCRP (World Climate Research Program), MAB (Man and Biosphere), IGBP (International Geosphere Biosphere Program), etc., in order to acquire additional knowledge necessary to respond effectively to global environmental threats. These programs provided a framework for de ning and funding research priorities at the national, supranational (e.g., European Union (EU)) and international level. This was made possible through cooperation between the science community and bodies such as WMO (World Meteorological Organization), UNEP (United Nations Environment Programme), WHO (World Health Organization), UNESCO (United Nations Educational, Scienti c and Cultural Organization), OECD (Organization for Economic Cooperation and Development), IUCN, etc. Assessments of research ndings, for example those of IPCC (Intergovernmental Panel on Climate Change), paved the way for the signing of various international conventions (e.g., Stratospheric Ozone Layer (1985), Climate Change and the Protection of Biological Diversity (1992)). It was soon realized that human factors were all important if successful solutions were to be found and implemented, hence the rise of research programs like the IHDP (International Human Dimension Program). Many environmental issues are complex and fraught with uncertainty, if not indeterminacy. This of course is compounded when the human element is factored in, hence the recognition of the precautionary principle and the need for humility on the part of scientists. This is now increasingly recognized and efforts are made to develop integrated environmental assessments taking into account all aspects of an issue and involving all stakeholders. Science also played a most important role in providing the basis for the development of technologies aimed at monitoring the environment and at curing environmental damage, or better yet, at preventing it through better industrial processes and cleaner products. The private sector is increasingly involved in funding R&D in this area. The paradigm of sustainable development, widely adopted since the 1992 UN Conference on Environment and Development, implies the integration of environmental concerns in all sectors of the economy and should guide future research priorities. Some of the main emerging issues for the 21st century are likely to be old issues, which take on new aspects as the result of the rapidly changing socio-economic scene due to globalization of the economy, the development of information technologies leading to the information society, and the growing impact of biotechnologies, as well as new social expectations in general. Surprises

cannot be excluded, however, despite progress in monitoring, modeling, and forecasting. Science must, of course, continue to improve the understanding of the basic life-support systems of the planet and there is still much to do in this area but it must also be very much concerned with policy-related research. This means supporting the goal of environmentally sustainable development through the better use of natural resources (eco-ef ciency) and modi cation of human behavior. " Science should be on tap, not on top," said Churchill. Policy-making must always be based on the best available science but many other, more subjective, factors have to be taken into account. The precautionary principle and scienti c information should be applied complementarily, not in opposition, to each other, as some would now like to see it. Finally, scientists should respect ethical standards with regard to scienti c integrity, quality assurance, recognition of uncertainties and of biases, as well as communication with decision makers and the public at large.

INTRODUCTION

The environment has never been static. All is in ux said a Greek philosopher 26 centuries ago. Astronomical and geological factors have produced considerable variations in climate and sea level over past millennia. Ecological succession has transformed terrestrial and aquatic biomes. However, man-made change has increased at an ever-growing rate and reached global proportions in the last 100 years, altering the composition of the atmosphere, profoundly disturbing biogeochemical cycles and drastically reducing biological diversity. Some of these changes have occurred as surprises while scientists predicted others, sometimes long before their actual appearance.

In the following sections the historical development of the GEC issue is discussed from the perspective of scientists. It is not intended to provide a comprehensive overview of scientific activities pertaining to the issue, but to discuss brie y the role of scientists in identifying and clarifying problems and their contributions in managing them, and to see what the future may have in store. The examples given are mainly at the international level but it should be realized that most major national research projects and programs on GEC have been designed and implemented in an international framework or context.

THE ROLE OF SCIENCE IN ENVIRONMENTAL POLICY

On defining environmental policy, as aimed mainly at managing man-made environmental risks (but also man-enhanced natural risks), a rational approach is first to gain adequate knowledge of the causes and effects of the phenomenon under consideration in order to assess the importance of the risk (*risk* is defined as the probability of occurrence of an undesirable effect or hazard). Thus, scientific information is necessary, if not sufficient, for successful control of the risk. There should also be the technical means to counter it, the political will to do it, and the necessary economic resources.

As recognized by Holdgate and White (1977), environmental issues, to which science can make profound contributions, may be grouped in three categories:

- those solved successfully by the application of existing scientific knowledge;
- those which existing knowledge could solve but where social or economic factors limit action;
- those requiring more scientific knowledge.

Scientists have been involved with man-made environmental change in various ways:

- identifying issues, elucidating their causes and effects and determining effective solutions and counter-measures (e.g., air pollution by sulfur dioxide (SO_2) and smoke);
- pursuing basic research on the structure and functioning of the earth systems (climate, biogeochemical cycles, energy ows, ecosystems, etc.);
- interpreting monitoring data, collected for other purposes, such as the study of fundamental processes, thereby detecting new issues (e.g., monitoring of ultraviolet (UV) radiation as a measure of stratospheric ozone above the Antarctic);
- performing comprehensive assessments of scientific information pertaining to an environmental issue, in order to present the information in a policy-relevant way (e.g., SCOPE at the non-governmental and the IPCC at the inter-governmental levels) and to define gaps in knowledge and research needs;
- carrying out state-of-the-environment reports at various geographical scales to assist decision making and inform the public.

While, initially, natural sciences were almost exclusively involved, the socio-economic disciplines have increasingly been called upon to resolve problems as it became evident that:

- perception of risk plays an important role;
- solutions often imply changes in human behavior;

- some environmental issues are characterized by complexity and uncertainty and bring into play the precautionary principle.

EARLY SCIENTIFIC CONTRIBUTIONS TO THE UNDERSTANDING OR PREDICTION OF MAN-MADE ENVIRONMENTAL PROBLEMS

Arrhenius in 1896 and Chamberlain in 1899 reasoned that the luxuriance of vegetation in the Carboniferous period was associated with the effect of high carbon dioxide (CO_2) concentration in the atmosphere. Arrhenius also foresaw the problem of acid rain.

In 1923, W Vernadski, a member of the Academy of Sciences of Russia, published a book in French (*La Géochimie*) presenting to a Western audience the results of Russian research at the end of the 19th and early 20th century (Vernadski, 1924). He outlined the carbon cycle, giving estimates of the amount sequestered in biomass and of the quantities released in burning coal and their possible impact on climate. He concluded, rightly, that humans had become a new geological force, moving chemical elements, such as metals, in amounts of the same order of magnitude as natural phenomena. He also mentioned the phytoplankton blooms in the Adriatic Sea, which form gelatinous masses and break down the silica balance in seawater. Vernadski introduced the *noosphere* concept as an addition to the geosphere and the biosphere, to designate the collective human thought, which impacts the environment (*see* Noosphere, Volume 5) (could we consider the Internet as a concrete manifestation of the noosphere?).

Continuous measurements of atmospheric CO_2 concentration were initiated in 1957 on Mauna Loa in Hawaii and have provided an invaluable baseline for monitoring changes in the carbon cycle. Similar measures were made in Scandinavia from 1955–1960.

The chemical constituents of precipitation were measured through a special observation network organized by the International Meteorological Institute of Stockholm University as early as 1954, and systematic observations were undertaken in the USSR in 1957, while in the USA measurements were made in 1955 and 1956, then resumed in the 1970s. All showed the rise of sulphates, nitrates and acidity.

Photochemical oxidants were identified as causing smog in Los Angeles in the 1950s. They were found to be secondary pollutants formed from nitrogen oxides and unburned hydrocarbons. This led to the adoption of catalyzers in the exhaust systems of automobiles and the banning of lead additives in gasoline since they poisoned the catalyzers. Elsewhere and later on, lead additives were phased out when epidemiological research showed the negative correlation between children's mental development and blood lead levels at even very low values.

The threat to stratospheric ozone caused by chloro uorocarbons (CFCs) emission was suspected by Rowland and Molina as early as 1972–1973. Stratospheric ozone had been measured with the Dobson spectrophotometer since the 1930s. Observations were started in the Antarctic during the International Geophysical Year (IGY) of 1957 and fortunately continued every year from March to October. This is how Farman discovered the so-called ozone hole in the Antarctic in 1982. It is interesting to note that satellite observations (Nimbus 7) from the same period did not detect the phenomenon because values lower than a certain level (180 Dobson units) were automatically deleted as being due to experimental error (Gribbin, 1988). The confirmation of ozone destruction by CFCs and other chemicals led to the adoption of the international convention for the protection of the ozone layer (Vienna, 1985) and its Montreal protocol of 1987. This was the first global environmental convention.

Inland waters became a concern with regard both to quantity and quality. The International Hydrological Decade (1965–1974), followed by the International Hydrological Program, assessed water stocks. Eutrophication of lakes and rivers became a large problem in many countries in the mid 1950s. The OECD-sponsored research in this area identified phosphorus as the main culprit. This made it possible to implement successful lake rehabilitation projects.

The IUCN, now the World Conservation Union, recognized early on the threat caused by the destruction of natural vegetation, in particular tropical forests, and the importance of the preservation of biological diversity.

The marine environment was the concern of, *inter alia*, the International Council for the Exploration of the Sea (ICES) together with the International Ocean Commission (IOC), and the Monaco Laboratory of the International Atomic Energy Agency. It organized inter-calibration exercises for the quantitative determination of very low concentrations of marine pollutants, following such events as the Minamata Bay mercury contamination and the detection of dichloro-diphenyl-trichloro-ethane (DDT) and polychlorinated biphenyl (PCB) residues in marine life.

Pollution by man-made chemicals was also a concern on land. Research showed that organo–mercuric compounds used for seed dressing killed birds in Sweden, that DDT made spring silent in the USA (Carson, 1962) and that it reduced predatory bird populations through thinning of eggshells and behavior modifications. As a consequence these pesticides were banned in many countries.

Mention should also be made of research on radioactive contamination, which was carried out in several countries, starting with the USA, in the Columbia River near Hanford (Washington) during World War II and culminating during the period of intensive nuclear weapons testing up to the test-ban treaty of 1963. Megaton-size hydrogen bombs detonated in the atmosphere generated global fallout, which

could be traced in all environmental compartments and along food chains, and it was discovered later that DDT residues circulated around the planet in the same way as strontium 90. The tracing of exposure pathways made possible by the high sensitivity of radiation detection, combined with radiobiological research, enabled the development of a methodology of radioprotection (critical radionuclide, critical pathway, critical target group) which was later adapted, *mutatis mutandis*, to chemical pollution and spurred the development of *eco-toxicology* (*see* Ecotoxicology, Volume 3).

INTERNATIONAL SCIENTIFIC ACTIVITIES IN THE ENVIRONMENTAL FIELD

The examples of early research, given above, led to more concerted programs aimed at gaining a better scientific understanding of all aspects of environmental issues. Many programs were carried out and funded at the national level and it would be impossible to review them here. However, most of these activities, especially if dealing with GEC, were related more or less closely to international efforts, which often provided them with a framework or at least a context. Therefore, only international projects and programs are brie y discussed hereafter, without any claim to comprehensiveness.

