Thermodynamic (temperature or moisture) factors favorable for tropical cyclogenesis include warm SST over the oceanic mixed layer, high humidity values well above the surface (5–7 km) and the potential for tall thunderstorm growth (Gray, 1968). In the present day climate, warm oceans correspond to SST $\geq$26.5 °C; areas of deep upward motion (also required for thunderstorms to grow) in the

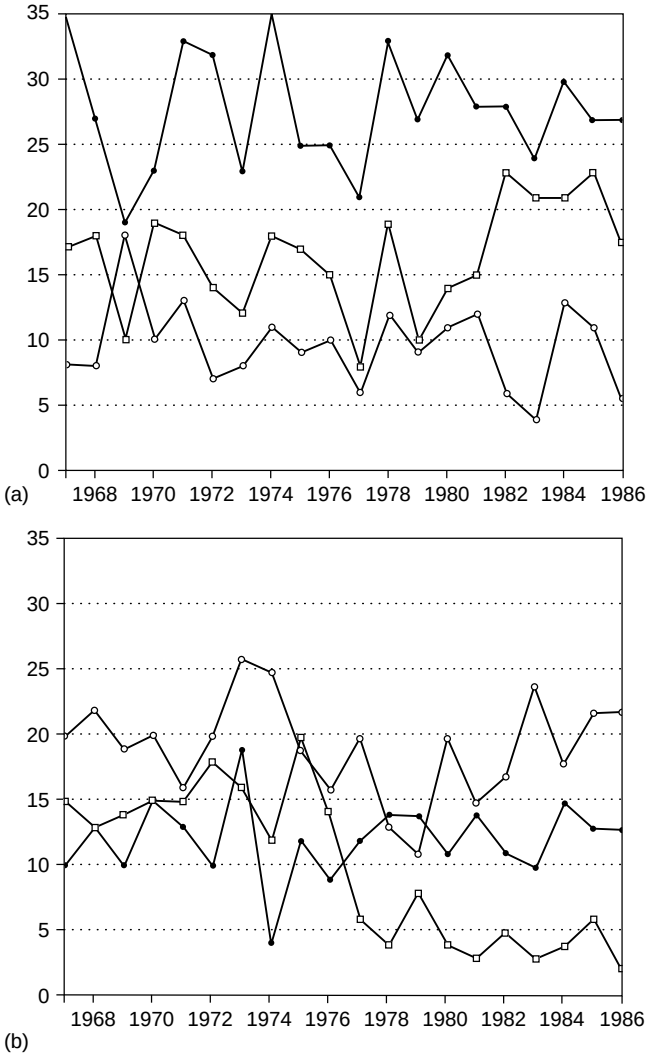

Figure 2 Annual tropical cyclone activity in each basin from 1967 to 1986: (a) North Atlantic (●), western North Pacific (○) and eastern North Pacific (□); and (b) north (□) and south (●) Indian Oceans and South Pacific–Australian region (○)

tropics are always located over waters with SST $\geq 26.5\,^{\circ}C$, so it is possible that this SST threshold condition is tied to the convection. This potential link becomes important when projecting tropical cyclone activity into the future as the climate regime changes.

McBride (1981) and others observe that these thermodynamic conditions are common in the tropical atmosphere, especially during the tropical cyclone season. McBride compared developing systems with non-developing ones that had been deemed likely to become tropical cyclones. The thermal characteristics of the developing and non-developing systems were essentially the same, leading McBride (1981) to conclude that these thermodynamic conditions were seasonal indicators of the likelihood of tropical cyclogenesis rather than indicators that an individual event was about to occur. This result is also important when considering tropical cyclogenesis in differing climate regimes.

Because the thermodynamic requirements for tropical cyclogenesis have been shown to be present throughout the cyclone season, the day to day variability of cyclone activity must be related to the dynamics of the genesis process (Gray, 1979).

The dynamic (wind related) factors associated with tropical cyclogenesis have been identified as locally enhanced, near-surface rotation (absolute vorticity) and small changes in the horizontal wind with height (vertical wind shear) over the center of the growing storm (Gray, 1968, 1979; and numerous others). Included in the absolute vorticity requirement is the condition that the system should not be too close to the equator (even though this is the region of warmest SST) because Earth rotation contributes to its development. In the Atlantic, easterly waves provide a dynamical seed for tropical cyclogenesis. In all other basins, the most dynamically favorable area for tropical cyclogenesis is in the region just poleward of the equatorial monsoon trough. (Gray, 1968). The monsoon trough is a region of both small vertical wind shear and enhanced near surface absolute vorticity; to both its north and south, the vertical and horizontal wind shear increases.

Watterson *et al.* (1996) used the presence of these thermodynamic and dynamic factors to diagnose tropical cyclogenesis from 10 years of gridded observations. Broad basins of tropical cyclogenesis were correctly identified, but the combination of these conditions did not isolate tropical cyclogenesis locations and neither did they replicate interannual variability. This study indicated that, if tropical cyclogenesis is deterministic, some undetected factor must also be present. Studies of the 30–60 day variation of tropical convection within a season (known as the Madden Julian Oscillation (*see* Madden- Julian Oscillation, Volume 1); Madden and Julian, 1972) indicate that inclusion of this ocean-scale modulation of the atmospheric winds and convection contributes to the likelihood of tropical cyclogenesis (Hendon and Liebmann, 1996).

In summary, the large-scale factors necessary for tropical cyclogenesis are present for the majority of the cyclone season. While they must be present for tropical cyclogenesis to occur, their presence does not guarantee that a storm will form.

INTERANNUAL FLUCTUATIONS IN TROPICAL CYCLONE NUMBERS

Interannual variability in any one of the cyclone regions is large, in spite of the overall global stability of cyclone frequency (Figure 2). Variations of two large-scale atmospheric and oceanic oscillations, the El Niño/Southern

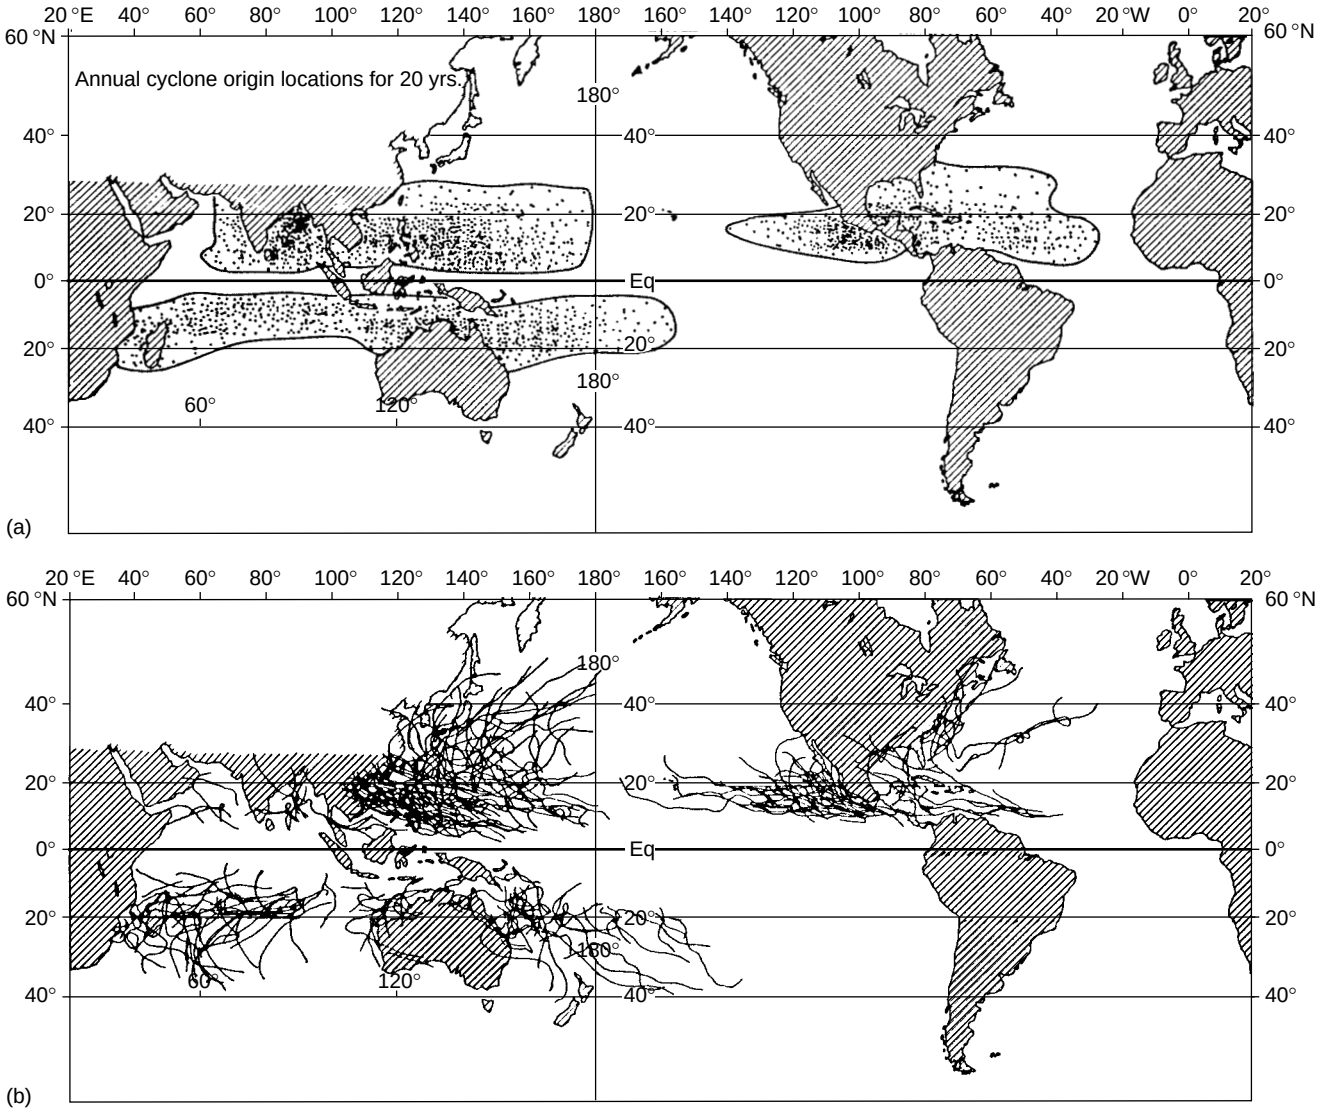

Figure 3 Global tropical cyclones: (a) genesis locations for a 20-year period and (b) tracks for a 3-year period. (Reproduced from Gray, 1979)

Oscillation (ENSO) and the Quasi-biennial Oscillation (QBO) (Gray, 1984; Shapiro, 1989), explain much of this variability (*see* El Niño and La Niña: Causes and Global Consequences, Volume 1).

Strong and significant links between tropical cyclone activity and the phase of ENSO have been detected in a number of ocean basins. In the western North Pacific and Australian regions, tropical cyclone activity is suppressed in stronger ENSO years and increased in the opposite extreme of anti-ENSO (Chan, 1985; Nicholls, 1989). Evans and Allan (1992) compiled the relative distributions of tropical cyclone occurrence in the Australian region for five ENSO and five anti-ENSO storm seasons. On the western Australian coast, tropical cyclogenesis extends further into the Indian Ocean in ENSO years compared to other seasons. This spread of tropical cyclogenesis away from the coast in an ENSO year is also evident in eastern Australia. This shift of storm activity results in decreased danger of tropical cyclone damage along the eastern Australian coast, while islands further out in the Pacific face an increased risk of cyclone strike. Similarly, ENSO enhances tropical cyclone activity in the central and eastern North Pacific (Chan, 1985).

ENSO effects on tropical cyclones in the eastern Pacific and Atlantic basins are out of phase: ENSO brings decreasing storm numbers in the Atlantic and increases in the eastern Pacific (Gray, 1984).

ENSO events occur at spacings of 2–10 years. The cause (or causes) of ENSO are still being investigated, but bursts of westerly (eastward) winds in the equatorial western

Pacific region just prior to the onset of an El Niño cycle have been well documented. Tropical cyclone activity close to the equator has been observed in advance of ENSO onset, suggesting that a tropical cyclones may enhance the equatorial westerly winds, providing one trigger for ENSO initiation. Other investigators argue that ENSO is purely ocean driven. Hence, while we have some understanding of the role of ENSO in moderating tropical cyclone variability, the question of whether tropical cyclones modulate ENSO remains open.

TROPICAL CYCLONE INTENSITY CHANGE

Tropical cyclone intensity is defined in terms of either the minimum central pressure or the maximum sustained surface wind of the storm. An intensity increase (increasing rotating wind and decreasing central pressure) is referred to as intensification or deepening; an intensity decrease (decreasing wind and increasing pressure) is referred to as weakening. Although heavy rainfall causes much damage associated with tropical cyclones, rainfall is not used when evaluating storm intensity.

Theories for Tropical Cyclone Intensification

Theories of intensification address limits on tropical cyclone intensity in the absence of adverse impacts of other weather systems, which are supposed to arrest intensification or even to cause the storm to decay. These theories predict the potential intensity (PI) of a tropical cyclone, which is the theoretical limit of tropical cyclone intensity if the environmental conditions are ideal. It is not clear that other weather systems provide only weakening effects on a tropical cyclone, but no existing theory incorporates external weather systems in a positive (intensifying) role.

Theories proposed to explain tropical storm intensification have key common elements. Heating due to a moist energy source is released into the atmosphere via deep thunderstorms. Because the storm traps the heat locally, it warms the air above the storm center and forces some air laterally out of the top of the column, dropping the surface pressure and increasing the surface winds. The stronger surface winds resulting from this intensification bring more moist energy into the storm and the cycle of intensification continues (Emanuel, 1999; Holland, 1997). The candidates for the moist energy source include atmospheric moisture convergence or ocean surface fluxes; air forced downward (subsiding) in the tropical cyclone eye is relatively dry, but also contributes to the atmospheric warming and the ultimate central pressure drop.

Observed Limits on Tropical Cyclone Intensification

A number of observationally based studies (e.g., Miller, 1958; Merrill, 1988; Evans, 1993; Emanuel, 1999) have examined the relationship between tropical cyclone intensity evolution and its environment. Miller (1958) and Merrill (1988) related the minimum probable central pressure for a hurricane to its underlying SST and its synoptic environment at 200 hPa. Miller (1958) concluded that maximum deepening is achieved with maximum outflow and minimum inflow at 200 hPa over water warmer than 26 °C. Merrill (1988) concurred, noting that while SST provides an upper bound, adverse environmental effects such as strong vertical wind shear across the storm center and may prevent a storm attaining its PI. Thus, the wind field surrounding the tropical cyclone has either a neutral or negative (weakening) effect on tropical cyclone intensification. Emanuel (1999) considered both SST and outflow (top of storm) temperatures to be critical in limiting a storm PI.

Evans (1993) examined the relationship between tropical cyclone intensity and the underlying SST for storms in all ocean basins. Scatter plots of storm intensity versus SST in the western North Pacific and North Atlantic basins for the 20 year period 1967–1986 are reproduced in Figure 4. Clearly, the highest intensities are achieved over tropical waters (SST $\geq$26.5 °C), although tropical storm intensities are also achieved over cooler waters (usually due to weakening storms moving out of the tropics). An alternative perspective can be gained by stratifying each observation by its SST, then compiling frequency distributions of observed storm intensity within these SST bins. When the entire lifecycle of each storm is considered, this analysis reveals that storms are likely to be the strongest over cooler, tropical water (e.g., stronger over 27 °C compared to 30 °C; Figure 5a). This is evidence of the evolving storm life cycle, because the mature storms move over cooler waters as they move further out of the tropics. If only the peak intensity of each storm is included, no discernible pattern relating SST and intensity emerges (Figure 5b). Clearly, SST does not override environmental interactions in determining the peak intensity achieved by an individual tropical cyclone.

Observed and theoretical peak intensities for the majority of storms occurring in the North Atlantic and western North Pacific basins over more than 40 years are analyzed by Emanuel (2000). He finds the cumulative distribution function for normalized peak winds of these storms to be linear, implying that there is a nearly equal likelihood that any given storm will achieve any intensity up to the potential intensity (PI). Further, the normalized lifecycles of Pacific and Atlantic storms (for seven days centered on the time of peak observed storm intensity) are remarkably similar.

In summary, observations demonstrate that a theoretical PI is rarely, if ever, reached by real storms (Figure 4). PI provides a useful indicator of the maximum devastation possible in a given climate regime, but does not provide guidance on the distribution of actual storm intensities likely in a given region.

TROPICAL CYCLONE MOTION

Early investigators believed that the mean horizontal wind averaged through the depth of the system provided reasonable estimates of the motion of a tropical cyclone (Helmholtz, 1867; Bjerknes, 1921). For this reason, it is referred to as the steering flow. However, there is a consistent discrepancy between the movement of a tropical cyclone and the steering flow due to spatial variation in the steering flow (Evans *et al.*, 1991) and to interactions of the storm with the Earth s rotation (Rossby, 1948). Other processes that potentially contribute to tropical cyclone motion are not yet well understood.

POSSIBLE CHANGES IN TROPICAL CYCLONES IN A WARMER CLIMATE

General circulation models (GCM) are the most sophisticated and flexible tool available for sensitivity studies of the climate system. The Atmospheric Model Intercomparison Project (AMIP), the Coupled Model Intercomparison Project (CMIP) and related endeavors have highlighted the strengths and weaknesses of GCM in studies of the Earth s climate. While concerns about model details and uncertainties on the effects of clouds remain, the major features of the present climate are well represented (Meehl *et al.*, 2000a; Easterling *et al.*, 2000).

There are many commonalties between simulations of climates with elevated levels of greenhouse gases by different GCM. Common elements include globally averaged warmer surface temperature, cooler temperatures high above the Earth s surface, and some evidence of more intense rain events (heavy rainfalls) and fewer light showers (Meehl *et al.*, 2000b). Much temporal and regional variability is simulated, with the largest surface warming and upper atmosphere cooling occurring inland and closer to the poles, generally milder winters and warmer nighttime temperatures. Coupled models indicate the possibility of more frequent ENSO-like patterns in both the atmosphere and ocean (Meehl and Washington, 1996).

Changes in the mean climate may be very different from changes in variability (Meehl *et al.*, 2000a). For example, the simulated warmer nighttime temperatures indicate less temperature change between night and day (less variability), but result in an overall warming.

The impacts of these simulated changes in the Earth s climate on tropical cyclones must be deduced based on an understanding of these systems in the present climate (Evans, 1993). Thus, we contemplate the most likely effects of this new, warmer climate regime on tropical cyclones as we now know them.

Mean Genesis Locations and Interannual Variability

Warming of SSTs and increasing moisture in the middle troposphere will extend the area of the tropics for which the thermal conditions for tropical cyclone genesis in the current climate are satisfied. However, the area of the tropical atmosphere that supports deep convection is unlikely to change (Royer *et al.*, 1996; Dutton *et al.*, 2001).

New results from coupled climate models indicate the possibility of a warmer climate that is more ENSO-like. In this scenario, the average tropical atmosphere and ocean circulations look more like the climate extreme that we refer

to as ENSO. Thus, we might expect the mean location of the monsoon trough to move and the distribution of tropical storm numbers among different ocean basins to change. If ENSO-like patterns prevail under these warmer climate conditions, storm numbers in the Atlantic and western Pacific Oceans may decrease and increased storm numbers in the eastern and central Pacific are possible.

Climate models are just beginning to approach the grid spacings necessary to start to resolve the large-scale features of individual tropical cyclones. In one of the first of these studies, Bengtsson *et al.* (1994) diagnose a global decrease in tropical cyclone numbers, by counting individual systems. However, concerns about cloud and ocean flux treatments in this and other GCM render this result preliminary.

Cyclone Intensity

The possibility of increasingly intense tropical cyclones in a warmer environment has been raised by a number of authors. This prediction is largely based on the potential for more intense storms over increasingly warmer SST (Lighthill *et al.*, 1994). Indeed, the modeling studies of Knutson *et al.* (1998) indicate that the theoretical maximum PI of a tropical storm in a warmer climate could increase by 5–10%. Because only a few intensity sensitivity studies are available, however, these data are preliminary.

Empirical studies of tropical cyclones demonstrate that the majority of storms never achieve their PI (e.g., Emanuel, 2000) and because a 5–10% intensity difference is well within the present range of intensity variability, such an increase would be difficult to detect for some time. Thus, while the potential likely exists for the strongest storms to become stronger in a warmer climate, the change in the peak intensity indicated (in the few studies available) is within the present range of interannual variability and so not possible to observe.

Tropical Cyclone Motion

Changes in the large-scale wind pattern could affect the preferred cyclone paths currently observed. These changes would impact rainfall, storm surge and wind damage statistics at storm affected locations. Should a warmer climate regime have more ENSO-like wind structure, the overall storm track pattern would be modified in response to altered steering flow; however, individual tracks will continue to show substantial variation from the average basic state (as they do in the present climate).

Hydrofluorocarbons

Hydro uorocarbons (HFCs) are compounds containing hydrogen, fluorine and carbon. The normal state of these compounds at standard temperature and pressure ranges from gases to liquids and waxes to solids. The gaseous HFCs can contribute to global climate change if they are emitted to the atmosphere. There are no known significant natural sources of HFCs. HFCs are removed from the atmosphere primarily through reaction with hydroxyl (OH) and their lifetimes range from about 1.5 to 250 years. These atmospheric lifetimes, combined with relatively strong infrared band strengths, lead to global warming potentials (GWPs) in the range 190–15 000 (*see* Global Warming Potential (GWP), Volume 1). For the most part, HFCs have been developed to replace ozone-depleting substances, primarily chlorofluorocarbons and hydrochlorofluorocarbons, that are being phased out under the Montreal Protocol on Substances that Deplete the Ozone Layer (*see* Depletion of Stratospheric Ozone, Volume 1; Ozone Layer: Vienna Convention and the Montreal Protocol, Volume 4). The commercially produced compounds are either non-flammable or low in flammability, low in toxicity, chemically and thermally stable and are compatible with a wide range of construction materials. The primary current and projected applications of HFCs are refrigeration, air conditioning, heat pumps and plastic foams for thermal insulation. In addition, small quantities of HFCs are used in specialty cleaning applications, for dispersing lubricants on computer discs, as a propellant in metered dose inhalers (e.g., asthma sprays), and as a non-flammable propellant in safety applications. The most abundant HFC in the atmosphere in 1995 was HFC-23 with a concentration of about 10 ppt. HFC-23 is produced as an unintended byproduct during the manufacture of HCFC-22 and much of what was produced has been emitted to the atmosphere.

MACK MCFARLAND *USA*

Hydrogen Peroxide Trends in Greenland Glaciers

Detlev Möller
Brandenburg Technical University, Cottbus, Germany

Hydrogen peroxide (H_2O_2), which is an important atmospheric oxidant, has been found at increasing concentrations in Greenland ice cores over the past 200 years. Most of the increase has occurred over the past 20 years (Sigg and Neftel, 1992; Anklin and Bales, 1997). Many trace species have been measured in Antarctic and Arctic ice cores that are unique in documenting the Earth's our past global

environment. Thus, it is possible to get not only information on the paleoclimate several thousands of years back, e.g., carbon dioxide (CO_2) concentrations over the last ice ages, and the occurrence of volcanic eruptions, but also on the increase of some compounds (e.g., nitrate, sulfate) with industrialization about 150 years ago. So-called primary compounds (e.g., heavy metals) may give an ice core concentration proportional to the emission strength. Secondary products (e.g., nitrate and sulfate) depend on the oxidation capacity of the atmosphere, because they are formed along different oxidation pathways from the primary ones.

Being a natural component of the atmosphere (having been found in rainwater more than 100 years ago), H_2O_2 is one of the species which is, to a large extent, responsible for oxidation of sulfur dioxide (SO_2) in the aqueous phase (cloud and rainwater) in the troposphere. H_2O_2 is produced in radical reactions that follow ozone photolysis. There is evidence for direct emission from biomass burning and non-radical and non-photolytic chemical formation. However, all atmospheric H_2O_2 sources are linked with human activities. Peroxides (like H_2O_2) have been found to be harmful. Radicals, subsequently produced after absorption, might impact enzymatic and genetic cell functions, called oxidative stress. Organisms have learned to build up antioxidant systems for repairing structural damages, which, however, will not completely compensate for this stress.

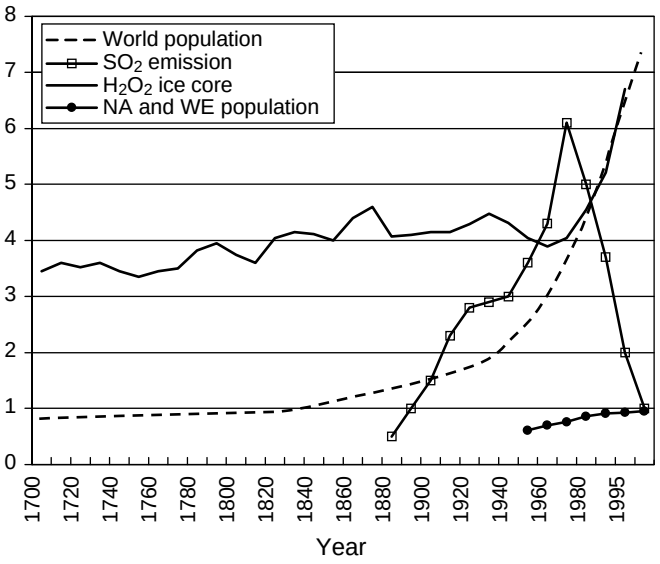

Figure 1 Comparison of 10 year averaged H_2O_2 concentrations in Greenland ice core in μM, world population and sum of population from Northern America and Western Europe (NA and WE) in 10^9 people and sum of Northern American and Western European SO_2 emission in 10^7 tons S year^{-1}; typical error bars ±10% for ice core concentration, ±20% for retrospective man-made SO_2 emission, ±50% for the 1995 figure and ±100% for the year 2000 figure (for references see Möller, 1999)

To begin to understand how the ice core concentration changes shown in Figure 1 may have arisen, we first need to consider the formation pathways of H_2O_2. In the gas phase the predominant mechanism is via $HO_2 + HO_2 \rightarrow H_2O_2$, with the reaction rate strongly depending on the water vapor pressure. The HO_2 radical required for this reaction is mainly formed through ozone, (O_3) photolysis via OH, which is in turn converted by carbon monoxide, CO and volatile organic compounds (VOC) to HO_2. Under NO rich conditions (polluted), HO_2 will be transformed back to OH, decreasing the H_2O_2 yield. Under NO poor conditions (clean background air), however, HO_2 reacts with O_3 resulting in a diurnal anticorrelation between O_3 and H_2O_2. Thus, only under moderately polluted conditions is HO_2 recombination a source of H_2O_2. H_2O_2 is a rather stable compound and does not undergo fast photochemical and gas phase reactions. The only sinks are dry deposition and scavenging by clouds and precipitation. Thus, transport of H_2O_2 over long distances is possible during essentially cloud-free conditions. Increasing emissions of CO and VOC are generally associated with the world s increasing population due to biomass burning and industrial activities. Consequently, one has to expect a positive correlation between the H_2O_2 signal and the world population (Figure 1), which, however, can be increased or weakened by other processes (*see* Troposphere, Ozone Chemistry, Volume 1).

H_2O_2 reacts in the liquid phase with dissolved sulphur dioxide, SO_2, forming sulfate. Despite the low volume fraction of cloud water in air (typically 0.3×10^{-6}) and the limited occurrence of clouds in time and space, it is now widely accepted that on average more than 80% of atmospheric non-seasalt sulfate is produced via the cloud phase. Thus, atmospheric H_2O_2 could be controlled to a large extent by SO_2 via liquid phase chemical processes.

To complicate matters, H_2O_2 in cloud drops may arise not only from scavenging of gaseous H_2O_2, but also from *in situ* liquid phase chemical reactions (Gunz and Hoffmann, 1990). One route involves the uptake of HO_2 and subsequent reactions, but we think (Moller and Mauersberger, 1992) that this source is negligible ($\sim 10^{-7}$ parts per billion (ppb) s^{-1}) compared to the gas phase production rate. Another aqueous phase formation mechanism for H_2O_2 may involve electron transfer to dissolved O_2 (Faust and Allen, 1992) where chromophores (e.g., aromatic carbonyles) in the droplets may be responsible for producing electrons after absorption of sunlight. The chromophores themselves could be products of biomass burning. Hence, besides sunlight, no gas phase oxidant precursor is needed in contrast to all other known H_2O_2 formation processes. Using the aqueous chemical rates, and considering cloud abundance within the planetary boundary layer (a factor of ≤ 0.1 has to be taken into account) we conclude that the mean liquid phase production of H_2O_2 may be of the same

order as the gas phase production ($\sim 10^{-5}$ ppb s^{-1}). This rate is related to summer and midday conditions. This leads us to conclude that H_2O_2 has a considerably lower annual mean production than given above, and large seasonal amplitude.

Recently, it has been proposed that biomass burning could be a direct source of H_2O_2. Another non-radical and light-independent H_2O_2 source is the gas-phase reaction between O_3 and olefins (ozonolysis). Under high humidity conditions, H_2O_2 may be formed directly; the mechanism for indirect formation via intermediate HO_2 radicals has been known for a long time (see references in Moller, 1989).

Besides the sulfur oxidation pathway, H_2O_2 is also consumed in its liquid phase via the Fenton reaction ($H_2O_2 + Fe^{2+} \rightarrow OH + OH^- + Fe^{3+}$) which, however, is relatively slow (Mn and Cu undergo similar Fenton-like reactions). Numerical modeling shows (Moller and Mauersberger, 1992) that cloud water accumulates H_2O_2 at all for concentrations of SO_2 smaller than 1 ppb.

Considering the production and loss terms for H_2O_2, the following relationships may be stated:

- Precursor emissions (CO, VOC) are proportional to human population when no alternative technologies and control techniques have been applied.
- Atmospheric H_2O_2 increases with increases in precursors (via O_3 formation).
- Atmospheric H_2O_2 increases with biomass burning (including wood burning).
- Atmospheric H_2O_2 is also produced photochemically within the gas and liquid phase as well at similar rates.
- Atmospheric SO_2 consumes H_2O_2 via the liquid phase.
- Seasonal amplitudes of atmospheric H_2O_2 (summer maximum) and emission of SO_2 (winter maximum) are anticorrelated; however, the amplitude for SO_2 is much smaller than that for H_2O_2.
- H_2O_2 ice core records represent the atmospheric burden of H_2O_2.

Considering all of these factors, we can now devise a scheme to explain the H_2O_2 trends in Greenland ice cores:

1. no significant trend in H_2O_2 in the period 1300–1750 (mean of $3.6 \pm 0.3\,\mu M$);
2. slow increase (0.2% $year^{-1}$) of H_2O_2 proportional to human population between 1750 and 1850 (i.e., wood burning as the main human energy source);
3. steady (mean of $4.0 \pm 0.6\,\mu M$), or decreasing H_2O_2 between 1850 and 1975 due to masking of the production term by the consumption of H_2O_2 due to highly dissolved SO_2 from fossil fuel combustion;
4. a marked increase in H_2O_2 by about a factor of 2 (5% $year^{-1}$) after 1975 due to widespread use of flue gas desulphurization and consequently decreasing SO_2 emissions as shown in Figure 1.

From the above arguments we calculate an annual flux of H_2O_2 in the Northern Hemisphere of about 0.9 Teq $year^{-1}$ (annual production rate half the summer time value given above, and a mean mixing depth of 1500 m). The corresponding SO_2 fluxes from North America and Western Europe (the principal sources of SO_2 to Greenland, see Figure 1) have dropped from 1.9 Teq $year^{-1}$ in 1970 to an estimated 0.3 Teq $year^{-1}$ in 2000. Clearly then, there has been a change from an oxidant- to a sulfur-limiting process. The recent ice core record of Anklin and Bales (1997) seems to confirm this. It shows an increase in the seasonal amplitude of H_2O_2 between 1988 and 1995 by a factor of about 5, due principally to higher summertime values. This agrees with our belief that H_2O_2 formation is dominated by the summer photochemical process.

An atmospheric increase of hydrogen peroxide in the Northern Hemisphere, which has to be expected as a consequence of the relationships presented here (and already forecast as a consequence of SO_2 emission abatement by Moller and Mauersberger, 1992), has not been checked with experimental data due to the lack of long-term gas phase H_2O_2 measurements. Such monitoring extending over several years is from Harwell (Dollard and Davies, 1993), showing a significant increase in gaseous H_2O_2 between 1987 and 1991 of $+0.028$ ppb $year^{-1}$ ($r^2 = 0.83$).

The hypothetical strong increase in H_2O_2 in the Northern Hemisphere must be seen in the context of a very slow population increase since 1950 (Figure 1) and may therefore only be a result of the strong SO_2 emission decrease. Considering the Southern Hemisphere, where most of the increase in the world population is occurring (Figure 1) and due to SO_2 emission abatement strategies probably applying in the future, a much stronger effect on atmospheric H_2O_2 could be possible. The consequences of increasing H_2O_2 are oxidative stress to vegetation (Moller, 1989) and possibly also to humans and animals, and may in future exceed, by several times, those arisen by O_3.

Hydrologic Cycle

Thomas Pagano and Soroosh Sorooshian
University of Arizona, Tucson, AZ, USA

The importance of water on Earth cannot be underestimated. Water is transported endlessly throughout the various components of the Earth's climate system, affecting every component along the way. Clouds and water vapor in the atmosphere influence the energy balance of the Earth, and snow and ice-covered surfaces reflect a significant amount of the Sun's radiation back to space. Water at and under the land's surface, in the form of stream flow or groundwater, plays an important role in the maintenance of living organisms and human societies. However, while water is a benefit, if it arrives at the wrong time, in the wrong quantity, or is of poor quality, it can be a severe hazard. To mitigate these hardships, humans have significantly altered the hydrologic cycle with construction of dams, cultivation of farmland, urbanization, draining of swamplands, etc. The local consequences of these changes can be dramatic, leading to environmental changes and, in some cases, local degradation. The global impacts are difficult to ascertain, however. With the increasing demand for freshwater resources and increased societal vulnerability to climate extremes, the effects on humans by water-related global environmental change remain an interesting but as of yet unresolved question.

INTRODUCTION

The hydrologic cycle is the perpetual movement of water throughout the various components of the Earth's climate system. Water is stored in the oceans, in the atmosphere, as well as on and under the land surface. The transport of water between these reservoirs in various phases plays a central role in the Earth's climate. Water evaporates from the oceans and the land surface into the atmosphere, where it is advected across the face of the Earth in the form of water vapor. Eventually, this water vapor condenses within clouds and precipitates in the forms of rain, snow, sleet, or hail back to the Earth's surface. This precipitation can fall on open bodies of water, be intercepted and transpired by vegetation, and become surface runoff and/or recharge groundwater. Water that infiltrates into the ground surface can percolate into deeper zones to become a part of groundwater storage to eventually reappear as streamflow or become mixed with saline groundwater in coastal zones. In this final step, water re-enters the ocean from which it will eventually evaporate again, completing the hydrologic cycle. The hydrologic cycle qualitatively, quantitatively, and conceptually is depicted in Figures 1–3.

The important reservoirs within the hydrologic cycle include:

Ocean

This vast body of salt water covers 70% of the Earth's surface; it stores and circulates enormous amounts of water and energy. In addition, patterns of ocean surface temperatures can exert a strong influence on circulation patterns in the atmosphere. Frequently, the ocean is divided into two parts, an upper and lower zone. The upper zone is considerably warmer and less saline than the lower zone, and the two are separated by a relatively sharp thermocline. The depth from the ocean surface to the thermocline can be as much as 400 m, but is generally less than 150 m.

Atmosphere

Water can be stored in the atmosphere as liquid in clouds or as water vapor. Water vapor content of the atmosphere is described by its humidity. Specific humidity is a measure of the water content per unit of dry atmosphere (typical values are $1-20\,g\,kg^{-1}$); relative humidity is the amount of water vapor present relative to the amount of water vapor that would saturate the air at a particular temperature. The presence of water in the atmosphere alters the radiation budget of the atmosphere, directly through latent heat and indirectly as both a reflector and absorber of radiation. Water in the atmosphere is the most significant contributor to the natural greenhouse effect.

Cryosphere

The largest stores of fresh water on the Earth are contained in glaciers and icecaps, primarily at high latitudes. The cryosphere has a significant impact on the climate of the Earth because snow and ice-covered surfaces have a very high albedo (comparable to that of clouds). The large volume of runoff from northern high-latitude rivers also influences the Arctic and Atlantic Ocean circulation, which impacts the climate in those regions. Despite the importance

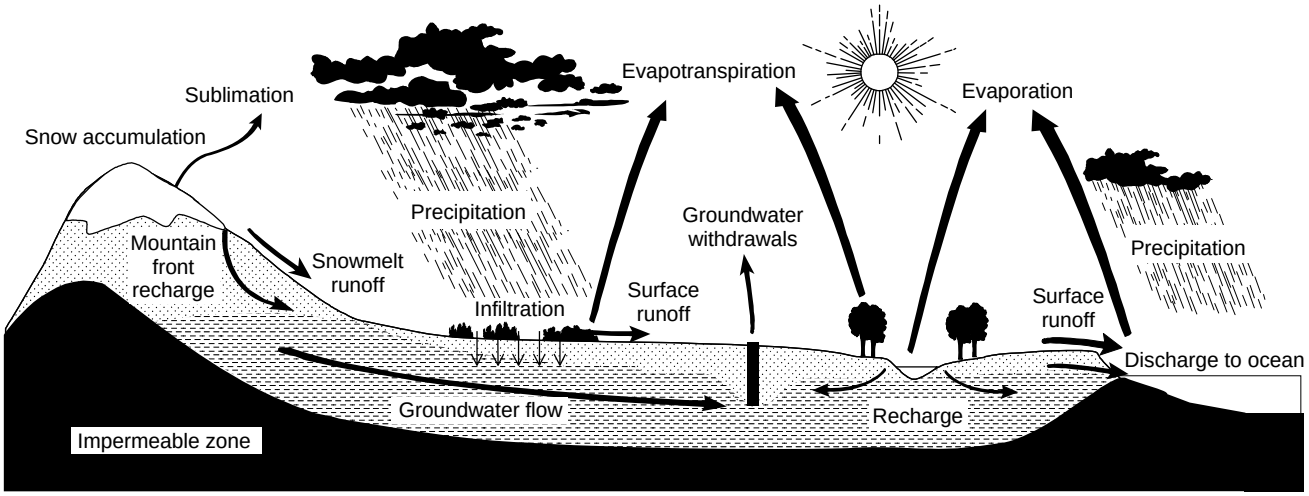

Figure 1 A schematic diagram of various fluxes within the hydrologic cycle. (Figure prepared by B Imam)

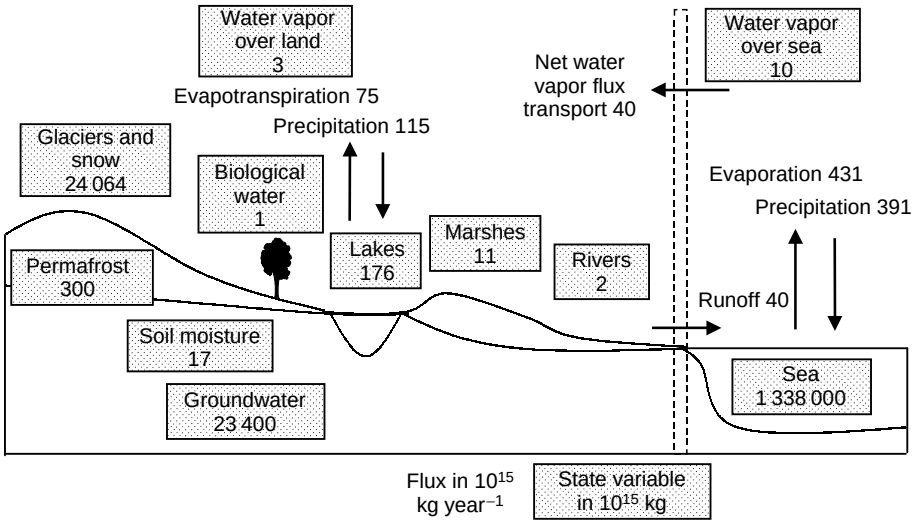

Figure 2 A diagram of the various fluxes and reservoirs within the hydrologic cycle with their yearly average magnitudes (after Oki, 1999) (reprinted with permission of Cambridge University Press). The magnitudes given are approximate, and differ from other authors. For example, see Chahine (1992); Figure 1 for comparison

of the cryosphere to the hydrologic cycle, relatively little is understood about this part of the climate system, partially because of the lack of adequate data in these often remote and difficult to access areas.

Groundwater

Water beneath the land surface can be classified in a variety of ways. Water closest to the surface (within a few meters) is considered soil moisture, and this water influences the evapotranspiration rate of water from the surface. Soil moisture that is frozen year-round is called permafrost. Deeper below the surface is the aquifer, where the water concentration in the rock and soil is sufficient for withdrawal by pumping. Groundwater for human activities is contained primarily in the aquifer. In this saturated zone, all available spaces within the rock and soil are filled with water. Between the aquifer and soil moisture lays an unsaturated intermediate (vadose) zone that has a lesser influence on the atmosphere than soil moisture. Despite the great societal importance of groundwater supplies, quality spatially distributed subsurface data are elusive.

Land Surface

Water on land can be contained in lakes and marshes as well as rivers and within living organisms (biological water). The volume of water stored on land is relatively small, but the flux of water throughout these systems is relatively

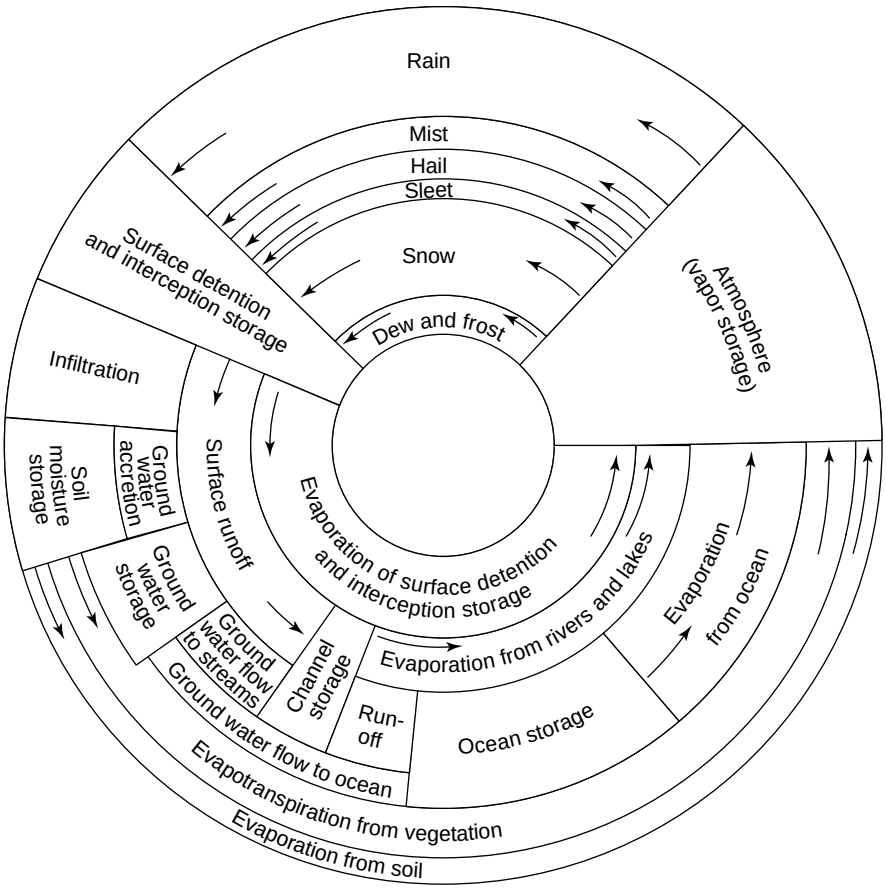

Figure 3 A conceptual diagram of the hydrologic cycle (after Wisler and Brater, 1959). (Reproduced by permission of John Wiley & Sons)

high. The relevance of this water to human activities is paramount.

In the broadest sense, the *major uxes* between reservoirs are:

Precipitation

Precipitation is the fall of solid or liquid water over land and oceans, and is the major driver of the hydrologic cycle over land. Hydrologists have traditionally recognized precipitation as the start of the hydrologic cycle because all other hydrologic phenomena (e.g., evaporation, runoff, recharge) result from it. The importance of precipitation to the hydrologic cycle cannot be overstated.

Evapotranspiration

Evaporation is the return of water from bare soil or open bodies of water (mainly the ocean surface) to the atmosphere. Transpiration is the transfer of water to the atmosphere through the stomata of vegetation. Collectively, they are considered evapotranspiration.

Runoff

Runoff is the transport of liquid water across the surface of the Earth. Excess water in saturated soils flows into rivers to the ocean, to terminal lakes or swamps. Groundwater can interact with streamflow in rivers if the water table is near the surface.

Water Vapor Transport

Atmospheric water vapor transport is the redistribution of atmospheric water vapor. Globally, there is a net transfer from over ocean to over land. This process is known as advection, and this flux is the major source of water vapor for precipitation over land, aside from recycling.

DESCRIPTIONS OF THE HYDROLOGIC CYCLE

Mathematical Models

Mathematically, the movement of water throughout the hydrologic cycle can be described using the hydrologic continuity equation:

$$I - O = \frac{\Delta S}{\Delta t} \quad (1)$$

where input (I) and output (O) depend on the reservoir in question (e.g., evapotranspiration is an input to the atmosphere, whereas precipitation is an output). The change in storage (S) in time describes the removal from or addition to present supplies to make up for the imbalance between input and output (in the case of the atmosphere, change in storage would signify a change in specific humidity).

In contrast to the atmosphere, the water balance of a surface portion of a river basin is considerably more complex. Water is input into this system through precipitation, surface runoff, and groundwater inflow from other parts of the basin. Water is lost through surface runoff, groundwater outflow, and evapotranspiration. The change in storage is reflected in changes in soil moisture content. A graphical depiction of a water balance for a portion of the atmosphere and land surface is shown in Figure 4.

On a global basis, the Earth is effectively a closed system, and the amount of water present remains relatively constant (i.e., $\Delta S/\Delta t \approx 0$). However, input and output rates of the hydrologic cycle vary regionally and on a wide range of time scales. Describing, quantifying, and predicting these variations are, in essence, major tasks in contemporary hydrology.

To describe and predict variations within the hydrologic cycle, considerable effort has been invested in developing computer-based numerical models of hydrology and climate. Every component of the climate system has its own models (from groundwater to oceanography and the atmosphere to the land surface) and, within disciplines, there are too many different models to be completely described here. For example, surface hydrologic models range from simple statistics, to regression models (such as the antecedent precipitation index and the soil conservation service curve number model) to more complex conceptual rainfall-runoff models (like the Sacramento model) and finally to the physically based distributed models such as HEC-1 and KINEROS. The spatial and temporal scales of their applications vary from model to model, but ranges from tens to thousands of square kilometers and from minutes and hours to days and years, respectively (Sorooshian *et al.*, 1996). The most complex models available are general circulation models (GCMs; *see* General Circulation Models (GCMs), Volume 1), which have full global representations of the ocean, atmosphere, cryosphere, and land surface. Most of the early work on GCMs related to refining the treatment of the ocean–atmosphere interface. Recently, increasing emphasis has been put upon the land surface–atmosphere interface, improving such models as the Biosphere Atmosphere Transfer Scheme and the Simple Biosphere model (*see* Land Surface, Volume 1). Lau *et al.* (1995) compared the ability of 29 GCMs in simulating various aspects of regional hydrologic processes and found them insufficient for use in climate studies related to continental scale water balance. Regardless, this is an area of very active research and as computing power rapidly increases in the near future, one can expect these models to improve.

Data

To date, there are several definitive works providing quantitative descriptions of the global hydrologic cycle

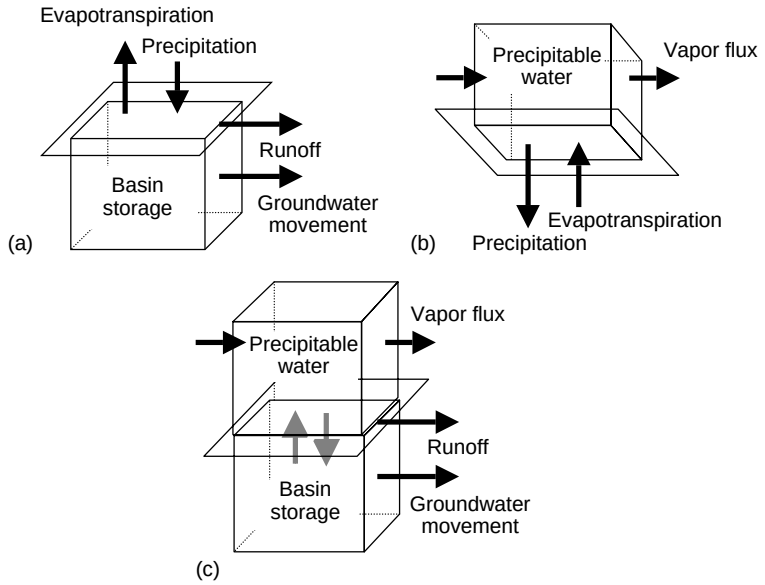

Figure 4 Mathematical schematic of a water balance for: (a) the land surface; (b) the atmosphere; and (c) the combined atmosphere and surface (from Oki, 1999). (Reprinted with permission of Cambridge University Press)

(for example, Korzun, 1978; Piexoto and Oort, 1992; Oki, 1999). The most comprehensive review of freshwater resources (supply and use) can be found in Shiklomanov (1999) http://espejo.unesco.org.uy/ and Shiklomanov (1997) http://pangea.upc.es/orgs/unesco/webpc/world_water_resources.html. Earlier works quantifying the complete water cycle have attempted analysis using sparse measurements; the creation of re-analyzed data sets by the European Center for Medium-Range Weather Forecasts and the National Center for Atmospheric Research (NCAR)/National Center for Environmental Prediction (NCEP) represents a significant advance to these kinds of studies. These data sets blend measurements from rawinsondes, satellite temperatures and moisture, cloud track winds, surface observations by ships, ocean buoys, land stations, aircraft reports, and GCM analysis of atmospheric dynamics. At present, reanalyzed data sets represent the best available global atmospheric water balance measurements.

Quality measurements of individual components of the hydrologic cycle also exist (*see* Earth Observing Systems, Volume 1). In particular, global records of precipitation and streamflow are maintained by the Global Precipitation Climatology Center (GPCC; http://www.dwd.de/research/gpcc/) and the Global Runoff Data Center (GRDC http://www.bafg.de/grdc.htm), respectively. Within the US, precipitation records are available from the National Climatic Data Center (NCDC; http://www.ncdc.noaa.gov/), and runoff is available from the US Geologic Survey (USGS; http://www.water.usgs.gov). Of all surface hydrologic variables, precipitation and runoff are the best measured, whereas data quality is considerably lower for other variables, such as snow, soil moisture, and evapotranspiration (Sorooshian *et al.*, 1996). One of the greatest barriers to adequately measuring the hydrologic cycle is the lack of spatially distributed data. Radar and satellite measurements (e.g., the Precipitation Estimation from Remotely Sensed Information using Artificial Neural Networks (PERSIANN) system, Sorooshian *et al.*, 2000) hold great promise in overcoming this barrier, but many of their benefits have yet to be fully realized.

OBSERVED CLIMATOLOGY

The quantities of water contained within the different components of the Earth s system are listed in Table 1.

Table 1 Distribution of water on Earth[a]

Form of water	Area covered (1000 km^2)	Volume (1000 km^3)	Share of world reserves of total water (%)	Share of world reserves of fresh water (%)
World ocean	361 300	1 338 000	96.5	–
Total groundwater[b] (saturated and vadose)	134 800	23 400	1.7	–
Predominantly fresh groundwater	134 800	10 530	0.76	30.1
Soil moisture	82 000[c]	16.5	0.001	0.05
Glaciers and permanent snow cover	16 000	24 000	1.74	68.7
Antarctica	14 000	22 000	1.56	61.7
Greenland	1800	2300	0.17	6.68
Arctic islands	230	83.5	0.006	0.24
Mountainous areas	220	40.6	0.003	0.12
Ground ice in zones of permafrost strata	21 000	300	0.022	0.86
Water reserves in:				
Lakes	2000	180	0.013	–
Fresh water	1240	91	0.007	0.26
Salt water	820	85	0.006	–
Marsh water	2700	11.5	0.0008	0.03
Water in rivers	148 800[d]	2.12	0.0002	0.006
Biological water	510 000	1.12	0.0001	0.003
Atmospheric water	510 000	12.9	0.001	0.04
Total water reserves	**510 000**	**1 390 000**	**100**	**–**
Fresh water	148 800	35 000	2.35	100

[a] The individual number and column totals may not exactly agree due to rounding. Table modified from Korzun (1978) (reproduced by permission of the United Nations Educational, Scientific and Cultural Organization).
[b] Not including groundwater reserves in Antarctica, broadly estimated at 2 million km^3.
[c] Soil moisture is the water contained within the top 2 m of soil. This does not include ice and snow covered land areas, permafrost regions and arid and semi-arid areas (which collectively cover approximately 65.5 million km^2).
[d] The area of rivers here is the entire land surface. The true area of rivers, in the sense of channels with flowing surface water, is extremely small (<1 million km^2).

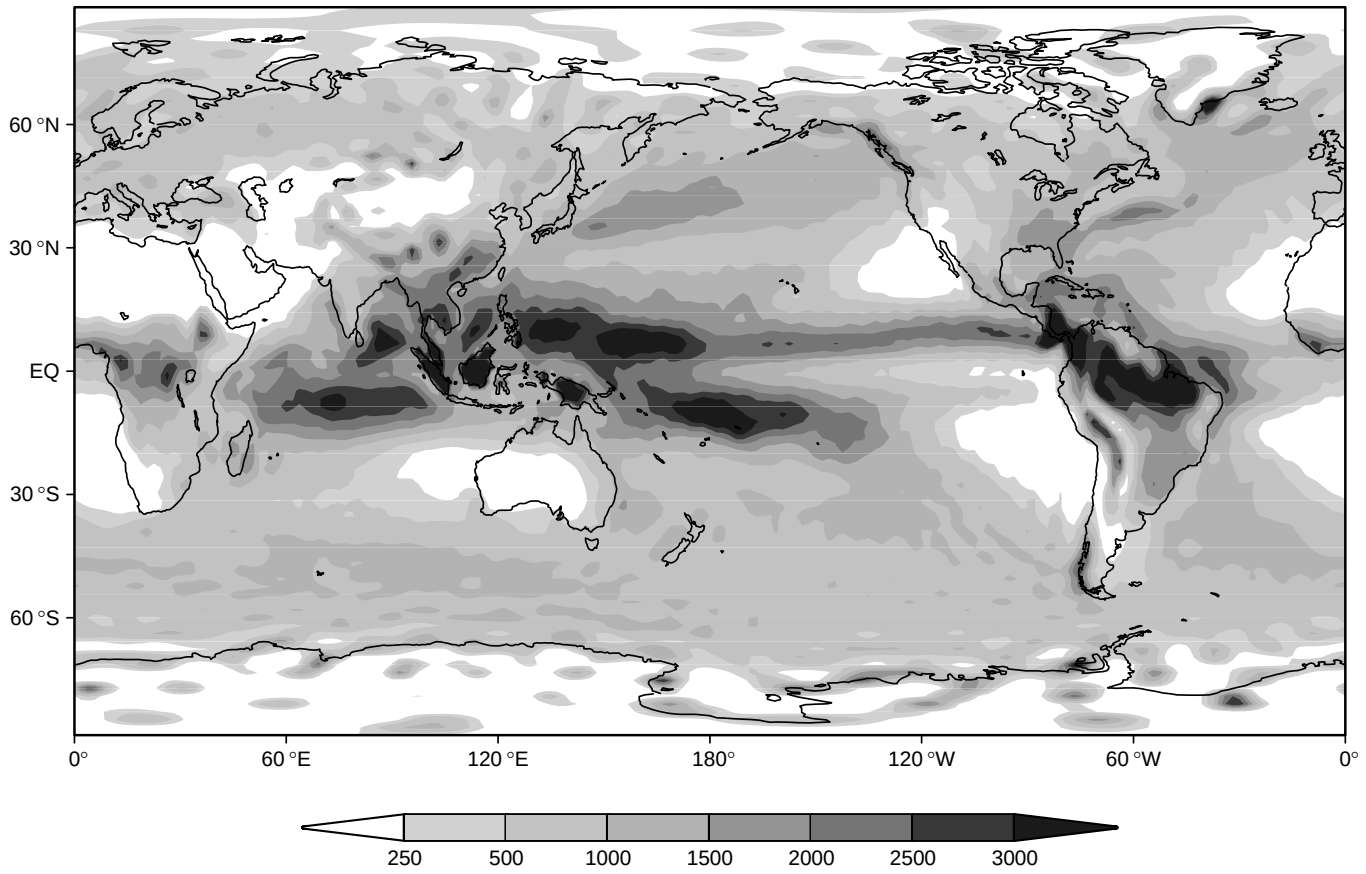

Figure 5 Yearly average precipitation from the NCAR/NCEP re-analysis of data from 1979–1995. Data are shown in mm year^{-1}. (Data provided by S Williams of UCAR)

The vast majority of the Earth s total water is contained in the oceans (96.5%, 1.34 billion km^3). The atmosphere contains a relatively small amount of the Earth s total water (0.001%, 12 900 km^3). Of the water not in the ocean (3.5%, 52 million km^3) and if the amount of water contained in polar ice caps and saline waters is excluded, only 15 million km^3 (31% of fresh, 0.8% of total) remain. If the water on the Earth fitted proportionately within a 200-liter (45 imperial gallon) barrel, the water contained in the atmosphere would fill just under half a liter, and freshwater lakes would fill a tablespoon. The water of all the Earth s rivers, from the Nile to the Amazon and the Yangtze to the Mississippi, would fit in the eye of a needle.

The average rate of exchange between the various components can be derived from Figure 2. The residence time (the average length of time that an element of water would spend in a component before moving on) is the total storage of the component divided by the rate of flux out of the component. For example, the residence time of water in the atmosphere is less than 10 days, whereas the ocean has a residence time of over 3200 years (longer for deep parts of the ocean). Depending on the aquifer, residence times for deep groundwater can be very long ($>$10 000 years). On human time scales, many groundwater supplies can be effectively considered non-renewable. Measurements of residence times are important in detecting, for example, an intensification of the hydrologic cycle associated with climate change. This intensification would appear as a decrease in the residence time of water in the atmosphere.

There is considerable spatial variation within the hydrologic cycle. Precipitation is generally higher in the tropics and along mid-latitude storm tracks (Figure 5). Precipitation patterns also vary by season, following the migration of the intertropical convergence zone, storm tracks, and monsoon systems. Global average precipitation is approximately 970–1000 mm year^{-1}, where average precipitation over the ocean is roughly 1100 mm year^{-1} and over land is 700–750 mm year^{-1} (Table 2). The average annual local precipitation rate can be as high as 13 300 mm year^{-1} in Lloro, Columbia and as low as 0.76 mm year^{-1} in Arica, Chile (US Army Corp of Engineers, 1997), although there are dry valleys in the interior of Antarctica that are believed to have not experienced rainfall in the last 2 million years. Globally, precipitation and evaporation are approximately in balance, although the ocean is considered a source for the

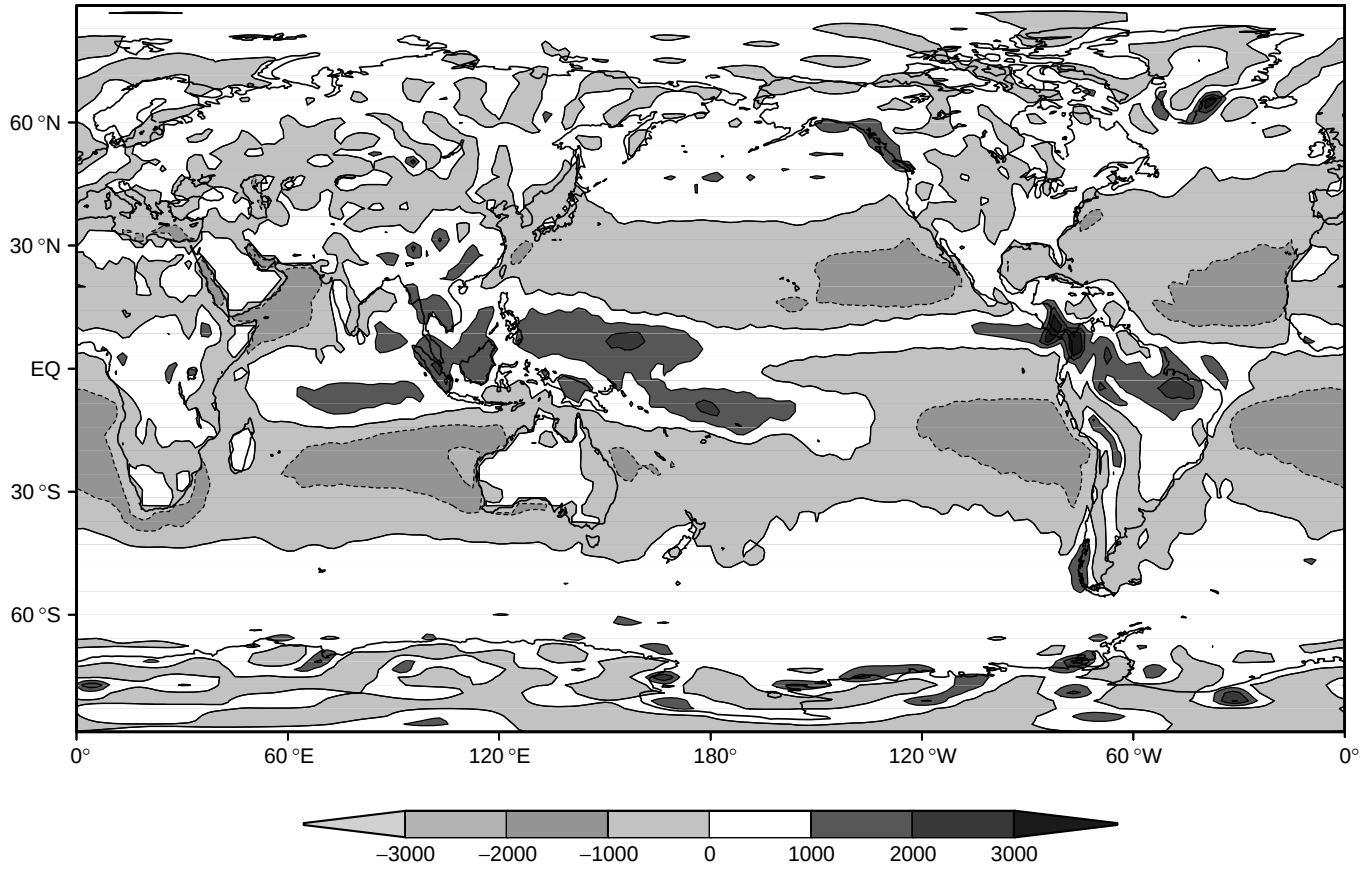

Figure 6 Yearly average precipitation-evaporation from NCAR/NCEP re-analysis data in millimeters year^{-1}. See also Figure 5

atmosphere with average evaporation-precipitation being 110 to 130 mm year^{-1}, and the land is considered a sink at -260 to -310 mm year^{-1} (Figure 6).

The numbers presented here are not exact and may disagree with those of other authors, emphasizing the level of uncertainty present when computing a water balance. The disagreement between authors can become large at finer spatial scales. For example, comparisons of two authors estimates of precipitation, evaporation, and runoff by continent and ocean are presented in Table 2.

VARIATIONS IN THE HYDROLOGIC CYCLE

Although general descriptions of the hydrologic cycle (such as those presented at the beginning of this article) make it seem relatively simple, once one starts to consider the smaller-scale aspects of the hydrologic cycle, it is, in reality, quite complex. Variations within the hydrologic cycle span a wide range of spatial and temporal scales. There are distinct seasonal variations to precipitation and evaporation, and fluxes within the hydrologic cycle vary with latitude and by continent, as stated earlier. However, precipitation also varies with altitude and orientation to local mountains, creating an enormous diversity of microclimates across the globe. Likewise, local weather conditions can change in a matter of minutes, leading to punctual events such as flash floods and microbursts, or they can evolve very slowly, such as long-term drought. Several studies have detailed the static aspects of the global hydrologic cycle, and the interesting new questions in hydrology and meteorology concern the hydrologic cycle as a dynamic system operating and interacting at a variety of scales. What causes drought? What makes one winter wetter or drier than any other? What are the implications of climate change for extreme events? All of these are questions facing researchers today.

One of the areas of increasingly more active research concerns variations within the Earth s climate on interannual, interdecadal, and longer time scales. Prior to the 1970s, solar variations were the most common natural explanation for year to year variations in climate and the hydrologic cycle. Streamflow of certain rivers could be correlated with various sunspot cycles, such as the 11-year cycle. Coincidentally, the earliest attempts at climate forecasting at the turn of the century were born out of attempts to link sunspot cycles with the periodicities found in climate time series, such as Indian monsoon rainfall (the variability of which is now known to be influenced by El Niño (*see* El Niño, Volume 1). However, the predictive skill of sunspot–climate relationships is low, and the relationships are unstable in space and time (Korzun, 1978; Allan *et al.*, 1996).

In recent decades, scientists have developed an appreciation for the relationship between the ocean and the atmosphere, in particular how seasonal patterns of local climate can be affected by ocean temperatures in remote areas (also known as teleconnections following Bjerknes, 1969). The El Niño/Southern Oscillation (ENSO, *see* El Niño/Southern Oscillation (ENSO), Volume 1) cycle is the most widely studied of this type of phenomenon. Recent large events have occurred in 1982–1983 and 1997–1998. The ENSO cycle is a coupled variation of the ocean and atmosphere in the tropical Pacific that impacts precipitation in many locations across the globe, from Peru to Africa, Australia and the US, among others (Ropelewski and Halpert, 1987). During warm ENSO events, ocean temperatures become warmer than usual in a region about the size of the US, extending from the coast of Peru to across the international dateline. This warming causes shifts in the patterns of convection in the tropics and, in turn, impacts the global atmospheric circulation. This favors seasonal precipitation anomalies in specific regions, such as floods and droughts. During cold ENSO events (La Niña), the same region of the ocean becomes colder than usual, and the global impacts are generally but not exactly opposite to those of warm ENSO events. These events occur irregularly every two to eight years and can last from one to several years. The breadth and magnitude of variations in the Earth s climate due to ENSO are second only to the changing of the seasons (Allan *et al.*, 1996). Predictions of ENSO have contributed successfully to seasonal forecasts of precipitation, which, in turn, can be very useful for water management (for example, Changnon and Vonnhame, 1986; Stern and Easterling, 1999; Changnon and Bell, 2000).

Variations and teleconnections on longer time scales also have major impacts on the hydrologic cycle. Two phenomena that have received considerable attention and research are the North Atlantic Oscillation (NAO, *see* North Atlantic Oscillation, Volume 1) and the Pacific Decadal Oscillation (PDO, *see* Paci c- Decadal Oscillation, Volume 1). The PDO concerns ocean temperature variations in the northern Pacific, whereas NAO concerns the northern Atlantic Ocean and atmosphere. The PDO operates on a time scale of 20–30 years, with observed shifts in the 1890s, 1920s, 1940s, 1970s and possibly the mid-1990s. The various phases of the PDO have been associated with wet and dry periods in North America and can serve to enhance or cancel the effects of ENSO, depending on their states. The NAO exerts a considerable influence on the hydroclimatology of Europe, Northern Africa, and the Middle East, among other regions. There is some evidence supporting the idea that variations in the North Pacific and North Atlantic are coupled and should be thought of as two manifestations of a single underlying phenomenon. Developing predictors of both of these oscillations remains an area for active research.

On centennial scales and longer, the hydrologic cycle has changed in both subtle and dramatic ways. Changes in the orbital parameters of the Earth with respect to the Sun have

been responsible for glacial periods in the Earth s history. During glacial periods, the extent of glaciers increases to much more than that of today. For example, during the most recent glacial maximum 20 000 years before the present interglacial, Chicago lay beneath more than 1 km of ice. Changes in the Earth s temperature and the volume of water trapped in glaciers caused the sea level to be about 100 m lower than today, drying up the English Channel. Clearly, large-scale weather patterns were altered, changing patterns of precipitation and the partitioning of precipitation into rain and snow. Likewise, continental streamflow would have increased as the glaciers melted. Changes in streamflow can impact ocean circulation. As the glaciers retreated from the most recent glacial maximum, and their waters released into the North Atlantic, the density of ocean surface water was reduced, and the formation of deep ocean water in this region was halted. As a result, Europe s temperature and hydrology was much different than today. On climate time scales, this switching was extraordinarily rapid, on the order of decades (*see* Thermohaline Circulation, Volume 1; Younger Dryas, Volume 1).

Aside from ocean and atmospheric variability, the land surface itself can impact precipitation in local and remote areas. Variations in soil moisture influence precipitation due to the amount of moisture that is recycled over land. Chahine (1992) estimated that a full 65% of land-falling precipitation comes from evaporation over the land, most of it advected in from other locations (see Trenberth, 1999a for further discussion on evaporation and moisture recycling). The amount of moisture available, as well as its spatial distribution, is important, even at fine scales; sharp soil–moisture gradients have been known to influence the development of tornadoes, for example. Discontinuities in soil moisture, such as those found at the interface between irrigated agriculture and native vegetation, tend to enhance shallow convective precipitation.

Vegetation also regulates the availability of soil moisture to the atmosphere through the opening and closing of plant stomata. Changes in surface vegetation can induce changes in local meteorology and climate. In particular, decreases in precipitation are believed to be associated with changes in land cover in south–east Asia and the Amazon (and in Africa; *see* Land Cover and Climate, Volume 1). Charney (1975) found that the absence of significant moisture sources might help to maintain deserts. In other words, the lack of local moisture for recycling purposes makes a desert a stable system and that, once an area has been made into a desert, it is difficult to change without external forcing (*see* Deserts, Volume 1).

HUMANS AND THE HYDROLOGIC CYCLE

One component of the hydrologic cycle that is frequently not directly included in its descriptions is human activity. The hydrologic cycle would continue, irrespective of human activities, but humans do have a significant impact on the terrestrial component of the hydrologic cycle. Likewise, changes in the hydrologic cycle can dramatically impact human activities, for better or for worse. Under growing population pressures, decreasing availability of freshwater per person, and potential global climate change, how this feedback will develop in coming years remains an interesting yet unresolved question.