United Nations Environment Programme (UNEP) (*see also* UNEP (United Nations Environment Programme), Volume 4)

In considering science and environmental policy, special mention must be made of the role of UNEP. Originating from the 1972 UN Conference on the Human Environment in Stockholm, which was based, as already mentioned, on a considerable scientific input, UNEP is often called the environmental conscience of the UN system. It has remained a program, not an agency or organization, providing a mechanism to integrate a large number of intergovernmental, non-governmental and national activities aimed at protecting the environment.

Despite its structural weakness and chronic under-funding, UNEP has many achievements to its credit, in the areas of global monitoring, environmental information and assessment, pollution control, chemical data banks (over 8000 chemicals in the International Register of Potentially Toxic Chemicals (IRPTC)), protection of marine resources, biodiversity (e.g., the Global Biodiversity Assessment of 1995, carried out by over 1500 scientists), climate (UNEP was co-founder of the IPCC, see later), desertification control, cleaner production, technology transfer, environmental education and awareness. One of its great successes is undoubtedly the 1985 Vienna Convention on the protection of the ozone layer, already mentioned, which was solidly grounded in science.

UNEP has always considered that one of its most important functions was the promotion of environmental science and information. It coordinated the production of a large number of state of the environment reports. More recently it started producing global environment outlooks (GEOs) – GEO 1, GEO 2000. These aim at providing an overview of major global environment concerns, their causes and impacts, and they identify, from a regional perspective, the priority issues that the international community should address. They are also meant to generate a continuous global assessment process through a scientific and policy-consultative mechanism with strong regional participation, by means of a network of public and non-governmental collaborating centers.

The global environment monitoring system (GEMS) was set up early by UNEP as a worldwide collective effort to monitor and assess the health of the global environment. Later, the global resource information database (GRID) was added to provide reliable geo-referenced data and information useful for policy purposes and decision-making. These two activities and the GEO process have now been integrated in a new Environmental Observing and Assessment Strategy, which enhances UNEP's role in this area and enjoys strong political support. The functional elements of this strategy are: assessment and reporting, environmental observing, data analysis and integration, and strategic oversight and early warning. This last element implies strengthening ties to the scientific community to ensure that the best scientific insights are available and, conversely, that research priorities to resolve uncertainties or to guide management decisions are made known to scientists.

To respond to the challenge of the goal of environmentally sustainable development, UNEP has moved into the area of environment and economics, concentrating on methodologies. This includes research on valuation of environmental and natural resources to be used in cost–benefit analysis, risk assessment, environmental impact assessment of projects and programs, and internalization of environmental costs. Work is also done on integrated environmental and economic accounting (IEEA) for national accounts in order, *inter alia* to bring out the implications of development plans on the depletion and degradation of natural resources, as well as on economic instruments.

From its inception, UNEP's leadership has consistently supported scientific research and worked closely with the ICSU and, in particular, SCOPE.

ICSU (*see also* ICSU (International Council for Science), Volume 4)

ICSU, now appropriately called the International Council for Science, has played a pioneering and major role,

on the international scene, in applications of science in environmental policy formulation.

As an independent body representing science on a worldwide level, ICSU is ideally suited to serve as a partner to policy makers to provide scientific understanding of problems of the global environment. As such, it helped, through its SCOPE committee, the UN in preparing the 1972 Stockholm Conference on the Human Environment and was the scientific advisor for the 1992 Rio United Nations Conference on Environment and Development (UNCED). ICSU's environmental involvement, however, dates back to 1957 when it organized the IGY, which served as a model for subsequent international environmental research and assessment programs (Greenaway, 1996). IGY was very successful in bringing scientists from many countries to make coordinated measurements of physical parameters at the time of the cold war, and it led eventually to the Antarctic Treaty. It served as a model for other international programs (*see* IGY (International Geophysical Year), Volume 1).

The International Biological Program (IBP), ran from 1964–1974 (biological processes require generally more time to be studied than physical phenomena). Its main thrust was to investigate biological productivity on land, in freshwater and marine environments. It also included a section on human adaptability. It resulted in a very large body of information on the productivity of ecosystems of all kinds and in many places and, as such, provided a valuable basis for later assessments of the effects of human disturbance on the environment (*see* International Biosphere Program (IBP) a Foundation for Global Studies, Volume 2).

SCOPE (*see also* SCOPE (Scientific Committee on Problems of the Environment), Volume 4)

SCOPE, was established by ICSU in 1969, following an initiative of T F Malone. Its mandate is to advance knowledge of the in uence of humans on their environment, as well as the effects of these environmental changes upon people ••• as well as to serve as a non-governmental, interdisciplinary and international council of scientists and as a source of advice for the benefit of governments ••• . Its function is thus to produce authoritative assessments of environmental problems in order to identify and prioritize research needs and to summarize scientific knowledge for use by policy makers.

As an interface between science and decision making, SCOPE has focused on major environmental issues such as environmental monitoring, climate, biogeochemical cycles, environmental chemicals and eco-toxicology, the environmental consequences of nuclear war, the role of biodiversity, invasive species, etc., and more recently to environmental sustainability as well as environment and economics. It has spawned a number of international research programs, such as the WCRP and IGBP mentioned later.

Man and Biosphere (MAB) (United Nations Educational, Scientific and Cultural Organization (UNESCO)) (*see also* UNESCO (United Nations Educational Scientific and Cultural Organization) and the Environment, Volume 4)

IBP, a non-governmental scientific program of ICSU led to the still-running intergovernmental MAB program of UNESCO. Its general objective is to develop the basis within the natural and social sciences for the rational use and conservation of the resources of the biosphere and for the improvement of the global relationship between Man and the environment; to predict the consequences of today's action on tomorrow's world and thereby to increase Man's ability to manage efficiently the natural resources of the biosphere.

MAB launched a large number of projects dealing particularly with the ecological effects of human activities on tropical and temperate forests, grasslands and savannas, arid ecosystems, freshwater and wetland systems, tundras, and interestingly, the ecological aspects of urban systems. After almost three decades, MAB has increased considerably the knowledge of the biosphere and the role of humans in its modifications. One of its major achievements is the network of *Biosphere Reserves* (*see* Biosphere Reserves, Volume 2), of which there are now 352, some of them very large, providing not only a rich basis for the study of biodiversity and its preservation, but also sites for the Global Terrestrial Observing System (GTOS), see the section on the global observing program. Over the years MAB has evolved and is now focusing on new approaches to facilitate sustainable development.

IUCN, Now the World Conservation Union (*see also* IUCN (The World Conservation Union), Volume 4)

While only partially a research organization, IUCN, which celebrated recently its 50th anniversary, has been an important international body whose mission to conserve the integrity and diversity of nature, and ensure that any use of natural resources is equitable and ecologically sustainable is embedded in science.

It is not a pure NGO (non-governmental organization) but a union of governments, governmental agencies (such as the Environmental Protection Agency in the USA) and NGO's working at protecting nature in the field and at the policy level. It has enlisted the help of many scientists and works closely with ICSU and its unions and committees as well as with UN organizations. Without going into detail, suffice it to say that, besides its well-known *red lists of threatened*

species, it was the first to advocate sustainable development in its World Conservation Strategy in the late 1970s, a concept adopted by the Brundtland Commission in 1987 and endorsed by the 1992 UNCED in Rio, and now the official policy of many countries and, among others, the EU. IUCN was also responsible for drafting the convention on the protection of biological diversity, which was eventually signed in Rio.

The UN Food and Agriculture Organization (FAO)

The mandate of the FAO is to raise levels of nutrition and standards of living, to improve agricultural productivity and to better the conditions of rural populations. Its motto is the access of all people at all times to the food they need for an active and healthy life. It is active in plant and animal production, forestry, fisheries, land and water development, nutrition, etc., but also in social and economic policies. A current priority is to encourage sustainable agriculture and rural development by means of a long-term strategy for the conservation and management of natural resources.

Together with the Consultative Group on International Agricultural Research (CGIAR), an informal association of donors which it sponsors jointly with UNEP and the United Nations Development Program (UNDP), FAO addresses the environmental problems generated by the otherwise beneficial green revolution which was initiated by the Rockefeller Foundation in the 1950s.

In pursuing its general objectives, FAO promotes scientific and technological research and maintains data bases of interest to environmental policy, for example in the areas of climate, water and soil resources, terrestrial ecosystem monitoring, etc.

World Meteorological Organization (WMO) (*see also* WMO (World Meteorological Organization), Volume 1)

WMO is concerned with weather and climate. It is among the sponsors of the WCRP and the IPCC. It also publishes periodic reports on the stratospheric ozone layer and other data of interest to environmental policy.

WCRP

This program is jointly supported by the WMO, ICSU and the IOC, itself linked to UNESCO. Initiated in 1980, it succeeded GARP, dating from 1967. It is aimed at developing the fundamental scientific understanding of the climate system and climate processes needed to determine to what extent climate can be predicted and the extent of Man's in uence on climate. The program includes not only observational and diagnostic research leading to a quantitative understanding of climate processes, such as exchanges between atmosphere, ocean and sea-ice, interactions between radiation, land surface and the hydrological cycle, but also the development of global climate models able to simulate the present climate and to predict climate variations at different time and space scales. It has a number of projects known by their acronyms: GEWEX (Global Energy and Water Cycle Experiment), CLIVAR (Climate Variability and Predictability), TOGA (Tropical Ocean Global Atmosphere), WOCE (World Ocean Circulation Experiment), etc., the results of which have provided substantial inputs to the assessments carried out by the IPCC, see later.

IGBP (*see also* IGBP Core Projects, Volume 2; IGBP (International Geosphere–Biosphere Programme), Volume 2)

As WCRP developed, it became evident that there should be a broadening of climate change to the concept of global change. SCOPE was instrumental in promoting this idea. G F White, its president at the time, and M K Tolba, Executive Director of UNEP, issued a declaration on Global Life Support Systems in 1979 in which they said ••• we draw attention to the fundamental scientific importance of understanding the biogeochemical cycles which link and unify the major chemical and biological processes of the earth's surface and the atmosphere. The idea was picked up by ICSU and eventually the IGBP was launched in 1986. Like other international environmental research programs, it provides a framework developed and controlled by a central scientific committee, within which countries and bodies such as the EU can fund and implement their own scientific priorities but in an integrated and coordinated way, thus using their resources more efficiently. Central funding is a persistent problem in these cases, hence the creation of the International Group of Funding Agencies (IGFA), which attempts not only to provide what was called glue money for this purpose but also to see that at the national or regional level relevant research is financed.

The goal of IGBP is to describe and understand the interactive physical, chemical and biological processes that regulate the total Earth system, the unique environment that it provides for life, the changes that are occurring in this system, and the manner in which they are in uenced by human actions.