Are humans affected by the hydrologic cycle? Certainly. Water is essential to life on Earth. The availability of water has shaped where civilizations have developed and thrived, just as lack of water has caused great hardships. Water is both a necessity and a resource for financial gains. Yet, while it is a benefit, it is also a hazard. On average, over $8 billion damages per year have resulted from flooding and hurricanes in the US alone (Kunkel *et al.*, 1999). Indeed, this does not include pandemic health hazards created by poor water quality.

Will humans affect the hydrologic cycle in the future? Undoubtedly. There is considerable evidence that humans have affected the hydrologic cycle in the past (Figure 7). Large dams, reservoirs, and extensive canal systems are perhaps the most visible testimony to this. In several basins across the globe, surface water resources have been so intensively developed that major rivers periodically cease flowing to the ocean (such as the Colorado River in the US and the Yellow River in China). Inter- and intra-basin transfers have significantly interfered with the natural distribution of water.

The most pervasive change to the hydrologic cycle due to human activities is associated with land-use change. These changes are very important to consider as, according to van Dam (1999, xiii), the effects of climate variability and change on the hydrological cycle will be coincident with those of changes in land use, which could be of the same order of magnitude. The various types of land-use changes range from deforestation to agriculture, urbanization to draining swamplands. The impact of these land uses on streamflow is presented in Table 3. The impacts arise from changes in surface albedo, surface roughness, surface permeability (the ability of water to pass through a surface, such as concrete), and the ability of the surface to intercept and evaporate moisture. These impacts are inherently scale-dependent, and most local land-use change will not have a major impact on the continental and global hydrologic cycle. However, the extent of land-use change in total is considerable; Flohn (1973) suggested that, over the last 8000 years, approximately 11% of the land surface has been converted to arable land, and 31% of forests have been modified from their original condition. Additionally, certain regions are poised to have a disproportionately strong impact on global circulation. For example, there is debate as to whether Amazon deforestation will

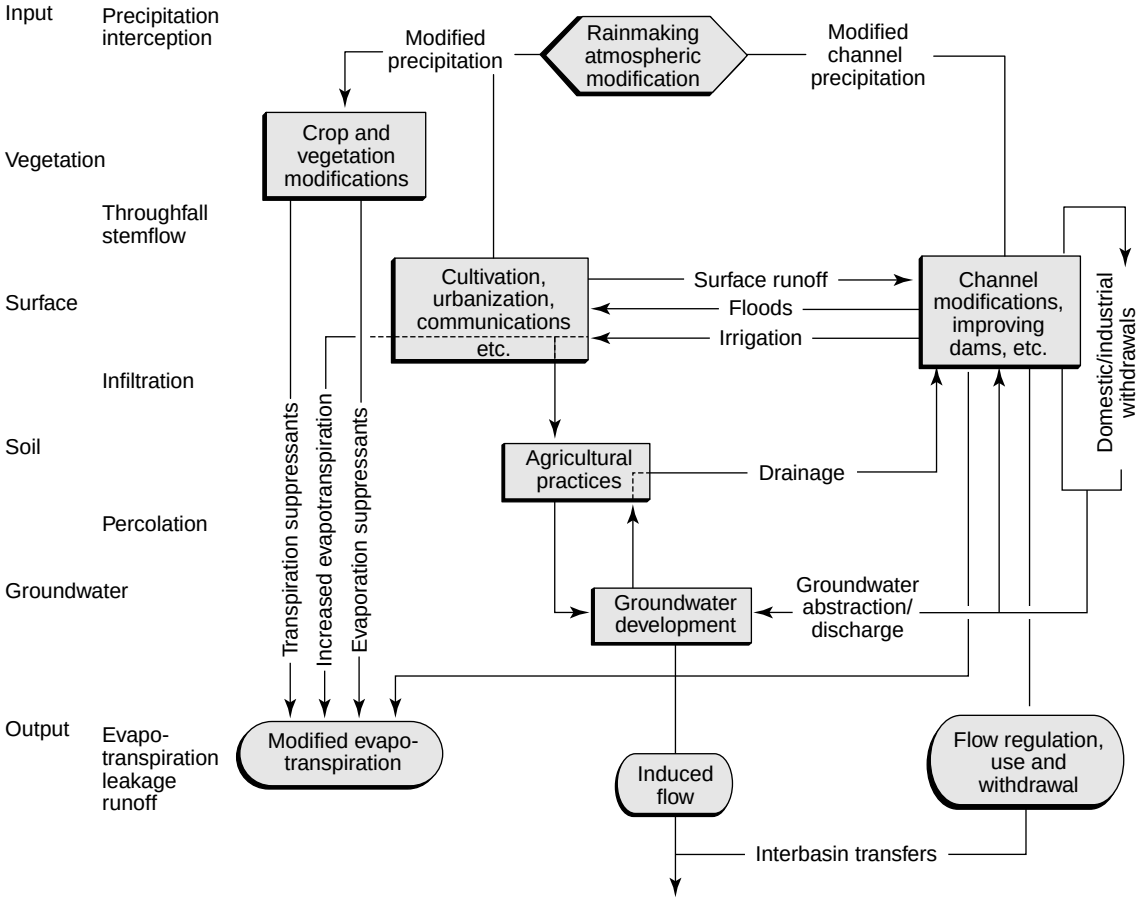

Figure 7 Systems diagram of the impacts of human activities on streamflow (from Ward, 1990). (Reproduced with the permission of McGraw-Hill Publishing Company)

have an impact on tropical and extratropical climate out of the region. Although this is an area of active research, the expected long-range impacts from Amazon deforestation outside the region remain unclear (Gash and Nobre, 1996).

While global fluxes or distributions of water may not be influenced by water quality, humans significantly impact water quality at every step of the hydrologic cycle. Since the 1970s, the primary atmospheric water quality concern has been acid rain. Acid rain damages trees, particularly at high elevations, and contributes to the acidification of lakes and streams. Regions already affected include North America and Northern Europe. Contamination of water at and below the land surface poses a significant threat to potable water supplies (see Fetter, 1998 and Bedient *et al.*, 1999 for further reading on groundwater contamination). Water quality can be affected by human activities in a multitude of ways, including effluent, leeching from landfills, industrial and mining activities, and agricultural fertilizer and pesticide runoff. In particular, the long-term isolation of hazardous radiological byproducts from water supplies poses a special challenge.

GLOBAL CLIMATE CHANGE AND THE HYDROLOGIC CYCLE

As mentioned previously, the magnitude of the impact of human activities on the hydrologic cycle is highly scale-dependent, and few activities manifest themselves on a global scale. However, the extra release of carbon dioxide (CO_2) into the atmosphere and the resulting possible changes in the hydrologic cycle are the subject of a considerable amount of research effort and political attention. A summary of these changes is provided in Table 4. While there is some uncertainty and debate concerning global warming, the theory as to why the hydrologic cycle may be affected is relatively straightforward.

Greenhouse gases in the atmosphere reflect and re-radiate outbound long-wave radiation back to the Earth s surface, increasing the surface temperature. CO_2 is one such gas, while water vapor, methane, and nitrous oxide are among some of the others. The relationship between the concentration of CO_2 in the atmosphere and the temperature of the Earth has been thoroughly documented on geologic

Table 4 Best estimates of climate change projections over the next 50–100 years

Indicators	Annual average change	Distribution of changes		Interannual variability	Significant transients	Confidence of projection	
		Regional average	Change in seasonality			Global average	Regional average
Temperature	+1 to +3.5 °C	−3 to +10 °C	Yes	Down?	Yes	High	Medium
Sea level	+15 to +95 cm	–	No	?	Unlikely	High	Medium
Precipitation	+7 to +15%	−20 to +20%	Yes	Up	Yes	High	Low
Direct solar radiation	−10 to +10%	−30 to +30%	Yes	?	Possible	Low	Low
Evapotranspiration	+5 to +10%	−10 to +10%	Yes	?	Possible	High	Low
Soil moisture	?	−50 to +50%	Yes	?	Yes	?	Medium
Runoff	Increase	−50 to +50%	Yes	?	Yes	Medium	Low
Severe storms	?	?	?	?	Yes	?	?

Source: Schneider *et al.* (1992) (reproduced by permission of John Wiley & Sons) and S Schneider (personal communication, July 27, 2000).

time scales. For instance, during the last glacial period when the atmospheric CO_2 concentration was closer to 200 parts per million by volume (ppmv), the Earth was 6–8 °C cooler than during pre-industrial conditions of 280 ppmv. The current atmospheric concentration of CO_2 is about 370 ppmv, and predictions of future concentrations range from 450–1000 ppmv in the year 2100. The anticipated increase in global surface temperatures over this period is from 1.4 to 5.8 °C (IPCC, 2001).

If the amount of long-wave radiation reflected back to the Earth s surface is increased, the potential evaporation from the ocean and the land surface may also increase. Likewise, because warmer air can potentially hold more water (the amount of water that it would take to saturate a parcel of air increases exponentially with temperature), humidity may increase. If the increase in water vapor storage in the atmosphere does not balance the increased evaporation, precipitation rates should change, on the average (*see* Water Vapor: Distribution and Trends, Volume 1). Due to complex feedbacks within the Earth s climate system, the anticipated impacts of global warming on the hydrologic cycle become considerably more difficult to predict beyond these first few conceptual steps. For example, a more vigorous atmospheric water cycle may involve increased low clouds that might reduce the amount of incoming radiation to the Earth s surface, leading to negative feedback and cooling. However, an increase in high clouds, which are efficient at reflecting long-wave radiation back to the Earth s surface while letting short-wave radiation pass through, would lead to positive feedback of further warming.

If understanding the impact of climate change on all aspects of the hydrologic cycle is difficult, translating these impacts into their effects on human activities is an even greater challenge. Humans are most sensitive to hydrologic variations, extremes, and certain sequences of events. Such questions as how climate change will affect the occurrence of drought in a particular region remain open to debate (although considerable effort has been devoted towards trying to answer these questions, see National Assessment Synthesis Team, 2000). Some scientists believe that the clearest changes associated with global warming will be in the occurrences of extreme events. Assuming that a climatological variable (e.g., precipitation, temperature) has a normal distribution, changes in the mean will bring proportionally greater shifts in intensity and frequency at the tails of the distribution (Trenberth, 1999b; see also Easterling, 2000a for an excellent discussion of the observed and anticipated changes in extreme events induced by climate change).

The atmosphere is not the only component of the hydrologic cycle that may be affected by global climate change; the ocean and cryosphere may also be impacted. Simulations of climate change have predicted that the greatest warming will occur at high latitudes. Locally, this poses a threat to regions with permafrost, where melting can cause land-surface subsidence and damage to structures. However, if temperatures are warm enough, glacial melt and thermal expansion of the oceans also may cause sea level changes over the next 100 years. This is of concern because a 1% decrease in glacial water content translates to approximately a 30 cm increase in sea level. To help put this in perspective, a 2-m rise in sea level could entirely inundate the Republic of the Maldives. Changes in surface albedo associated in the change from ice to bare ground or open ocean is a positive feedback, associated with increased absorption, higher temperatures, and possibly increased melting. The predictions of sea level increase range from 13–94 cm by the year 2100 (IPCC, 1995). Such a change could have dire consequences for coastal ecosystems.

The response of the hydrologic cycle to climate forcing can also be nonlinear. Large temperature rises at high

latitudes, increases in precipitation, and glacial melt may alter the vertical density profile of the North Atlantic Ocean, causing a slowing or collapse of the deep-water formation, greatly impacting the climate of Europe, as was seen during the younger Dryas period. Model simulations of doubling CO_2 concentrations predict a decrease in deep-water formation, with eventual recovery after concentration stabilization, whereas quadrupling concentrations leads to thermohaline collapse and very slow recovery. These simulations are highly model-dependent, but they do emphasize the presence of thresholds and triggers within the climate system (*see* Climate Change, Abrupt, Volume 1).

The expected impacts of climate change on surface runoff and groundwater recharge remain unknown, in part due to the fine spatial scale being considered, and unknown changes in seasonality and timing of precipitation. However, the possible ramifications of these changes should not be underestimated. In regions where water resources are fully committed or over-committed, declines in supply can lead to regional disputes and international conflict. A comprehensive database of articles related to water resources and climate change in the US has been compiled and is available at http://www.pacinst.org/CCBib.html.

20TH CENTURY OBSERVED CHANGES IN THE HYDROLOGIC CYCLE

One of the most difficult challenges in detecting changes in the hydrologic cycle is the lack of globally complete, high-quality long-term measurements. In particular, existing observations of soil moisture and evaporation are unsuitable for studies of long-term changes. Likewise, it is difficult to estimate the underlying climatological frequency of rare events (e.g., floods) from existing data sets, much less detect changes in the frequency or magnitude of these events. Attributing the observed changes to human activities or natural variability represents a special challenge in and of itself. Nonetheless, there are some detectable trends in the modern instrumental precipitation data, primarily towards drier conditions in the tropics and wetter conditions in the extra-tropics. Fewer trends have been detected in streamflow. A summary of recent hydrologic trends is presented in Table 5.

A thorough review of the observed global changes in precipitation is provided by IPCC (1995). A review of changes in the US was done by the National Assessment Synthesis Team (2000). Annual precipitation in the US has increased by 5%, primarily in autumn and in the eastern two–thirds of the country. These increases have been associated with modest increases in heavy rainfall events (i.e., $>5\,\mathrm{cm\,day^{-1}}$, Karl *et al.*, 1995). Streamflow trends are consistent with these increases; geographically widespread regions of the US have experienced increases in the annual median and minimum daily flows. This suggests that, overall, there is more water, in general, in US rivers today and that droughts have not been as extreme as they were in the 1950s–1970s (Lins and Slack, 1999). Easterling *et al.* (2000b) found that precipitation extremes are on the rise in many locations across the globe, but reminded us of the danger of drawing firm conclusions based on analysis of relatively short data records. Likewise, recent changes in the frequency of warm ENSO events and the state of the PDO (since the 1970s) have made sole attribution of the observed climate changes to anthropogenic activities difficult.

Table 5 Observed trends in the hydrologic cycle

Variable	Observed trend	Confidence
Ocean		
High clouds	Increase 1951–1981	Low
Mid-level clouds	Increase in Northern Hemisphere, mid-latitude 1951–1981	Low
Convective clouds	Increase 1951–1981	Low
Fair weather cumulus clouds	Decrease 1951–1981	Low
Water vapor	Increase 1973–1988	Low
Evaporation in tropics	Increase 1949–1989	Medium
Land		
Mid- to high-latitude clouds	Increasing 1900–1980s	Medium
Mid- to high-latitude precipitation	Increasing since 1900	Medium
Northern Hemisphere subtropical precipitation	10% decrease since 1970	Medium
Evaporation in US and FSU[a]	Decreasing since 1950	Low
Soil moisture in FSU[a]	Increasing 1970s–1990s	Low
Runoff	Pattern consistent with precipitation changes	Medium

TOWARDS IMPROVED UNDERSTANDING OF THE HYDROLOGIC CYCLE

Although the hydrologic cycle has been studied for well over a century, with considerable work being done in recent decades, many unresolved questions and expanding

frontiers in water cycle research remain. In particular, understanding the impacts of human activities on the hydrologic cycle is an area of active research. Considerable effort is also being devoted to understanding the linkages between the ocean and atmosphere in the tropics (such as ENSO), as well as at mid-latitudes (through PDO, NAO, and through changes in ocean thermohaline circulation). Increased attention has been devoted to land surface and hydrologic representation in large-scale computer models, the intent of which is to improve predictions of variations in the hydrologic cycle on interannual and longer time scales. Medium-range weather predictions can also improve through having a better understanding and model representation of soil–moisture processes (Chahine, 1992). Finally, groundwater and surface interactions, ranging from the amount of water recharged into an aquifer from snowmelt to the hydrology of natural springs, are some of the least understood components of basin-scale water balances.

Improved understanding of the hydrologic cycle is not limited to the understanding contained within the scientific research community. It is also that of the operational water management community, the general public, and other water resources stakeholders. Concepts such as climate stationarity (the belief that the underlying statistics of the climate of a particular region are constant in time) are key assumptions for most water management planning and design, although the research community has long recognized the flaws in this assumption. For example, for structural design purposes, relatively brief historical records are used to estimate the magnitude of the flood that would happen once in a 100 years. If the historical period being considered contains unusually wet or dry spells, this approach will not give a representative estimate of what may happen in the future. Likewise, most regions lack legal recognition of the connection between the groundwater and surface-water components of the hydrologic cycle. The impacts of excessive groundwater withdrawals on streamflow are fairly well understood by the scientific research community, although few, if any, regions have laws that reflect this understanding.

There are several major research programs designed to develop a more sophisticated understanding of the hydrologic cycle. One such program, the Global Energy and Water cycle EXperiment (GEWEX, *see* GEWEX (Global Energy and Water Cycle Experiment), Volume 1), was initiated in 1988 by the World Climate Research Programme (WCRP, 1990; Chahine, 1992). Part of GEWEX is designed to observe and model the hydrologic cycle, with the ultimate goal of predicting global and regional climate change. The program includes large-scale field activities and intensive measurements, as well as modeling and research. GEWEX has contributed to the development of improved numerical models and the creation of state of the art climate data sets, and it is also helping to achieve its goals of improving resource management through scientific outreach to the engineering and other user communities.

Hydrology

The science of water, the study of the distribution, conservation and use of the water of the Earth: these are examples of some of the dictionary definitions of *hydrology*. They are usually too broad, however. As an earth science, hydrology invariably deals with fresh and brackish water. Salt water belongs to oceanography, while the study of water in the atmosphere is part of meteorology. Indeed some would argue that hydrology starts where meteorology stops, but there is an area of overlap termed *hydrometeorology*. There are similar overlaps with a number of other sciences, e.g., that with geology is *hydrogeology*. Hydrology developed largely as an applied science, but in recent years it has metamorphosed into a distinct discipline.

The purview of hydrology is best described by two widely accepted definitions (UNESCO/WMO, 1992).

1. Science that deals with the waters above and below the land surfaces of the Earth, their occurrence, circulation and distribution, both in time and space, their biological, chemical and physical properties, their reaction with the environment, including their relation to living things.
2. Science that deals with the processes governing the depletion and replenishment of the water resources of the land areas of the Earth, and treats the various phases of the hydrological cycle.

Hydrology can also be seen through the eyes of those bodies with programs in the sciences. For example, the International Association of Hydrological Sciences (*see* IAHS (International Association of Hydrological Sciences), Volume 1) deals with: surface water, groundwater, erosion, snow and ice, water quality, water resources systems and atmosphere–soil–vegetation relations and the use

of remote sensing and tracers. The Association focuses on the study of the hydrological cycle on the Earth and the waters of the continent; including their physical chemical and biological processes, their relation to climate and to other physical and geographical factors as well as the inter-relations between them. Assessment of water resources, hydrological forecasting and flood and drought prediction, for design purposes are germane to its purpose.

I

IAHS (International Association of Hydrological Sciences)

The IAHS is the oldest and foremost international non-governmental organization (NGO) in the fields of hydrology and water resources. Incorporating the International Commission on Glaciers, which had been set up in 1894, it was established in 1922 with the aim of bringing together hydrologists from all countries to promote the hydrological sciences.

IAHS promotes the study of all aspects of hydrology; fosters discussion, comparison and publication of research results; and initiates and coordinates research that requires international cooperation. To fulfill these aims, the association organizes assemblies, symposia and workshops in various parts of the world, publishes the proceedings of these meetings as well as a scientific journal, contributes to a wide range of international initiatives and generally fosters activities and collaboration in hydrology and water resources.

IAHS is one of the seven associations that form the International Union of Geodesy and Geophysics (IUGG), which was established in 1919 to promote physical, chemical and mathematical studies of the Earth and its spatial environment. IUGG is itself one of the 20 scientific unions that are grouped within the International Council for Science (ICSU), an international NGO, which was established in 1931 to promote international scientific activity for the benefit of mankind.

IAHS maintains close collaboration with the United Nations Educational, Scientific and Cultural Organization (UNESCO) and the World Meteorological Organization (WMO) through their respective hydrology and water resources programs, the International Hydrological Programme (IHP) of UNESCO, and the Hydrology and Water Resources Programme (HWRP) of WMO.

For further information, contact Dr Pierre Hubert, Secretary General, IAHS, Ecole des Mines de Paris, 35 rue Saint Honoré, 77305 Fontainebleau, France.

JOHN S PERRY *USA*

IAMAS (International Association of Meteorology and Atmospheric Sciences)

The IAMAS is one of seven associations making up the International Union of Geodesy and Geophysics (IUGG), which is in turn a component of the International Council for Science (ICSU). These bodies provide an organizational structure for the scientists of the world to come together to present, discuss, and promote the newest achievements in their fields of research. The objectives of IAMAS are to promote the study of all problems relating to the sciences of the atmosphere; initiate, facilitate, and coordinate research that requires international cooperation; and to stimulate discussion and provide for publication of the results of research in this field. The IAMAS is organized into ten commissions, each of which focuses on a particular aspect of this research field. The international commissions presently active are the International Commission of Atmospheric Chemistry and Global Pollution (ICACGP), International Commission for Atmospheric Electricity (ICAE), International Commission of Climate (ICCl), International Commission for Clouds and Precipitation (ICCP), International Commission for Dynamic Meteorology (ICDM), International Commission of Meteorology for the Middle Atmosphere (ICMMA), International Commission for Planetary Atmospheres and their Evolution (ICPAE), International Commission for Polar Meteorology (ICPM), International Ozone Commission (IOC), and the International Radiation Commission (IRC).

A major role of IAMAS and the commissions is to organize international conferences and symposia. In addition, IAMAS has recently undertaken a major activity in cooperation with the World Meteorological Organization to strengthen linkages with universities around the world as a means of improving the ability of scientists in this field to respond to society s needs for information. Further information is available at http://iamas.org/.

MICHAEL C MACCRACKEN *USA*

IAPSO (International Association for the Physical Sciences of the Oceans)

The IAPSO is one of seven associations making up the International Union of Geodesy and Geophysics (IUGG), which is in turn a component of the International Council for Science (ICSU). These bodies provide an organizational structure for the scientists of the world to come together to present, discuss and promote the newest achievements in their fields of research. IAPSO became a separate organization in 1929 and has held periodic assemblies every 2–4 years since that time (except during World War II). The primary goal of IAPSO is to promote study of scientific problems relating to the oceans and the interactions taking place at the sea floor, coastal, and atmospheric boundaries. To address this goal, IAPSO organizes international meetings and fora, establishes commissions to encourage and co–ordinate research activities, provides basic services significant to the conduct of physical oceanography and publishes proceedings and reference materials. IAPSO commissions include the Commission on Mean Sea Level and Tides, the Commission on Sea Ice, the Commission on Cooperation with Developing Countries, and the Tsunami Commission, which is jointly sponsored by the IUGG s International Association of Seismology and Physics of the Earth s Interior. The IAPSO also is a sponsor of the Permanent Service for Mean Sea Level and the IAPSO Standard Seawater Service. IAPSO also maintains formal liaison with ICSU s Scientific Committee on Oceanic Research (SCOR) and United Nations Educational, Scientific and Cultural Organization s (UNESCO) Intergovernmental Oceanographic Commission (IOC). Further information is available at http://www.olympus.net/iapso/.

MICHAEL C MACCRACKEN *USA*

Icebergs

Icebergs are large pieces of floating glacier ice (not sea ice) that protrude more than 5 m above the water and are more than about 10 m across. Smaller pieces of floating glacier ice are called *growlers* if they are almost awash, protruding no more than about a meter, or *bergy bits*, if they are intermediate in size. Eighty to ninety percent of the mass of a freely floating iceberg lies below the water surface. Often, due to faster melting of the ice above water, an iceberg has an underwater projection, dangerous to ships, called a *ram*.

Icebergs form by calving from the termini of glaciers where they meet a lake or the ocean. Antarctic ice shelves calve huge tabular (flat-surfaced) icebergs; the largest ever reported was twice the area of Connecticut. Icebergs in Antarctica mostly remain in the waters near the continent and are seldom found in shipping lanes. This is not so in the Northern Hemisphere. Icebergs from Greenland are commonly found in the North Atlantic and a rapid retreat of the terminus of Columbia Glacier in Alaska led to a large influx of icebergs into Prince William Sound, which is used by supertankers carrying oil from the Alaska pipeline.

Icebergs are responsible for almost all of the ice loss from Antarctica ($2000\,km^3\,year^{-1}$) and much of that from Greenland ($300\,km^3\,year^{-1}$). Exact discharge rates are not known, partly because the calving of large icebergs is infrequent. An ice front may creep forward for decades or centuries and then re-establish its earlier configuration in a single calving event. Conversely, the calving of a state-sized iceberg does not imply climatic change. Glaciologists do not have a satisfactory predictive model of calving and consequently cannot forecast the effect of climatic change on iceberg production. However, it is noteworthy that several small ice shelves in the northern Antarctic Peninsula have broken up into icebergs in the last decade, during a pronounced warming in that region.

IGAC (International Global Atmospheric Chemistry)

The IGAC Project was initiated in 1988 by the Commission on Atmospheric Chemistry and Global Pollution of the International Association of Meteorology and Atmospheric Sciences (IAMAS) in response to growing concern about observed changes in atmospheric composition and their potential impacts on humankind. IGAC became a Core Project of the International Geosphere–Biosphere Programme in 1990 (*see* IGBP Core Projects, Volume 2).

IGAC s goals are to:

- develop a fundamental understanding of the processes that determine atmospheric composition;

- understand the interactions between atmospheric chemical composition and physical, biospheric, and climatic processes;
- predict the impact of natural and anthropogenic forcings on the chemical composition of the atmosphere.

The atmosphere is chemically complex and dynamic, interacting internally between troposphere and stratosphere, and externally with oceans, land, and biota. Atmospheric composition has changed over geologic time, and ice core records indicate that it has changed markedly so over at least the last 400 000 years. Human activities have raised concentrations of radiatively active greenhouse gases and aerosols, and diminished the ozone layer, potentially impacting the biosphere.

After atmospheric carbon dioxide (CO_2), which undergoes exchanges with the land and ocean but is not chemically altered in the atmosphere, the most important long-lived greenhouse gas is methane. Methane has major natural and anthropogenic sources and is destroyed mostly by oxidation in the atmosphere. Nitrous oxide (N_2O), with a similar range of sources, and the purely anthropogenic chlorofluorocarbons are also greenhouse gases, although their climate forcing is offset partially by the changes in concentration of stratospheric ozone they destroy.

Ozone is a key atmospheric chemical and protective ultraviolet shield. Its chemistry is influenced by many other trace species. It is also toxic to humans and vegetation, and is an important greenhouse gas.

Gaseous sulfur compounds, both natural and anthropogenic, are oxidized to form sulfate aerosols which have an important effect on albedo, partly counteracting climate forcing by the greenhouse gases.

Atmospheric chemistry is closely linked to industrial activity, climate, and land-use through many interrelated processes. IGAC is dedicated to understanding this complex system through a combination of observations, theory, and laboratory and modeling studies.

IGY (International Geophysical Year)

The IGY (1958–1959) was a highly successful international program conducted with the goal of observing geophysical phenomena and securing data from all parts of the world, and conducting this effort on a coordinated basis by fields, and in space and time, so that results could be collated in a meaningful manner.

In 1952, the International Council of Scientific Unions (later renamed the International Council for Science (ICSU)) proposed the IGY, modeled on the International Polar Years of 1882–1883 and 1932–1933. The aim was to allow scientists from around the world to take part in a series of coordinated observations of various geophysical phenomena employing rapidly advancing observational techniques, notably the then-new resources of space technology.

The IGY was overseen by an ICSU Special Committee for the IGY, which acted as the program s governing body. Supporting activities were organized in many countries. For example, a US National Committee, under the aegis of the US National Academy of Sciences, organized US participation in the IGY. Specialized groups developed programs in many areas of geophysics: aurora and airglow, cosmic rays, geomagnetism, glaciology, gravity, ionospheric physics, longitude and latitude determination, meteorology, oceanography, rocketry, seismology, and solar activity. A major goal, achieved by the Soviet Union followed shortly by the US, was to launch the first artificial Earth satellites. In successfully launching science into space, the IGY may have scored its greatest breakthrough.

IGY activities literally spanned the globe from the North to the South Poles, and ultimately 67 countries participated. Although much work was carried out in the arctic and equatorial regions, special attention was given to the Antarctic, where research contributed to improved meteorological prediction, advances in the theoretical analysis of glaciers, and better understanding of seismological phenomena in the Southern Hemisphere.

IHP (International Hydrological Program)

Water – the source of life and human civilization – is surely one of the major issues of the 21st century. During

the coming years, problems of water quality and availability will affect the lives of virtually everyone on the planet. Regions of the world facing water shortages are growing in area and number while the demand for water is estimated to have risen six or seven times from 1900 to 1995 – more than double the rate of population growth. Issues concerning the world s fresh water highlight the dilemma facing humankind. Can competition between the environment and development be transformed into a partnership between the two, so that the goal of sustainable development is met?

The IHP is an intergovernmental applied research and education activity under United Nations Educational, Scientific and Cultural Organization (UNESCO) auspices and is designed to help nations to improve their knowledge of the water cycle and thereby increase their capacity to better manage and develop their water resources. It aims at the improvement of the scientific and technological basis for the development of methods for the rational management of water resources.

The program started as the International Hydrological Decade (IHD, 1965–1974) and was followed by the IHP as a long-term program executed in phases of a six-year duration. The general objective of the IHD, and later of the IHP, is to improve the scientific and technological basis for the development of methods and the human resource base for the rational management of water resources, including the protection of the environment. Over time, the program has evolved from being research oriented to placing increased emphasis on practical aspects of hydrology and water resources. The program s major current theme is *Hydrology and Water Resources Development in a Vulnerable Environment*. Eight subsidiary themes have been identified that cut across different hydrological scales and different climatic regions, but have integrated water management in a vulnerable environment as a common issue:

- global hydrological and biochemical processes;
- ecohydrological processes in the surficial zone;
- groundwater resources at risk;
- strategies for water resources management in emergency and conflicting situations;
- integrated water resources management in arid and semi-arid zones;
- humid tropics hydrology and water management;
- integrated urban water management;
- transfer of knowledge, information and technology.

The IHP carries out a wide variety of activities to address these issues. For example, IHP sponsors postgraduate hydrology courses in the field of hydrology and water resources management with emphasis on a interdisciplinary approach. It is also engaged in preparing computer-based learning materials for *distance learning* (*see* Distance Learning and Environment, Volume 4) and, in cooperation with other United Nations agencies, a broad range of publications.

At the global level the intergovernmental council for IHP plans, coordinates and monitors all IHP activities, which are executed by the secretariat either directly or with the help of committees, working groups or rapporteurs. At the national level, the IHP is coordinated and executed by national committees. The UNESCO regional offices are responsible for regional implementation.

For further information, contact Dr A Szollosi-Nagy, UNESCO, 7 Place de Fontenoy, 75352 Paris Cedex-07, France.

JOHN S PERRY *USA*

Imbrie, John

(1925-)

John Imbrie, US paleoclimatologist and paleoceanographer masterminded the analysis of paleoceanographic data to demonstrate that the Earth s orbital variations in seasonal insolation paced the multiple glacial/interglacial cycles of the current ice age. Having begun his career as a Paleozoic brachiopod paleontologist with geology degrees from Princeton (BA in 1948) and Yale (PhD in 1951), Imbrie achieved considerable recognition for his contributions to paleoecology and for introducing multivariate statistical methods to the study of sediments. He did this research while teaching at Columbia University from 1952–1967, where he became chair of the Geology Department in 1966. When he moved to Brown University in 1967, he switched to studying microfossils in the Quaternary sediments of marine cores. He saw a major paleoclimatic opportunity to study the past distribution of microscopic marine organisms within the vast core collection at the Lamont–Doherty Geological Observatory at Columbia University. Working with Nilva Kipp as his assistant and with the numerous collaborators within *Climate: Mapping and Prediction* (CLIMAP) (*see also* CLIMAP (Climate: Long-range Investigation, Mapping, and Prediction), Volume 1), Imbrie helped found and direct this National

Science Foundation-sponsored multi-institutional project that extended from 1971 to 1981 within the International Decade of Ocean Exploration, Imbrie was co-author on three papers (Imbrie and Kipp, 1971; Hays *et al.*, 1976; and CLIMAP, 1976) that gained him international recognition and election to the National Academy of Sciences in 1978. In addition to providing convincing evidence for the Milankovitch hypothesis of orbitally forced glacial/interglacial cycles (*see* Milankovitch, Milutin, Volume 1; Orbital Variations, Volume 1), these papers also showed how to estimate sea-surface temperatures from microfossils in marine cores, and provided the boundary conditions for running a global climate model to simulate the climates of the last glacial maximum, 21 000 years ago.

From 1973 to 1975, Imbrie served on a National Research Council panel that developed a 10-year research program for advancing understanding of the climate system. With George Denton and Wallace Broecker, Imbrie wrote an appendix to the main panel report that helped shape paleoclimatic research for the next decade, during which paleoclimatology became central to an understanding of climate dynamics in atmospheric and ocean sciences. Imbrie and Imbrie (1979) provide a highly readable summary of the historical development of the astronomical theory of ice ages and of Imbrie s contributions to it. This book won the Phi Beta Kappa Science Award for science writing. From 1981 to his retirement in 1990, Imbrie helped direct SPECMAP, another multi-institutional project concerned with spectral analysis of 100 000-year or longer paleoclimatic time series. This project resulted in multi-authored papers (Imbrie *et al.*, 1992, 1993) summarizing the structure and origin on the major glaciation cycles. He was a MacArthur Fellow from 1981–1985 and has received numerous honors and medals.

Infrared Radiation

V Ramaswamy

Geophysical Fluid Dynamics Laboratory, Princeton, NJ, USA

Infrared radiation is one of the two critical components in the heat balance of the planet taken as a whole, being distinct from the other component (viz., solar radiation). It is comprised of radiative energy emitted by the Earth's surface and the atmosphere. In contrast to solar radiation, which is a source of heat from the Sun into the climate system, the infrared radiation represents a loss of heat from Earth. The absorption and emission of infrared radiation by the Earth's surface and atmosphere constitute the basis for the greenhouse effect, and play a critical role in governing the climate of the planet.

CONCEPTS

Infrared radiation (also known as longwave, terrestrial or thermal infrared radiation) consists of electromagnetic waves propagating at the velocity of light ($3 \cdot 10^8\ m\ s^{-1}$), with wavelengths greater than about 3 μm (micrometers or microns). Defined in this manner, the outgoing radiation from Earth also includes the traditional microwave spectrum. Instead of wavelength, the infrared radiation can be described in terms of frequency space, where a unit commonly used is the wavenumber, which is inversely proportional to wavelength and is expressed in inverse centimeter units. In these units, the outgoing infrared radiation consists of wavenumbers less than about 3000 cm^{-1}. From quantum mechanics, the propagation of electromagnetic radiation can also be thought of as occurring in the form of discrete particles called photons. The spectrum of Earth s longwave radiation is almost completely separated from that of solar radiation, with most of the energy contained

in the 5–100 μm range (or 2000–100 cm^{-1}). Longwave radiation is absorbed and emitted by the planetary surface and by atmospheric constituents including gases, aerosols, and clouds. On an annual basis, the longwave irradiance or flux (energy per unit area per unit time) emitted by the Earth s surface–atmosphere system, very nearly balances the net input of solar radiation, such that the climate system is in radiative equilibrium in the absence of externally applied forcing (e.g., due to natural or human induced factors).

The fundamental laws governing longwave radiation are formulated with respect to a black body, i.e., a conceptually idealized object that is a perfect absorber of radiation of all wavelengths incident on it and that also emits the maximum energy possible at a given temperature. Planck s law states that the intensity (energy per unit time per unit area per unit solid angle per unit wavelength) of radiation emitted by a black body at any wavelength is uniquely determined by its temperature; the emitted radiation is isotropic, i.e., the intensity is independent of direction. The total irradiance emitted by a black body integrated over all wavelengths, given by the Stefan–Boltzmann law, is proportional to the fourth power of the absolute temperature. According to Wien s law, the wavelength of maximum radiation by a black body is inversely proportional to its absolute temperature.

In practical terms, the emission and absorption of radiation by the surface and atmospheric constituents (e.g., molecules and particles) are described with reference to a black body. A measure of how strongly a body radiates at any wavelength is given by the emissivity (a fraction between zero and one), which is the ratio of the actual emission to a black body emission at the same wavelength and temperature. Likewise, the absorptivity of a material is defined as the ratio of the radiation absorbed by that material to that absorbed by a black body. According to Kirchhoff s law, in thermodynamic equilibrium (valid below an altitude of about 70 km), any selective absorber of radiation at a given wavelength is also a selective and an equally effective emitter of radiation at the same wavelength. At any wavelength, the intensity of the radiation emitted by a non-black body is the product of its emissivity and the black body emission at that temperature.

ATMOSPHERIC GASES

The absorption and emission of longwave radiation by atmospheric gases occurs at specific wavelengths depending on their atomic and molecular structure. The atmospheric gaseous constituents can be viewed as entities possessing energy states associated with the vibrations of the atoms about their mean positions in a molecule and the rotation of the molecules about their center of mass. Further, according to quantum mechanics, electrons can occupy only certain orbital configurations within atoms, and only certain vibrational and rotational states are permitted for a molecule. Specific combinations of the electron orbits and the vibrational and rotational states determine the energy level of a molecule. A molecule may make a transition to a higher energy level (an excited state) by absorbing photons, or through collisions with other molecules. Likewise, it may proceed from a higher to a lower energy level by emitting photons either spontaneously or via collisions. The interaction of a molecule with photons is quantized, in that only certain discrete changes in energy levels are permitted, and these remain the same for both absorption and emission. Both the wavelengths (or frequencies) at which such transitions are possible and the energies associated with them are characteristic for each molecule, giving rise to line like features of distinct strength (absorption lines) in the observed spectra of the molecule. The individual spectral lines of the molecules are not sharp, but rather have finite widths in wavelength space, according to the Heisenberg uncertainty principle. Within the atmosphere, the width of the spectral lines is further broadened due to the random thermal motions of the molecules (Doppler broadening) and frequent collisions between molecules (collisional broadening). Below about 30 km altitude, the widths are determined largely by collisional broadening. For any specific molecule, a large series of closely spaced spectral lines in a narrow interval of the spectrum is referred to as its absorption band. Isotopes of molecules can also possess significant absorption bands; these bands are displaced in wavelength with respect to that of the parent molecule depending on the mass of the isotope.

If radiation at a particular wavelength incident on a gas cannot excite its atoms and molecules, energy is neither absorbed nor emitted at that wavelength. The major constituents of the atmosphere by volume viz., nitrogen (N_2) and oxygen (O_2), have no absorption bands in the longwave spectrum. Thus, only gases present in trace amounts in the atmosphere are infrared active and responsible for the longwave radiative process. Molecules that have significant absorption bands in the 5–100 μm wavelength (2000–100 cm^{-1}) region include water vapor (H_2O), carbon dioxide (CO_2), ozone (O_3), methane (CH_4), nitrous oxide (N_2O), and the halocarbons (such as chlorofluorocarbons, CFCs); these constitute the so-called greenhouse gases. Water vapor is the strongest longwave gaseous absorber, absorbing virtually throughout the longwave spectrum. It has strong absorption bands extending from 17 μm (588 cm^{-1}) toward longer wavelengths, and also in the 5–8 μm (2000–1250 cm^{-1}) region. In other spectral regions, water vapor absorption, though not as strong, is not negligible.

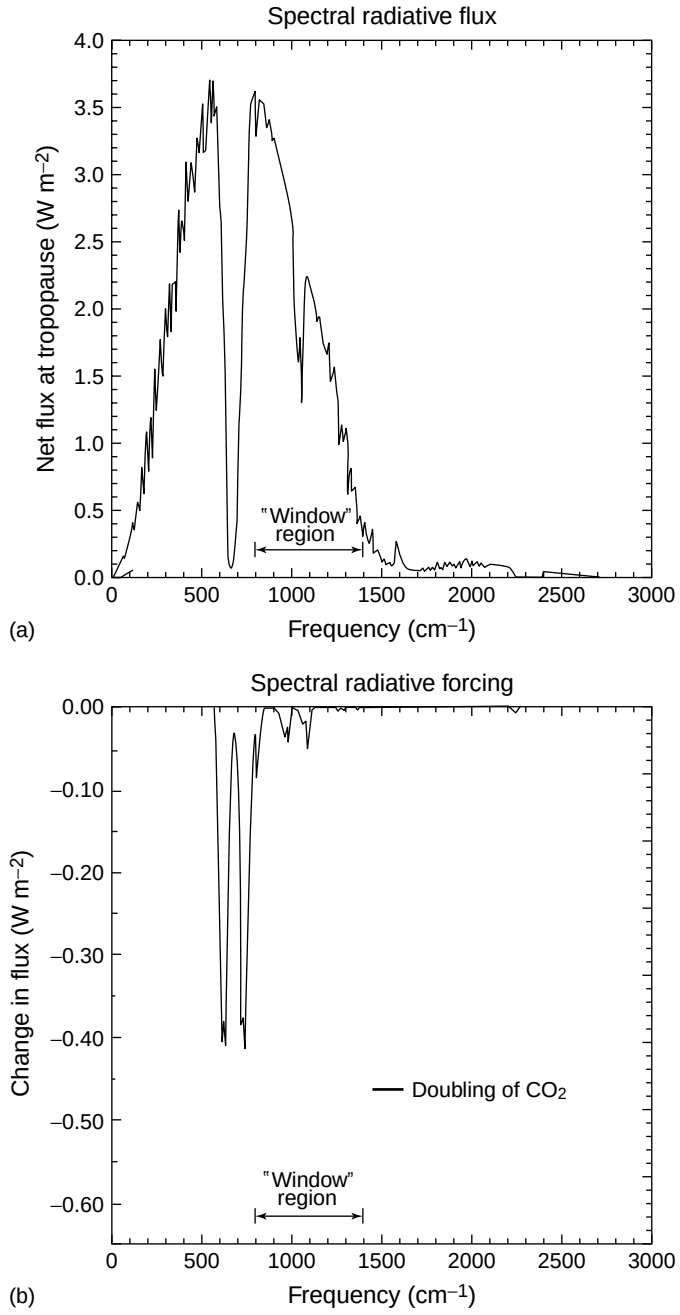

Figure 1 (a) Infrared radiation spectra of the net outgoing radiative flux at the tropopause (i.e., surface-troposphere system) in clear sky, typical mid-latitude summer conditions containing water, carbon dioxide and ozone. The concentration of carbon dioxide (300 ppmv) corresponds approximately to the value at the beginning of the 20th century, while the other gases are held at 1980 climatological values in this calculation. The so-called *window region* is labeled. The spectral absorption by the three gases becomes evident by examining the reduction seen in the net outgoing flux at the respective band locations of the concerned gases (see text). (b) Change in the spectral flux due to an instantaneous doubling of the carbon dioxide concentration. This is referred to as a radiative forcing of the surface-troposphere system. Note that the center of the carbon dioxide band (667 cm^{-1}) does not yield as substantial a reduction in the flux as do the wings of the band. This is because the center of the band is strongly absorbing and is already quite saturated for the base concentration assumed, so that additional absorption in this region due to an increase in carbon dioxide leads to only a small decrease in the spectral flux (or, equivalently, a small enhancement of the spectral greenhouse effect). However, away from the band center and in the wings, where the absorption strength of the molecule is less relative to the center, there is no saturation. Here, there results a substantially larger decrease of the spectral outgoing infrared flux (or a larger enhancement of the spectral greenhouse effect) due to the increase in carbon dioxide

The strongest carbon dioxide absorption bands are centered in the 15 μm (667 cm^{-1}) region (see Figure 1), with a minor band at about 10 μm (1000 cm^{-1}). Among the gaseous absorbers, water vapor and carbon dioxide together dominate the longwave radiative process in the troposphere. Ozone has an important band centered at 9.6 μm (1042 cm^{-1}), which is especially important for the longwave radiative process in the stratosphere. Among the species present in lesser concentrations, methane has a band centered at 7.8 μm (1282 cm^{-1}), nitrous oxide has bands centered at 4.5 (2222 cm^{-1}), 7.8 (1282 cm^{-1}), and 17 μm (588 cm^{-1}), and the halocarbon molecules (e.g., CFCs) absorb in the 7–14 μm (1429–714 cm^{-1}) region. The 8–12 μm (1250–833 cm^{-1}) spectral region in general exhibits the weakest gaseous absorption. At any wavelength, the absorptivity of a gas depends on its concentration and on the strength of its absorption band. The intensity of the emitted radiation depends on the absorptivity and temperature of the gas.

ATMOSPHERIC PARTICLES

Particles in the atmosphere also absorb and emit longwave radiation. Particles active in this process include aerosols (such as sulfate, sea salt, dust, and soot), water drops and ice crystals. The absorption and emission of longwave radiation by these particles depends on their size, shape, and composition. Aerosols, with the exception of dust and soot, consist essentially of spherical particles; water clouds also consist of spherical drops, but ice clouds contain nonspherical crystals. The longwave absorption property of the particles varies with wavelength, although this is less pronounced than with the gaseous absorbers. Within liquids and solids, the absorption and emission takes place throughout a continuous spectrum of wavelengths, in contrast to molecular absorption and emission. The region of most significance for longwave radiative interactions with particles is the 8–12 μm (1250–833 cm^{-1}) portion of the spectrum, because this is where gaseous absorption is weakest, while aerosols and clouds have moderate to strong absorption features here. As in the case of gases, the absorptivity of particles, at any wavelength, is governed by the absorption strength and concentration of the species. Clouds composed of water drops in the lower portions of the atmosphere tend to act as black bodies; that is, they are almost completely absorbing at all wavelengths in the longwave spectrum. In general, clouds composed of ice crystals and aerosol layers tend not to behave as black bodies and have absorptivities less than unity. Again as for gases, the intensity of radiation emitted by a particle at any wavelength depends on absorptivity and temperature. For most practical applications, the various types of surfaces on Earth can be considered to have uniform properties and to absorb and emit longwave radiation like black bodies. This assumption holds true for water, snow, and vegetated surfaces; the exceptions are desert surfaces, whose longwave properties depart from that of a black body.

RADIATION PROCESS

In addition to the selective characteristics of spectral absorption and emission by atmospheric species and the surface, the amount of longwave radiation absorbed, transmitted, and emitted in the atmosphere is governed by the vertical variation of the atmospheric mass, the species concentrations, and the temperature. If the total absorptivity at any wavelength due to all the species is less than unity, a portion of the radiation at that wavelength is transmitted. If there is no absorption at that wavelength, the radiation passes unimpeded. Thus, radiation emitted under cloudless skies from a black body surface is strongly absorbed in the major bands of the various gases, notably water vapor and carbon dioxide; a certain amount is emitted by these gases in the same bands. The net effect at the top of the atmosphere is a decrease of the radiation in these bands compared with that emitted by the surface. In contrast, a large part of the 7–13 μm (approximately 1400–800 cm^{-1}) radiation emitted from the surface escapes to tropopause and then to the top of the atmosphere, to space. This spectral region is commonly referred to as a window region (see Figure 1). The portion of the longwave radiation that does not escape to space is trapped by the infrared active gases, leading to a warming of the surface and the troposphere (*see* Greenhouse Effect, Volume 1).

At different altitudes, the absorption and emission processes, when integrated over all wavelengths, result in either a net loss of longwave radiative energy (radiative cooling) or a net gain (radiative warming). This is in contrast to solar radiation, which always acts to warm the atmosphere. If more radiation is emitted than is absorbed in any region, radiative cooling occurs; the converse leads to radiative warming. In the clear sky troposphere (below about 12 km), longwave cooling is essentially due to water vapor and carbon dioxide. The cooling decreases with height, becoming small near the tropopause.

In cloudy atmospheres, layers containing thick clouds tend to behave very nearly as black bodies, especially in the case of water clouds. For such layers, the general tendency is for a radiative heating near the base of the cloud (due essentially to absorption of radiation from below) and a cooling at the top (due essentially to emission of radiation). However, the magnitudes and thus the net radiative gain or loss by the cloud as a whole depends on the vertical location of the cloud, the cloud top and cloud base. Layers containing clouds in the lower troposphere experience strong radiative cooling. The thicker the cloud is, the more it acts like a black body and the stronger the cooling. In layers with

cirrus clouds, however, in the upper troposphere (around 12–17 km), there tends to be a net radiative warming. In the lower stratosphere (around 20 km), ozone absorption causes warming; in the rest of the stratosphere (above about 25 km), there is cooling owing to water vapor, carbon dioxide, and ozone. On an annual basis, the global mean stratospheric longwave cooling very nearly balances the solar heating owing to absorption of solar radiation by ozone, resulting in a state of radiative equilibrium for that region. This is in contrast to the troposphere, where longwave cooling and solar heating do not balance each other; the residual energy is manifest in non-radiative processes such as dynamical motions and latent and sensible heat fluxes. Above about 60 km (the mesosphere), the longwave cooling is due to carbon dioxide.

The Earth s surface is also affected by atmospheric longwave radiation. Most of the radiation received at the surface is due to emission by tropospheric water vapor and carbon dioxide. In the 8–12 μm (1250–833 cm^{-1}) region, there is a strong contribution resulting from clouds, particularly from low lying clouds that radiate virtually as black bodies.

PHYSICAL EFFECTS

Perturbations in amounts of longwave radiation occur in response to changes in the concentrations of the various absorbers, gases, aerosols, and clouds. As a result of human activities, the concentrations of certain greenhouse gases (carbon dioxide, methane, nitrous oxide, and halogenated species including CFCs) have been increasing over the past century or so. These have increased the trapping of longwave energy in the atmosphere, giving rise to concerns about possible global climatic warming. If increases in water vapor accompany the increases in trace gases, this would exacerbate surface warming. Changes in the concentrations of the longwave absorbers, including aerosols and clouds, also perturb the radiative cooling of the atmosphere. The destruction of ozone in the stratosphere by the CFCs (the ozone hole phenomenon), increases in greenhouse gases, and growing concentrations of stratospheric aerosols following volcanic eruptions perturb the longwave radiative cooling of the stratosphere, causing changes in temperatures there as well.

Over the past approximately four decades, different kinds of instruments that measure longwave radiation have been devised to make inferences about the climate system. These fall into two broad categories: some measure radiant energy at different wavelengths; others measure the total longwave irradiance. Over the past two decades, satellites have permitted a reliable global monitoring of the longwave irradiance emitted by the Earth. Observations confirm that, in clear skies, water vapor is the dominant infrared absorber (i.e., major component in the present day greenhouse effect). Observations also indicate that longwave trapping is most effective in the moist tropics and least effective in the drier subtropical regions. Clouds are even more effective in trapping longwave radiation, especially the deep convective clouds in tropical regions whose tops are located at altitudes in the upper troposphere. The present global effect of clouds in reducing the longwave irradiance at the top of the atmosphere is equivalent to about seven times more than the effect that would result from an instantaneous doubling of carbon dioxide, and about 14 times more than the effect of increases in greenhouse gases over the past century. Considering the secular increases in greenhouse gases, the accompanying feedbacks due to increases in water vapor and changes in clouds (amounts, locations and properties) constitute critical factors in quantifying global climate change.

The effect of clouds on longwave radiation is the opposite of their effect on solar radiation. As a consequence of the absorption and the emission processes, the longwave radiation spectrum at the different altitudes and at the top of the atmosphere is a function of the vertical distribution of temperature and the absorptivity of the various species. For this reason, remote sensing by satellites at different wavelengths in the longwave (including the microwave) spectrum has been found to be useful in extracting information about the atmosphere. This principle has been exploited to infer temperature and species concentrations, especially above the tropopause. It is also being used to deduce physical properties of clouds.

Intertropical Convergence Zone (ITCZ)

Rainfall over many parts of the tropical oceans occurs primarily in a long, zonally oriented band that is more or less parallel to and slightly off the equator. This band is referred to as the *Intertropical Convergence Zone* (ITCZ). As well as high rainfall, the ITCZ is a band of relatively low pressure and high convective cloud amount; it marks the meeting of the Northern and Southern Hemisphere trade winds (the Doldrums). The ITCZ occurs over areas of high sea surface temperature in the Atlantic and Indian Oceans. The ITCZ tends to follow the annual latitudinal cycling of the Sun, migrating seasonally towards the warmer hemisphere. However, in the central and eastern Pacific the ITCZ tends to remain in the Northern Hemisphere. Air that converges in the lower levels of the atmosphere due to the meeting of the trade winds rises through the clouds in the ITCZ and emerges in the upper troposphere. After it emerges, the air participates in the Hadley Circulation (*see* Hadley Circulation, Volume 1), which carries it into the subtropics, where the air descends, eventually becoming entrained again into the source region for the trade winds.

The ITCZ is one of three characteristic near-equatorial large-scale precipitation features that is evident in the seasonal or annual mean motions of the atmosphere. The zonal character of the ITCZ is broken over Africa and South America, as well as over the Indonesian maritime continent. Over these continental areas, the precipitation is spread over a larger band of latitudes than in the ITCZ. In contrast to the ITCZ, the continental-type precipitation features, which are associated with the rising branches of the Walker Circulation, straddle the equator, at least in the annual mean. During an El Niño, the Indonesian continental-type precipitation region moves eastwards and replaces the ITCZ in the central Pacific (*see* El Niño and La Niña: Causes and Global Consequences, Volume 1). Also, there is another persistent band of precipitation in the Southern Hemisphere tropical Pacific known as the South Pacific Convergence Zone that slants away from the equator from west to east.

EDWIN K SCHNEIDER *USA*

Ionosphere

Ionosphere is the upper region of the atmosphere that contains a significant concentration of ions and free electrons. The ions are a result of the absorption of solar radiation and cosmic rays by atoms and molecules and by ionization due to collision among the particles. The ionosphere is usually identified as the region above 60 km above the Earth s surface, and is often divided into three layers. The *D region*, which exists from about 60 km to about 120 km in altitude, has a significant diurnal variation with high concentrations of ions during daylight hours, when solar radiation creates ions at a rate higher than natural ion removal, and much lower concentrations at night, when electrons naturally recombine with positive ions. The higher regions, the *E region* that occupies the layer from about 120 km to about 180 km, and the *F region* identified as the region above about 180 km, do not show a strong diurnal variation as both the rates of creation and removal of ions are much slower due to the lower densities there. The ionosphere is important for radio communication because longer wavelength (amplitude modulation (AM) radio frequencies) radio waves are absorbed and reflected by the D and E regions of the ionosphere, establishing limits to the effective transmissions of these wavelengths (though with a diurnal variation to these limits as the weakened D region does not impede transmission at night). Shortwave radio wavelengths can penetrate the lower D and E regions but are reflected by the F region, allowing transmission to longer distances through reflection off the higher layer. Much shorter wavelengths

(frequency modulation (FM) radio and television, radar, and visible light) are not reflected by the ionospheric layers.

KEITH L SEITTER *USA*

IPCC (International Panel on Climate Change)

The IPCC was established jointly by the World Meteorological Organization and the United Nations Environment Programme in 1988. The IPCC operates independently, but in support of the United Nations Framework Convention on Climate Change (UNFCCC). The IPCC s mandate is: (i) to assess available information on the science, the impacts and the socio-economic aspects and consequences of climate change and on the policy options to address climate change; and (ii) to provide, on request, scientific/technical advice to the Conference of the Parties to the UNFCCC and its bodies. While the IPCC assessments strive to be policy relevant and analyze policy implications, they do not recommend international or national policies. The First Assessment Report completed in 1990 in three volumes, including suggested possible elements for a framework convention, played a key role in the negotiations leading to the establishment of the UNFCCC. The Second Assessment Report, completed in 1995 in four volumes, played a similar role in support of the negotiation of the Kyoto Protocol. The IPCC s Third Assessment Report is to be published in four volumes during 2001. In addition, a number of special reports and papers have been prepared dealing with such issues as regional climate change, climate change and aircraft, technology transfer, and carbon sequestration.

Authors for the chapters of an IPCC report are selected from among nominations by governments of scientists and other experts. Author teams normally include at least one expert from the developing world. The authors draft chapters that undergo: (i) review by experts in the subject throughout the world, and (ii) technical review by governments. The Summaries for Policymakers of the reports are approved line-by-line; the underpinning scientific reports are accepted or adopted in whole at the plenaries. Differing but technically well-founded views are stated as such.

The IPCC also develops methodologies such as Guidelines for National Greenhouse Gas Inventories, Technical Guidelines for Assessing Climate Change Impacts and Adaptations.

IRI (International Research Institute for Climate Prediction)

Scientists have long recognized a connection between the ocean and the atmosphere. This interaction influences rainfall and temperature patterns around the world. Droughts and floods associated with climate variability frequently cause economic and social damage in many regions. Advances in Earth science research have provided breakthroughs in forecasting related impacts, such as those associated with El Niño.

The IRI was first proposed at the United Nations Conference on Environmental and Development (UNCED) in 1992. IRI was envisaged as a multinational, end-to-end, climate research and applications system for producing and distributing experimental seasonal-to-interannual climate forecasts, complementing existing global ocean and atmospheric observing systems and process studies.

IRI was formally launched during the International Forum on Forecasting El Niño in 1995, and later established in 1996 through an agreement between the US National Oceanic and Atmospheric Administration (NOAA) and Columbia University s Lamont-Doherty Earth Observatory located in Palisades, NY. The Taiwan Central Weather Bureau joined as a major supporter of IRI in 2000. IRI is currently organized to integrate five major functions: modeling and prediction, experimental forecasting, applications, climate monitoring and dissemination, and training.

IRI links the physical, environmental, social and economic sciences with the goals of understanding impacts and vulnerabilities, and developing key applications and capacity building projects to demonstrate the value of climate forecasts. IRI acts to help decision-makers to manage risks in climate sensitive sectors such as agriculture, water management, fisheries, disaster relief, human health and energy. Working with international and regional partners, IRI brings together scientists with potential users of climate information helping countries in Latin America, the Caribbean, southern Africa, Southeast Asia, South Asia and North America to prepare for or to mitigate the severe

weather-related impacts of climate fluctuations. In this way, IRI catalyzes regional responses to global problems.

Further information on IRI may be obtained by contacting: The International Research Institute for Climate Prediction, 61 Rt. 9W, PO Box 1000, Palisades, NY 10964, USA. Tel. 845-680-4468; Fax: 845-680-4866; http://iri.ldeo.columbia.edu/

ISCCP (International Satellite Cloud Climatology Project)

ISCCP was organized in 1982 as the first project of the World Climate Research Programme to obtain the global, multi-year satellite observations of cloud properties, needed to determine how clouds alter the radiation balance of Earth, and what role they play in the global hydrological cycle (*see* Cloud- Radiation Interactions, Volume 1). Cloud–radiation and cloud–precipitation interactions produce a complex set of feedbacks on climate change that are not yet well understood, limiting the certainty that can be placed on projections of future climate. Since July 1983, institutions in five countries have collected infrared and visible radiances measured by the international constellation of weather satellites. The radiances are sampled in space and time, calibrated, geo-located and placed into a common format; the first ever global radiance dataset with 30 km, 3 h time resolution was released in 1984. The radiances are then analyzed to characterize cloud property variations over diurnal to decadal time scales and mesoscale (at 50–100 km) to global scales; the first global cloud data products were released in 1988. Currently, these global datasets cover a time period from 1983 to 1999; processing is expected to continue until at least 2005. Together with cloud datasets from surface observations and weather balloon measurements and additional special satellite measurements, the ISCCP cloud datasets describe the variations of cloud cover, top and base heights, optical and layer thicknesses, particle sizes and column water amounts. All of this information is now being used to quantify the effects of clouds on Earth s planetary and surface radiation balances, to determine how atmospheric motions produce clouds, and to determine the relationships between cloud properties and precipitation. More details about ISCCP can found in a series of articles in the *Bulletin of the American Meteorological Society* (Schiffer and Rossow, 1983; Schiffer and Rossow, 1985; Rossow and Schiffer, 1991; Rossow and Schiffer, 1999). Project status, as well as complete documentation of all datasets, can be found on the ISCCP Web site at http://isccp.giss.nasa.gov.

ISLSCP (International Satellite Land Surface Climatology Project)

The ISLSCP operates under the auspices of the World Climate Research Programme (WCRP). Established in 1983, originally under the United Nation s Environment Programme, the goal of ISLSCP is to promote the use of satellite data for improving land-surface data used in climate studies (*see* Land Surface, Volume 1). The project has been instrumental in developing global land-surface data employed in climate models and in the design and implementation of important field experiments.

The First ISLSCP Field Experiment (FIFE) was conducted between 1987 and 1989 in the Konza Prairie in Kansas, USA. The aim of FIFE was to develop satellite-derived data on land-surface conditions relevant to biomass, vegetation cover type and temperature, and vegetation and soil processes such as transpiration and photosynthesis. Between 1994 and 1996 ISLSCP continued and extended its field activities to the Boreal ecosystems–atmosphere study (BOREAS) in Canada (*see* Boreal Ecosystem- Atmosphere Study (BOREAS), Volume 2).

The stated objectives of the ISLSCP are:

- to demonstrate the types of surface and near-surface satellite measurements that are relevant to climate and global change studies;
- to develop and improve algorithms for the interpretation of satellite measurements of land-surface features;
- to develop methods to validate area-averaged quantities derived from satellite measurements for climate simulation models;
- to prepare the groundwork for future operational production of land-surface data sets, which can be directly applied to climate problems.

ISLSCP was integrated into the WCRP as part of the Global Energy and Water Cycle Experiment in 1992 (*see* GEWEX (Global Energy and Water Cycle Experiment), Volume 1). Since then the project s emphasis on global satellite-derived information pertaining to soil and vegetation has become an important input into numerical climate models. An on-going goal of ISLSCP is to identify influences that are responsible for changes in the interactions between the atmosphere and land-surfaces in terms of both physical and biological quantities and relate these to the exchange of energy and water between the land surface and atmosphere, weather and climate.

ANN HENDERSON-SELLERS *Australia*

Isostasy

The word *isostasy* (Gr. *isostasios*, in equipoise) is widely employed in the subjects of geophysics and geology to denote the state of gravitational equilibrium into which the Earth would evolve (the state of isostatic equilibrium) should the gravitational forces acting on the system become unbalanced for any reason. The concept was originally introduced to understand the subsurface distributions of mass that would have to exist beneath continental mountain ranges in order that the anomalously light material of which they are constructed be in gravitational equilibrium with their surroundings (see e.g., Holmes, 1965). However, it is also employed to understand the nature of the deformation of the solid Earth that is produced where large ice sheets develop on the continents as a consequence of climate change. In this situation the surface of the solid Earth comes to be viscoelastically depressed by the weight of a load of large spatial scale to a degree such that the Archimedes force of buoyancy due to the surface displacement balances the weight of the load. One then speaks of the system as being in a state of glacial isostatic equilibrium.

IUGG (International Union of Geodesy and Geophysics)

IUGG is an international scientific non-governmental organization, established in 1919.

This organization is one of the 25 scientific unions presently grouped within the International Council for Science (ICSU – formerly International Council of Scientific Unions).

IUGG is dedicated to the scientific study of the Earth, including applications to societal needs, such as mineral resources, mitigation of natural hazards and environmental preservation. Its objectives are the promotion and coordination of physical, chemical and mathematical studies of the Earth and its environment in space. They include the shape of the Earth, its gravitational and magnetic fields, the dynamics of the Earth as a whole and of its component parts, the Earth s internal structure, composition tectonics, the generation of magmas, volcanism and rock formation, the hydrological cycle including snow and ice, all aspects of the oceans, the atmosphere, ionosphere, magnetosphere and solar terrestrial relations, and analogous problems associated with the moon and other planets.

The IUGG is comprised of seven associations, each responsible for a specific range of topics or themes within

the overall scope of the union s activities and each with a sub-structure. These seven international associations are:

International Association of Geodesy (IAG);
International Association of Seismology and Physics of the Earth s Interior (IASPEI);
International Association of Volcanology and Chemistry of the Earth s Interior (IAVCEI);
International Association of Geomagnetism and Aeronomy (IAGA);
International Association of Meteorology and Atmospheric Sciences (IAMAS);
International Association of Hydrological Sciences (IAHS);
International Association for the Physical Sciences of the Ocean (ASPSO);

Besides, inter-association committees and commissions have been established, e.g.,

The Committee on Mathematical Geophysics (CMG);
The Committee on the Study of the Earth s Deep Interior (SEDI);

The union also co-sponsors the Federation of Astronomical and Geophysical data analysis Services (FAGS) and is a partner with other Unions of ICSU in inter-union bodies such as the International Lithosphere Program.

Members to the union are countries; there are 75 such members as of January 1st, 2000. They participate in the union through IUGG committees set up by the national academy or another body that adheres to the union.

IUGG holds General Assemblies at 4-year intervals and each of its associations also organizes a scientific assembly in its own area of research between general assemblies of the union.

J

Jet Stream

Reid Bryson
University of Wisconsin, Madison, WI, USA

The jet stream or band of maximum winds in the upper troposphere was first recognized as an important global phenomenon in 1944. Normally it consists of two segments in the Northern Hemisphere, one from western North America to Northern Europe, and the other from western North Africa across Asia and the Pacific. Such segments tend to spiral toward the pole in both hemispheres, and change latitude with the seasons. The main jet streams are in the westerlies, but there are also some easterly jet streams, mostly in the tropics.

DEFINITION

The standard glossary definition of the jet stream is:

> Relatively narrow river of very strong horizontal winds (usually 50 knots or greater) embedded in the planetary winds aloft. These jets are typically located in the upper troposphere above regions of strong horizontal temperature contrasts (fronts) ••• . Several major jet streams include the polar jet and the subtropical jet.
>
> (Geer *et al.*, 1996)

The definition omits the fact that these elongated west–east bands are nearly always composed of high-speed westerlies, but does include the relationship between the horizontal temperature contrast and the winds aloft over that zone of contrast. That is more obvious in climatic data than in daily weather.

ORIGIN AND DESCRIPTION

The basic equations of motion require that, once above the friction layer, the change of wind velocity with height must be proportional to the horizontal temperature gradient (contrast). Thus, the higher one goes in this region of contrast, the stronger will be the winds. Indeed, the upper westerlies of both Northern and Southern Hemispheres exist because the poles are colder than the equator. Above about 10 km elevation the south–north temperature gradient tends to reverse, so that the winds decrease upward above that level. Consequently, the level of the jet stream core of maximum winds is generally at 10–13 km above sea level.

Thus, one expects strong winds above the regions of the earth where there is a strong temperature gradient. In the European sector, this means a jet stream in the Mediterranean region where Europe to the north is much colder than Africa to the south, and in the Scandinavian–Baltic area where the air flowing into Europe from the Atlantic is warmer than the cold Arctic air flowing from the ice covered Arctic Ocean. The former position has far more temperature contrast than the latter. Similarly, in the North American sector, the land–Gulf of Mexico and Arctic Ocean–land contrasts give two regions of high probability of strong westerlies aloft. Again, the lower latitude jet stream is the stronger, climatically. The locations of these core areas change with the seasons.

Over the Atlantic and Pacific Oceans there is essentially only one such region of strong temperature gradient each. These lie roughly over the Gulf Stream and Kuroshio oceanic warm currents, respectively. Consequently there is not a continuous or multiple or single jet stream running around the Northern Hemisphere (Figure 1). The numbers along the heavy line give the mean wind speed in meters per second at maxima and significant points.

In January, and the winter season in general, a westerly jet is found over the southern United States and off Southeast Asia, with maxima near the southeast coasts. In crossing the oceans, both shift northward, the Asian jet less than the North American jet, and in the mean they weaken near the eastern edge of the oceans. The main Eurafrican jet starts near the Atlantic over North Africa, weakens in the vicinity of the Himalayas and India, and then strengthens as it becomes the southeastern Asian jet. Thus, the jet stream is not one continuous band of high winds about the Northern Hemisphere.

In July, the jet axis comes closer to being a single river of air but the winds are weaker and more indefinite in position near the west coasts of Eurasia and North America.

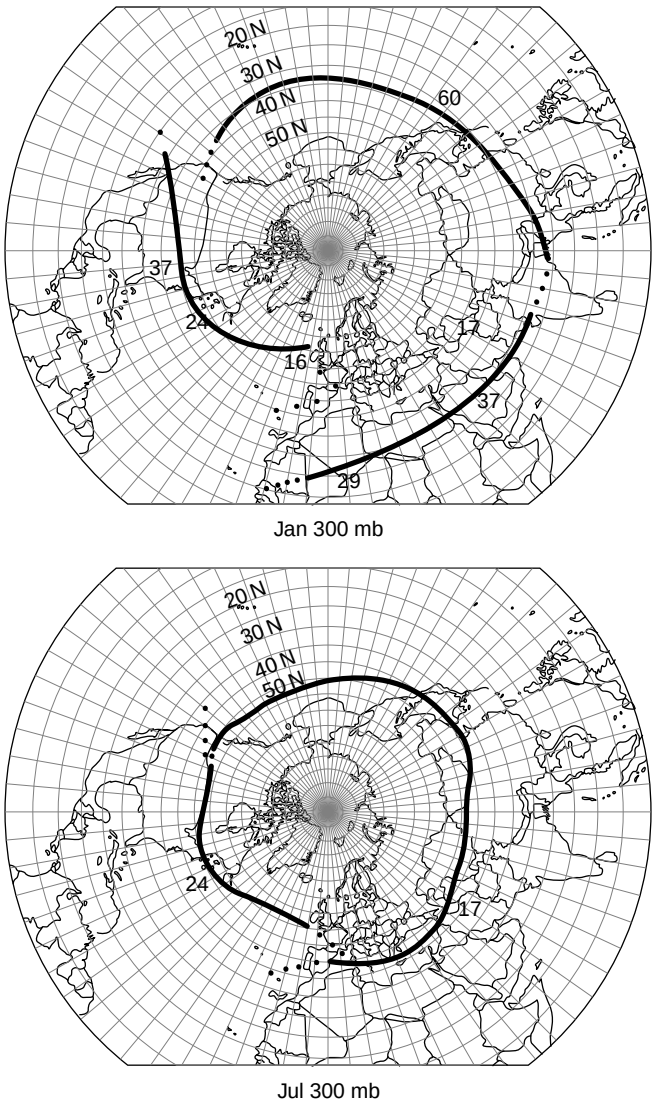

Figure 1 The heavy lines show the position of the axis of the jet stream at 300 mb. The values are mean wind speed in meters per second. By far the strongest westerlies along the jet axis in January are off Japan

The Southern Hemisphere has corresponding jet streams, but in that largely water hemisphere the pattern is simpler. There are also segments of weaker, easterly jets at times and in places where the equatorial region is cooler than the tropical region somewhat to the poleward, e.g., subsaharan Africa.

HISTORY

The first observations of large-scale features of the atmosphere with winds in excess of what might occasionally be observed at the ground came with the development of high-flying aircraft. In the mid-1930s there were some encounters with winds on the order of 80 m s^{-1} or less. With the advent of the Second World War, aircraft in Europe occasionally met even stronger winds, but there was little notice taken in the meteorological community at large, possibly due to restrictions in access to information.

During the same time period the Japanese became aware of high winds aloft. With the advent of high altitude bombing missions over Japanese targets in the fall of 1944, a different wind problem arose than in Europe, and produced widespread interest and discussion.