The science plan was published in 1990 after long and careful preparation. Six key questions are currently addressed by eight so-called core projects (acronyms given below). These are:

- how is the chemistry of the global atmosphere regulated and what is the role of biological processes in producing and consuming trace gases? (International Global Atmospheric Chemistry Project, IGAC);

- how will global changes affect terrestrial ecosystems? (Global Change and Terrestrial Ecosystems, GCTE and Land Use and Land Cover Change Project, LUCC);
- how does vegetation interact with physical processes of the hydrological cycle? (Biospheric Aspects of the Hydrological Cycle, BAHC);
- how will changes in land-use, sea level and climate alter coastal ecosystems, and what are the wider consequences? (Land–Ocean Interactions in the Coastal Zone, LOICZ);
- how do ocean biogeochemical processes in uence and respond to climate change? (Joint Global Ocean Flux Study, JGOFS and Global Ocean Ecosystem Dynamics, GLOBEC);
- what significant climate and environmental changes have occurred in the past and what were their causes? (past global changes, PAGES).

There are also crosscutting activities dealing with data and information systems, global analysis, interpretation and modeling (Global Analysis, Integration, and Modeling, GAIM), analysis, research and training at the regional level (global change system for analysis, research and training, START).

Thus, IGBP is a strategic research effort, which, while dealing with fundamental scientific issues, focuses on those questions that are most likely to lead to a practical and predictive capability, and consequently contribute to policy decision-making. IGBP has already produced a wealth of data. Just to mention one example, much of the scientific basis for the 1995 report (up-dated in 1997) of IPCC Working Group (WG) II on the impacts of climate change comes from IGBP-related research.

International Human Dimension Program (IHDP) (*see also* IHDP (International Human Dimensions Programme on Global Change), Volume 4)

After the initiation of IGBP, the international scientific community came to realize that the response of human societies to GEC was as important to understand as the physical mechanisms involved, in order to devise policies to mitigate and adapt to it. Hence the IHDP which was launched by the International Social Science Council (ISSC) in 1990 and consolidated in 1996 when ICSU joined in.

Human dimensions are defined as the ways in which individuals and societies contribute to GEC, are in uenced by it and mitigate it and adapt to it.

After a slow start, IHDP seems to be running well, with, currently, four science projects:

- LUCC jointly with IGBP;
- GEC and human security (GECHS);
- institutional dimensions of GEC (IDGEC));
- industrial transformation (IT).

DIVERSITAS (*see* DIVERSITAS, Volume 2)

This is a program aiming at coordinating a worldwide research effort on biological diversity. Established in 1991, it is sponsored by UNESCO and various bodies of ICSU, including SCOPE and the International Union of Biological Sciences (IUBS) thus involving NGOs and an intergovernmental bodies. Its goal is to provide accurate scientific information and predictive models of the status of biodiversity and sustainability of the use of biotic resources as well as to build a worldwide capacity for the science of biodiversity. It is expected to provide scientific input to the implementation of the Convention on Biological Diversity. Its achievements have been somewhat limited so far. Noteworthy is the work done by SCOPE on the ecosystem function of biodiversity and on the problem of invasive species, the latter now undertaken with the financial support of GEF (Global Environmental Facility), a joint program of the World Bank UNDP, and UNEP, see later). DIVERSITAS is now organizing an International Biodiversity Observation Year (IBOY), which should begin in 2001.

Global Observing Programs

The purpose of these programs is to provide a continuous check of the environmental status of the planet. They include the Global Climate Observing System (GCOS), which collects and disseminates data, on, e.g., the El Nino phenomenon, the Global Ocean Observing System (GOOS) with modules on pollution, living marine resources, coastal problems, and the Global Terrestrial Observing System (GTOS) looking at changes in land quality, freshwater resources, biodiversity, pollution, etc. Using remote-sensing data from space as well as ground level observations, the overall system aims at bringing science and policymaking closer together in order to address global change issues.

The systems are not yet all operational. If properly funded, they should provide invaluable help in framing and assessing the effectiveness of worldwide environmental policies.

IPCC (*see also* Intergovernmental Panel on Climate Change (IPCC): an Historical Review, Volume 4)

IPCC is a unique body. Placed at the interface between science and policy for the issue of man-induced climate change, it was set up in 1988 by WMO and UNEP with a scientific mandate but within a political institutional framework. Because of its *modus operandi* it is actually more a transitional zone that a sharp interface. Its most scientific component is WG I, which provides assessments of the science of climate change while WG II assesses the impacts of climate change. Initially, WG III was established to formulate response strategies but in 1992 WGs II and III

were merged with the task of assessing response options in addition to impacts; and a new WG III was created to look at the socio-economic dimension of climate change and other cross-cutting issues.

The IPCC decision-making process involves three levels: the scientific core in each WG, the WG plenary and the full plenary. In the plenaries, every line in the draft reports is discussed at length until a consensus is reached. This leads sometimes to situations where statements accepted by the scientists are watered down to satisfy representatives from countries with no notable scientific expertise but strong vested economic interests in, e.g., fossil fuels.

IPCC, however, has succeeded in enlisting the participation of most leading scientists in the relevant fields who review all published literature (including that originating from WCRP and IGBP). It has produced so far two major assessment reports with executive summaries (1990 and 1995) plus many scientific and technical papers, and is preparing its third assessment report. One of its most well known statements (1995) is that the balance of evidence suggests that there is a discernible human in uence on global climate. There are still some *bona de* scientists, however, who dispute this statement, not to speak of various national and international industrial lobbies.

Four years after the establishment of IPCC the United Nations Framework Convention on Climate Change (UNFCCC) was signed in 1992 in Rio and a Conference of the Parties was subsequently set up. The fact that the Kyoto Protocol of 1997 includes obligations to reduce greenhouse gases emissions (5.2% below the 1990 levels by 2012!) is considered a mark of the success of IPCC, even though the reduction is much too small to achieve what IPCC estimates to be necessary to slow down global warming to an acceptable rate.

Be that as it may, IPCC may be considered as a model exemplar in the science-environmental policy dialogue. Its integrated assessments have so far not been replicated for other global environmental issues.

ASCEND 21

ASCEND 21 stands for an Agenda of Science for Environment and Development into the 21st Century. It was prepared by ICSU in cooperation with the Third World Academy of Sciences (TWAS) through a conference, which took place in Vienna in 1991. Aimed at defining a science agenda for the next 10–20 years, it was to provide a consolidated contribution to the 1992 UNCED Conference (where ICSU was the official scientific advising body) as well as a perspective for the future direction of international science in the areas of environment and development.

It proved to be a most valuable exercise in that top scientists from around the world jointly produced a broad review of the issues of highest priority, including the unknowns and uncertainties, and recommendations for mid and long term research. It covered the major driving forces (population, land use, industry and wastes, energy, health), scientific understanding of the Earth system (global cycles, atmosphere, marine and coastal systems, land resources, fresh water resources) and the contribution of science to environment and development strategies (quality of life, public awareness, capacity building, policies for technology, institutional arrangements).

The conference provided a fundamental input for the formulation of Agenda 21 adopted in Rio.

Global Environmental Facility (GEF) and Scientific and Technical Advisory Panel (STAP)

The GEF was established in 1991 as a joint program between UNDP, UNEP and the World Bank, in the context of preparation for UNCED, in order to help solve global environmental problems. Essentially, it provides funding, mostly to developing countries, to meet the costs of measures to fulfill international obligations in four areas related to GEC, namely the protection of biodiversity, of the ozone layer and of international waters, as well as the reduction of greenhouse gases emissions.

It was soon realized that before taking decisions to spend large sums of money on projects, GEF needed sound scientific advice, hence the setting up of STAP. STAP provides objective, strategic and technical advice on GEF policies, operational strategies and programs and also performs reviews of projects, using a roster of experts. One of the main studies it is currently conducting is the global international waters assessment (GIWA).

Commission for Sustainable Development (CSD), (*see also* CSD (Commission on Sustainable Development), Volume 4)

The UN CSD was set up to ensure effective follow-up of UNCED and in particular of the implementation of Agenda 21. It does not have any scientific program as such but some of its activities call for scientific information and research. An example is the definition and testing of indicators of sustainable development, which has spurred much research on this subject throughout the world.

OECD (*see also* OECD (Organization for Economic Co-operation and Development), Volume 4)

The OECD, sometimes called the rich countries' club, although concerned mostly with economic issues, was a pioneer in the assessment of environmental chemicals, i.e., manufactured substances that found their way into the environment and could cause harm to humans and ecosystems. The reason for concern by an economic

organization was that uneven constraints put to the marketing of new chemicals would interfere with free trade. Testing systems were devised for the evaluation of degradability, pathways, exposure patterns, toxicological and eco-toxicological effects, etc., stimulating research in these fields. More recently OECD was instrumental in organizing work-sharing in the assessment of high production volume chemicals, marketed since before systematic testing was imposed.

OECD has also done significant work in environmental data reporting on the basis of the pressure–state–impact (PSI) scheme, on assessment of country environmental performance, on the development of a core set of environmental indicators and it is now much involved in environmental economic issues, sustainable consumption and production, as well as eco-efficiency.

World Health Organization (WHO)–International Program on Chemical Safety (IPCS)

WHO has been concerned with environmental health and, in cooperation with UNEP and ILO (International Labor Organization), launched in 1980 the IPCS which developed a number of valuable activities in two directions: to establish the basis for the scientific health and environmental risk assessment for safe use of chemicals, and to strengthen national capabilities for chemical safety, especially in developing countries. IPCS has promoted methodological research on health and environmental assessment of chemicals and established guideline values for many chemicals. It was the initiator of the International Forum on Chemical Safety in 1994, where government representatives meet to reach consensus in implementing Chapter 19 (Chemicals) of Agenda 21. WHO has recently downgraded IPCS, which is unfortunate considering the persisting concern with chemical risk, to wit the current scare about endocrine disruptors.

United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR)

UNSCEAR reviews and assesses scientific data on the biological effects of ionizing radiation and has published much information on environmental radioactive contamination, critical radionuclides, pathways and population groups. It provides background material to the international commission on radiation protection (ICRP) for setting and revising radioprotection norms.

United Nations Economic Commission for Europe (UNECE)

The UNECE (which covers also the USA and Canada) was an early player in environmental issues and provided a good example of successful regional science-policy cooperation. A major achievement was the 1979 Geneva Convention on long-range transboundary air pollution (LRTAP), originating from concern over acid precipitation and based on a well-coordinated research effort (involving among others the International Institute of Applied System Analysis (IIASA) where scientists from the Soviet block cooperated with those from the West). This involved inventories of SO_2 emissions in Europe and modeling of transport so that countries could be assigned emission reduction targets. The convention established a broad framework for cooperative action on reducing the impact of air pollution and set up a process for negotiating concrete measures to control emissions of air pollutants through legally binding protocols.

To implement this process a scientific program was set up, called EMEP (co-operative program for monitoring and evaluation of the long-range transmission of air pollutants in Europe). Its role is to supply governments with qualified scientific information to support the evaluation and further development of the various protocols on emission reductions (sulfur, nitrogen oxides, volatile organic compounds, heavy metals, persistent organic pollutants). It does this by collecting emission, air and precipitation data and modeling atmospheric transport and deposition of air pollution.