As shown in Figure 1, there are two main locations for branches of the jet stream in Europe: one in the Mediterranean–North African latitudes and one in the Scandinavian area, both with monthly average wind speeds ranging up to 40 m s^{-1} in the south and less than half that in the north. Most aircraft operations were between the two branches. On the other hand the monthly mean speeds in eastern North America and in the Pacific near Japan are 50–100% greater, and the aircraft operations in the Pacific crossed the jet stream position nearly every day in the cooler months. Winds of nearly 120 m s^{-1} were observed. This was sufficiently close to the speed of the aircraft to pose serious military problems. One might say that this was when the jet stream as a large-scale, significant feature of the atmospheric circulation was discovered (Bryson, 1994).

Immediately after World War II a great deal of research effort was devoted to the study of this newly recognized large-scale feature of the atmospheric circulation (Reiter, 1967).

SIGNIFICANCE

The jet stream, lying above the greatest temperature gradients, i.e., the fronts, is therefore the approximate path of frontal cyclones. However, the fast-moving winds of the jet stream must follow the laws of air dynamics and thus do not follow the fronts in detail. The daily adjustment of the one to the other is a large part of mid-latitude meteorology. Climatically speaking, the concordance of mean frontal position and mean jet stream position is much better, as indicated previously. Changes of mid-latitude climate and changes in the mean position of the jet stream are therefore closely related. For example, periods when the hemisphere is warmer are times when the jet stream and associated fronts are generally farther poleward than in cooler times.

JGOFS (Joint Global Ocean Flux Study)

The role of the ocean in controlling climate change through the storage and transport of heat (and liquid water) was recognized early on by the World Climate Research Programme. The joint Scientific Committee on Oceanic Research (SCOR)/International Oceanographic Commission (IOC) Committee on Climatic Change and the Ocean (CCCO) proposed a global survey of the oceanic carbon dioxide budget field. The World Ocean Circulation Experiment (WOCE) agreed to make berths available on ships taking part in the WOCE Hydrographic Programme for the necessary measurements. The formal organization of JGOFS was carried out by SCOR. JGOFS is now a core project of the International Geosphere–Biosphere Programme, although responsible directly to SCOR.

The oceans contain some 50 times as much carbon dioxide as the atmosphere, and small changes in the ocean carbon cycle can therefore have large atmospheric consequences. Many scientists worldwide are addressing aspects of the ocean carbon cycle, but to determine overall net fluxes, and the processes controlling them, is beyond the capability of any one nation. JGOFS therefore plans and executes research that requires international cooperation. Twenty-one countries contributed to JGOFS planning or field work.

The scientific goals of JGOFS are:

- to determine and understand on a global scale the processes controlling the time-varying fluxes of carbon and associated biogenic elements in the ocean, and to evaluate the related exchanges with the atmosphere, sea floor and continental boundaries;
- to develop a capacity to predict on a global scale the response to anthropogenic perturbations, in particular those related to climate change.

Operationally, the program s activities seek to assess more accurately and improve understanding of the processes controlling regional to global and seasonal to interannual fluxes of carbon between the atmosphere, surface ocean and ocean interior, and their sensitivity to climate changes.

JOHN S PERRY *USA*

Junge Layer

The *Junge layer* is the name given to the background stratospheric sulfate aerosol (SSA) layer that was first directly observed by Professor Christian Junge in 1961 (Junge *et al.*, 1961). This layer is located at an altitude of about 20 km. Junge and his colleagues found that this aerosol layer was composed mostly of sulfuric acid (H_2SO_4) particles. They found it particularly interesting that the layer seemed to be present even long after volcanically injected sulfur dioxide (SO_2) should have oxidized to form H_2SO_4 and been removed from the stratosphere over periods of a couple of years (*see* Volcanic Eruptions, Volume 1).

Observations of the Junge layer during volcanically quiescent periods suggest that the sulfur contributing to the SSA layer may be coming from oxidation of the upward mixing of SO_2 emitted in the lower troposphere, from the upward transport of carbonyl sulfide (COS) that is emitted naturally from the ocean and anthropogenically by industry, or from the upward transport of SO_2 emitted by jet aircraft. However, the recent upward trends in the SSA, which are not readily explained by these factors, suggest that perhaps volcanically injected sulfur may be remaining in the stratosphere longer than had previously been thought (Godin and Poole, 1998).

Professor Junge (1912–1996), who was a leading German scientist, is also well known for many contributions to atmospheric research. Among other insights, he is credited with being the first to describe the continuous size distribution of atmospheric aerosols (*see* Aerosols, Stratosphere, Volume 1; Aerosols, Troposphere, Volume 1). In addition, Junge s book in 1963 on *Atmospheric Chemistry and Radioactivity* established the subject as an important new research field. Up until that time, there were few atmospheric chemists; and national meteorological services generally considered the field to be outside their terms of reference.

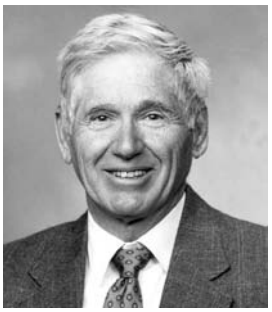
MICHAEL C MACCRACKEN *USA*

K



Keeling, Charles David

(1928-)

The epochal discovery that the concentration of carbon dioxide (CO_2) in the Earth s atmosphere is rising was made by C D Keeling, based on a series of extremely accurate measurements beginning in 1958 and continuing to the present time. Keeling, born in 1928, graduated from the University of Illinois and earned a PhD in chemistry from Northwestern University. He began a postdoctoral fellowship at the California Institute of Technology in 1953, where he developed an interest in measuring atmospheric CO_2 that would prove to dominate his professional life. While a postdoctoral fellow, Keeling designed and built a manometer to measure CO_2 accurately, and found that a concentration of about 310 parts per million by volume (ppmv) was apparently characteristic of the free atmosphere over large regions of the Northern Hemisphere. This surprising result, which seemed clear to Keeling by 1956, would soon upset the prevailing opinion at the time that CO_2 concentrations varied widely over a range of about 150–450 ppmv.

Keeling received important early encouragement from Harry Wexler, in charge of research at the US Weather Bureau in Washington, DC, and from Roger Revelle, director of the Scripps Institution of Oceanography in La Jolla, CA (*see* Revelle, Roger Randall Dougan, Volume 1). Both Wexler and Revelle were instrumental in planning the International Geophysical Year (IGY), an 18-month global program that took place in 1957–1958. At Revelle s invitation, Keeling moved to Scripps in 1956 and, except for brief visits elsewhere, has spent his entire career there. As part of the IGY, Keeling began measurements in Antarctica and at the Mauna Loa Observatory in Hawaii. The Mauna Loa record of CO_2 measurements began in 1958 and quickly yielded important new results. By 1960, in a paper published in *Tellus*, Keeling could report a distinct seasonal cycle of CO_2 concentration in the Northern Hemisphere. Based on carbon isotopic ratio data from his early measurements as a postdoctoral fellow, Keeling proposed in the 1960 *Tellus* paper that the activity of plants growing on land caused the seasonal cycle. CO_2 concentrations were largest in northern spring, when most plants begin to grow, drawing down the atmospheric CO_2 levels. Finally, in the same paper, Keeling noted the possibility of a worldwide increase from year to year.

The Mauna Loa record of CO_2 concentration continues to the present day, and the graph of rising CO_2 concentration as a function of time over more than four decades is now known as the Keeling curve (see Figure 1). This record, now supplemented by measurements at other sites, demonstrates conclusively that CO_2 concentrations are rising and that the primary cause is the burning of fossil fuels: coal, oil and natural gas (*see* Carbon Dioxide, Recent Atmospheric Trends, Volume 1; Carbon Cycle, Volume 2). All discussions of the possibility of global climate change due to human activities begin with this solid empirical evidence, which no reputable scientist doubts. Charles David Keeling thus deserves credit for alerting humankind to the fact that it is changing the chemical composition of the global atmosphere. In addition, the CO_2 concentration observations have yielded a rich harvest of insights into the carbon cycle. It is important to realize that these measurements, which are now sustained by international collaboration, were originally made simply because of the dedication, perseverance and skill of one scientist. In the research community, Keeling s stubborn insistence on highly accurate and completely trustworthy CO_2 concentration measurements is legendary. In fact, Keeling has continually struggled with government agencies for financial support to maintain these measurements according to the high scientific standards that he considers necessary. He has documented these efforts in detail in an autobiographical article (Keeling, 1998). A popular account of Keeling s work in the context of global change science, rich in anecdotal material, has been provided by Weiner (1990). Keeling won the Blue Planet Prize in 1993 for his work.

RICHARD C J SOMERVILLE *USA*

Kondratyev, Kirill Yakovlevich

(1920-)

Professor Kirill Kondratyev, a Russian atmospheric scientist of considerable renown, has spent most of his life in Leningrad/St. Petersburg. He entered University there in 1938 but his studies were interrupted by World War II. He joined the army and was wounded during the blockade of Leningrad. After recovering in a hospital in western Siberia, he trained with a parachute division and then returned to the front line west of Moscow. Wounded again in 1944, Kondratyev was demobilized.

When the war ended, Kondratyev resumed his academic studies at the University of Leningrad, graduating in 1946. He immediately became Assistant Professor, then Professor, then Head of the Department of Atmospheric Physics, and finally Rector (1964–1970). At the same time, he was Chief of the Department of Radiation Studies at the Main Geophysical Observatory in Leningrad. Kondratyev became world famous during this period for his many publications in the field of atmospheric radiation. One of his major works was his monograph *Radiative Heat Exchange in the Atmosphere* (Kondratyev, 1965). He won the prestigious World Meteorological Organization/International Meteorological Organization (WMO/IMO) Prize in 1967.

In the 1970s, Kondratyev broadened his scientific interests, becoming a leading figure in remote sensing of the atmosphere from satellites, and today he is still Editor-in-Chief of the journal, *Studying the Earth from Space*. For years, he has collaborated with the leading specialists in

space research (including the astronauts themselves) in his country. One of his important findings during this period was that stratospheric aerosols are significant absorbers in both the short- and the long-wave regions of the spectrum; thus aerosols may cause either cooling (by reflection) or warming (by absorption).

In 1982, Kondratyev joined the Institute for Lake Research, and then in 1992, the Research Centre for Ecological Safety. The changes in affiliation reflect his broadening interest in larger-scale environmental issues:

- climate change, both natural and anthropogenic: in the 1980s Kondratyev became convinced that greenhouse-gas warming was almost inevitable;
- geosphere-biosphere interactions, especially those triggered by massive human disruptions of the Earth System;
- sustainable development: by the early 1990s, Kondratyev was thinking about the urgent need for social scientists to become involved with physical scientists in studies of the global environmental problems.

In addition, Kondratyev has contributed to the solution of the problem of the optimization of global-change observing systems.

Professor Kondratyev has published many research papers and monographs. In 1982, he was elected a full member of the Russian Academy of Sciences, and he has received many international honors and awards. These include the Symons Gold Medal of the Royal Meteorological Society (UK), as well as the IMO Prize. He is *Honoris Causa* of the Universities of Lille, Athens and Budapest. He is co-chairman of the Board of Nansen, a newly created Russian-Norwegian environmental and remote sensing center.

Krakatau Volcanic Eruption

see Volcanic Eruption, Krakatau (**Volume 1**)

L

La Niña

La Niña is a climatological phenomenon akin to El Niño, but with opposite tendencies in the tropical Pacific Ocean and atmosphere. La Niña is characterized by stronger than normal trade winds and colder than normal tropical Pacific sea surface temperatures. It is also characterized by, unusually high surface atmospheric pressure in the eastern tropical Pacific and low surface pressure in the western tropical Pacific in association with the Southern Oscillation. Like El Niño, La Niña typically lasts 12–18 months. La Niña s effects on global weather variability are roughly (though not exactly) opposite to those of El Niño.

El Niño, La Niña, and the Southern Oscillation are often referred to collectively as ENSO (El Niño/southern oscillation), a cycle that oscillates from year to year between warm, cold, and neutral states in the tropical Pacific. The term La Niña (Spanish for the girl) was coined in the mid-1980s by scientists investigating the oscillations between warm and cold conditions in the tropical Pacific. La Niña has also been referred to as anti-El Niño, the cold phase of ENSO, and El Viejo (the old man).

See also: El Niño and La Niña: Causes and Global Consequences, Volume 1; El Niño/Southern Oscillation (ENSO), Volume 1.

MICHAEL J MCPHADEN *USA*

Lamb, Hubert H

(1913- 1997)

Hubert Lamb was a pioneering climatologist and founding Director of the Climatic Research Unit at the University of East Anglia. For much of his career he found himself fighting the received wisdom that climatology was purely a statistical exercise and an academic backwater. Lamb did more than any other climatologist to convince the skeptics that climate change was relevant to the modern world although, paradoxically, he remained skeptical of the enhanced greenhouse gas effect as a forcing factor.

Professor Lamb was born on September 22, 1913 in Bedford, England to the expectations of a family with a distinguished academic pedigree. His grandfather, Horace Lamb, was an eminent mathematician, known to generations of meteorologists through his textbook on hydrodynamics. His father was a professor of engineering. As a child, Lamb was a frequent visitor to tea with Lewis Fry Richardson. Richardson s Quaker philosophy was to be a strong influence throughout the rest of Lamb s life although they never talked about weather or climate; this was deeply ironic since Richardson is well known as the pioneer of numerical weather forecasting (*see* Richardson, Lewis Fry, Volume 1).

Lamb started a degree in natural sciences at the University of Cambridge, but eventually switched over to geography. This training inspired his openness to interdisciplinary studies and fostered his interest in climate–human interactions. In 1936 he took a post at the UK Meteorological Office, but was posted to the Irish Meteorological Service during World War II. Producing weather forecasts for the new transatlantic passenger flights was a challenge because British observations were not available to the neutral Irish. Lamb gleaned most of his information from arriving aircrews. A perfect safety record was early, and convincing, evidence of the scientific insight and intuition that was to characterize much of his professional life. This was also evidenced by his prediction, when a meteorologist on a whaling ship in the Southern Ocean, of the existence of a major topographic barrier in the interior of Antarctica on the basis of synoptic analysis.

On his return to a land posting, Lamb devised and refined a daily weather classification for the British Isles that may prove to be one of his most lasting memorials to climatology. Starting in 1861, and still continuing today, it represents the longest daily record of airflow records for any part of the world. One of the most striking consequences

of the Lamb weather type catalogue was the way he used it to demonstrate the nature of circulation changes, especially in westerly flow, around the British Isles. This observation provided the stimulus for a significantly growing interest in climate change. Lamb s work on weather types is highly cited, and this approach has been shown to have a wide utility for examining the links between circulation and surface temperature, rainfall, pollution, and even ecology. Because of their links with surface variables, Lamb weather types have also been used to assess global climate model results and to generate scenarios of the future climate.

Another significant contribution that Lamb has made to the study of climate was the reconstruction of monthly mean sea level pressure maps over the North Atlantic and Europe using old meteorological archives extending back to the 1750s. The work for which he is most likely to be remembered by those outside climatology was his reconstruction of the characteristics of the Medieval Warm Period (*see* Medieval Climatic Optimum, Volume 1) and of the Little Ice Age period (*see* Little Ice Age, Volume 1), which he suggested extended over parts of the Northern Hemisphere from about the middle of the 16th century into the 17th century with also some later, but shorter, periods. In these studies, Lamb exploited a myriad of sources with great imagination, and well and truly established the importance of climate in the history of our forebearers.

Lamb also started to make connections between sea surface temperature and the atmospheric circulation. This work deepened his conviction of the importance of climate change on time scales of significance to modern mankind. Lamb was also fascinated by the links between climate and human history, and started to work with geologists, botanists and historians on this issue. He became as well known to the practitioners of other disciplines as he did to climatologists.

In 1970 he produced one of his landmark publications; a chronology of volcanic eruptions and a dust veil index (*see* DVI (Dust Veil Index), Volume 3) following each eruption back to the 1500s. It also contained a treatise of the scientific basis of the volcanic forcing mechanism, and an analysis of the observational evidence linking climate change and volcanic events. This work was a classic example of Lamb s interdisciplinary skill, and this was his major strength: combining knowledge from different fields and setting the agenda for the next generation of researchers. This demeanor was crucial for the eventual success of the Climatic Research Unit, which he founded in 1972.

Lamb died on June 28, 1997. His research had been recognized formally through awards such as the Murchison Award of the Royal Geographical Society, the Symons Gold Medal of the Royal Meteorological Society, and the Gold Medal of the Swedish Geographical Society. His legacy is the scientific method of the interdisciplinary study that climatology has become.

Land Cover and Climate

Roger Pielke, Sr
Colorado State University, Fort Collins, CO, USA

Land cover includes soil type, vegetation type and fractional coverage, snow, lakes, marshes and ponds. Land cover is a dynamic component of the Earth's climate system. It changes on all time and space scales, and is altered by human activity. It is conventional to separate land cover interactions into short (seconds to days), medium (weeks to seasons and years), and long (decade to century and longer) time scales. With respect to vegetation interactions, short, medium, and long-term interactions within the climate system are referred to as biophysical, biogeochemical, and biogeographical processes, respectively. Natural changes have occurred over all of these time scales. For example, during the Pleistocene geological time, continental-scale glaciers covered large portions of the higher latitude landmasses of the Northern Hemisphere. In this article, the focus will be on land cover change and climate that has occurred, and is expected to continue to occur, on decade to century time scales.

The conversion of a landscape by human activity or natural processes is an obvious environmental change. The biodiversity of an area, for example, will be altered when a landscape is changed (Stohlgren, 1999). Natural landscape change includes lightning-started res, certain insects and disease infestations, vegetation succession during recovery from disturbance, and weather extremes such as drought and oods in watersheds not affected by human activities. Human-caused landscape changes include, among other activities, clear-cutting of forests, agriculture, urbanization, draining of wetlands, human-ignited res, and the introduction of exotic plants and animals.

These changes have obvious local effects, but regional and global in uences have also been reported. Moreover, it is actually arti cial to separate natural from human landscape disturbance if adjacent and/or distant human alteration of the environment in uences what occurs over the natural landscape. For example, air pollution from an urban area that is near a national park or wilderness area may alter vegetation growth due to wet and dry disposition of pollutants.

LOCAL SCALE LANDSCAPE CHANGES

Figure 1 provides a schematic illustration of how the surface energy budget and overlying atmosphere are altered as a result of the conversion of a forested area to agriculture. This figure, based on real observational data, indicates that there are several significant alterations of the surface heat energy budget, including different amounts of absorbed solar insolation, different partitioning between sensible and latent heat (evaporative and transpired) turbulent fluxes, and soil heat flux. The water budget, including runoff and infiltration, is also changed. Landscape alterations also change biodiversity, with new plants (crops) being introduced to replace the natural vegetation. Exotic invasive plants, insects and other non-indigenous animals (e.g., goats, etc.) may be introduced, and even invade adjacent forested areas.

Other obvious anthropogenic landscape changes include urbanization, irrigated crops, afforestation, and domestic grazed areas. Each of these local changes can affect the local and nearby climate and other aspects of the environment. The effect of long-term land use change on the climate usually needs to be investigated with a model. Only rarely are long-term observed weather data available whose collection began when the landscape was natural. Figure 2 illustrates the effect in a model simulation of a landscape change from a natural short grass prairie to the current landscape of mixed agriculture and short grass in the central Great Plains of the US. With the current landscape (top), deep cumulonimbus convection (which was observed) results. When the natural landscape was assumed as the bottom boundary condition, only shallow cumulus clouds developed. The reason for the difference is

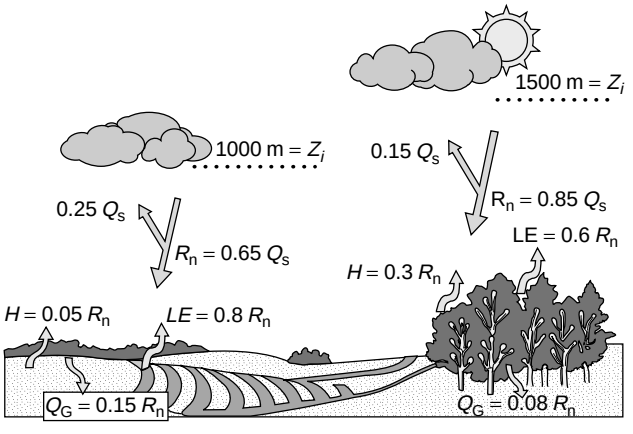

Figure 1 Schematic diagram of the differences in surface heat energy budget and the planetary boundary layer over a forest and over a cropland. Horizontal fluxes are left off the Figure. The symbols refer to: H, sensible turbulent heat flux; Q_s, solar insolation; Z_i, top of the atmospheric boundary layer; LE, latent turbulent heat flux; Q_G, ground heat flux; R_n, net radiative fluxes. (Adapted from P Kabat, personal communication, 1999)

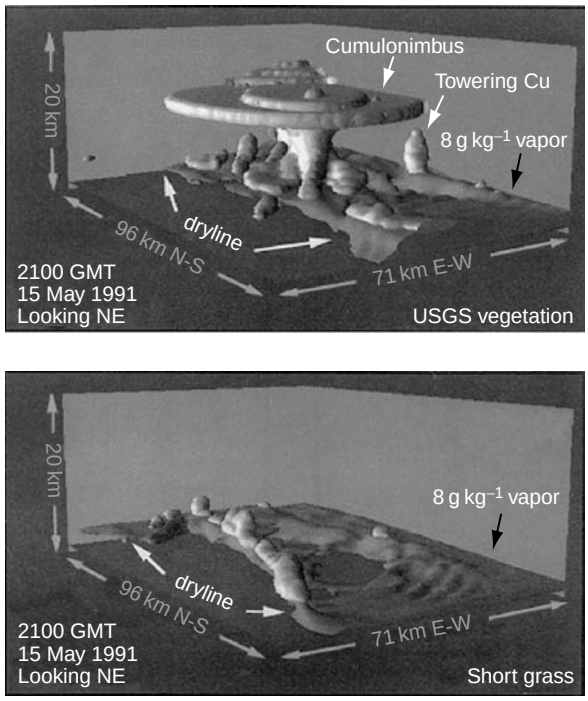

Figure 2 Mesoscale atmospheric model output of cloud and water vapor mixing ratio fields for a region in the Texas and Oklahoma panhandle for 21 GMT on May 15, 1991 with the current landscape (a) and the natural landscape (b). The initial atmospheric structure and lateral boundary conditions are identical for both landscapes. The clouds are depicted by white surfaces with the sun illuminating the clouds from the west. The water vapor mixing ratio of 8 g kg^{-1} in the planetary boundary layer is depicted by the grey surface. Visible ground indicates that the water vapor mixing ratio is less than 8 g kg^{-1} through the entire boundary layer. The vertical axis is height, and the backgrounds are the north and east sides of the domain (United States Geological Service (USGS)). (Reproduced from Pielke *et al.*, 1997)

that surface moisture fluxes were increased by the agricultural landscape because the area of transpiring leaf surface became larger. The reduced water vapor in the atmosphere with the natural landscape resulted in a smaller amount of energy for thunderstorm development.

REGIONAL SCALE LANDSCAPE CHANGES

Landscape changes occur over regional areas. Most of the eastern two-thirds of the US has been changed, for example, as vast areas have been converted to agriculture and deforested. Figure 3 documents estimates of regional changes of landscape for several specific regions of the US. Several regions (such as the Phillipines) have had a rather consistent decrease in forest cover during the 20th century, while New England has become reforested after deforestation prior to the mid-19th century. The effect of weather on these human-caused changes in landscape

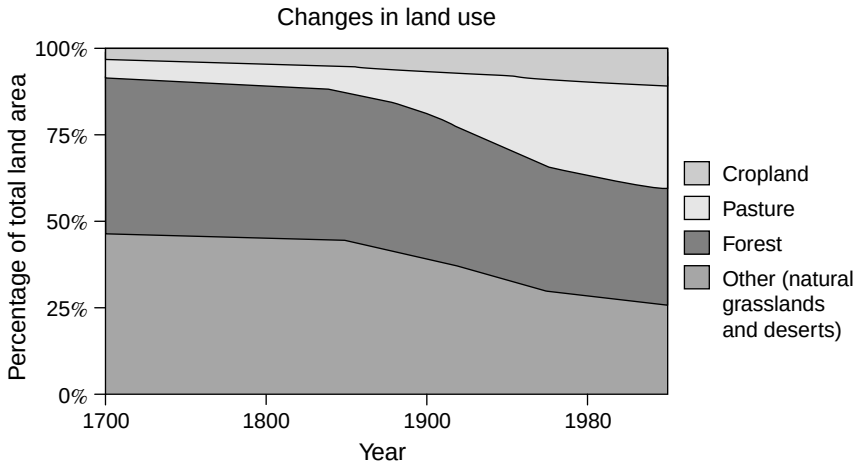

Figure 4 Estimated global land use changes from 1700 to 1995. The land use from top to bottom in the figure are cropland, pasture, forest and others, respectively. (Reproduced from Klein, 2001)

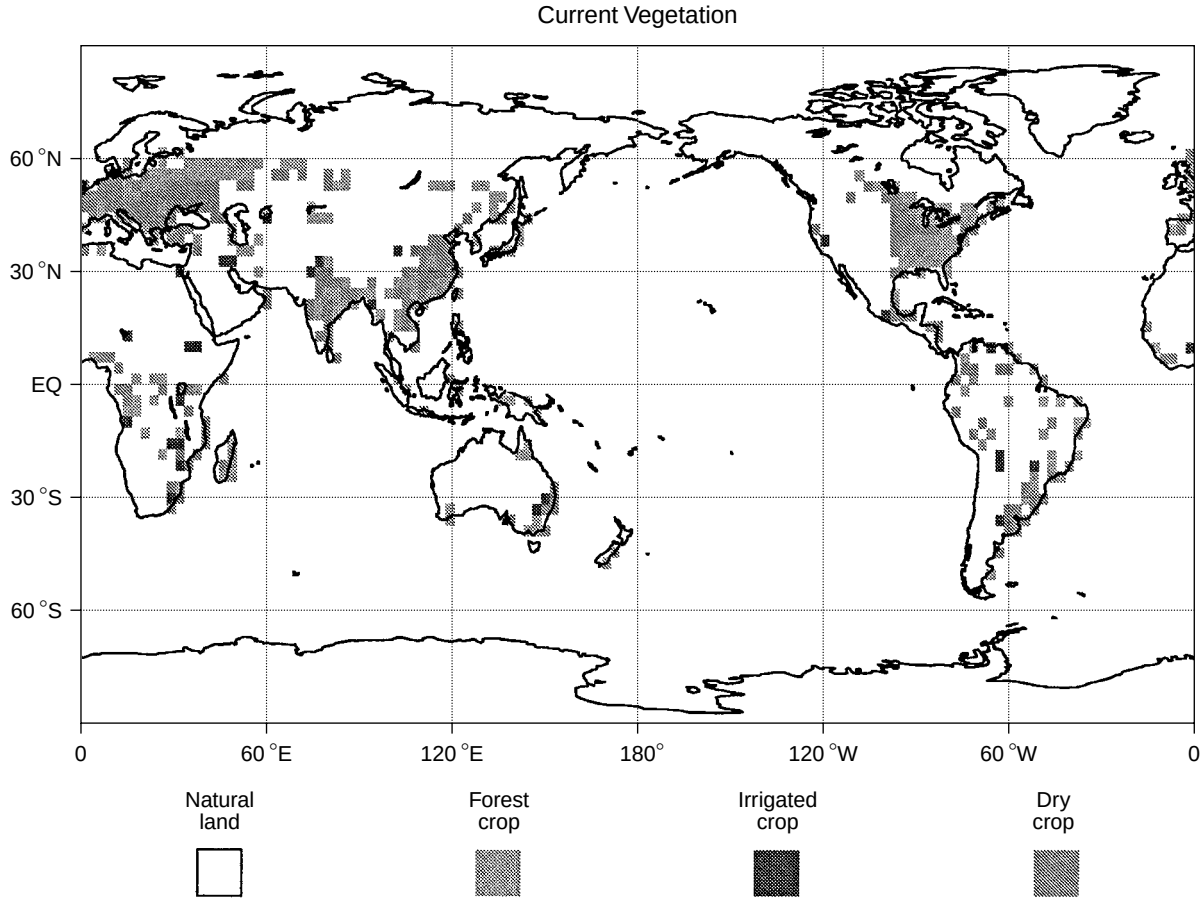

Figure 5 Regions in the NCAR Community Climate Model – 3 GCM, where land was changed from the natural landscape to its human disturbed form. (Reproduced from Chase *et al.*, 2000)

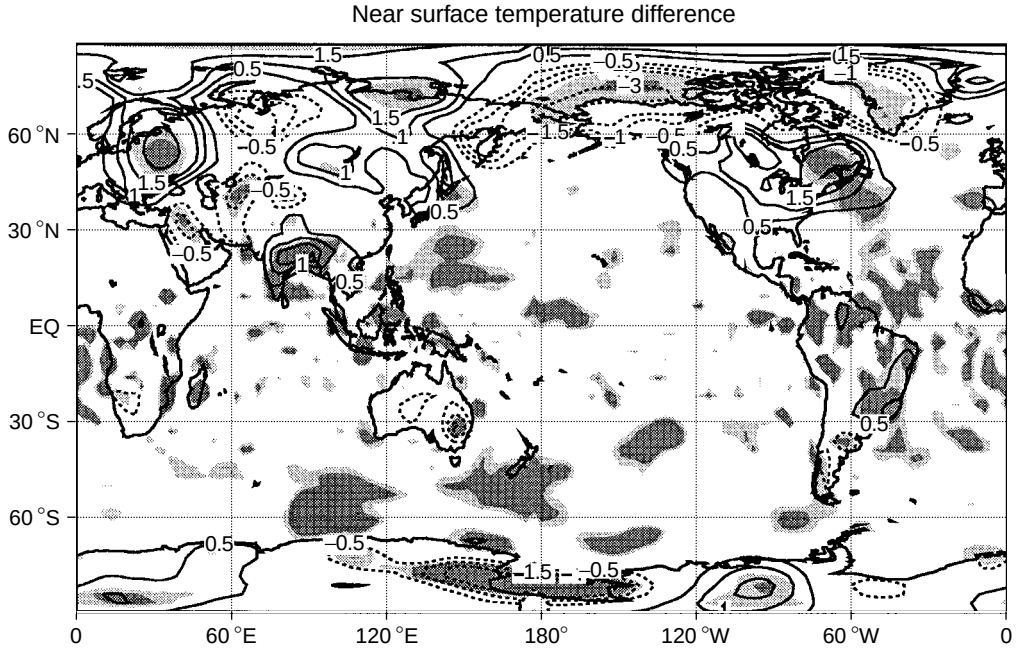

Figure 6 Difference in January global temperature, averaged over 10 years of simulation, where the current landscape instead of the Earth's natural landscape is used in the regions shown in Figure 5. Locations which are statistically different are shown by gray shading. That statistically significant changes appear distant from regions where surface cover changes is a result of changes in the global atmospheric circulation (*see* **Pacific–North American (PNA) Teleconnection**, Volume 1). (Reproduced from Chase *et al.*, 2000)

can be illustrated based on results from a recent study. Assuming identical large-scale weather conditions based on observations, an atmospheric model was integrated for a two-month summer period using observed landscapes of South Florida for 1900, 1973, and 1993 (Pielke *et al.*, 1999). The 1900 landscape was essentially the natural landscape of the region (Costanza, 1975). Compared with the model runs when the 1900 landscape was used, there was a 9% decrease in rainfall averaged over South Florida using the 1973 landscape, and an 11% decrease when the 1993 landscape was used. Corresponding to the decrease in rainfall, the South Florida region warmed an average of about 0.5 °C. The limited available precipitation and temperature records are consistent with this trend.

GLOBAL SCALE LANDSCAPE CHANGES

The cumulative change of landscape by people is estimated to affect directly 40% or more of the Earth's land surface. Figure 4 illustrates the change of different land cover since about 1700, as estimated by the Land Use Change Committee of the International Geosphere–Biosphere Programme (IGBP). A concern, which these data illustrate, is that most land use change occurred in the 1900s, and the change continues to accelerate. Recent general circulation model (GCM) sensitivity simulations suggest that these landscape changes have global effects. Because landscape changes are long-term, cover a large area, and directly affect thunderstorm activity, the influences on weather can extend over large distances. Such a response is similar to El Nino and La Nina effects on weather, except that the land use change persists for a very long time (unlike the tropical Pacific sea surface temperature anomaly, which flip-flops between warm and cold sea surface temperatures).

As an example of the global effect of land use change, Figure 5 indicates regions where land cover is assumed to have been modified by human activities in a GCM study of the effects of changes in the natural landscape. Even over a short time period of 10 years, the two different landscapes produce different large-scale weather patterns. Figure 6 shows how much these landscape changes have altered January temperatures in the model. Regional patterns of warming and cooling occur, as the polar jet stream is changed in its long-term average position at this time of year, as a result of the land use change.

CONCLUSIONS

A major conclusion is that human and natural landscape changes have had effects on the climate on regional and global scales. The human-caused land cover changes in the last 100 years, and even more seriously in recent years,

appear likely to have had an increasingly significant effect on climate and other aspects of the environment, including biodiversity, water quality and quantity.

Land Surface

Ann Henderson-Sellers

Lucas Heights Science and Technology Centre, New South Wales, Australia

The land surface is at the front line of concerns about global environmental change. People live on the land surface: it is where we grow our food, build our homes and collect our drinking water. The land surface is vital for our survival. However, exploitation of large areas of the continents for current societal needs is causing massive disturbances that are contributing to and are impacted by global changes.

Human-induced land-use change (the activity) and consequent land-cover change (the result) are inescapable features of global environmental change. Over half the world's continental surface has already been discernibly altered by people: forests replaced by fields, valleys flooded for reservoirs, and roads and cities sprawled across coastal regions and many valleys. People's activities cause, or contribute to not only desertification, deforestation, salinization and soil erosion, but also afforestation, irrigation and landscape development.

INTRODUCTION

Ten percent of the ice-free land area of the world (about 13 500 million ha) is under permanent cultivation, 25% is pasture, 30% is forest and woodland, and the remaining 35% comprises tundra, desert, degraded land, built-up areas and parks. *Per capita* contributions now amount to eroding, lifting and removing about 10 tonnes of minerals every year. The global total of about 50 Pg exceeds by at least a factor of three the sediment load transported annually to the sea by rivers, which also includes a significant input resulting from human activities.

The major types of human-induced land surface change are deforestation (and reforestation), desertification (and irrigation of vegetation), agricultural expansion (and land abandonment) and soil erosion (and fertilization). These changes are widespread and prompt additional impacts such as soil degradation and salinization; increases in aerosol concentrations; changes to greenhouse gas concentrations and nutrient loading of waterways and coastal waters. Dam-building, reclamation and erosion of coastal zones, irrigation of arid land, urbanization, and industrialization are often very important locally, but seem unlikely to cause anything other than local environmental changes.

Richards (1986, 1990) studied the global environmental aspects of land-cover changes over the past three centuries and calculated that woodlands and forests have decreased in area by 1200 million ha and that croplands have increased

by 1200 million ha while grasslands and pasture have declined in area by about 500 million ha. Over the much shorter period of only 15 years from 1973 to 1988, the FAO (1990) estimated that croplands have increased by 57 million ha, pastures decreased by 11 million ha, and woodlands and forests decreased by 141 million ha. The rate of global urbanization is very difficult to estimate but seems likely to be at least 2 million ha year^{-1}. These estimates seem to indicate that land surface changes due to human activities are accelerating. Land surface changes in the future will be driven primarily by population change but will also depend and also on affluence/poverty, technological development, economics, and dietary preferences. In the 21st century, the greatest pressure for changes to the land surface seems likely to be in the tropics.

LAND SURFACE–CLIMATE INTERACTIONS

The relationships between the land surface and the global environment are very complex. The potential contributions to global environmental change due to land surface changes include: greenhouse gas emissions; aerosol (particulates and droplet) loading; surface reflectivity (albedo) and emissivity disturbances; and impacts on the surface roughness and surface hydrology. Land clearance and land-use changes are now recognized as having the potential to affect local, regional and global characteristics (Figure 1). However, the mechanisms by which large-scale changes occur and the types of feedback likely are, as yet, not understood. For example, Zhang *et al.* (1996) have identified a means by which tropical deforestation can produce global-scale impacts in addition to the known contribution to the greenhouse gas burden and disturbance to regional hydrology.

Henderson-Sellers (1995) illustrates the potential importance of land surface changes with a series of simple calculations. Assuming that one-quarter to one-third of the contribution to the projected doubling of the atmospheric CO_2 will be due to land-cover change (e.g., Houghton *et al.*, 1990, 1996) implies that its contribution to radiative forcing will be about $+1\,W\,m^{-2}$. The possible effect of aerosols from both human-induced and natural biomass

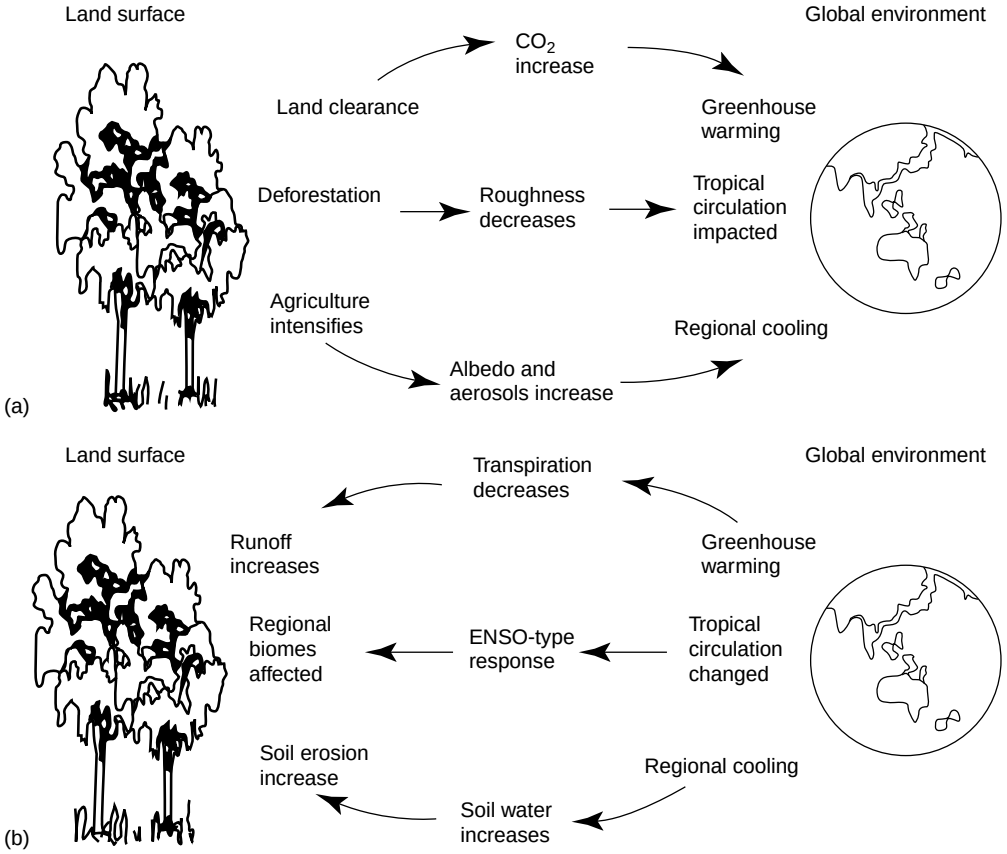

Figure 1 Schematic of some of the ways in which land surface changes and global environmental changes may interact: (a) land surface changes prompt disturbances that contribute to global changes; and (b) global environmental changes affect the land surface impacting vegetation, soils and hydrology. The examples (picked from a wide range of possible interactions) are illustrative also of the likelihood of synergies (e.g., between greenhouse warming and ENSO-like disturbances) and of feedback (e.g., intensification of agriculture associated with increased soil erosion)

burning is of a similar magnitude but in the opposite sense: a cooling of $-1\,W\,m^{-2}$ (e.g., Andreae, 1995). A plausible increase in continental albedo of +5% (from a forest albedo of 15% to a grassland albedo of 20%) would give a decrease in absorbed solar radiation of around $-3\,W\,m^{-2}$ (Henderson-Sellers and Gornitz, 1984). These very simplistic calculations suggest that the global environmental impact of land surface changes through surface albedo increases, combined with possible aerosol cooling, could very roughly counterbalance the currently projected radiative forcing from a CO_2 doubling (Figure 1). While the actual effects may be different, the need to include land surface changes as part of global change calculations is clear (*see* Land Cover and Climate, Volume 1).

In that over 70% of the energy absorbed into the climate system is absorbed at the surface and one-third of the surface is land, experiments with climate models have identified sensitivities of the global environment to conditions at the land surface, the hydrology and to the vegetation cover. For example, Shukla and Mintz (1982) show that moisture evaporated from the surface has a considerable impact on rainfall. In this early global climate model experiment, evaporation from the land surface was forced to be equal to either the potential evaporation (assuming land was fully wet) or set equal to zero (assuming land was totally dry) at all land-surface points. The calculated values of July precipitation were sharply reduced in the latter case and there was also a shift in the position of the remaining maxima of rainfall over the continental areas. This experiment, although testing a limit, indicated the importance of treating evapotranspiration from the land surface to accurately model the global hydrological regime and prompted an intensified focus on land surface modeling (*see* Earth System Processes, Volume 1).

REPRESENTATIONS OF LAND SURFACES

The treatment of the land surface in models has changed markedly over the history of climate modeling (e.g., McGuffie and Henderson-Sellers, 1997). The Budyko or *bucket* model dates back to 1969 (Manabe, 1969). This bucket (Figure 2a) assumed a maximum soil water depth, termed the *eld capacity*. The bucket fills when precipitation exceeds evaporation and, when it is full, excess water is assumed to run off. The bucket model has been demonstrated to be inadequate for heating the diurnal cycle, particularly when details of changes of the atmosphere and surface are needed. As a result, treatments of energy and moisture exchanges at the land surface have been made more detailed and, hopefully, their results have become more realistic (Figure 2b, cf. Figure 3).

It has also been found necessary to treat changes in land cover. Land surface change typically modifies the surface albedo and can also involve an alteration in the roughness of the surface: for example, removing trees decreases the roughness (Figure 1). In simulating the effects of changes in land cover, the canopy area and the resistance of the vegetation to transpiration may also be altered, as may the soil state and its characteristics, including drainage. Surface albedo and roughness have been found to be the two factors likely to be the most important factors in affecting the regional climate.

EFFECTS OF LAND SURFACE CHANGES

Two types of human-generated land surface changes, deforestation and desertification, have been simulated in a number of global climate models (GCMs). Among the relevant properties of tropical forests are that they have a very low surface albedo throughout the year because their leaf area and stem area are larger than those of any other vegetation and the trees are tall. Replacing the tropical forest with grasslands would lead to three primary changes at the land surface; similar changes would also occur in the event of desertification.

1. The surface albedo would be increased, which reduces absorption of solar radiation and causes a reduction in net radiation available at the land surface.
2. Reductions in the leaf area and stem area would lead to a decrease in the water holding capacity of the vegetation and thus reduce the re-evaporation of the intercepted precipitation and the flux of water from the soil moisture reservoir to the atmosphere through transpiration.
3. The grassland replacing the tropical forest (or, for desertification, the bare soil replacing the scrub) would be shorter and smoother than the rainforest so that the surface roughness is reduced and the surface frictional forcing is weakened.

When deforestation is simulated, changes in both albedo and roughness length occur, whilst for desertification only the surface albedo is usually modified because any roughness length change is assumed to be small (although the ratio of old to new roughness lengths is roughly commensurate in the two cases). Henderson-Sellers (1995) summarizes the mechanisms implicated in global change.

Tropical deforestation and desertification cause surface albedo increases of between about 0.01 and 0.10. Assuming annual incoming solar radiation of $300\,W\,m^{-2}$ (typical for the tropics), the absorbed solar radiation in these locations could be reduced by up to $30\,W\,m^{-2}$ (e.g., Mylne and Rowntree, 1992). If net surface longwave radiation remains unchanged, less energy is therefore available for latent or sensible heat flux from the surface and for transfer into the ground, causing the temperature to decrease. Secondary effects include decreased evaporation and decreased precipitation. The decrease in net radiative heating of the

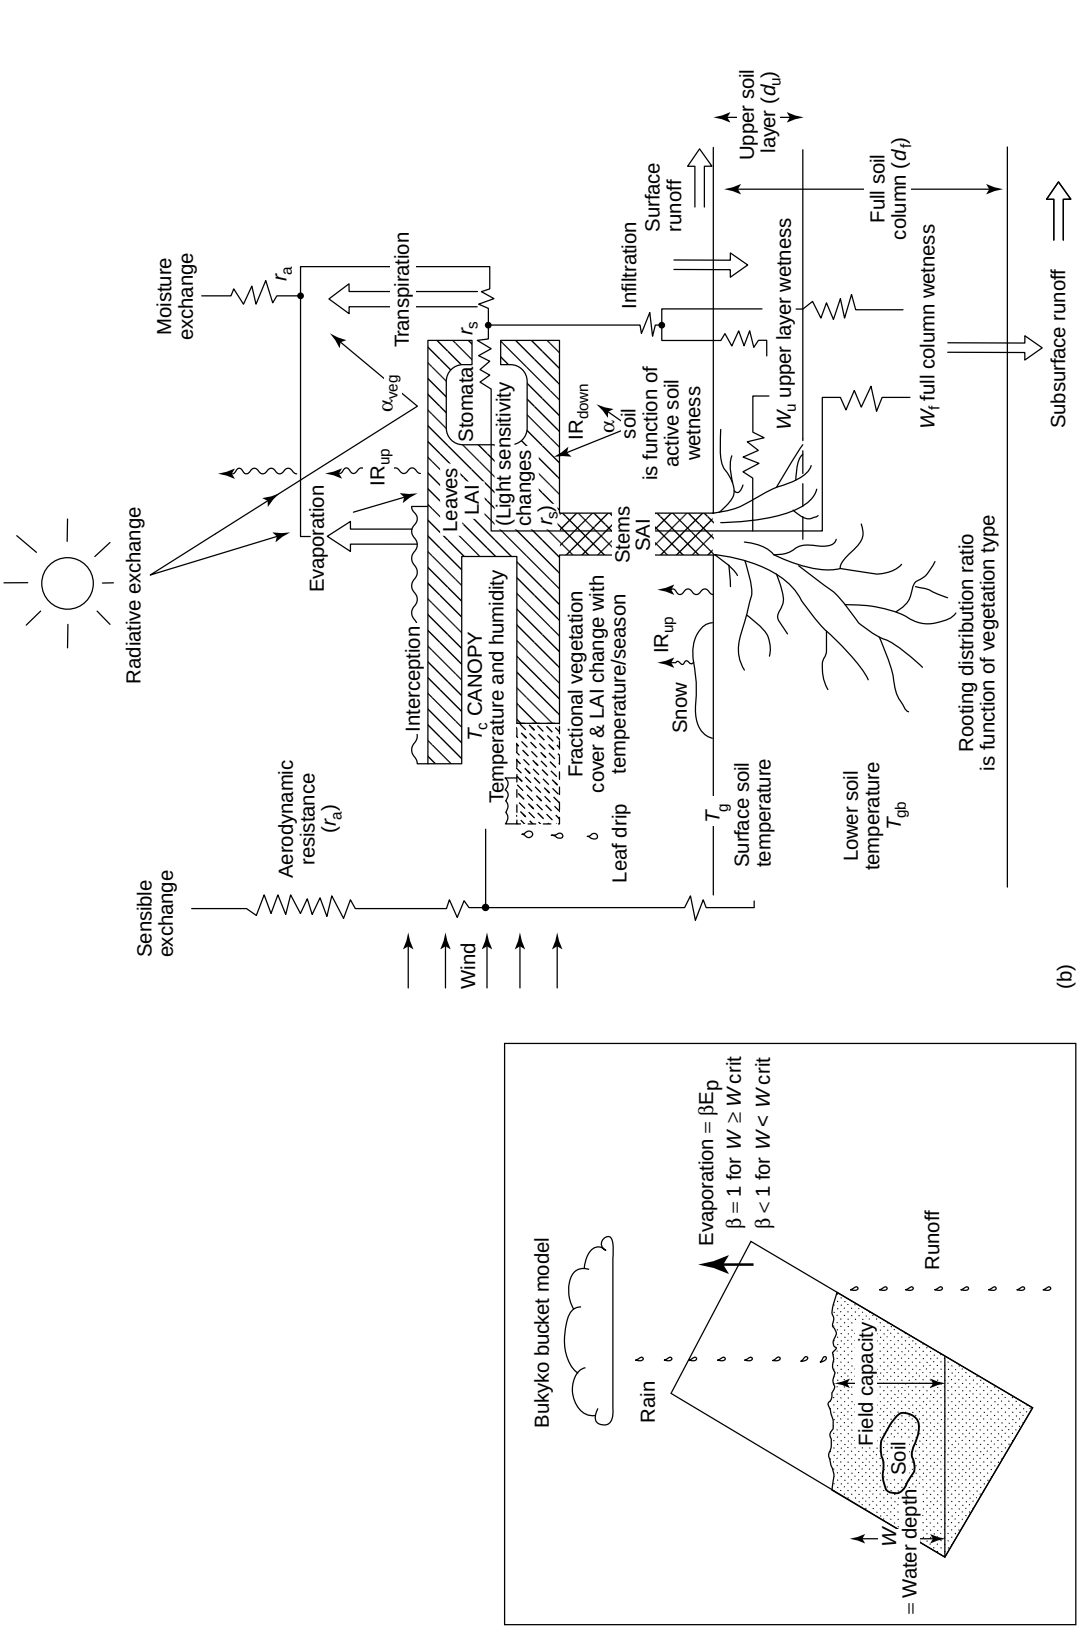

Figure 2 (a) An illustration of the simple bucket land surface scheme (from *A Climate Modelling Primer,* McGuffie and Henderson-Sellers, 1997. © John Wiley & Sons Limited. Reproduced with permission). (b) An illustration of the processes included in more complex land surface schemes. Such a change includes representations of the radiative, latent and sensible heat fluxes occurring at the surface, and simulates the movement of soil moisture below the ground and through the plants (from *A Climate Modelling Primer,* McGuffie and Henderson-Sellers, 1997. © John Wiley & Sons Limited. Reproduced with permission)

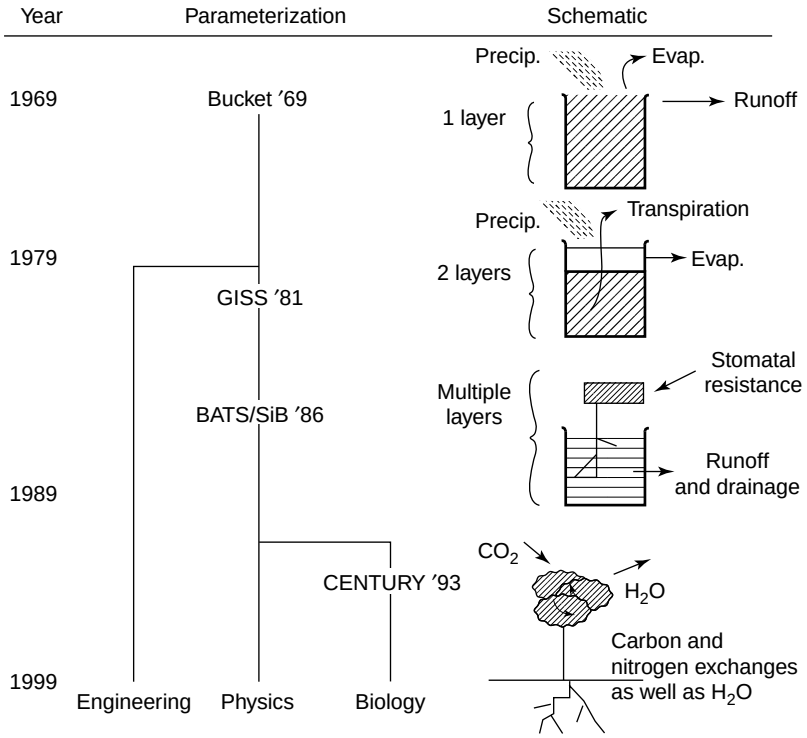

Figure 3 Schematic showing the time-line of development of soil moisture schemes used in models of global environmental change since the development of models to simulate the global climate. These range from the engineering solution of the Manabe bucket (Manabe, 1969), through the soil physics parameterizations of the Goddard Institute for Space Studies (GISS) GCM (Hansen *et al.*, 1981) and the biosphere–atmosphere transfer scheme (BATS) and simple biosphere (SiB) schemes (Dickinson *et al.*, 1986; Sellers *et al.*, 1986) to carbon sequestration models such as CENTURY (Parton *et al.*, 1993)

atmosphere and the surface leads (e.g., Charney, 1975) to a reduction in the upward movement of the air, reducing moisture convergence and rainfall. These changes in turn prompt changes in the surface water budget and hence in soil moisture. If the decrease in precipitation exceeds that in evaporation, drying out of the soil occurs, prompting further decreases in evaporation. As is evident in desert areas, this can lead to an increase in sensible heat flux and an increase in surface temperature even though the albedo increases. On the other hand, the combined impact of multiple processes may be sufficient to cause a larger decrease in evaporation than in precipitation, tending to increase soil moisture. Such a reduction in precipitation would tend to further increase albedo as vegetation and soils dry.

Deforestation causes a decrease in surface roughness from a forest roughness length of around 2 m to a grassland value of about 0.05 m (somewhat less for desertification). Decreasing the roughness reduces the turbulent fluxes of sensible and latent heat and of momentum between the land surface and the atmosphere. This reduction causes an increase in the surface temperature that prompts a negative feedback because the warming will tend to increase sensible and latent heat fluxes. The effect of an increase in surface temperature and thus increased longwave radiation from the surface is to decrease the net radiation, prompting decreased ascent and inhibiting precipitation. In addition to the reduction in evaporation due to the reduced roughness length, there is a further reduction caused by the reduction in the transpiration from the smaller amount of biomass (i.e., less vegetation and the much shorter roots of grasses than those of trees). This combined reduction in evaporative flux acts to further inhibit precipitation.

The decrease in surface roughness also decreases the turbulent momentum flux, which decreases the surface drag and increases the surface wind. Decreased drag results in decreased cross-isobaric flow and hence decreased moisture convergence. This further contributes to a reduction in the tendency for the air to rise and hence tends to decrease precipitation. A decrease in precipitation will cause a further decrease in soil moisture, although this will be somewhat counter-balanced by the decreased evaporation. Not only is the net outcome of these two effects uncertain but there are also possibilities for positive feedback on evaporation caused by the changes in soil moisture.

As can be surmised from this analysis, it is very difficult to anticipate the direction and magnitude of the regional environmental changes following from desertification and deforestation. The imposition of an albedo increase might

cool the surface and thus prompt atmospheric descent. The imposition of a reduced roughness length is likely to reduce evaporation, and hence warm the surface, but also to prompt descent or at least decreased ascent in the air.

The overall result of increasing albedo (whether from deforestation, salinization, or other factors) will depend crucially on the relative strengths of the processes, the strengths of the identified feedback, the time periods over which each operates, and other impacts, such as changes in cloudiness (e.g., reduced cloud cover is likely to allow increased absorption of solar radiation and thus increase the net radiation balance, thereby acting as a negative feedback on the imposed albedo increase itself).

Zhang *et al.* (1996) examined the surface and atmospheric energy budgets derived from a GCM in order to improve understanding of the simulated climatic changes after tropical deforestation. Generally, the canceling effects of increased surface albedo and decreased evapotranspiration explain the small changes in surface temperature over deforested regions. Their analysis also suggests that:

1. Cloud radiative forcing plays an important role in shortwave radiation processes, while the influence of increased surface albedo is mitigated dramatically by the decrease of cloud amount.
2. The effect of the change in net longwave radiation is larger than the effect of the shortwave radiation change, a result not emphasized in previous simulations.
3. Changes in cloud radiative forcing increase the daily variability of the surface temperature even though the daily mean surface temperature may only show small changes.
4. In spite of the increase of surface albedo over deforested regions, the net radiative energy heating the atmosphere is actually increased by the changes in cloud radiative forcing and longwave radiation.
5. The role of changes in latent heat flux is the most important factor in the net reduction of the atmospheric energy budget.

Based on this evaluation, Zhang *et al.* (1996) asserted that changes in latent heat flux, themselves the result of the reduction of surface roughness length and the changes in surface radiative energy, are the primary reasons for the calculated reduction of precipitation over deforested regions from which rainforest has been removed.

Given the number of interacting mechanisms and various types of situations, however, the net effect of feedbacks and differing magnitudes and time-scales of responses remains uncertain. In addition, it is not yet known how to relate these local impacts to regional changes such as atmospheric moisture convergence, which is mainly controlled by larger-scale circulation characteristics (Rowntree, 1991). The possibility of regional-scale atmospheric responses to land-cover change has been noted, for example, by, Shukla *et al.* (1990) with reference to tropical deforestation and by Charney *et al.* (1977) with reference to desertification. Major atmospheric features being investigated in current simulations include connections to the Hadley and Walker circulations and the tropical jets, because these dynamical processes can cause the regional influences to have effects outside of where they are initiated. Because the tropics are the primary energy source (because of high solar irradiation) and the moisture source (because of high sea surface temperatures) for the global climate, changes in the land surface in the tropics can influence global climatic conditions.

Given the many types of possible interactions, it is important to treat the state of the continental surface, particularly the biomes it will support, as coupled and integral parts of the global environment (e.g., Kump and Lovelock, 1995). The rates and types of land-use changes, both anthropogenic and in response to climate, are thus likely to modify the climate as well as the sources and sinks of greenhouse gases, aerosols and moisture. The resulting changes will also alter the locations in which land cover is sustainable and offer insights into the consequences of long-term changes in land use.

At present, the computational links between biology and climate in global environmental models are in a developmental stage. While global maps agree on the locations of the major deserts, ice caps and forests, many differences are evident when particular regions are examined in detail. The challenge being undertaken is to reconcile these results so that the land-surface in all its manifestations from the locus of human life to a driver of global climate is fully considered.

Lapse Rate

The *lapse rate* is the rate of decrease of temperature per unit change of height.

The temperature of the atmosphere normally decreases with increasing altitude in the lower part of the atmosphere, the *troposphere*. The rate of decrease is termed the *lapse rate*, and is on a global average $6.5\,^{\circ}\mathrm{C}\ 1000\,\mathrm{m}^{-1}$ (or $3.5\,^{\circ}\mathrm{F}\ 1000\,\mathrm{ft}^{-1}$). This decrease continues upward to about 10−15 km reaching the tropopause, which is the boundary with the stratosphere. Within the stratosphere, the temperature increases or varies little with height, and the lapse rate is thus close to zero.

The Earth s surface and lower atmosphere are heated by solar radiation, while the upper atmosphere is cooled by radiation to space. It is thus not surprising that temperature declines with height. A more important factor, however, is the change in temperature produced by upward and downward motions of air. As an air parcel rises, the pressure of the surrounding air decreases; the air parcel therefore expands and its temperature drops. The reverse occurs as air descends. This rate of change is about $10\,^{\circ}\mathrm{C}\ 1000\,\mathrm{m}^{-1}$ ($5.5\,^{\circ}\mathrm{F}\ 1000\,\mathrm{ft}^{-1}$).

Rising air often contains water vapor that condenses as the air cools, forming clouds and rain and releasing the heat originally absorbed in evaporation (latent heat). Because of this heat release, the rising air parcel may become warmer, and therefore lighter, than its surrounding air. The resulting buoyancy accelerates its ascent, producing even more cooling and condensation. These processes of radiation, cooling and heating by rising and descending air, and condensation in rising air columns determine the actual ambient lapse rate.

The lapse rate in turn influences the rates of vertical overturning of air that disperses pollutants and drives storm systems. When the lapse rate is small, or even negative (an *inversion*, with temperature increasing with height), upward and downward movements of air are inhibited. For example, an inversion layer formed by strong cooling near the surface can trap pollutants over a city until solar radiation warms the layer enough to start convective mixing. As another example, a Los Angeles-type inversion based at 500 m or so (a so-called *subsidence inversion*) also traps pollutants in the air below. On a global scale, the degree of stability

or instability of the atmosphere as a whole is an important factor in determining the number and intensity of storm systems.

JOHN S PERRY *USA*

Last Glacial Maximum

The *Last Glacial Maximum* (LGM) was the time of maximum extent of the continental ice sheets during the most recent glacial period. The LGM peaked about 21 000 years ago (*see* Earth System History, Volume 1). The most recent glacial cycle began about 115 000 years ago, with major development of ice sheets starting at 75 000 years ago. Continental ice sheets, which could have been as much as 4000 m thick, covered large portions of North America and Eurasia. Major ice sheets included the Laurentide ice sheet in eastern North America, the Cordilleran ice sheet in western North America, the Fennoscandian ice sheet in northwestern Europe, the Barents and Kara Sea ice sheets in eastern Eurasian Russia, and the West Antarctic ice sheet. The LGM is defined by oxygen isotope stage 2 from ocean sediments. While the overall timing of the LGM has been based on oxygen isotope ratios of ocean sediments, it corresponds to land-based periods such as the Wisconsin (maximum extent in eastern North America), the Weichselian (maximum extent in western Europe), and the Wurm (maximum extent in the Alps) (Crowley and North, 1991). In addition to the presence of the ice sheets, CO_2 levels at the LGM were about 200 ppmv (compared to 265–275 ppmv from 10 000 years ago to the start of the industrial period in the early 19th century), and solar insolation was close to its present seasonal and latitudinal pattern (Kutzbach *et al.*, 1998). Sea level, was, on average, about 120 m lower than present (Fairbanks, 1989). During the LGM, temperatures are estimated to have been from 10 to 21 °C colder in Greenland, Antarctica, and tropical ice caps (Dahl-Jensen *et al.*, 1998; Severinghaus and Brook, 1999; Jouzel, 1987; Thompson *et al.*, 1995). Lowland tropical temperatures and sea surface temperatures, on the other hand, are estimated to have been about 5 °C colder (Stute *et al.*, 1995) or perhaps lesser amounts (CLIMAP, 1981). The world was more arid than present, although circulation changes resulted in certain areas being wetter.

Latent Heat

Latent heat is the internal potential energy of a substance by virtue of its molecular configuration and structuring described by the phase or state of the substance, i.e., solid, liquid, or vapor. This potential energy is distinct from the internal mean molecular kinetic energy measured by temperature. A phase change results in a transformation between latent heat and sensible heat. Depending on the direction of transformation, the result is an internally produced internal source or sink of sensible heat for the substance. This source or sink affects the internal mean molecular kinetic energy (temperature) of the substance in the same way as sensible heat transfer between the substance and surrounding material. Latent heat energy is thus latent or hidden from the internal mean molecular kinetic energy until phase change occurs, when it becomes manifest as a source or sink of sensible heat for the substance.

In environmental applications, latent heat usually refers to the latent heat associated with water. Water exists readily in all three phases (ice, liquid and vapor) and commonly undergoes phase changes which are important for

influencing temperature in the atmosphere and at the Earth s surface. For the case where the air temperature is less than that of the human body, a human hand held up in the wind will feel cooler if it is wet than if it is dry. For the dry hand situation, the hand feels cool because of a sensible heat transfer from the hand to the air. For the wet hand situation, the water on the hand will evaporate (a phase change from liquid to vapor), which converts sensible heat to latent heat, representing a sensible heat loss from the water which lowers its temperature. This cooling increases the sensible heat transfer from the human hand, which then feels cooler.

The evaporation of water at the Earth s surface and condensation higher up in the atmosphere results in a net transfer (flux) of latent heat from the land and ocean surface to the atmosphere and thereby is a net sensible heat source for the atmosphere. This transfer between the Earth s surface (ocean and land) and atmosphere is an important factor in the global energy balance and temperature distribution. The upward latent heat energy transfer is three times as large as the sensible heat transfer and accounts for 15% of the total upward energy transfer on a global and annual average basis. (Note: radiation accounts for 80% of the transfer of energy from the surface to the atmosphere.)

DAVID HOUGHTON *USA*

Lifetime (of a Gas)

Lifetime of a gas in the atmosphere is a characteristic of its rate of removal from the atmosphere. The *e-folding lifetime* is generally used, although *half-life* or *half-lifetime* is sometimes given. The *e*-folding lifetime is the time required for the atmospheric concentration of a gas to decrease to $1/e$, or 36.79% of its original concentration in that $e = 2{\bullet}7183$. The half-lifetime is the time required for the concentration of the gas to decrease to half of its original value.

The total lifetime of the gas can be represented in terms of the partial lifetimes due to different loss processes, such as those due to chemical or photochemical reactions, loss to the ocean or soil, or washout. The total lifetime, τ, is related to the sum of the partial lifetimes, τ_i, where i represents the individual loss processes through the identity

$$\frac{1}{\hat{\tau}} = \sum \frac{1}{\tau_{\mathrm{i}}} = \frac{1}{\tau_1} + \frac{1}{\tau_2} + \frac{1}{\tau_3} + \cdots \qquad {\bullet}1{\bullet}$$

In atmospheric chemistry, atmospheric lifetime of a gas is often used to denote the turnover time. Turnover time (T) is the ratio of the mass (M) of the atmospheric content of the gas to the rate of removal (S), such that $T = M{\bullet}S$. For most gases, the turnover time is equivalent to the adjustment time or response time (T_{a}), the timescale characterizing the decay of an instantaneous pulse emission of the gas into the atmosphere. For example, for chlorofluorocarbon (CFC)-11 ($CFCl_3$), $\tau = T = T_{\mathrm{a}} = 50$ years due to its removal via photochemical processes.

Where the removal frequency is not constant or where several reservoirs exchange with the atmosphere, the equality between T and T_{a} no longer holds. An important example of this is carbon dioxide (CO_2). Because of the rapid exchange of CO_2 between the atmosphere and the oceans and the terrestrial biosphere, the residence time of a particular CO_2 molecule is only about four years. However, a high fraction of the CO_2 removed from the atmosphere each year is returned to the atmosphere from these reservoirs within a few years. In this case, the adjustment time is more representative of the actual removal of atmospheric CO_2 (the net lifetime of all additional CO_2 molecules in the atmosphere). Calculating this net response time gives a result of roughly 100 years, which is primarily dependent on the rate of transport of CO_2 from the upper levels of the ocean to deeper layers. For CO_2, the adjustment time varies with time, being shorter just after the addition of a pulse as the CO_2 pulse redistributes in part to the land and upper ocean, and then longer once the land and upper ocean have reached a balance with the atmosphere. Methane (CH_4) is another gas where T does not equal T_{a} as a result of a nonlinear relationship between CH_4 and its loss through reaction with OH.

DONALD J WUEBBLES *USA*

Lightning

A natural electrical discharge in the atmosphere of several kilometers in length is called a *lightning ash*. These flashes are usually associated with cumulonimbus clouds (thunderclouds), but also occur in nimbostratus clouds, snowstorms, dust storms, and sometimes in the erupting gas of a volcano. The flash originates from a region of net charge, either positive or negative, when the electric field exceeds the dielectric strength (insulator strength) of air. Within a thunderstorm the flash can occur within a cloud, between clouds, or between a cloud and air, and these are all referred to as *cloud ashes*. If the flash occurs between the cloud and the ground, the flash is called a ground flash. Cloud flashes are the most common, followed by *ground ashes*.

Only cloud-to-ground lightning flashes are composed of one or more lightning strokes, which the eye can perceive as

a flicker. Although these flashes are less frequent than cloud flashes, they represent about 20% of lightning flashes and cause virtually all the damage associated with lightning. The cloud-to-ground lightning flash begins with electrical breakdown in the cloud from the charged region. A faint luminous process in regular distinct steps, of approximately 50 m length, at time intervals of 50 μs, descends in a downward branching pattern toward the ground. Carrying currents on the order of hundreds of amperes, this stepped leader or initial stroke propagates at a velocity of about $1•5 \times 10^5\,\mathrm{m\,s^{-1}}$, or one 2/1000th the speed of light. Within 50 m or so of the ground, the stepped leader is met by an upward discharge moving at one-third the speed of light which produces the luminous return stroke with peak currents averaging 30 000 amperes and temperatures of 30 000 K, or five times hotter than the surface of the Sun. Several subsequent strokes usually occur and have lower peak currents. The subsequent strokes complete the lightning flash, all occurring within about 200 ms.

RICHARD E ORVILLE *USA*

Lightning and Atmospheric Electricity

Colin Price
Tel Aviv University, Ramat Aviv, Israel

Although invisible to the eye, we are continuously surrounded by natural electric elds and electric currents owing in the atmosphere. This electricity in the atmosphere is generated by global thunderstorm activity, which results in 50- 100 lightning ashes every second somewhere on the globe. These electric elds and currents would disappear within a few minutes if all thunderstorm activity were to cease on our planet. The global electric parameters can easily be monitored in fair-weather regions of the globe, and in recent years researchers have shown that these global electric parameters may be useful tools for studying global climate change.

In 1752, Lemonnier discovered that the air above the Earth had a persistent electric field, which in fair-weather conditions is directed downwards, and has an average magnitude of 130 Volts meter^{-1} ($\mathrm{V\,m^{-1}}$). Knowing the dielectric coefficient of air, it was found that the charge on the Earth, as a result of this field, was negative, and has a magnitude of approximately half a million Coulombs. Since air is an excellent insulator, it was believed for more than 100 years that this was a permanent static feature of the Earth System. In 1887, Linss discovered that the atmosphere had a slight conductivity due to ions in the atmosphere. This resulted in the measurements of fair-weather atmospheric currents of approximately $2\,\mathrm{pA\,m^{-2}}$ flowing from the atmosphere to the Earth s surface. Over the entire Earth s area, this results in a current of 1000 A, which should neutralize the Earth s charge in less than 10 min. However, the charge remains.

In the 1920s, it was suggested that in order to maintain the Earth s negative charge there needs to be a generator. Global thunderstorm activity was proposed as this generator, and it was shown soon after that the diurnal variations of the surface electric field, known as the Carnegie curve, are well correlated with the diurnal variations of global thunderstorm activity.

With the discovery of the ionosphere in the 1920s, a global picture was proposed, called the *global atmospheric electric circuit*. The overall picture is that of a spherical capacitor formed by a conducting Earth, a conducting upper atmosphere, and a leaky dielectric in between. Currents in the atmosphere are generated in regions of thunderstorms by lightning and point discharge currents (St Elmo s fire). These currents flow upward toward the ionosphere. At altitudes of 60–100 km the atmosphere becomes highly conductive, and these currents spread laterally around the globe, returning to the Earth s surface in the fair-weather regions of the world, and then flowing through the conductive Earth back toward the thunderstorm regions, closing the global circuit. The resultant ionospheric potential between the ionosphere and the Earth s surface is approximately 250 kV.