CURRENT CHALLENGES AND PRIORITIES FOR GEC SCIENCE

In attempting to discuss the role of global environmental science in the 21st century, one has first to consider the rapidly changing societal context in which environment policy has to operate. Spurred by geopolitical upheavals (e.g., the collapse of the Soviet empire) and technical progress (in particular information and communication technologies), the phenomenon of globalization has accelerated with the free movement of capital and goods, the general adoption of the Western model, the decreased power of governments in relation to that of multinational corporations and even of NGOs. The World Trade Organization (WTO) is now taking decisions affecting the global environment and that of individual countries, sometimes even ignoring existing multilateral environment agreements, and the environmental constituency in the UN is no match for it. There are also rising social and environmental expectations and changing consumer preferences.

The paradigm of sustainable development, with its social, economic and environmental components, has been formally adopted worldwide. It is generally agreed that, despite the vagueness of the concept, sustainable management and use of natural resources and sustainable patterns of production and consumption are the only ways to meet the needs of present and future generations. A central concept in this respect is *eco-ef ciency* which aims to make increases in production of goods and services generate proportionally

less environmental damage and less use of natural resources (*see* Eco-efficiency, Volume 4).

To strive toward this goal implies the integration of environmental and economic decision-making and the inclusion of an environmental dimension in all sectoral policies (agriculture, industry, energy, transport, tourism, etc.). A logical approach is the driving forces, pressures, state, impacts and responses (DPSIR)-framework (*see* DPSIR (Driving Forces Pressures State Impacts Responses), Volume 4). In the past, responses dealt mainly with correcting the impacts on human health and on the environment. Then came action on pressures, such as emission reductions of air and water pollutants. In future the emphasis should be put on action at the driving force level. This can be done either by modifying the processes and products, which provide a certain service or in managing demand for this same service, or more likely both. Policies should aim at optimizing the responses, helped by science, which should not only identify the issues but also contribute in determining the most effective options. Once a policy is implemented, its effectiveness should be checked, using performance indicators, especially at the economic sector level. Here again is a priority for research.

Another consideration is that of complexity and uncertainty. Major issues relating to natural systems (such as climate) are complex in themselves and fraught with uncertainty and this is compounded by the need for modifications of human behavior in order to implement solutions. Adding to the negative attitude toward science, which has been developing, particularly in the area of risk assessment and management, new ways must be found to achieve effective interaction between scientists, whether they be in the natural or social sciences, and all other stakeholders. Hence the development of *post-normal science*, i.e., science which takes account of the uncertainty of quantitative data and the biases of scientists themselves (*see* Post-normal Science, Volume 5). In this respect, the implementation of the precautionary principle poses problems. Precaution should not be opposed to science-based regulation but the two should be complementary. As Churchill said during World War II, science should be on tap, not on top, in the sense that decisions should always be based on the best available scientific information but that may not suffice. Scientific risk analysis is unavoidably and inextricably intertwined with subjective framing assumptions, values, trade-offs and expectations of surprise (Stirling, 1999).

Policy-related research is under strong pressure to provide magic numbers (as few as possible), to facilitate the tasks of political and administrative decision makers, hence the current high popularity of indicators. While these can undoubtedly be useful tools, much care must be exercised in selecting them and especially in clarifying their limits. Indicators are useless if the data on which they are based are lacking or unreliable. Hence the need for continuing time series of good quality data, and accessibility thereof, on the five components of the DPSIR scheme. These concern not only environmental, but also economic and social parameters. This huge task is currently undertaken by such bodies as the United States Environmental Agency (USEPA) or the European Environment Protection Agency, for their respective territories, while UNEP attempts to coordinate the information worldwide through its new Monitoring and Assessment Strategy.

It is now broadly recognized, as acknowledged again in a 1998 joint report of UNEP and the World Bank, that it is in a holistic, integrated manner that global environmental issues must be tackled, taking account of linkages between these issues (climate change, loss of biodiversity, stratospheric ozone depletion, freshwater degradation, land degradation and desertification, deforestation and unsustainable use of forests, marine environment and resource degradation, persistent organic pollutants) but also between environmental issues and human needs (food, shelter, health and clean water).

Against this background GEC science should of course continue to concentrate on basic research into the functioning of the life support systems of the planet and how these are affected by human activities, as done by WCRP and IGBP (which might avoid some of the surprises) but it should also detect and tackle emerging issues and do more policy-related research. As confirmed by a recent survey of environmental experts carried out by SCOPE for UNEP's GEO 2000, the results of which are summarized by Munn *et al.* (1999), the issues of high priority are not necessarily new. These issues could be either transformations of old issues in response to increasing scientific and technological knowledge and to evolving socio-economic, cultural and environmental conditions, or policy issues, such as the long-term environmental impacts of economic globalization.

Among the emerging science-driven issues those already well-recognized are: sustainable management of natural resources; socio-economic drivers of environmental change (population, globalization, changing production and consumption patterns, transport, tourism, urbanization); assessing the interactions amongst the global mega-issues, such as population, environment, development; intensification of environmental stressors, such as exposure to man-made chemicals or disruption of biogeochemical cycles. Another set of emerging issues consists of those with low or unknown probability but unacceptable consequences, such as natural disasters, biotechnology (genetically modified organisms (GMOs)), the rapid evolutionary nature of microbes and other pests and the collapse of ecosystems.

Policy-driven issues included, *inter alia*, environmental impacts of proposed strategies and policies (such as the Kyoto protocol on greenhouse gases emissions), implementation issues (e.g., how to implement the precautionary

principle) and how to make progress with well-recognized problems such as road transport.

The experts consulted in the SCOPE survey defined a large number of research needs related to these emerging environmental issues. Methodological needs came up preeminently as could be expected, considering the complexity of most issues and the necessity to combine quantitative natural science data with qualitative social science data. More specific priorities included: comprehensive environmental and health research in the tropical regions; ecosystem restructuring and movement in response to global change; more work on biogeochemical cycling, especially the decoupling of the carbon and nutrient cycles and the effects of the global nitrogen overload; the effects of multiple stresses on ecological and social systems; perturbations of the hydrological cycle; the environmental implications of GMOs; health-environment links; mechanisms of carbon dioxide sequestering in nature and through technology. Other environmental engineering R&D needs concerned chemicals (disposal of persistent substances, reduction of residues in food, risk assessment, chemical time bombs), cleaner production in general, improvement of water management systems and efficient energy systems. Economic issues such as natural resource and ecological accounting, the valuation of ecological services, etc., were also mentioned.

Essentially the same priorities for GEC science were identified in more general terms by the UNESCO–ICSU Conference on Science for the 21st century held in Budapest in June 1999. In its Science Agenda-Framework for Action, the Conference said, areas requiring special attention include the freshwater issue and the hydrological cycle, climate variations and change, oceans, coastal areas, polar regions, biodiversity, desertification, deforestation, biogeochemical cycles and natural hazards. It called for the vigorous pursuit of the international research programs such as IGBP, as well as for long-term monitoring of all components of the earth system. It also stressed the need for a solid scientific basis for technological development directed toward safe and clean production, greater efficiency in resource use and more environmentally friendly products.

No less importantly, and as general recommendation for all fields of science, the conference called for high ethical standards, in terms of scientific integrity and quality control, knowledge sharing, communication with the public and education of the younger generation. This applies particularly to GEC science, considering the need to establish relations of trust among all stakeholders to achieve progress toward the goal of sustainable development.

Policy Responses to Public Health Issues Relating to Global Environmental Change

ALEYA EL BINDARI HAMMAD

The Robert S Wagner School of Public Health Services, New York, NY, USA

Health security rests on the principle of equity, which allows human beings to live with the security of knowing that they have access to health care which is affordable, relevant and of good quality. Health security is needed throughout the entire life span of human beings, and encompasses all aspects of the right of every individual to the highest attainable standard of physical and mental health, including the right to food in suf cient quantity and of good quality, the right to decent housing, the right to live and work in an environment where known health risks are minimized, and the right of access to education and information on health.

The WHO Task Force on Health in Development (1994) Geneva.

There are three inextricable links in the chain of human development - health security, economic development, and environmental protection. At the end of the 20th century, only one of these has seen great positive change from its condition at the beginning of the century. Economic growth has taken place at an unprecedented rate. When wealth is examined from a safe distance, and as a mathematical mean, the planet is, scally at least, wealthier several-fold. Yet for all the additional comfort and improvements in quality of life that this should herald, we nd that we do not fare so well. The environment teeters dangerously on the brink of complete destruction. Health indicators show severe regression in the human condition; old diseases are back with a vengeance, and new ones are daily created by our poor understanding and use of our resources, both natural and derivative. What is perhaps most worrisome is that public health, the eld which contributed most to the improvements in human health and which spurred all development and innovation, is in decline. The global decline in the profession is mirrored in the decline in the health of each individual in any society, developed or developing. In early 1940, the discovery of therapies, especially the sulfonamide group of drugs and insulin, contributed to an increase in therapeutic interventions and gave tremendous con dence to new technical and scienti c approaches in medical care. With the control of infectious diseases and the acceleration of scienti c discovery in the medical eld, the in uence of public health diminished, giving hospital-based curative services a more prominent place, and gradually the lion's share of resources. Nevertheless, public health in the mid 20th century contributed tremendously to the improvement of the general environment and to major programs for controlling communicable diseases such as cholera. Public health strategies were pivotal in malaria control programs and in the growth of the health profession. This last was accomplished by an investment in institutional capacity-building through the establishment of schools for health workers for the development of public health cadres such as sanitarians, nurses, and health controllers. It is during this period that quarantine and other preventive services were established, through the leadership of WHO (World Health Organization) greatly enhancing the free movement of people, goods and services between countries.

Declarations, conventions, and conferences have made a virtual truism of the statement that human development and environmental protection are mutually dependent. And yet, at a time when we are armed both with the knowledge that human beings are at the center of concerns for sustainable development, that the right to development must be ful lled so as to equitably meet developmental and environmental needs of present and future generations, and that human beings are entitled to a healthy and productive life in harmony with nature, the actions taken so far continue to treat health and environmental concerns as separate disciplines (Rio Declaration, 1992). Conferences on health are held separately from those on the environment. Economic conferences pay at least super cial attention to environmental questions but almost none to health concerns. Health protection and promotion have received little recognition in environmental policies and development plans, and have

rarely been identi ed as an important factor in environmental or development programs. That the most pressing problems of ill health and premature death are caused by biological agents in the human environment - in water, food and soil - seem to be nothing more than curious side effects, that can be solved without direct attention to themselves.

The unacceptable numbers of infants and children dying from diarrheal diseases is largely the result of contaminated food or water. Likewise, hundreds of human beings, very often at the peak of their productivity, suffer unnecessarily from debilitating intestinal infections seeping them from their energies; malaria continues to take its toll unabated. Whilst many of these health risks are found in the developing world, there still are serious environmental health problems shared by both industrialized and developing countries. These include respiratory ailments caused by biological agents in the air, both indoors and outdoors, and chemical and physical hazards in their home, workplace or wider environment.

The third link in the chain - economic growth, based on market models - has widened rather than narrowed the gap between health and the environment. Social conditions are treated in the market as costs and risks, not as prerequisites for and aspirations of any civilization. The emphasis of the market on the preeminence of the individual, the vast monetary fortunes amassed by players in the market, and the global celebration of consumption and ostentatious display of wealth, have each contributed to a growing public perception that there is no need to look out for the needs of other individuals. Others are to be viewed as competitors. This perception has contributed to the decline of the notion of society and as such, to the decline of any institutions and professions that place value and respond to humanity as a society of beings interdependent on each other and on the living environment.

Sustained, unregulated, economic growth has been shown, in a growing body of evidence, to have negative consequences on the environment and biophysical resources. Yet here again, where inroads have been made against the cycles of production and consumption that deplete resources at an alarming rate, they have been in the evidence presented of the risks posed to the individual's health.

It is as if the concept of human development has set about to sabotage itself, by pitting the values of one link - economic growth and individual prosperity - against the values of the other two - protection and enhancement of all those factors which contribute to harmony. In part as a result of this, public health concerns continue to be pushed to the margins. Yet sustained economic growth, particularly if the desired outcome is measured by the levels at which consumption occurs in the West, is unsustainable in its impact on the environment and unpalatable in its consequences for the whole human condition - taking into account the physical, psychic, intellectual, emotional, and mental dimensions.

It is perhaps time for those concerned about human development to make known to the public, government, and private sectors the link between environmental and health concerns, and to use their conjoined strength to put an end to business as usual.

It is our ability to take these facts and devise ways of better managing the interaction between human activities, and the physical and biological environment that will enable us to meet current and future needs sustainably.

THE BEGINNINGS OF PUBLIC HEALTH AWARENESS

Health is worth the world, There is nothing more precious than health! are common sayings in many cultures. Usually, they are evoked with nostalgia by those who are passing through either temporary or permanent episodes of ill health. The human being very often has taken for granted the enjoyment of good health and is reminded of it only when he/she loses it.

From ancient history to the present day, most cultures have continued to exercise rituals and practices and have adhered to various rules to restore health and sometimes, to protect it. Some of these traditional practices work, and extensive research has and continues to be undertaken to discover the therapeutic basis for such healing practices. Many traditional healing practices draw their ingredients from the environment – plants, natural springs, the sand, the sea, the earth, and the atmosphere. It is the living environment that is the cornerstone for good health.

In addition to traditional healing practices, public health is as old as humankind and there is evidence that many public health measures were practiced by ancient civilizations. It has evolved throughout the years to reach its present form, which dates back to 19th century Europe during the Industrial Revolution. At that time, public health concerns were linked predominantly to sanitary action required to address problems caused by environmental and lifestyle factors. More specifically, in the first instance, they dealt with issues emanating from overcrowding, food and potable

water resulting from rural-urban migration. Many of the public health laws that were passed, such as those in England, dealt with environmental issues of sanitation, clean water, and clean cities. These activities proved to be very successful in the emergence of developed countries. With the development of germ theory in the 1870s, the introduction of massive vaccination and immunization practices was added to public health functions. It is this phase that ushered in many of the social services addressed to community groups, such as school health services and community health projects.

In 1923, Winslow provided a definition of public health that has been widely used to define its scope and function, and provide the basis upon which public health programs were designed. In 1952 and 1953, expert committees from the WHO amended slightly Winslow's definition to include both mental and physical health, as follows:

> Public health is the science and art of preventing disease, prolonging life, and promoting mental and physical health and efficiency through the organized community efforts for the sanitation of the environment, the control of communicable infections, the education of the individual in personal hygiene, the organization of medical and nursing services for the early diagnosis and preventive treatment of disease and the development of social machinery to ensure to every individual a standard of living adequate for the maintenance of health, so organizing these benefits as to enable every citizen to realize his birthright of health and longevity.
>
> (WHO, 1952)

Studies of the period spanning 1801–1971, undertaken by scholars such as McKeown, showed that health indicators such as those in England in the mid-1970s, improved primarily as a result of better standards of living and public health initiatives like better sanitation, clean water and better housing, rather than by the provision of medical care *per se*. The dictum that prevention is better than cure proved its worth in countries such as China and Sri Lanka and in the State of Kerala, India, in which there was a strong commitment to the goals of equity and concerted efforts to ameliorate the conditions of disadvantaged and poorer social groups. Many resources for satisfying health needs were health-related resources from other sectors, namely the entitlement to adequate food; basic education and knowledge, which enhanced the capacity to cope with health problems, particularly the capacity of women to deal with maternity and child care; and a well-distributed social and economic infrastructure leading to improved housing, water, sanitation and transportation facilities, including ready access to health services. All these improvements built the capacities for families and communities to lift themselves out of conditions of absolute poverty and the cluster of health risks it created. Even at income levels below US$350, life expectancies at birth in China and Sri Lanka as early as 1983 were estimated at 69 and 67 years, respectively – higher than the average life expectancy of 65 years for the upper-middle income group of countries, with an average *per capita* income of US$2050 (WHO, 1986).

Parallel to this, scientific knowledge and the development of technologies for curing diseases were progressing at a remarkable rate. Gradually, emphasis on public health and the development of the peripheral infrastructure weakened, and more weight was given to curative care, which increasingly absorbed the larger part of resources. As a result, urban-based curative hospitals were given priority over peripheral health units, greatly contributing to inequities in health status both within and between countries. The dominance of urban-based medical care exists to this day, and has contributed to the gap between urban- and rural-based health care, and ultimately between those who can afford and those denied health services. The inequity in health status is a phenomenon that characterizes many countries, both developed and developing.

The dominance of urban-based medical care in developing countries is reinforced by two very important values that predominate. The first is the appeal that medical high technology has on people and the value they place on obtaining this type of service. The second is the gradual decline in the quality of health care and in employment conditions in the public sector; and an attendant lowering in the confidence of individuals in state-owned and state-operated health institutions, occurred as governments began to economize on public expenditures, and the real wages and salaries of public servants began to fall behind those paid by the private sector. Patients were encouraged directly or indirectly to seek more and more services in the private sector if they had the ability to pay. Patients and the wider population began to perceive a difference – real or imagined – between services which further affected the quality of services delivered by the public sector. Public policy has so far failed to resolve these dilemmas. It should be stated, however, that by their very nature, the services provided by the private sector are demand-led and will therefore concentrate in the provision of services in areas where purchasing power is high (WHO, 1997a).

The costs of individual medical interventions have escalated around the world, but the state of health of the people has not improved in relation to expenditure. In fact, the resurgence of diseases such as cholera, schistosomiasis, tuberculosis, and the emergence of new diseases like the acquired immunodeficiency syndrome (AIDS) pandemic, has brought into focus the urgent need to revisit the whole question of how best to promote and ensure healthier nations within development strategies, and has focused attention again on public health measures as central to any debate on health.

Debates on health cannot be separated from debates on overall development. Patterns of development are dominated by economic forces, and recently, the model

of the market economy has been widely accepted. This development has promoted the drive towards systems that are consumer-oriented. The excessive use of market-driven policies has had negative social consequences on the poorest segments of society. This scenario has led to environmental degradation, taking place at an alarming rate, and continues to have serious consequences on health, as will be discussed in the ensuing paragraphs.

ENVIRONMENT AND HEALTH

Human beings live within an environment which constitutes an array of elements – physical, chemical, social, cultural and economic – varying according to local geography, season, infrastructure, time of day, and activity undertaken. Even though there is an intimate relation between the individual and the environment, this relation is highly complex. There is no single best way of viewing this relationship, which reveals all interactions and possible entry points for public health interventions, especially as the situation evolves and is constantly changing.

Global environmental change itself is a complex issue that is both the cause and the consequence of human dynamics. Before the middle of the 20th century, scant attention was paid to the notion that the manner in which humans interacted with their environment, and exploited resources, could permanently and negatively affect these same. If anything, innovations in the taming of the wild and harnessing of resources for human consumption were seen as advancements in the development and civilization of humanity, and perhaps rightly so. Innovations in water distribution and water purification through piping, damming, separation of potable water from sewage, for example, went a long way in the eradication of diseases that had threatened to destroy urban populations, and availed humans of natural resources for the production of energy. The same was true for medical, agricultural and industrial innovation.

Health depends on the ability to understand the interaction between the physical and biological environment, and the human activities undertaken. There are two concerns to be taken into consideration. The first is to respond concretely to people's needs, especially for health; the second is ecological sustainability, ensuring that natural resources are not depleted and natural systems not damaged or degraded by actions undertaken by humans, or for the benefit of humans. Meeting the basic human needs of present and future global populations for food, water and energy without depleting or damaging the global resource base as well as avoiding the adverse health and environmental consequences can be achieved only if individuals have the knowledge and the means to in uence action.

In 1989 at the first European Conference on the Environment and Health, environmental health was defined as:

> Environmental health comprises those aspects of human health and disease, that are determined by factors in the environment. It also refers to the theory and practice of assessing and controlling factors in the environment that can potentially affect health.

The conference agreed that important factors in the environment that affected health included, chemical and microbial agents and those factors, which affected the broad physical, psychological, social and aesthetic environment.

Beginning with the most basic needs, environmental health development stages can be characterized as:

- Physical survival – food, drinking water and shelter.
- Awareness raising – knowledge and understanding of factors affecting environmental health.
- Health and social care, environmental protection – responsive and appropriate health services, establishment of environmental management institutions.
- Preventive measures – controlling environmental pollution, prevention of illness.
- Promotion of environmental health – health supportive community structures, healthy and environmentally sound behavior and lifestyles.
- Well-being.

CHALLENGES FOR PROTECTING HEALTH

The economic circumstances and crisis, which predominated in the 1960s, and persisted into the 1980s and 1990s, resulted in major economic reforms and structural adjustments leading to a drastic curbing of public health expenditures. Old policies that were based on the fundamental values of equity and public responsibility, which characterized the public health strategies of the early part of this century up to the mid-1980s, were gradually replaced by new policies that promoted the market economy and privatization.

The failure of macroeconomic policies to ensure equitable distribution of wealth has contributed to increased poverty. Not only have poor people remained poor, but so have large numbers of poor nations, producing pockets of deprivation and subhuman living conditions in the urban areas that are sometimes worse than those in the rural areas (WHO, 1997b).

The contamination of water, air and food affects millions of people worldwide, exposing humans, in varying degrees, to pathogens and subsequent adverse health effects. In most situations, exposure to a wide array of health hazards occurs simultaneously, frequently resulting in the aggravation, exacerbation, and complication of health complaints. The problem of air pollution has reached global proportions, and the guidelines for air quality provided by WHO are often exceeded by a substantial margin. The developing countries register the most indoor exposure with negative

consequences on health, affecting more than 1000 million people (WHO, 1997c).

The contamination of water and food, inadequate sanitation, and little or no treatment of sewerage have contributed to much of disease incidence. In the developing countries, only 10% of sewage is believed to receive any type of treatment before being discharged into the environment. Much of the infections, injuries and vector-borne diseases are due to inadequate collection and disposal of solid waste, especially in the urban areas. The number of people without adequate sanitation is on the rise and is estimated to have surpassed 3000 million by the year 2000 (see Figures 1 and 2) (WHO, 1997c).