The variability of the global circuit can theoretically be monitored from only a single site on the Earth s surface. Indeed, simultaneous measurements of the global circuit on opposite sides of the globe show remarkable agreement. This implies that global thunderstorm activity that varies on hourly, daily, seasonal and interannual time scales can also be successfully monitored via the global circuit from only a few stations. Furthermore, because lightning and thunderstorm activity are closely related to the global climate system, changes in the global climate may be reflected in changes in the global electric circuit.

Recently it has been shown that the variability of the global electric circuit, measured from a single location, is well correlated with tropical and global surface temperatures, as well as other important climate parameters such as upper tropospheric water vapor. Moreover, modeling studies using global climatic models indicate that global lightning frequencies are very sensitive to changes in global surface temperatures.

plants); in others, energy for organisms (heterotrophs) is dominated by plant material originating in the catchment. A third source of energy comes from chemical reactions, and some organisms (chemoautotrophs) are able to facilitate these to derive their energy.

PIERRE HORWITZ *Australia*

Limnology

The word *limnology* stems from *limnos*, Greek for lake, originally implying a freshwater, still and permanent water body; this stereotypic notion has been expanded in recent usage to include:

- flowing and non-flowing waters (ponds, lakes, creeks, rivers, swamps, etc.);
- constructed wetlands (drains, channels, dams, reservoirs, etc.);
- subterranean water (namely aquifers, cave water, water-saturated substrates).

Limnology includes those fields dealing with bodies of freshwater, including the nature of a basin, the substrate and its form (geology and geomorphology), the way in which water moves over the surface or underground (hydrology), movement within a water body (hydrodynamics), or interaction between the water and the atmosphere (meteorology). Other central fields include the chemical constituents and processes in water (water chemistry), along with its contamination and use (environmental sciences). Studies of the microbes, plants and animals which live in, or rely on, water bodies (biology), their productivity and utilization (for example, aquaculture) and the way they interact with each other and their non-living surroundings, indicate that limnology can be regarded as a significant branch of ecology.

Important differences in the subject matter of the science arise from:

- Degrees of permanence of the water (from permanently inundated, through seasonally and predictably filled, to intermittently and unpredictably filled hollows).
- Degrees of salinity encountered in inland waters, which range from fresh at one end of a continuum of ionic concentrations, to brackish, saline and hypersaline waters; anions and cations originate from sea spray, groundwater and/or soil and rocks. Salt lakes can be internally drained evaporative basins which accumulate salts, or those that occur in catchments influenced by the discharge of saline groundwater.
- Energy source: some waters have energy pathways dominated by photosynthetic organisms (photoautotrophs) living in the water itself (like algae and water

Lithosphere

The rigid outermost part of the solid Earth is called the *lithosphere*. Its outer boundary forms the surface of the land and the floor of the ocean. The lithosphere interacts with the overlying convecting atmosphere and hydrosphere and with the convecting mantle below. Organisms live on and interact with the surface of the lithosphere and bacteria live inside it to depths of perhaps 1 km. Time scales of interaction at the Earth s surface range from fractions of a second, in lightning strikes, through tens of thousands of years, in soil formation, to hundreds of millions of years in basins of sedimentary rock deposition. The lithosphere is broken into about a dozen large plates that together completely cover the Earth s surface. The plate boundaries form a continuous network in which most of the Earth s volcanic activity, earthquakes and mountain-building are concentrated. Lithospheric plates move horizontally with respect to each other in response to ridge-push and slab-pull forces applied at their margins. Although the plates rotate rigidly across the Earth s surface at velocities in the range of $2-10\,\mathrm{cm\,year^{-1}}$ they respond by downward flexure, on wavelengths of 100–1000 km, to loads (including ice-sheets and newly deposited sedimentary rocks) applied from above. Areas centered on the Baltic Sea and on Hudson s Bay are presently flexing upward at a few $\mathrm{mm\,year^{-1}}$ in response to the removal, within the past 20 000 years, of ice sheet loads.

New lithosphere is continuously being generated at oceanic spreading centers and in complementary destruction, oceanic lithosphere up to 170 million years old is being taken into the Earth s interior at subduction zones. This cyclical process, called *plate tectonics*, which serves to remove most of the Earth s internally generated heat, has been going on for about 4 million years. Production of the continents, which are less susceptible to recycling than is the ocean floor, has been a substantial by-product of the plate tectonic process over that time. About 25% of the heat generated in the Earth s interior is conducted to the surface through the lithosphere at a gradient of approximately $20\,^{\circ}\mathrm{C\,km^{-1}}$. That gradient can be strongly perturbed by the passage of hot or cold fluids and by temperature changes

at the Earth s surface in response to global climate change. The mechanical lithosphere is divided into chemically distinct upper and lower parts. The upper part, called the *crust*, is made of rocks containing 50% silica under the ocean floor and of rocks containing 65% silica under the continents. The lower part of the lithosphere, the *lithospheric mantle*, is everywhere made of rock containing 42% silica. Solid Earth scientists take great interest in the behavior of the lithosphere in plate boundary zones where tectonic activity is concentrated. At spreading center boundaries in oceans, the thickness of the lithosphere approaches zero, although it rapidly thickens as newly formed ocean floor cools and ages. In mountain belts at active convergent boundaries the crust thickens and becomes hot. Deep under the mountains the temperature in degrees Kelvin exceeds 65% of the melting points of the constituent rocks, at which temperature the lithosphere loses its rigidity.

KEVIN BURKE *USA*

Little Ice Age

Michael E Mann
University of Virginia, Charlottesville, VA, USA

*The term Little Ice Age was originally coined by F Matthes in 1939 to describe the most recent 4000 year climatic interval (the Late Holocene) associated with a particularly dramatic series of mountain glacier advances and retreats, analogous to, though considerably more moderate than, the Pleistocene glacial uctuations. This relatively prolonged period has now become known as the Neoglacial period. The term Little Ice Age is, instead, reserved for the most extensive recent period of mountain glacier expansion and is conventionally de ned as the 16th- mid 19th century period during which European climate was most strongly impacted. This period begins with a trend towards enhanced glacial conditions in Europe following the warmer conditions of the so-called medieval warm period or medieval climatic optimum of Europe (*see *Medieval Climatic Optimum, Volume 1), and terminates with the dramatic retreat of these glaciers during the 20th century. While there is evidence that many other regions outside Europe exhibited periods of cooler conditions, expanded glaciation, and signi cantly altered climate conditions, the timing and nature of these variations are highly variable from region to region, and the notion of the Little Ice Age as a globally synchronous cold period has all but been dismissed (Bradley and Jones, 1993; Mann* et al., *1999). If de ned as a large-scale event, the Little Ice Age must instead be considered a time of modest cooling of the Northern Hemisphere, with temperatures dropping by about 0.6 °C during the 15th- 19th centuries (Bradley and Jones, 1993; Jones* et al., *1998; Mann* et al., *1998, 1999).*

Documentary accounts of dramatic mountain glacier retreats and advances during past centuries, widespread historical documentation of weather conditions (e.g., Pfister, 1995, 1998) and even a handful of several centuries-long thermometer measurements (e.g., Bradley and Jones, 1993) provide incontrovertible evidence of the occurrence of the Little Ice Age in Europe and other regions neighboring the North Atlantic during the 16th–19th centuries. This climatic era has, in fact, been pictorially captured in paintings detailing the greatly expanded range of various mountain glaciers in the French and Swiss Alps during past centuries. The juxtaposition of such early artists renderings of such glaciers against their modern photographic counterparts, provides a particularly graphic illustration of the dramatic climatic changes associated with the Little Ice Age in Europe (Figure 1).

These dramatic glacial advances often had important practical consequences for nearby human populations. In the Chamonix valley near Mont Blanc, France, numerous farms and villages were lost to the advancing front of a nearby mountain glacier. The damage was so threatening that the villagers summoned the Bishop of Geneva to perform an exorcism of the dark forces presumed responsible (this procedure, as for most human attempts at weather modification, does not appear to have been successful). Such societal threats were common during the late 17th and early 18th centuries, as many glaciers expanded well beyond their previous historical limits. Colder conditions combined with altered patterns of atmospheric circulation, appear to be tied to the prevalent crop failures in the more northern areas of Europe of the time. There are widespread reports of famine, disease, and increased child mortality in Europe during the 17th–19th century that are probably related, at least in part, to colder temperatures and altered weather conditions. Certainly, not all consequences of the associated climate changes were deleterious for European society. In London, the freezing of the Thames River, commonplace during the era, was celebrated with a winter carnival. The colder climate, furthermore, appears to have served as inspiration for writers of the time. The greater frequency of cold, icy winters sentimentally framed author Charles Dickens notion of the old-fashioned white Christmas. The unusually cold summer of 1816 (the year without a summer – see discussion herein) forced Mary Shelley to spend her summer vacation at Lake Geneva indoors, where she and her husband entertained each other with horror

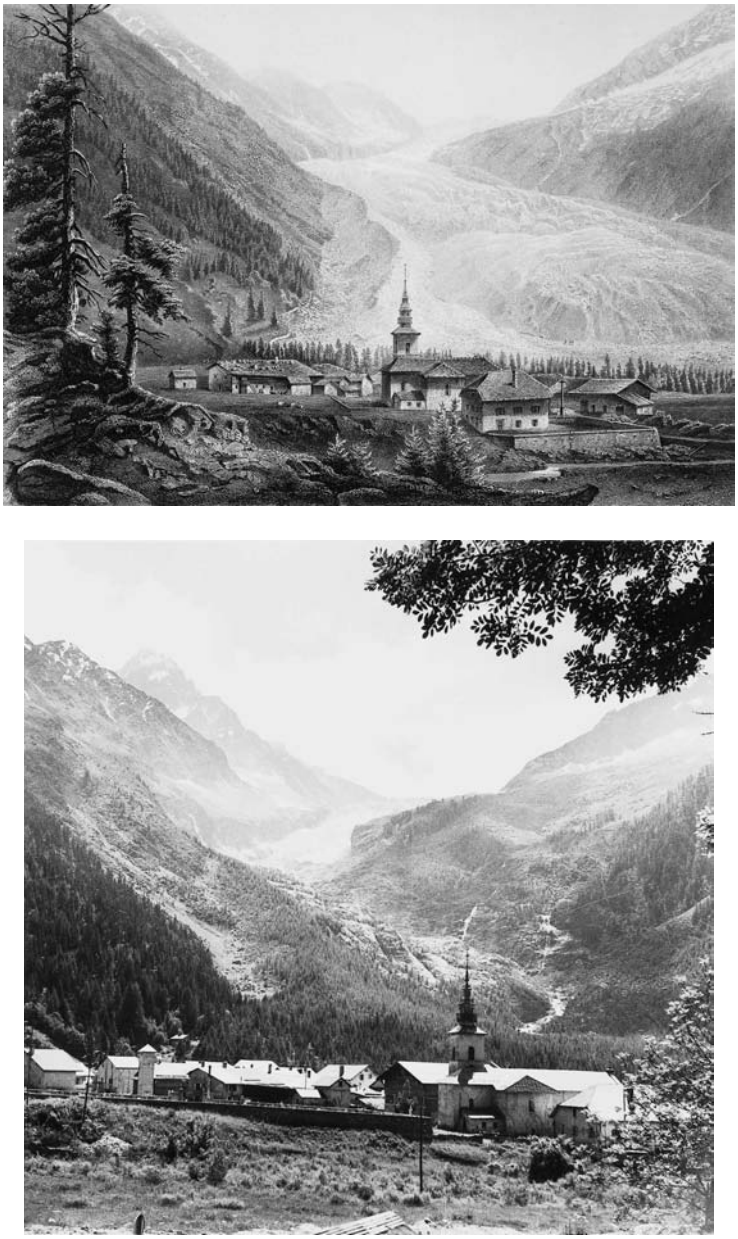

Figure 1 A portrait of the Argentiere glacier in the French Alps from an etching made between 1850 and 1860 just prior to its dramatic withdrawal, and a modern photograph of the glacier from a similar vantage point taken in 1966. (Reproduced by permission of Doubleday and Company, Inc., from Le Roy Ladurie, E, 1971 (Plates XXI and XXII))

stories, one of which resulted in her writing the novel *Frankenstein* (see Le Roy Ladurie, 1971).

The Little Ice Age may have been more significant in terms of increased variability of the climate, rather than changes in the average climate itself. The most dramatic climate extremes were less associated with prolonged multiyear periods of cold than with year to year temperature changes, or even particularly prominent individual cold spells, and these events were often quite specific to particular seasons. In Switzerland, for example, the first particularly cold winters appear to have begun in the 1550s, with cold springs beginning around 1568: the year 1573 had the first unusually cold summer (Pfister, 1995). The increased variability of the climate may have led to alternations between unusually cold winters and relatively warm summers. A severe winter preceded the hot summer that precipitated the Great Fire of London in 1666. A harsh winter followed by a warm summer may have added to the discontent of peasants who stormed the Bastille in Paris during the summer of 1789.

The cooling of the Little Ice Age has frequently been blamed for the demise of Norse settlements in Greenland

that had been established during the early centuries of the second millennium. This premise appears, however, to have only limited validity. Expanded sea ice extent in the North Atlantic certainly created problems for fishermen in Iceland and Scandinavia, and for the Norse settlements in Iceland and Greenland. Increased winter sea-ice cover closed off previously accessible trade routes between Scandinavia and Greenland during the late 14th century, cutting off trade with mainland Europe, upon which the Norse settlements relied. The collapse of Norse colonies in Greenland, however, represented a complex reaction to changing climate conditions (including seasonal precipitation/snowfall as well as temperature patterns), and their interaction with societal dynamics, and cannot be understood simply in terms of a lowering of temperatures in the region. In fact, as discussed below, temperature variations in western Greenland in past centuries bear only a limited resemblance to those in Europe, which conventionally have best defined the Little Ice Age.

Outside of the North Atlantic region, the large-scale signature of the Little Ice Age becomes even less clear. Unlike the true ice ages of the Pleistocene, which were marked by a clear global expression associated with dramatic growth of all the major continental ice sheets and a substantial lowering of global temperatures (probably $2-3\,^{\circ}C$ below current levels), the available evidence does not support the existence of a continuous period of cooler global temperatures synchronous with cold conditions in Europe. What evidence is available suggests, instead, generally colder conditions anywhere from the 13th through 19th century, quite variable in timing from region to region, and in most cases punctuated with intermittent periods of warmth (see Bradley and Jones, 1993; Pfister, 1995). Direct indications of climate variability (e.g., long thermometer measurements or reliable historical documentary records) are rarely available outside Europe and neighboring regions. There are some long instrumental climate records in North America dating back to the mid 18th century and historical information exists in the form of documentary evidence from parts of Canada and the northeastern US from early European settlers, and anecdotal reports from Native Americans in western North America. Such evidence gives a mixed picture of the Little Ice Age in North America. For example, the 17th century, the coldest century in Europe, does not appear to have been unusually cold in North America. By contrast, during the 19th century, as Europe was recovering from Little Ice Age conditions, North America was experiencing some of its coldest temperatures. There are reports, for example, that New York harbor froze over during this period of time. There is also some long-term human documentary evidence of climate changes in Russia and China that provide yet a different picture of temperature variations in past centuries from that of Europe (see Bradley and Jones, 1993 and references therein).

There is geological information from the position of moraines or till left behind by receding glaciers that provide a more global, albeit indirect, picture of the advances (and, less precisely, the retreats) of mountain glaciers. Such evidence suggests, for example, increased glaciation in certain regions of the world outside Europe prior to the 20th century, including Alaska in North America, and New Zealand and Patagonia in the Southern Hemisphere (see Grove, 1988). However, the precise timing of glacial advances in these regions (and even between the western and eastern Alps) differs considerably from region to region, suggesting the possibility that they represent roughly coincident, but independent regional climate changes, rather than globally synchronous increased glaciation. Owing to the complex balance between local changes in melting and ice accumulation, and the effects of topography, all of which influence mountain glacier extent, it is difficult to ascertain the true nature of climate change simply from evidence of retreat of mountain glaciers alone. For example, both increased winter precipitation (through greater accumulation) and lower summer temperatures (through decreased melting or ablation) can lead to increases in glacial mass. Furthermore, the inertia of large glaciers dictates that they respond relatively slowly, and with delays of decades to centuries, in response to any contemporaneous climate changes.

Other information is thus necessary to assess the global-scale climate variations of past centuries. A variety of other types of information is fortunately available to help provide a truly global-scale picture of climate change during past centuries (Bradley and Jones, 1993). These types include a few long-term historical documentary records (particularly outside Europe), supplemented by proxy climate records such as growth and density measurements from tree rings, laminated sediment cores, annually resolved ice cores, isotopic indicators from corals, and long-term ground temperature trends from borehole data. While these indirect measurements of climate change vary considerably in their reliability as indicators of long-term temperatures (varying in the degree of influence by non-climatic effects, the seasonal nature of the climate information recorded, and the extent to which the records have been verified by comparison with independent data), they are, nonetheless, essential for documenting global-scale patterns of temperature change in past centuries.

Comparing temperature estimates over the Northern Hemisphere and globe during past centuries from these different sources provides considerable insight into the regional variability and extent of the Little Ice Age (Figure 2). Slightly preceding the increased growth of mountain glaciers across Europe during the 17th–19th centuries is evidence of a depression of temperatures in the region (Central England – panel e) relative to modern levels by approximately $0.4\,^{\circ}C$ during the period 1500–1800 and by more than $0.6\,^{\circ}C$ during the 17th century period

of peak cold. The conclusion that the region exhibited its coldest conditions during the 17th century, and began warming significantly during the 19th century, is independently confirmed from tree ring reconstructions of European summer temperatures (see Jones *et al.*, 1998). A Little Ice Age is not as plainly evident in temperature estimates for Western Greenland (panel d), reinforcing the notion that the collapse of Norse civilization in Greenland was not simply a response to cooling temperatures. Temperature trends in Scandinavia (panel f) show some similarities with both those of Greenland and central England, further emphasizing the importance of regional variation in temperature trends over the past few centuries even in the North Atlantic and neighboring regions. In fact, the Little Ice Age appears to have been most clearly expressed in the North Atlantic region in terms of altered patterns of polar atmospheric circulation. Such altered patterns of circulation likely impacted seasonal snowfall patterns in a way that the Norse could not easily adapt to, and may explain differences between temperature variations in Europe and those in Iceland and Greenland. For example, the winter of 1833/1834, an unusually warm winter in central Europe,

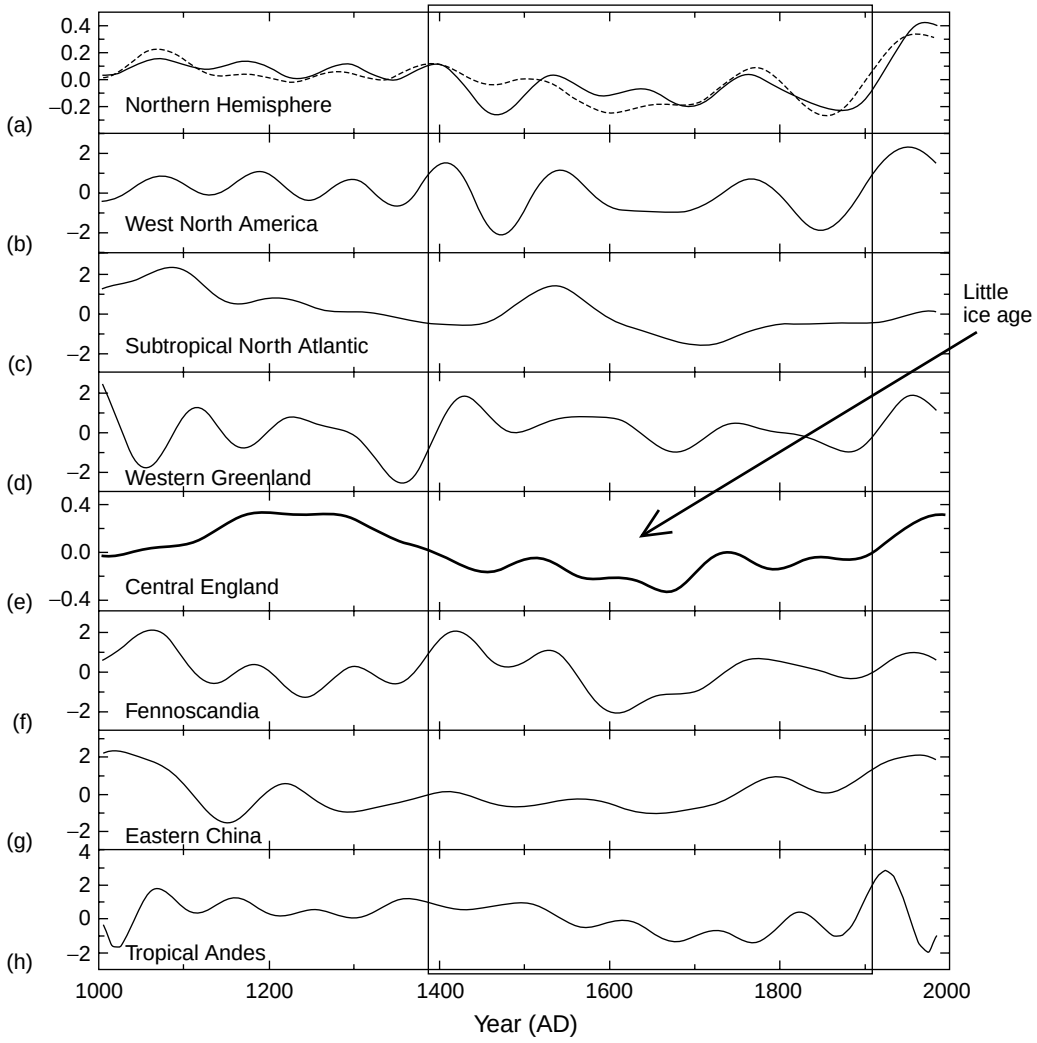

Figure 2 Estimated relative temperature variations during the past millennium for different regions. The records have been smoothed to emphasize century and longer-term variations. (a) Northern Hemisphere mean temperatures as estimated for the annual mean over the entire hemisphere (solid – Mann *et al.*, 1998, 1999) and over the extratropical region during the warm season (dashed – Jones *et al.*, 1998) based on global databases of proxy climate indicators, (b) tree ring data from western North America, (c) sediment record from the Sargasso Sea of the tropical North Atlantic, (d) ice cores from western Greenland, (e) a combination of thermometer, historical and proxy data records from central England, (f) tree ring data from Fennoscandia, (g) phenological evidence from eastern China and (h) ice core data from the tropical Andes of South America. Temperature scale is in °C for (a) and (e), and indicates relative temperature variations otherwise. Panel (e), which best defines the European Little Ice Age, is highlighted, with the large rectangle (extending from about AD 1400 to 1900) indicating more broadly the consensus among regions of the coldest period

appears to have been associated with dramatic changes in storm tracks over Europe, consistent with colder than normal conditions evident in Iceland that same year. While the 17th century appears to represent the timing of peak cooling in Europe, the 19th century was more clearly the period of peak cold in North America (panel b). In both the subtropical North Atlantic (panel c) and the tropical Andes of South America (panel h), peak cooling is evident during the 17th and 18th centuries. Even farther a field in eastern China (panel g), there is less evidence of any distinct cold period during the latter centuries of the millennium, with temperatures rather relatively uniformly depressed from about AD 1100–1800.

Some of the regional variability evident during the Little Ice Age can be understood in terms of changes in atmospheric circulation patterns. Such patterns, particularly the North Atlantic Oscillation (*see* North Atlantic Oscillation, Volume 1) – the dominant mode of atmospheric circulation variation in the North Atlantic and neighboring regions – have a particularly strong influence on winter temperatures in Europe. While the coldest year overall in Europe, 1838, was indeed one of the coldest over much of the Northern Hemisphere (the late 1830s were generally quite cold, perhaps due to the effects of the large volcanic eruption in Coseguina, Nicaragua during 1835 – see discussion herein), conditions were, nonetheless, relatively mild over significant portions of Greenland and Alaska. In fact, unusually cold, dry winters in central Europe (e.g., 1–2 °C below normal during the late 17th century) appear to have been associated with the flow of continental air from the northeast towards western Russia and Europe, conditions which, along with warmer than normal temperatures in Greenland and other regions, are consistent with the positive phase of the North Atlantic Oscillation. Warmer than normal winters in Europe, and cooler than normal temperatures in Greenland, tend to arise during the opposite phase.

While the peak maximum cooling occurred at quite different times throughout the Northern Hemisphere, an overall pattern does emerge when one composites regional variations into an estimate of large-scale mean temperature changes (see Mann *et al.*, 1998, 1999; Jones *et al.*, 1998). For the Northern Hemisphere on the whole (both annual mean and extratropical summer – see Figure 2, panel a), the period 1400–1900 appears to have been moderately cooler (approximately 0.3 °C) than the earlier period AD 1000–1400 and about 0.8 °C colder than the late 20th century. Following the cold late 15th century, the 17th and 19th centuries appear as the coldest centuries within this period (although, as discussed above, the spatial pattern of this cooling is quite distinct for the two periods). If one wishes to define the Little Ice Age proper as a time of large-scale cooling, it must be defined as a period of only moderately cooler Northern Hemisphere temperatures from about 1400–1900 (see Figure 2), preceding the rapid warming of the 20th century. For the Southern Hemisphere, evidence for a comparable Little Ice Age is far more diffuse (e.g., Jones *et al.*, 1998).

The existence of the Little Ice Age (whether defined by the particularly cold conditions in Europe during the 16th–18th centuries, or the more modest large-scale cooling of the 15th–19th centuries) invites questions as to what factors may have led to such a cooling.

This unusual period in climate history occurred before the likely influence of human activity (e.g,. the burning of fossil fuels associated with the industrial revolution). Though some of the long-term cooling of the climate prior to the 20th century might have been associated with astronomical factors, such factors cannot explain the pronounced and relatively short-duration cooling observed in many regions.

The explanation for the Little Ice Age must thus lie in other natural causes, whether associated with external forces, or internal noise in the climate system. The injection of sunlight-reflecting sulfate aerosols by explosive volcanic eruptions, for example, may be responsible for some of the cooling of the early and mid 19th century, in particular (see Lean *et al.*, 1995; Mann *et al.*, 1998). A prominent example is the 1815 eruption of Tambora in Indonesia that is typically blamed for the year without a summer. While parts of eastern North America and Europe experienced notable cooling, the observation that other regions, including the western US and the Middle East, appear, in fact, to have been warmer than usual is consistent with a hypothesized relationship between volcanic forcing of climate and the response of the North Atlantic Oscillation. The longer-term variations, and in particular cooler temperatures during the 17th century and warmer temperatures during the 18th century were likely to have been related to a concomitant increase in solar output by the Sun by approximately 0.25% following the Maunder Minimum of the 17th century (Lean *et al.*, 1995; Mann *et al.*, 1998) (*see* Maunder Minimum, Volume 1). Finally, changes in the ocean circulation (e.g., the Gulf Stream) of the North Atlantic, and associated impacts on North Atlantic storm tracks, may have emphasized temperature changes in Europe. The relative influences of these various external and internal factors on climate change during past centuries are an area of active climate research.

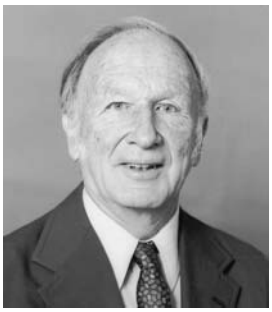
Lorenz, Edward N

(1917-)



Even if it is not common that a discovery in one field of science turns out to be of fundamental importance in several other fields, it does occur. And certainly it did occur when Edward Lorenz published his findings on the limitations of the predictability of the atmosphere, which in turn led to his pioneering work on deterministic chaos.

Before elaborating on the importance of these and other scientific contributions by Professor Lorenz we should identify some of the milestones in his life beginning with his birth May 23rd, 1917 in West Hartford, CT, USA, where he also grew up. His father was a mechanical engineer, and his mother did social work. Already as a child he demonstrated an unusual skill in solving mathematical puzzles, and as a young boy his favorite occupations were playing chess and collecting stamps.

After finishing school in 1934 he went to Dartmouth College, where he majored in mathematics, and in 1938 he entered the Mathematical Department of Harvard University. Here he was fortunate in having an eminent mathematician as advisor, Professor George Birkhoff, and he received his Master s degree in 1940.

Then came Pearl Harbor and the entrance of the USA into World War II, causing a radical turn of the Lorenz career. He applied for a meteorological course at Massachusetts Institute of Technology (MIT) and served in the US Army Air Corps 1942–1946 as weather forecaster in different places in the tropics, including Saipan and Okinawa.

After the war, Lorenz decided to continue his studies in meteorology. He returned to MIT, where he obtained his doctorate in 1948 and was offered a job by Professor Henry Houghton as a research scientist at its Department of Meteorology. Given his interest in mathematics and the experience he had achieved as a forecaster during the war, it was natural that he became actively engaged in research within the field of dynamic meteorology.

Thus, he became actively involved (together with Professor Victor Starr) in a project on the general circulation of the atmosphere. This research led to his introduction of the concept of available potential energy and clarification of how the work performed by the atmospheric engine is used to maintain the kinetic energy of the circulation against a continuous drain of energy by frictional dissipation (Lorenz, 1955).

In 1962, he was appointed Professor of Meteorology at MIT and at about that time he became deeply engaged in the problem of the predictability of weather. In a paper published in 1963, he was able to prove that there is a maximum time beyond which it is impossible to compute a useful forecast. After that time, any small error in the initial state used as input to the computations (for example caused by the flaps of a butterfly s wings) would have been amplified to such an extent that the value of the forecast would have become totally degraded (Lorenz, 1963).

It was in connection with this research that Lorenz s epoch-making work on deterministic chaos began. His papers focused on the behavior of physical systems that

seem to proceed according to chance even though their behavior is determined by precise physical laws. That is, the variations of such systems are not random, but only appear to be random. Although his thinking was stimulated by his familiarity with atmospheric processes, his ideas have since permeated virtually every branch of science (Lorenz, 1993).

Professor Lorenz was elected as a Member of the US National Academy of Sciences in 1975. He has also been elected as foreign member by academies of sciences in many other countries, and has received numerous honorary degrees and awards including the Kyoto Prize, the Roger Revelle Medal, the Holger and Anna-Greta Crafoord Prize, and most recently the IMO Prize of the WMO (AMS, 2001).

Lovelock, James

(1919-)

James Lovelock is an inventor and independent scientist. In the 1950s Lovelock carried out pioneering work on the detection of trace gases. This work culminated in the invention of the electron capture detector, a device capable of detecting electron absorbing compounds in the gas phase at concentrations as low as 10^{-14} (1 part in 100 trillion). Such instrumental capability revolutionized environmental chemistry. For example, halogenated compounds are efficient at electron capture and some are important anthropogenic environmental contaminants, both as persistent toxins and in relation to the catalytic destruction of stratospheric ozone (*see* Depletion of Stratospheric Ozone, Volume 1). Other compounds that absorb electrons are products of microbial processes. The ability of Lovelock s detector to measure trace amounts of such compounds as methyl iodide and dimethyl sulfide opened up new vistas in knowledge of global biogeochemical cycles.

Lovelock s other great contribution to environmental science arose directly from his studies of trace gases in the atmosphere. In 1972 he put forward the revolutionary idea that the composition of Earth s atmosphere is a construct of the biosphere acting as a quasi-organismic system. He gave the system the name Gaia (*see* Gaia Hypothesis, Volume 5). Lovelock published three books on this stimulating, controversial way of looking at the interaction of biosphere, atmosphere, hydrosphere and lithosphere (*Gaia: A New Look at Life on Earth*, *The Ages of Gaia: A Biography of our Living Earth*, and *Healing Gaia: Practical Medicine for the Planet*).

Since the 1970s Lovelock has worked outside the institutional confines of academia, government and industry and this independence was integral to his personal, radical approach to doing science. He has been a Fellow of the Royal Society since 1974, President of the Marine Biological Association from 1986–1990, and in 1997 he was a recipient of the Blue Planet Prize.

M

Madden–Julian Oscillation

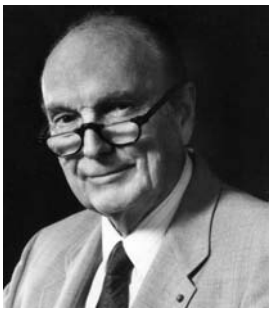
The *Madden-Julian Oscillation* (MJO) is the major mode of variability in the tropics on time scales of one to a few months. For this reason, it is often referred to as the 30–60 or 40–50 day oscillation. The MJO is particularly evident in the variation of tropical easterlies (the west to east winds) over the tropical Pacific and Indian Oceans. It is also evident in the variations of the sea surface temperature, cloudiness, and rainfall. The MJO is named after Roland Madden and Paul Julian, both at the National Center for Atmospheric Research in Boulder, CO, who in the early 1970s identified the oscillation when analyzing the fluctuating character of the winds over the tropical Pacific Ocean.

In that the major seasonal to interannual mode of climate variability in the same regions is the El Niño/Southern Oscillation, there is great interest in understanding the various interactions between these two oscillations. For example, there are some suggestions that the intensity of El Niño events might be influenced by the phase of the MJO when the El Niño begins (*see* El Niño and La Niña: Causes and Global Consequences, Volume 1).

MICHAEL C MACCRACKEN *USA*

Malone, Thomas F

(1917-)



Meteorologist and seasoned initiator and organizer of cooperative scientific activities, Thomas Malone has greatly influenced the linking of research and public policy relating to environmental understanding at the global, national, and local levels. Born in South Dakota, USA in 1917, and completing his ScD at Massachusetts Institute of Technology (MIT) in 1946, Malone served successively on the Faculty of MIT, 1941–1955; Research Director for the Travelers Insurance Company, 1965–1970; Dean at the University of Connecticut, 1970–1973; Director of the Holcomb Research Institute, Butler University, 1973–1983; Scholar in Residence, St. Joseph College, 1983–1991; and Director, Sigma Xi Center, Research Triangle, NC, 1992–1998.

At the international level, Malone was a prime mover in the creation of the International Geosphere-Biosphere Programme, as outlined in the book of which he was co-editor (Malone and Roederer, 1985). He was an organizer and first Secretary-General of the International Council for Science (ICSU) Scientific Committee on Problems of the Environment (SCOPE) (*see* SCOPE (Scienti c Committee on Problems of the Environment), Volume 4). In that capacity, he helped initiate studies on the design of global environmental monitoring systems and on the environmental effects of large dams. Later, he was a principal consultant to the World Conference on the Human Environment at Stockholm, and then an active participant at the Earth Summit at Rio in 1992. He was an influential member of the international committee of scientists that assessed the possible environmental effects of a nuclear war in 1985 and of the United Nations (UN) Task Force that outlined the basis for UN consideration of this issue. He also was a key figure in the early establishment of the Global Atmospheric Research Programme, having negotiated the cooperative agreement between ICSU and the World Meteorological Organization leading to worldwide experiments in 1978 that evolved into the World Climate Research Programme (*see* WCRP (World Climate Research Programme), Volume 1).

At the national level, Malone was an active member of the National Academy of Sciences, and steered its foreign activities during 1978–1982. He has chaired an array of National Research Council units that examined programs in atmospheric sciences, geophysics, environmental studies, and international scientific relations, including

global change (1962–1991). This same skill in dealing with a diversity of both scientific and organizational criteria has enabled him to play a role in organizing the National Center for Atmospheric Research at Boulder, CO. He also has devoted time to the application of scientific judgment to problems of motor vehicle safety and assessment of acid precipitation.