Water, especially safe water, is essential for life and for health. Up to 800 million people gained access to safe drinking water between 1990 and 1994. However, because of population growth, the net gain of percentage of the population covered was much smaller. It is believed that the scarce water supplies will constitute a major political issue in the 21st century, and will be the cause of wars and con icts between countries and regions. On the other hand, water pollution from the discharge of sewage and industrial waste remains a major problem leading to unacceptable human exposures due to the consumption of contaminated drinking water. Recently, the contamination of coastal water has become a major concern of many countries. Estimates suggest that if the provision of safe water and appropriate sanitation coverage are achieved for populations who are currently at risk, it would lead to the reduction of diarrheal deaths by two million, and the reduction of the prevalence of schistosomiasis and trachoma by 150 million and 75 million cases, respectively (see Figure 3) (WHO, 1997c).

Figure 1 Sanitation coverage by region, 1994

Poor management of water resources and agricultural development has been largely responsible for the substantive increase of vector-borne disease such as malaria, schistosomiasis and dengue fever. There is no doubt that if past mistakes are to be avoided and lessons are to be drawn from activities undertaken, strong and coherent harmonization and planning between the relevant sectors concerned is paramount in order to ensure a more integrated approach in implementing health and environment projects.

Because food is essential to a healthy life, if not appropriately monitored nationally and internationally, it can become the route for many pathogens and toxic chemicals. The race for opening new markets by the food industry has led to the increasing use of chemicals in food production. These include food additives, pesticides, animal drugs, and other agro-chemicals such as fertilizers. The latter may be responsible for different types of health effects such as nausea, vomiting, impaired immune function, birth defects, neotoxicity, and cancer. Food contamination monitoring is becoming an increasingly important feature of food control program in both developed and developing countries. Whereas the monitoring and enforcement of public health regulations seem to be working in developed countries, which constantly uncover the tendency of industry to violate those regulations, standards and norms, developing countries may be especially vulnerable where either public health regulations are lacking, or their enforcement is ineffective.

There are many recent examples where the enforcement of such a regulation has prevented the major spread of food-borne diseases during the period of 1997–1999. The new variant of Creutzfeldt-Jakob disease (nvCJD) – a degenerative brain condition that appeared to be linked to the consumption of beef and other products from cattle suffering from, or infected by the agent-causing bovine spongi-form encephalopathy (mad cow disease) – resulted in the slaughtering of cows in the UK, and a ban on the export of beef from the UK to the European countries. The

Figure 2 Sanitation services coverage to the year 2000 in developing countries

latter incident has put pressure on the European Union (EU) to tighten controls on animal feed. A recent food scare in Belgium was caused by the apparent contamination of feed with dioxin. The ARD German television network reported that companies in Brittany and Central France were putting residues from septic tanks and waste plants, into the feed of pork and poultry. Because of the threat to health, food-store chains in Germany withdrew the sale of poultry that might have been fed on meal mixed with sewage (The International Herald Tribune, 1999). These incidents did not happen in Europe alone. The contamination of chicken in Hong Kong resulted in the elimination of thousands of chickens by public health authorities to prevent further spread of disease throughout the territory.

The World Trade Organization plans to refer to Food and Agriculture Organization (FAO)/WHO codex alimentarius the arbitration of disputes involving food, health and safety requirements that seem to be on the increase, provided these are used as the basis of non-tariff barriers. Consequently, food contamination monitoring is becoming an increasingly important feature of food control programs in both developed and developing countries.

The contamination of foods by chemicals is also becoming an area of grave concern for the developing countries, and the major cause of diarrheal diseases. Statistics indicate that food-borne diseases of microbiological origin are increasing worldwide. This may be due to a slackening of standards, poor personal hygiene, and poor food control and

Figure 3 Per capita annual fresh water available (km^3) in 1990 and 2025 for selected countries

inspection procedures. The health impacts range from mild indisposition to life-threatening illness. The people most affected are the poor, who are also vulnerable to lack of food and under-nutrition.

The contamination of soil by pathogens as well as by chemicals is a major contributor to human exposure to environmental health hazards. Whether contamination is due to poor sanitation or application of agricultural chemicals, improper disposal of hazardous waste or deposition of air-pollutant particles such as lead, it has become of particular concern. Soil contamination leads to ground-water pollution and uptake of contaminants by crops that are later on consumed by people (see Figure 4).

It is not surprising that with the present rate of urbanization, inadequate housing is becoming a prominent contributor to poor health. The absence of a safe and secure structure, lack of sanitation facilities, overcrowding, and lack of tenure and security, have resulted in ill health and the spread of infectious diseases. Around 50% of the poor in developing countries live in conditions of extreme deprivation.

With the emphasis placed on profit-making at any cost, indiscriminate industries have mushroomed in developing countries, with little or no respect for safety and health standards in the workplace. Environmental health hazards in the workplace are very serious, affecting a significant proportion of the workforce. The garment, bidi and carpet industries are notorious examples of hazardous working conditions with harmful effects on health. Many of the laborers are young children who are af icted with physical and mental injuries, in addition to infections and chronic ailments, which make them invalids for the rest of their lives. A great proportion of them do not survive beyond 35 years of age. Many occupational injuries and diseases are not reported, and therefore go undetected. Those that are recognized cause 125 million people to suffer each year from occupational injury (The International Herald Tribune, 1999).

The rather recent discoveries of global climate change and ozone layer depletion, points to further adverse effects on the health of populations. Among the hazards that are forecast are the increasing severity of heat waves, changes in the areas affected by vector-borne diseases, and an increase in ultraviolet exposure resulting in more skin cancers and cataracts.

Different environmental factors can contribute simultaneously to the occurrence of a given disease. This is the case for acute respiratory infections in children, for example, which is linked to several factors, including exposure to indoor air pollution, crowding and poor housing, and malnutrition. For respiratory disease to actually develop, exposure to other factors must occur. The prevention of acute respiratory infection therefore, will depend on a combination of interventions directed at the different contributing factors as illustrated in Table 1 below.

It is necessary to underscore the importance of getting away from the single-bullet interventions, frequently known as vertical programs, that not only absorb many resources, but have been unable to address other important aspects which contribute to the predominance of a disease. Only policies that enhance an integrated approach, ones that address multiple factors, can truly contribute to the health conditions that are potentially related to several environmental exposure situations.

HEALTH OUTCOMES AND VALUE SYSTEMS

Up to a few decades ago, resources on our planet were considered infinite, there to be exploited. It was only in the early 1960s that harmful environmental change began to be systematically recorded. Threats to human health were traced to the same development processes that had affected the environment and development. The first environmental protection or green activist movements focused their efforts on exposing environmental degradation as a result of industrial processes, by highlighting the negative health consequences on individuals. Their strategy, in bringing home the impact of working conditions and the manner of waste disposal, set much of the tone for the ensuing debate about environmental restoration. If industry was responsible for the destruction of the environment, let industry be exposed and brought to account. Tremendous success was seen, governments enacted bills – like the Occupational Safety and Health Act in the US – to protect the lives and health of workers. But when the same approach began to be applied to actions whose direct adverse in uences could be seen, such as deforestation, much more limited headway was made (see Figure 5).

The movement to protect the environment falls into two classes. The first tackles the health outcomes of environmentally unfriendly strategies. If the contamination of water by myself causes cholera or dysentery or typhoid and could in turn kill me, then I have a vested interest in clean water. Immediate problems are identified, and immediate results are seen from changes in behavior. This strategy aims at behavior modification. The more the problem is personalized and is seen as threatening to one's own survival and well-being, the more successful the strategies aiming at behavior modification.

Table 1 Potential relationships between exposure situations and health conditions

	Exposure situations					
Health conditions of concern	Polluted air	Excreta and household wastes	Polluted water of deficiencies in water management	Polluted food	Unhealthy housing	Global environmental change

The second strategy tackles the value systems that humans employ in their use of natural resources. And these are much harder to identify and to change. Value systems are seen in the way in which humans identify their relationship with the rest of life on the planet. They are also seen in the national and global social, economic, cultural, and educational systems. Because these notions are abstract to the individual, and because changes in attitudes do not afford tangible beneficial or even measurable results, there is less incentive for humans to undertake to change them.

Government policies and programs vary according to the prevailing value system. For example, if equitable sharing of available wealth is part of this value system, policies will be designed to promote social equity. Similarly, if health is a priority, resources will be channeled into health protection. Both of these were illustrated by the previously mentioned examples of China, Sri Lanka and Kerala. The concept of sustainable development has introduced an additional component of value systems, namely intergenerational equity, which stipulates meeting the needs of the present without compromising or threatening the ability of future generations to meet their own needs. Obviously, the debate concerning the right balance between the allocation of resources for the protection of the environment and health, and the allocation of resources for lifestyle enhancement still continues, despite warnings that progress is slowed down when populations suffer from ill health, and life-support systems are degraded.

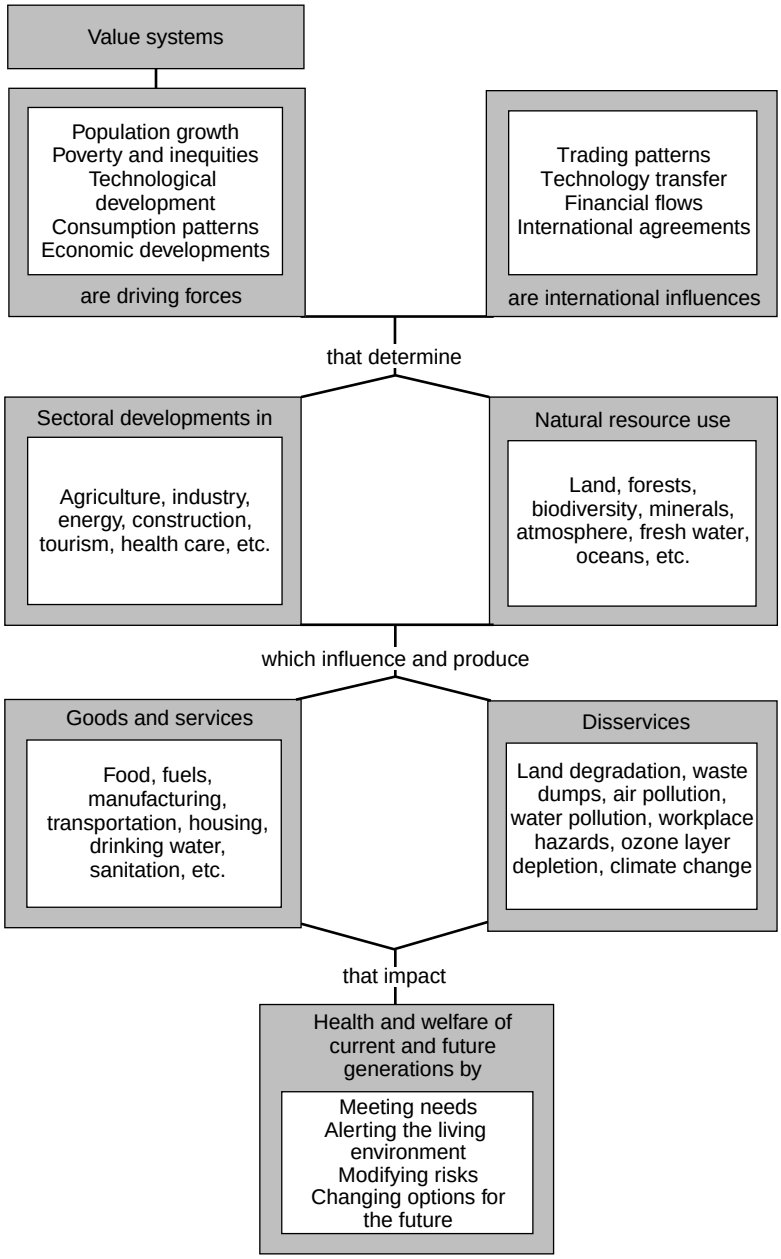
People worldwide must be made aware of what is at stake. They need to be enlightened and empowered. Several steps must be taken to mobilize people's relevant participation. National and international frameworks providing the necessary knowledge as well as the resources, must be made available.

CONTINUING CHALLENGES TO THE ENVIRONMENT AND PUBLIC HEALTH

Population Dynamics

Any discussion on health, the environment and development has to include a discussion on population – its size and its effects on consumption levels. This is because the latter largely determine the impact that the human population will have on the environment. It must also include an analysis of distribution of income and assets in order to allow appreciation of the difficulties faced by those people whose health is compromised by a lack of them. Since macroeconomic policies affect all sectoral policies, it is important to know the macroeconomic framework used by governments to set their economic, social, and environmental policies. This is important in order to assess whether appropriate changes are made to promote health and sustainability.

The world's population grew more than five-fold between 1800 and 1990 to reach 6000 million people in 1999 (UN, 1994). Up to 80% of the global population are in the developing countries. Projections suggest that world population will reach 8000 million by 2020 (UNFPA, 1997). If the world population continues to grow at this



Sustainable development can be described in terms of the elements in this figure, interlinking in a logical manner: the driving forces, intermediate elements and the eventual impact or effect on the health and welfare of current and future generations.

Source: Mr. Nitin Desai, Under-Secretary-General for Policy Coordination and Sustainable Development, UN in "Health and Environment in Sustainable Development: Five years after the Earth Summit", WHO, Geneva, 1997.

Figure 5 Elements of sustainable development

rate, resources such as water will be severely depleted by then. This will bring a host of new health threats to add to those existing threats that will be severely exacerbated.

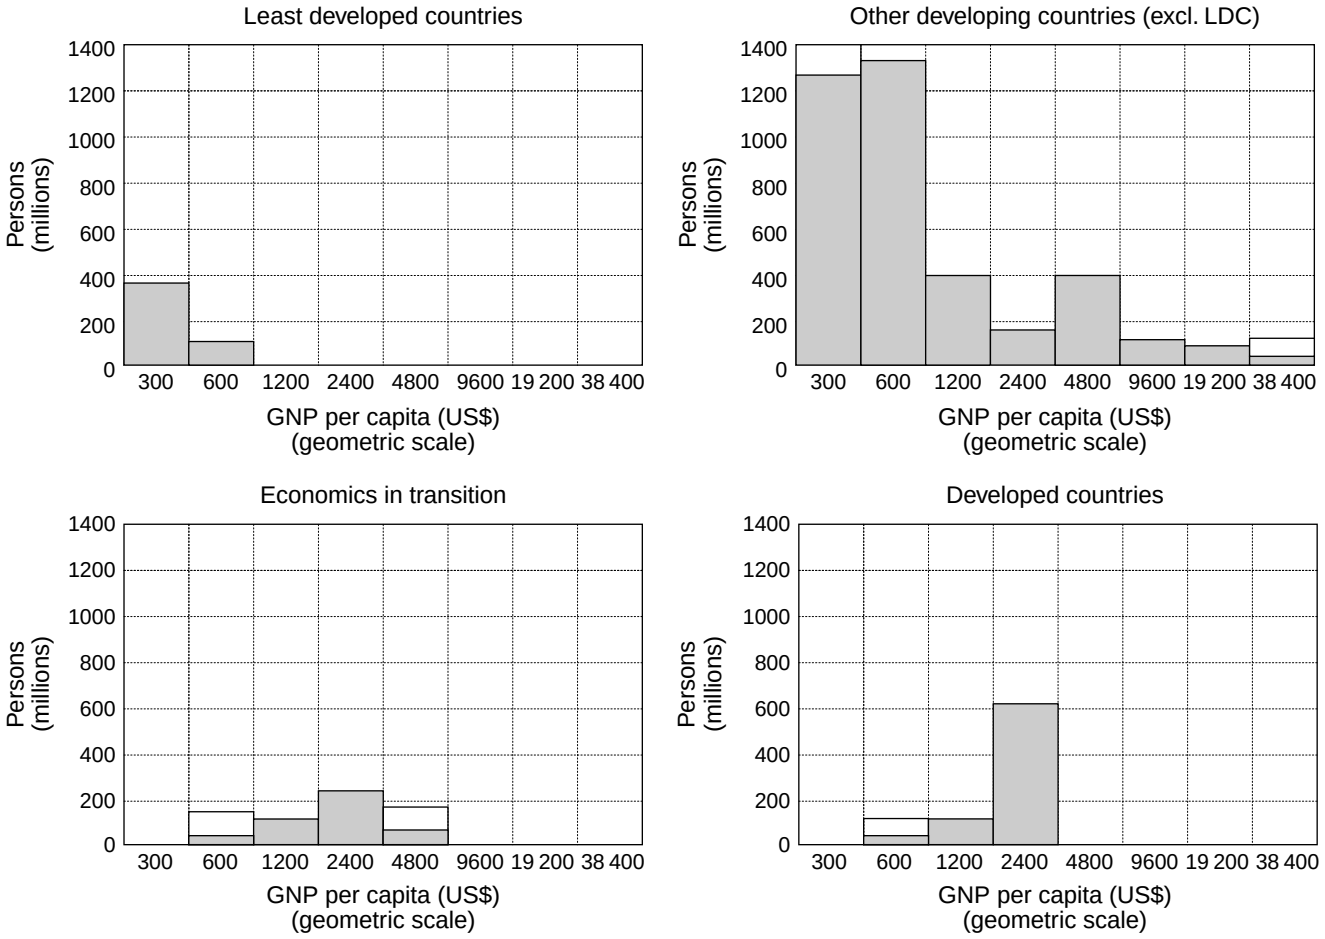
In developing countries, where population growth is still high, pressures on scarce resources make it difficult to improve living conditions. Existing infrastructures are rundown, as city authorities are unable to provide the

extra services required by the rapid population growth. In developed countries, population levels are largely static, enabling a greater level of prosperity and leading to increased consumption and even over-consumption with little regard to their possible planetary impact: the depletion of non-renewable resources, the degradation of soil and water resources, and the emission of gases that threaten the ozone layer and climatic stability. The question of sustainability is undoubtedly being raised as many more countries are aspiring to comparable levels of consumption (see Figure 6).

The United Nation Development Programme (UNDP) 1998 Human Development Report brings out the stark facts on consumption patterns and illustrates the consequences of both over-consumption in the developed world and under-consumption and human deprivation, the lot of the poor in the developing world. The report brings to light the ever-expanding consumption patterns that put strains on the environment. It identifies emissions and wastes that pollute the earth and destroy ecosystems, and highlights growing depletion and degradation of renewable resources that undermine livelihoods. It points out that in the final analysis, it is poor people and poor countries who are unable to protect themselves, and bear many of the costs of unequal consumption. According to the report, a single child born in the industrial world contributes more to consumption and pollution over his/her lifetime than do between 30 and 50 children born in the developing countries (UNDP, 1998).

The report goes on to recommend that poor countries need to accelerate their consumption growth, without following the path taken by the rich and high-growth economies over the past half century. It points out that the developing countries today can leapfrog to patterns that are pro-environment and pro-poor, by ensuring also that consumption of over one billion poor people be raised (UNDP, 1998).

In addition to consumption patterns, there are environmental implications of high population growth, which are far-reaching for many low-income countries.



Source: Based on data from the World Bank in "Health and Environment in Sustainable Development: Five years after the Earth Summit", WHO, 1997.

Figure 6 Share of GNP per capita (US$) by population size and level of development, 1993

Indeed, a strong relationship exists between population growth and poverty. The source of much suffering, ill health and death, poverty can act as an additional pressure on the environment. Poor people having few or no resources, have littlechoice but to exploit rather than protect the environment. Given that experience shows that fertility rates are closely associated with infant mortality rates and child health in general, a sustained global decrease in fertility will depend on general health improvements, including the amelioration of living standards. In fact, steps that reduce infant and child mortality also tend to promote reduction in fertility rates, namely: a secure livelihood, better health and education of mothers and girls, improved water supplies, sanitation and nutrition, together with effective reproductive services integrated into health care systems available to all. It is important to sustain reductions in fertility by implementing programs that remove the economic necessity for poorer groups to have large families, since in many poor countries, children are the principal source of income and provide the only social security available in old age. Programs such as the ones developed by WHO in seven African countries, whereby investing in poor women in raising income levels, coupled with functional literacy and community-based health services, contributed in improving the conditions of these women and their children. This approach provided women with a viable alternative for gainful living other than having more children (WHO, 1992).

Population Structure and Changing Health Concerns

Policies on population dynamics are intended to minimize the pressure on natural resources, primarily by minimizing the number of people who need these resources – although we have seen that 20% of the world's people in the highest income countries account for 86% of total private consumption expenditure, the poorest 20% a minuscule 1.3% (WHO, 1992). The carrying capacity of the planet is calculable, and the growth rate of the world population exceeds the rate at which resources to support human life can be replenished. In the 20th century, much attention was given to reducing fertility rates, particularly in developing countries, where the infrastructure to support citizenry is either weak or non-existent. Much less has been done on investing in human development, in reducing the gap between the rich and the poor, in expanding the knowledge base for all people, and in applying technologies that are environmentally sustainable for poor and af uent consumers.

The manner in which population growth is treated is instructive about the prevalent attitudes towards public health. In developing countries, much attention is given to the distribution of prophylactics – condoms and birth control pills that are mainstays of the pharmaceutical industry. The argument is that the use of condoms prevents the spread of sexually transmitted diseases, limiting the need for clinical intervention, reducing the risk of pregnancy, and preventing the spread of AIDS. Birth control pills, by enabling mothers to either space pregnancies or avoid unwanted births, put power in the hands of women, and limit both child and maternal morbidity and mortality. Programs supported by international donors and lending institutions support the distribution and educational campaigns associated with condom and pill use. But the use of these programs continues to be limited. Several factors contribute to this. First, the high-technology nature of the industry that produces prophylactics means that most developing countries either have to import them, or create industries for their local production. Second, education is a key component of the success of contraceptive use, which in many parts of the world where illiteracy is high means additional investment in the programs.

Poverty on the Increase

There is no doubt that people lacking economic and other resources, those denied opportunities to improve their condition, and those suffering from natural or man-made disasters and/or warfare are affected by the most severe environmental problems. Inequity is a major factor affecting the health-and-environment link. As long as large-scale inequity remains, the environment and health status will be continuously compromised. About 2900 million people live in countries where the *per capita* gross national product (GNP) is less than US$600. In contrast, about 800 million people live in countries where *per capita* GNP is greater than US$9600, the highest being Luxembourg where *per capita* GNP is US$37 320 (UN Statistical Yearbook, 1995).

Poverty as re ected by global inequity is actually increasing. In 1970, the richest 20% of humanity had roughly 30 times more income than the poorest 20%. Today, the richest one-fifth receive more than 60 times as much as the poorest one-fifth does. The wealth of the richest people in the world is staggering. The net worth of the world's 358 richest people is larger than the combined annual income of the poorest 45% of the world's population, that is 2300 million people (UNDP, 1996).

Between one-fifth and one-quarter of the world's population live in absolute poverty. More than 90% of this group, live in developing countries. A combination of increasing numbers of people, land given over to large-scale agro-business, and inequality in land tenure is not only leading to population movement, but also forcing those with least opportunities to settle in environmentally poor areas with the lowest potential for development.

Poverty and environmental degradation are inextricably linked. The world's poorest people are found predominantly in two types of areas: in remote and ecologically fragile

rural areas, and at the margins of expanding urban areas (Leonard, 1989). The precarious conditions of both expose poor populations to health risks that range from inadequate water and fuel supplies, to water-borne diseases, ambient and indoor air pollution, and to natural and technological disasters. The least developed countries have been affected by diminishing overseas development assistance and slow economic growth. Those living in absolute poverty include a high proportion of women, children, refugees and other displaced persons who lack access to education, employment, health care and other basic resources. These groups often interlink and overlap because the fundamental cause of their condition is the same – lack of power, low status, and a lack of opportunities.

Women, Poverty and Diminishing Resources

It has been stated that women provide the best illustration of the combined impacts of poverty, unemployment and social disintegration, on health and quality of life. Because women account for more than 70% of the agricultural workforce in many parts of Africa, and in others they are one-quarter to one-third of the sole breadwinners of the world's households, their poor health status has serious repercussions for economic development.

In spite of the overall improvement of women's health as shown by their increased life expectancy, many of them suffer loneliness, alienation, disability and poverty during old age (WHO, 1997c).

Although there has been a positive relationship between women's literacy, fertility, as well as prevention of disease and health conditions that affect them, women are still denied access to education. Illiteracy prevents them therefore, from understanding how their body functions, how they can prevent disease and protect themselves, and how they can avoid engaging in harmful practices. Insufficient access to existing methods of disease prevention has contributed to the problems they face on sexually transmitted diseases. They have had to contend with the use of technologies that were devised for men when attending to agricultural chores. And they have had to survive with very inadequate nutritional intake whose cumulative effects have permeated the different phases of their lives, sometimes transmitting the effects of deficiencies to their offspring (WHO, 1997c).

In a highly competitive climate where there is emphasis on the production of cheap tradable goods, women have been the ones recruited to work with the lowest possible wages in working conditions that are full of health risks and expanding long hours, at the expense of their health. When there are layoffs to be made, it is the women who are the first to lose their jobs. The high incidence of acute and chronic health problems is testimony to their poor working conditions.

Almost everywhere, women are victims of violence ranging from sexual abuse to social and economic disadvantage. Gender violence is a universal plague, grossly under-reported. In some countries, domestic violence is the leading cause of injury among women of childbearing age; up to 35% of women's visits to emergency treatment centers are on account of violence. Studies show that the prevalence of violence against pregnant women ranges from 7–20%, and in some instances, even more, and that such violence is more common than many other conditions routinely screened for during pregnancy (World Health Report, 1997). Violence against women is an important cause of morbidity and mortality throughout their life span, and more recently, elderly women have been particularly the target of aggression.

Finally, it is women who must cope with the stress and pressures as mothers, wives, daughters, sisters and caregivers, sometimes during famines and wars, often bearing the extra burden of coping with the unemployment of a husband or a child, the drug abuse of a brother, or the rape of a daughter (World Health Report, 1997).

Violence Reaching Epidemic Proportions

As we enter the 21st century, we carry with us the signs and symptoms of a deep social crisis facing almost all societies. This crisis is characterized by persistent high unemployment, poverty, and social disintegration. The most glaring results of social disintegration related to poverty and unemployment is demonstrated by the worldwide increase of violence. Violence is a major public health issue. It is the most complex problem that the public health field has ever addressed, and will be one of the most threatening factors in uencing sustainable development. Since there is no single cause, there is no single solution.

While there is no single direct relationship between poverty and violence, a close association does exist between inequity and violence. It is not that the poor are intrinsically more violent than other members of society, but rather that the inequities they suffer combined with disempowerment, fear, insecurity, oppression, hopelessness, and the depression these cause, are contributing factors to violent behavior.

Violence may erupt as a result of structural factors such as patterns of economic, social and political domination; lack of exemplary leadership that may stir the anguish of those who see no future reward for their efforts, or those for whom the future seems bleaker than the present, or to any situation marked by cruelty, discrimination, rejection, or forcible and arbitrary domination. Relatively easy access to ever-more sophisticated weapons of destruction, has allowed the level of violence in societies to escalate. New structures of violence, borne out of the overwhelming temptation of quick and easy access to huge fortunes,

have emerged such as transnational criminal organizations engaged in illegal trade in narcotics, arms and other goods. The frequent association of violence with drugs and alcohol use has been recognized. This has often led to the corruption of social values, and even of institutions such as the judicial systems. A violent culture transmits the values that sustain it – in the family, at the school, in the arts, or in the mass communication media.

What has violence – be it towards children, associated with gender, or ethnic or race – to do with public health policies and environmental consequences?

The cost of violence is incalculable in terms of mortality, disability, destruction of the infrastructure, and damage to the environment, let alone the financial implications of reconstruction and rehabilitation. The injuries inflicted by modern weapons of war, have had devastating effects on the life of the civilian population, and on the destruction of the environment. Water resources have been polluted, crops and harvests have been destroyed, and fertile agricultural land has become barren.

The use of landmines, for example, has not only inflicted irreparable pain and suffering – maiming men, women, and children – but their effects continue to be felt even when the conflict has ceased. The use of chemical weapons represents an alarming threat to the populations that were exposed and to the environment, and will continue to threaten the health of the population exposed long after they have been deployed. The inhalation of toxic substances seriously enhances the risk of damaged immune system and fatal cancer. The rehabilitation of war victims is an additional social and economic requirement, carrying with it tremendous cost implications. Many war victims may never recover, and others may be permanently disabled.

In some countries, health gains that were obtained with great effort and commitment in the last decade, were wiped out as a consequence of war, tribal, or ethnic conflict. Mozambique, Angola and Sierra Leone are dramatic examples where children paid the price of extraordinary violence. The latest report by United Nations Children's Fund (UNICEF) on the child mortality survey in Iraq in 1999, provides alarming figures. Infant mortality rates have increased from 47 deaths per 1000 live births, for the period 1984–1989, to 108 per 1000 live births for the period 1994–1999. The under-5 mortality rate has increased over the same period from 56 deaths per 1000 live births to 131 deaths per 1000 live births (UNICEF, 1999).

Other consequences include destruction of the health infrastructure, pollution of water, leading to epidemics difficult to contain in situations of conflict. Violence draws off from the already limited resources required for the prevention and treatment of diseases. But the financial costs are but one aspect; the added costs includes those associated with the insecurity and fear arising from violence. Demands for more and better law enforcement police and military forces divert resources from a socially oriented strategy.

Finally, the total cost of all forms of violence – be it at home, in schools, in the community, or emanating from local conflicts that inflict major human rights abuses, uprooting many people, and fueling the refugee crisis – lead to mental and physical traumas that may never be measurable. The health consequences are likely to be long term and passed on to later generations.

A Glimpse of Hope

It is encouraging that some countries in Europe are increasingly denouncing lack of commitment and action by the rich countries, in helping poor countries overcome unbearable poverty. At a meeting held in Utstein Abbey in Western Norway in 1999, ministers for international development discussed how to make more progress in the fight against poverty. Although they concluded that they did not possess the power to reverse the current poverty trends, they shared the belief that they had a responsibility for building stronger coalitions for change. They focused particularly on the need to improve coordination among donors and to support the fight against corruption, and to deliver on the promise of deeper debt relief, strengthening the ability and resolve of the international community to respond to conflict and crises. They agreed on an eleven-point agenda that will be subsequently reviewed for progress.

The Dutch Minister for Development Cooperation, the Norwegian Minister for Development and Human Rights, the British Secretary of State for International Development, and the German Minister for Development Cooperation went on to state that the poorest countries were weighed down with too many donors, and that scarce government capacity was tied up in meetings with the donors and preparing reports to justify the use of aid funds. They stated that donors too often determined priorities and tied aid to the purchasing of goods and services from their countries. They proposed that the donor community should not undermine the efforts of poor countries or try to run their own programs. The donor community must be willing to let go and see their partners in real command of development strategies.

Referring to poverty, the ministers commented on two critical factors: first was the collective ability of bilateral and multilateral debtor countries to secure sufficient financing based on transparent and fair burden sharing; second was the ability to transform debt relief into real poverty reduction and sustainable development. Strengthening the social dimension of the International Monetary Fund's (IMF's) structural adjustment facility for the poorest countries was considered a key contribution. Many more issues were dealt with and concrete proposals made, which were not only creative but were for the first time, sincere in

illustrating the partnerships that have to be forged between countries in need of assistance and the donor community (Herfkens *et al.*, 1999).

Lifestyles, Health and Environmental Implications

Af uence by most definitions means increased *per capita* consumption of food, goods and services. This increased consumption and production depletes natural resources and produces wastes, some of which can have severe effects on the environment and human health. Although population growth contributes to these developments, more important are the lifestyle patterns that drive people to consume. This lifestyle is predominantly found in af uent countries but is rapidly being adopted in all countries. In terms of sustainability, three of the most important consumption issues are diet (particularly the consumption of meat), consumption of certain raw materials and persistent chemicals, and the consumption of fossil fuels and associated carbon dioxide emissions. The consumption of grain, beef and water has tripled, while paper use has risen six times over the past 45 years (UNDP, 1998).

Richer populations not only consume greater variety and amounts of food, increasing the environmental effects of transport and storage of food, but also greater amounts of specific foods, which likewise have environmental implications. Increased demand for meat has many consequences. For example, it intensifies marine fishing, pushing some fisheries towards extinction and shifting the ecological balance of the oceans; it increases the demand for pasture, thus increasing the rate of deforestation and associated loss of biodiversity in some areas; and it diverts more of the world's basic food supply to animals, thereby making agriculture and fishing less efficient in meeting human nutritional needs (FAO, 1996).

Another lifestyle issue that has grown in importance especially among youth groups in the world, is engaging in health-damaging behavior such as drug and alcohol consumption, smoking, encouraging the cultivation of coca and other crops for purposes other than their therapeutic reasons, and their illicit marketing worldwide. The consumption of the world's raw materials, especially toxic metals such as lead, cadmium (Cd) and mercury (Hg) have great environmental health risks. Obviously depending on the degree to which human populations are exposed, the production figures are such and their emissions, especially of lead (Pb), are the subject of great concern.