Although Malone has had a profound influence on national and international research and policy, he has provided continuing support for the constructive roles of local governments and of individual scientists in dealing with environmental problems. Thus, in the period 1988–1998 he served first as executive scientist for the Connecticut Academy of Science and Engineering on problems of sustainability, and then as director of the national Sigma Xi Center addressing current scientific issues.

To a large degree, the current organization for understanding and dealing with environmental issues reflects the vision and persistence that Malone has brought to finding constructive, solidly based lines of action (Malone, 1992).

GILBERT WHITE *USA*

Manabe, Syukuro

(1931-)

Dr Syukuro Manabe has been a world renowned pioneer and leader in mathematical modeling of human-caused climate change since the 1960s. He was a senior scientist at the Geophysical Fluid Dynamics Laboratory (GFDL), National Oceanic and Atmospheric Administration (NOAA) (1958–1997, now retired) and is currently a senior scientist at the Earth Frontier Research System, Japan (1997–present).

Manabe was born in Shingu-Mura, Uma-Gun, Japan on September 21, 1931. His father and other relatives were strongly centered within the medical profession. Manabe often humorously commented that, in his family s view, he had abandoned the highest calling, medical practice, for the lesser pursuit of climate science. The very presence of his biography in this Encyclopedia suggests that his medical relatives have undoubtedly reconsidered their original assessment by now.

Manabe received his PhD in 1958 from Tokyo University in Geophysics. Shortly thereafter, he joined Joseph Smagorinsky in the General Circulation Research Section of the US Weather Bureau, in Washington, DC, which soon was renamed the Geophysical Fluid Dynamics Laboratory (GFDL). GFDL is now located at Princeton University and is part of the US National Oceanic and Atmospheric Administration (NOAA).

Over his more than 40-year career, Manabe has been the world s leader in developing the field of climate modeling, its use in understanding the workings of the climate system, and in defining the quantification of human-caused climate change (greenhouse warming) (*see* General Circulation Models (GCMs), Volume 1). Recently, each of these research challenges has become a major international priority. Remarkably, the essence of the field today remains very similar to Manabe s pioneering vision.

Over his first decade of research (basically, the 1960s), he developed the world s first successful multilevel, 3D atmospheric circulation model in collaboration with Joseph Smagorinsky, and applied it to a pioneering determination of the role of the hydrological cycle in the climate system. He led the effort to produce the first model that included the stratosphere and the associated transport and chemistry of ozone. He and Kirk Bryan developed the world s first coupled atmosphere–ocean model. Such coupled models have now become indispensable for studying natural and human-caused climate changes. Most importantly, during that decade, he and Richard Wetherald were the first to develop a self-consistent simple 1D (altitude only) model of the global heat balance and apply it to assess the sensitivity of climate to changes in the chief radiatively important gases, carbon dioxide (CO_2), water vapor (H_2O), and ozone (O_3). In addition, Manabe and Wetherald presented the first assessment of the positive feedback effect of water vapor on CO_2 induced global warming. This work also highlighted the strong cooling of the stratosphere in response to increased atmospheric CO_2 concentrations. The greenhouse theory of climate change took its modern shape from these results, which were later supported by comprehensive three-dimensional models. Radiative-convective models similar to this one are still important analytical tools for interpreting the results from 3D models. It is not surprising that this work is still frequently quoted.

In his second decade of research during the 1970s, Manabe continued his systematic effort to model and understand the Earth s climate system. During the first half of this period, he published the first realistic simulations of the global hydrological cycle and the circulation of the tropics using the pioneering 3D atmospheric model he developed during the preceding decade. He continued his collaborative efforts with Kirk Bryan and Michael Cox to develop a model of the coupled atmosphere–ocean climate system, producing ever more realistic model simulations. It was during this second decade that he began his now world-renowned effort to understand the 3D, global sensitivity of the climate system to various perturbations such as added CO_2. This led to pioneering and still central studies on the effects of increasing CO_2 and changes in the solar output. It was this effort, more than any other, that led to today s enlightened understanding and appreciation of the greenhouse climate warming problem. Others have followed with major advances, but Manabe s research achievements still provide the foundation for the ongoing public debate on human caused climate change.

In many respects, the third decade of Manabe s climate research was even more noteworthy. His prodigious energy, diagnostic genius, and unique creativity pushed climate dynamics into new frontiers during the 1980s. He, Theodore Terpstra, and Douglas Hahn demonstrated the role of mountains in shaping the circulation of the atmosphere, most notably, that of the Indian summer monsoon. With Ronald Stouffer and Richard Wetherald, he continued his attack on the CO_2 climate warming problem by exploring regional and seasonal effects, as well as the first studies of the influence of changing clouds on climate sensitivity. His pioneering work that first projected a substantial drying of summer soil moisture in semi-arid continental regions in a greenhouse-warmed Earth is now the focus of major scientific, economic, and political attention. Also, in collaboration with Kirk Bryan and Anthony Broccoli, he attempted to simulate the warm CO_2-rich climate of the Cretaceous period and the cold climate of the last glacial maximum. These studies provided many new perspectives on the lessons of paleo-climate for today s climate change problems.

Manabe s fourth research decade in the 1990s, showed no loss of his research creativity and energy. Working with his colleagues, Thomas Delworth, Thomas Knutson, and Ronald Stouffer, Manabe and his team produced a number of insights on the roles of the ocean in climate change, including the possibility of multiple equilibrium states. During this period, he also pioneered the investigation of a possible slowdown or collapse of the overturning circulation of the North Atlantic caused by increasing greenhouse gases. The details of this phenomenon are still under intensive investigation today by a number of researchers. This period was especially marked by Manabe s pioneering attempt to simulate and understand decadal-scale natural climate variability, today a major international research priority. Referring to their successful simulation of low frequency variability of global mean surface temperature, Ronald Stouffer and Manabe concluded that the 20th century surface warming 0.6 °C cannot result solely from natural climate variations. They then concluded that the observed warming should, to a significant degree, be caused by the thermal forcing due to increased greenhouse gases in the atmosphere.

Manabe and his colleagues then took on the problem of time-dependent responses of the climate system to slowly increasing greenhouse gases. This work eventually produced a heightened awareness of the daunting character of the greenhouse warming problem by investigating the climate s response along its entire natural time scale of many hundreds of years. Even today, his original choice of investigating the problem out to doubled and quadrupled atmospheric CO_2 levels over the pre-industrial amounts still brackets the policy debates. Doubled CO_2 is essentially the commitment that society has made, and quadrupled CO_2 is where we are currently heading without focused mitigation of CO_2 emissions. More recently, in cooperation with the Intergovernmental Panel on Climate Change (IPCC) 1995 assessment process, scientists from the UK Hadley Centre and Manabe s team independently showed that the added greenhouse gases, offset somewhat by human-emitted sulfate aerosol particles, match the global-mean surface-air temperature warming over the past century rather well. Together with the study of natural climate variability mentioned above, these groups results played a key role in the formulation of the IPCC s now famous statement, The balance of evidence suggests a discernible human influence on global climate .

Now in his fifth decade of research, Manabe is at the Earth Frontier Research System in Japan. He is currently heavily involved in assisting the daunting Japanese effort to produce a very high resolution, comprehensive climate model using the world s most powerful supercomputer. The outcome of this effort is still unknown. However, if it succeeds, Manabe s uniquely perceptive insights and helpful advice will most likely have played a very substantial guiding role.

Manabe has achieved numerous national and international recognitions for his climate modeling research. These include: the Japan Meteorological Society s Fujiwara Award; the American Meteorological Society s Meisinger Award, Second Half Century Award, as well as the Carl-Gustaf Rossby Research Medal, Fellow, and Honorary Member; the American Geophysical Union s Roger Revelle Medal and Fellow; European Geophysical Society s Milutin Milankovich Medal; Member of the National Academy of Sciences; Foreign Member of Academia Europa; Foreign Fellow of the Royal Society of Canada; US Department

of Commerce Gold Medal; Presidential Meritorious Rank Award; Blue Planet Prize; Asahi Prize; and the Volvo Environmental Prize.

The world of government, commerce, and environment has now increasingly realized how vitally important it is to understand climate, predict its variations, and project its long-term changes. Without Syukuro Manabe s pioneering accomplishments and intellectual leadership, today s global awareness of climate issues might still be but a dim hope in the minds of a small number of scientists and visionaries.

Maunder Minimum

Sunspots are relatively dark locations on the Sun s surface. The earliest observations of sunspots appear to have been made in China and Korea around 800 BC, and scattered records of sunspots exist over the centuries. Regular telescopic observations of the Sun began in the early 17th century, including records of sunspots. It was noted very early that the number of sunspots varied over about an 11-year cycle (*see* Sunspots, Volume 1). However, beginning in about 1645, the number of sunspots that were observed precipitously declined, and from 1645 to 1715 sunspots were rare events. This period is now known as the *Maunder Minimum*, after the solar astronomer E W Maunder (1890, 1894), who investigated the dearth of sunspots following earlier work by Sporer (1887). The reality and significance of the phenomenon were clearly established by exhaustive research by J Eddy (1976).

Reconstructions of solar activity based on various proxy data sources suggested that *solar irradiance* was significantly reduced during this period (*see* Solar Variability, Long-term, Volume 1). However, only in the last two decades have very accurate measurements been possible using satellites that can view the Sun from above the atmosphere. These measurements indicate that variations in solar radiation over the solar cycle vary by a few tenths of a percent. Roughly simultaneous to the Maunder Minimum, generally cooler climatic conditions prevailed in Europe. The exceptionally cold winters associated with these conditions led to suggestions that the world was experiencing a Little Ice Age, although newer evidence suggests that the severe cold was not a global phenomenon (*see* Little Ice Age, Volume 1). How the cooling in Europe, the winter climate of which is determined mainly by oceanic conditions in the Atlantic Ocean, may be tied to variations in solar output remains to be fully elaborated.

Medieval Climatic Optimum

Michael E Mann
University of Virginia, Charlottesville, VA, USA

*The Medieval Climatic Optimum (also known as the Little Climatic Optimum, Medieval Warm Period, or Medieval Warm Epoch) refers to a period of climatic history during which temperatures in Europe and neighboring regions of the North Atlantic are believed to have been comparable to, or to have even exceeded, those of the late 20th century. This period is conventionally believed to have occurred from approximately 900- 1300 AD, terminating with the more moderate conditions of the 15th century, and the Little Ice Age (*see *Little Ice Age, Volume 1) which impacted Europe during the 16th- mid 19th centuries. The Medieval Climatic Optimum appears to have been in large part a feature of the North Atlantic and neighboring regions (Wigley* et al., *1981). Indeed, when Lamb (1965) coined the term Medieval Warm Epoch, it was based on evidence largely from Europe and parts of North America. Regional temperature patterns elsewhere over the globe show equivocal evidence of anomalous warmth (see Wigley* et al., *1981; Hughes and Diaz, 1994) and, as Lamb (1965) noted, episodes of both cooler as well as warmer conditions are likely to have punctuated this period.*

It is evident that Europe experienced, on the whole, relatively mild climate conditions during the earliest centuries of the second millennium (i.e., the early Medieval period). Agriculture was possible at higher latitudes (and higher elevations in the mountains) than is currently possible in many regions, and there are numerous anecdotal reports of especially bountiful harvests (e.g., documented yields of grain) throughout Europe during this interval of time.

Grapes were grown in England several hundred kilometers north of their current limits of growth, and subtropical flora such as fig trees and olive trees grew in regions of Europe (northern Italy and parts of Germany) well north of their current range. Geological evidence indicates that mountain glaciers throughout Europe retreated substantially at this time, relative to the glacial advances of later centuries (Grove and Switsur, 1994). A host of historical documentary proxy information such as records of frost dates, freezing of water bodies, duration of snowcover, and phenological evidence (e.g., the dates of flowering of plants) indicates that severe winters were less frequent and less extreme at times during the period from about 900–1300 AD in central Europe. Lamb (1965) (*see* Lamb, Hubert H, Volume 1) concluded that winters in Europe were less severe, and summers far drier, during the interval from AD 1080–1200. Farther south in the subtropical North Atlantic, there is also evidence for warmer sea surface temperatures during Medieval times (Keigwin, 1996).

Some of the most dramatic evidence for Medieval warmth has been argued to come from Iceland and Greenland (see Ogilvie, 1991). In Greenland, the Norse settlers, arriving around AD 1000, maintained a settlement, raising dairy cattle and sheep. Greenland existed, in effect, as a thriving European colony for several centuries. While a deteriorating climate and the onset of the Little Ice Age are broadly blamed for the demise of these settlements around AD 1400, the best evidence suggests that it was a combination of societal factors and trade relationships with mainland Europe. These in turn were probably influenced by a variety of seasonal climatic changes that were occurring throughout the North Atlantic region, rather than any simple local cooling trend (see McGovern, 1981, and also *see* Little Ice Age, Volume 1).

Although Lamb (1965) did not argue for a globally-synchronous warm period, his characterization has often been taken out of context, and used to argue for global-scale warmth during the early centuries of the millennium comparable to or greater than that of the latter 20th century. The best available evidence does not support such a notion. Outside of Europe and other regions neighboring the North Atlantic, the evidence for a Medieval Warm Period is indeterminate, at best (see Hughes and Diaz, 1994). Even those regions which appear to have experienced greater warmth exhibited it at quite different times. Indirect estimates of temperatures over the globe (based on proxy climate indicators such as tree rings, ice cores, and ocean sediments, and in certain regions, human documentary and phenological evidence – *see* Little Ice Age, Volume 1, Figure 2) provide an estimate of the considerable regional variations in timing of cold and warm periods around the globe during the Medieval period. Estimates of long-term changes in Central England temperatures (the basis, in large part, for the original definition of the Medieval Warm Period) suggest warmth during the period from about AD 1150–1350 (though the reliability of these estimates has been called into question – see Hughes and Diaz, 1994). In contrast, estimates of temperatures in western Greenland from ice cores (relevant to the earlier discussion of the Norse colonization of Greenland) suggest anomalous warmth locally only around AD 1000 (and to a lesser extent, around AD 1400), and in fact, quite cold temperatures during the latter part of the 11th century. The seasonality of this warmth (e.g., winter or summer) indicated by such proxy information is, however, not clear. Estimates of both sea surface temperatures in the subtropical North Atlantic from sediment cores and tree rings from Scandinavia and Eastern China imply unusually warm conditions only during the 11th and early 12th centuries. There is no evidence of unusual warmth in either tree-ring estimates of western North American temperatures or ice-core based estimates of temperatures in the tropical Andes of South America.

Figure 1 compares estimated temperature variations for the Northern Hemisphere as a whole (based on combined temperature information over the globe from indirect sources) with estimated temperature trends in Central England alone. Northern Hemisphere annual mean temperatures (Mann *et al.*, 1999) and extratropical summer temperatures (Jones *et al.*, 1998), suggest only slightly warmer temperatures (a couple of tenths of a °C) during the

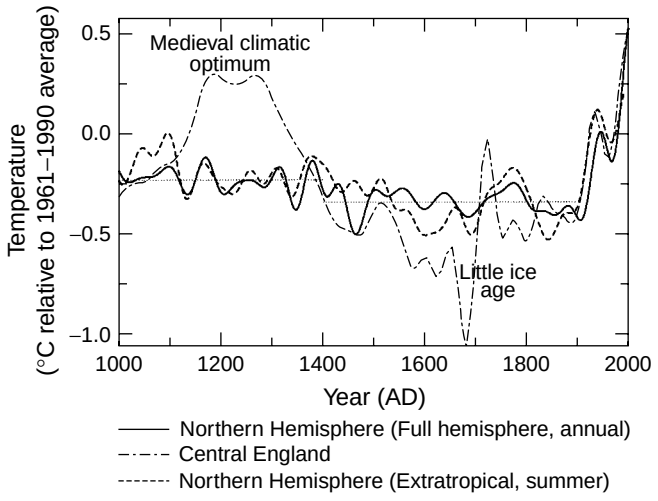

Figure 1 Estimated temperature variations during the past millennium for (1) the entire Northern Hemisphere estimated for the annual mean over the entire hemisphere (solid – Mann *et al.*, 1999) and over the extratropical region during the warm season (dashed – Jones *et al.*, 1998) based on global databases of proxy climate indicators, and (2) central England, based on a combination of thermometer, historical and proxy data records from central England (Lamb, 1965). Horizontal dashed lines indicate the moderately different Northern Hemisphere annual mean temperatures during the periods AD 1000–1400, and AD 1400–1900

period AD 1000–1400 relative to the later, colder period AD 1400–1900 (the latter associated with the Little Ice Age). Moreover, unlike European temperatures that indeed indicate a distinct warm phase earlier in the millennium, the large-scale trend represents a relatively monotonic long-term cooling. The less variable long-term fluctuations in temperature for the entire Northern Hemisphere result from the fact that the timings of cold and warm periods, so highly variable from region to region, tend to cancel in a hemispheric average. If one were to define hemispheric cold and warm periods during the past millennium by modern standards, only the 20th century could be termed a warm period; the period AD 1000–1400 would be termed a moderately warm period, and the period 1400–1900 a moderately cold period. Evidence for the Southern Hemisphere is far sketchier, and it is difficult as yet to reach any confident conclusions, although estimates of Southern Hemisphere temperatures (Jones *et al.*, 1998), uncertain as they are owing to the small amount of available information, show no evidence of a Medieval Climatic Optimum.

Thus, current evidence does not support the notion of a Medieval Climatic Optimum as an interval of hemispheric or global warmth comparable to the latter 20th century. Astronomical climate forcing may have contributed to a long-term cooling trend throughout the second millennium that terminated in the 20th century. Increased northward heat transport by an accelerated Atlantic thermohaline ocean circulation during Medieval times may have warmed the North Atlantic and neighboring regions, causing the warmest temperatures to be evident in Europe and lands neighboring the North Atlantic (albeit at notably varying times within the broader period of AD 900–1300).

A variety of factors thus may have contributed to both the moderate warmth of the Northern Hemisphere and the more sizeable and distinct North Atlantic/European warming during the early centuries of the second millennium.

Mesosphere

The *mesosphere* is the layer of the Earth s atmosphere from about 50 km to about 85 km that lies above the stratosphere and in which the temperature decreases with height. A peak in temperatures occurs at the boundary between the stratosphere and mesosphere, called the *stratopause*, the result of heating due to absorption of ultraviolet solar radiation by ozone. The temperature decreases with height throughout the mesosphere up to the *mesopause*, above which (in what is known as the *thermosphere*) the temperature begins increasing with height due to absorption of solar radiation by oxygen molecules. It should be noted that the *ionosphere*, which overlaps both the mesosphere and thermosphere, is defined in terms of the ion concentrations present (also created by the absorption of solar radiation), while the stratosphere, mesosphere, and thermosphere are defined by the vertical temperature structure of those layers.

Mesozoic

The *Mesozoic* era was the middle era during the last 570 million years (Ma). It followed the Paleozoic, with the transition at 220 Ma before present (BP), and came before the Cenozoic, which started 65 Ma BP. The Mesozoic lasted 155 Ma (Matthews, 1984). The Mesozoic era contained three periods, the Triassic, Jurassic, and Cretaceous (*see* Cretaceous, Volume 1) in order from earliest to latest. The

Mesozoic is best known as the age of the dinosaurs. The Permo–Triassic and Cretaceous–Tertiary boundaries represent two of the most severe extinction events in Earth s history, each resulting in a dramatic change in the Earth s biota. The term Mesozoic was first coined by John Phillips in 1840, based on the fossils found in specific stratigraphic formations in Wales (Prothero, 1990). The paleogeography of the Mesozoic began as a single pole-to-pole supercontinent known as *Pangaea*. During the course of the next 155 Ma, North America separated from Africa and South America, Europe separated from Africa, Africa separated from India and Antarctica, and later from South America, and India and Australia separated from Antarctica, forming the equatorial Tethys Sea and later the Atlantic Ocean (Scotese and Golonka, 1993). The mid-late Cretaceous represents a time of high sea levels (300–500 m greater than present) and high atmospheric carbon dioxide (CO_2) concentrations due to sea floor spreading (resulting from increased volcanism) and was most likely a warm, ice-free period. The entire Mesozoic probably represents a relatively warm period in Earth s history (Crowley, 1991). Petroleum reserves in Saudi Arabia were formed during the Jurassic to mid-Cretaceous, while the uplift of the Rocky Mountains began during the Cretaceous (Matthews, 1984).

Meteorology

Meteorology is the study of the atmosphere. The term has traditionally been used to refer to all aspects of the study of the atmosphere and atmospheric phenomena, but in recent decades has been more often applied to theory and applications associated with understanding and predicting the weather. Current usage treats meteorology as a subset of the broader atmospheric sciences.

KEITH L SEITTER *USA*

Methane

Michael C MacCracken

Lawrence Livermore National Laboratory, Livermore, CA, USA

Methane (CH_4) is the most abundant organic compound in the atmosphere. Although chemically very simple, methane is an unusual gas in that it is: (a) a source of energy when combusted; (b) able to absorb infrared energy and so is a contributor to the Earth's greenhouse effect; and (c) chemically decomposed in the atmosphere along chemical pathways that affect atmospheric chemistry and the cleansing capacity of the atmosphere. Methane is produced as a consequence of biological processes, being created when biological materials decompose in the absence (or near absence) of oxygen. Because of this, methane is most often generated underground or underwater or in the guts of animals. The methane that comes out of deep wells in the Earth was created when very old biological matter decomposed far underground. This methane is often associated with oil and coal-containing formations that derive from biological matter buried tens to hundreds of millions of years ago. Because methane is valuable as a source of energy when burned (known familiarly as natural gas), every effort is made to make sure that this methane is piped without leakage to combustion devices; this is largely successful and improvements are being made. Methane also comes from decomposition that takes place in the organic mass of accumulated materials in wetlands, below rice paddies, land lls, and in the guts of ruminant animals and termites.

Because methane has not been fully oxidized, its chemical bonds contain energy that can be released through chemical reactions in both the stratosphere and troposphere. In the stratosphere, methane affects the ozone concentration and is also the primary reactant in chlorine deactivation (Cl^- reacting to form hydrochloric acid (HCl)). After finally breaking down chemically, water is a major by-product, and the increasing methane concentration is leading to an increase in the stratospheric water vapor concentration. In the troposphere, the primary chemical destruction mechanism is initiated via the reaction with the hydroxyl radical (OH), which is a reactive molecule that helps break down a wide range of pollutant compounds that reach the atmosphere (*see* OH- Radical: is the Cleansing Capacity of the Atmosphere Changing?, Volume 2). As a result, methane affects the concentrations of OH, tropospheric ozone (O_3), and formaldehyde (COH_2). The present atmospheric lifetime of methane as a result of this and other minor reactions is estimated to

be about 8.4 years, which is the shortest lifetime of the various greenhouse gases whose concentration is being significantly affected by human activities. Increases in the methane concentration tend to reduce the OH concentration, thereby lengthening the lifetime of methane in the atmosphere.

Ice core records indicate that the concentration of methane has varied over the past 420 000 years, being about 400 parts per billion by volume (ppbv) during glacial peaks when wetland extent was likely at a minimum and about 700 ppbv during the peaks of interglacials when conditions were warmer and wetter. For the 10 000 years prior to the Industrial Revolution, the concentration was relatively steady at about 750 ppbv, indicating that natural emissions must have been roughly 200–250 teragrams of methane per year.

Since about 1750, the methane concentration has risen by about 150% and is now about 1750 ppbv. This amount is consistent with a human-induced augmentation of emissions to a level that is about two to three times the natural level. Because methane is a result of such basic human activities as growing rice and cattle, projections are that the emissions are likely to grow with world population unless control measures are taken. Observations do indicate that the increase in concentration is continuing, but there are year-to-year variations that are not fully understood and the rate of rise has been dropping somewhat, although it is not yet well established if this is due to reductions in human-induced emissions, reductions in natural emissions due to climate fluctuations, or changes in atmospheric chemistry.

On a per mass basis, at present methane and carbon dioxide (CO_2) concentrations (and assuming a 100-year time frame), methane is over 20 times as effective at trapping infrared radiation compared to carbon dioxide (*see* Global Warming Potential (GWP), Volume 1). For this reason, although the methane concentration is only about 1/200th the carbon dioxide concentration, the increase in the methane concentration has augmented radiative forcing by about one-third the increment caused by the increase in the carbon dioxide concentration. In addition, chemical model studies indicate that the OH concentration drops about 0.3% for each 1% increase in the methane concentration. Because of its relatively large effect, because it has a relatively short atmospheric lifetime, and because capture of methane is relatively inexpensive and when captured methane can be used as a fuel, significant attention is being devoted to controlling the emissions of methane that result from human activities. Control measures include capture at landfills and sewage treatment plants and altering agricultural activities, including the growing of rice and the feed provided to cattle.

An important potential climatic feedback involving methane is that global warming may lead to melting of the permafrost in high latitudes, and that this warming would accelerate the release of methane that is trapped in the ice below the land surface and in the sediments of the continental shelf. Release of this trapped methane (*see* Methane Clathrates, Volume 1) and the more rapid decomposition of biological materials would enhance the release of methane to the atmosphere, accelerating global warming.

Methane Clathrates

Nick Sundt
Office of the US Global Change Research Program, Washington DC, USA

Under high pressure, low temperatures and relatively quiescent conditions, very large amounts of gaseous methane (CH_4) have been trapped in frozen water within ocean sediments and on land in association with permafrost. The methane molecules are enclosed within tiny cages that are formed as water crystallizes around the gas molecules, thereby forming clathrates. The term clathrate refers to the enclosure of one kind of molecule within a crystal lattice formed by another compound.

In addition to the methane within clathrates themselves, additional methane may be trapped as clathrate layers, which block routes through which methane otherwise would freely escape. Various land and ocean drilling programs have found methane clathrates in permafrost and concentrated in oceanic sediments along the margins of continents.

Clathrates form when methane is introduced to a favorable combination of low temperatures, high pressure and water. Among major sources of methane are bacteria breaking down organic matter and geologic faults that allow older methane to rise from deeper below the Earth s surface. Over millennia, methane sources have fed the process in which clathrates trap large volumes of the gas that otherwise might have been vented to the atmosphere.

Estimates of the amount of methane locked up by clathrate formations vary widely across studies, although scientists agree that vast quantities are present. According to the US Department of Energy (Tomer, 2000), worldwide oceanic hydrate resources are estimated to range from 850 to ~1 400 000 trillion cubic meters (30 000–49 000 000 trillion cubic feet (Tcf)) and worldwide continental resources are estimated to range from 140

to 340 000 trillion cubic meters (5000–12 000 000 Tcf). By comparison, conventional worldwide gas resources are estimated to be about 370 trillion cubic meters (13 000 Tcf). Indeed, some estimates of methane clathrate resources exceed the combined global reserves of conventional gas, coal and petroleum.

Within the context of climate change, the clathrates are important for two reasons. First, methane clathrates hold very large amounts of energy. However, because the resource often is diffuse and difficult to access, it is not known what fraction might be economically and safely exploited within the foreseeable future. Indicative of the potential importance of methane clathrates, the US Department of Energy has calculated that even if only 1% of the methane hydrate resource (in the US, mainly in Alaska and on adjacent continental shelves) could be made technically and economically recoverable, the US could more than double its domestic natural gas resource base.

Combustion of such large volumes of methane would add carbon dioxide emissions to the atmosphere. However, if methane were burned instead of coal, the total emissions of carbon dioxide would be relatively lower because methane is characterized by lower carbon emissions per unit of energy produced. In addition to the carbon dioxide emissions, it would be very likely that unburned methane would be emitted directly to the atmosphere at various stages in the fuel cycle. This would be particularly important because methane is about 10–20 times more potent as a greenhouse gas than carbon dioxide, although its lifetime in the atmosphere is much shorter (*see* Global Warming Potential (GWP), Volume 1).

The second reason that methane clathrates are potentially important contributors to climate change is that, under the right environmental conditions (lower pressures or higher temperatures, for example), clathrates can relatively quickly release their captive methane to the atmosphere. If such disturbances were to occur on a large enough scale, sufficient methane could be released to the atmosphere to noticeably affect climate. Indeed, recent research suggests that enormous amounts of methane have been periodically vented from clathrates in the distant past. Norris and Rohl (1999) present evidence suggesting that, over a period of a few thousand years or less, a methane release of an estimated 1200–2000 billion tonnes of carbon (Gt C) occurred 55 million years (Myr). For comparison, the pre-industrial atmospheric burden of methane was about 1.5 Gt C and the current burden is about 3.5 Gt C, with current annual emissions of about 0.3 Gt C year^{-1} each occurring due to both human and natural activities (IPCC, 2001). Significant global ecological impacts followed the release 55 Myr ago and included widespread extinctions of species living on or near the seabed.

Norris and Rohl found evidence indicating that the initial release of methane was triggered by slope failure, i.e., submarine landslides. They further concluded that the initial pulse of methane helped warm the atmosphere, which then warmed the oceans, leading to further slope failures and melting of hydrates. They also suggest that subsequent releases might have continued this positive feedback process for about 30 000 years.

Other scientists have identified other possible occurrences of massive releases of methane clathrates, including some at about 120 Myr and about 90 Myr ago (reported in Kerr, 2000). The events were followed by dramatic and widespread ecological changes. For example, Kennett *et al.* (2000) report evidence from the Santa Barbara Basin off the coast of California of at least four episodes of brief, but large releases of methane from continental margin sediments, each of which was associated with millennial scale bottom water temperature changes. Their findings support mounting geologic evidence for past pervasive, massive methane releases from the marine sediment reservoir.

Findings that there have been massive methane releases in the past raise concerns that the human induced buildup of greenhouse gases in the atmosphere could trigger similar methane releases in the future. Of concern too is the possibility that large-scale commercial exploitation of methane hydrates could disturb the reservoirs enough to inadvertently prompt large and rapid methane releases.

The economic potential of the resource, however, has prompted significant interest by governments and industry in tapping methane clathrates for energy. In the US, the Methane Hydrate Research and Development Act was signed into law in May 2000, authorizing a five year, $47.5 million effort directed by the Department of Energy. The Japanese research and development effort is led by the Ministry of International Trade and Industry, and a drilling ship has been used to obtain samples and learn more about the resource.

For the future, balancing the interest in exploiting the energy resource with the potential for its effects on climate (which could be moderating, if methane reduces coal use, or amplifying, if substantial methane escapes to the atmosphere) will be a key challenge.

Methyl Bromide

James H Butler

National Oceanic and Atmospheric Administration, Boulder, CO, USA

Unlike most of the halogenated gases involved in stratospheric ozone depletion, atmospheric methyl bromide has both natural and anthropogenic sources. Also, its sinks include more than just atmospheric reactions - it is removed by the ocean, by soils, and possibly by plants. These differences from chloro uorocarbons (CFCs), chlorocarbons, and halons, along with the fact that the atmospheric budget of this gas is unresolved, have made it more dif cult to estimate accurately the contribution of anthropogenic methyl bromide to stratospheric ozone depletion. Considerable progress in understanding the behavior of this ozone-depleting gas has been made over the past decade, but signi cant uncertainties remain.

Methyl bromide (CH_3Br) is an atmospheric trace gas of both natural and anthropogenic origin. It is present in the atmosphere at a mole fraction, or volume-mixing ratio, of around 10 parts per trillion (ppt $= 10^{-12}$ moles of specific gas per mole of air). Its known sources include oceanic emission, biomass burning, agricultural application as a biocide, leaded gasoline combustion, and disinfestation of buildings and structures. Until the 1990s, little attention had been paid to this gas in the atmosphere, in part, because of its low mixing ratio and short atmospheric lifetime.

Methyl bromide is of concern because it is the primary carrier of bromine to the stratosphere and because reaction-rate enhancements due to bromine make it 50–60 times more effective than chlorine on a per atom basis in removing ozone from the stratosphere (Kurylo *et al.*, 1999). Thus, 10 ppt of bromine would be the equivalent of 500–600 ppt of chlorine. (The 1999 amount of organic chlorine in the atmosphere is about 3500 ppt, of which only 600–700 ppt occurs naturally.) Normally, a short atmospheric lifetime, such as that for CH_3Br, reduces the significance of the compound in depleting stratospheric ozone by maintaining a low mixing ratio in the atmosphere. This is reflected in the calculation of its ozone depletion potential (ODP) (*see* Ozone Depletion Potential (ODP), Volume 1), which has become an essential consideration in determining whether an anthropogenic, ozone-depleting compound should be scheduled for phase out. However, because CH_3Br contains bromine, its ODP remains high, even with its relatively short lifetime.

In the early 1990s atmospheric methyl bromide was thought to emanate naturally from a large oceanic source and to be destroyed exclusively by reactions in the atmosphere, predominantly with tropospheric OH (Albritton and Watson, 1992) (*see* OH- Radical: is the Cleansing Capacity of the Atmosphere Changing?, Volume 2). Anthropogenic emissions, mainly from disinfestation of soils, commodities, and structures, were considered responsible for 3 ppt of CH_3Br in the atmosphere. Biomass burning and emissions from burning leaded gasoline were thought to be possible contributors, but were not quantified at that time. Recognizing that there was a paucity of information on this important atmospheric gas, scientists began working to understand its cycling and atmospheric budget more completely. The results were surprising in a number of areas.

The first of these surprises was that the ocean was not the large source it was thought to be, but rather, a small net sink for atmospheric CH_3Br (e.g., Lobert *et al.*, 1995). This net sink, however, results from rapid aquatic production and degradation working in opposition in the surface ocean, leaving it largely undersaturated. In some areas, where production exceeds degradation, the ocean is supersaturated in methyl bromide, but most of the time, in most of the surface ocean, methyl bromide is undersaturated. Due to the fact that the degradation rate of CH_3Br is so high virtually everywhere in the surface waters, it had to be included as a significant component of the atmospheric lifetime computation. Subsequent calculations of

Table 1 The influence of newly identified plant sources on the atmospheric budget of CH_3Br[a]

Source type	Emissions (Gg year^{-1})	Sink type	Uptake (Gg year^{-1})

[a] Summary taken from Yvon-Lewis (1999), which lists specific references. All values are from Chapter 2 of the *1999 WMO Scientific Assessment of Ozone Depletion* (Kurylo *et al.*, 1999) and references therein except where noted. The numbers in parentheses represent the range of uncertainty for the best estimate shown.
[b] The ranges in the oceanic source and sink terms must keep the accepted range in the net flux of -3 to -32 Gg year^{-1}.
[c] The use of methyl bromide as a biocide includes treating agricultural products for export, including items such as timber (durables) and fresh fruits and vegetables (perishables).
[d] Items are from work that was published after the WMO report was finalized.
[e] Global estimate for green plants not yet available.
[f] Totals are rounded to the nearest integer.

the atmospheric lifetime of CH_3Br yielded a rate that was almost equal to the loss due to reaction with OH in the troposphere (Yvon-Lewis and Butler, 1997). This alone lowered the atmospheric lifetime of CH_3Br from 2.0 to 1.0 years.

At about the same time, studies of the terrestrial environment revealed additional sinks and sources of atmospheric CH_3Br (e.g., Shorter *et al.*, 1995). The discovery that CH_3Br was degraded rapidly in a variety of soils, mainly by prokaryotic bacteria, lowered the atmospheric lifetime even further. Studies of isolated plant leaves and stems from over 100 species of plants demonstrated that the biosphere was also involved in the degradation of methyl bromide (Jeffers and Wolfe, 1997). Whether this loss to plants turns out to be a significant sink or not depends upon further research. At this time, it appears to be small on a global basis. The few field studies of CH_3Br fluxes between plants and plant ecosystems and the atmosphere, however, reveal net emissions from the plants rather than net losses (Table 1). These are each small, but significant, in the global atmospheric budget of this gas.

Our current understanding of atmospheric CH_3Br is that of a gas with numerous, diverse sources and significant sinks on land, in the ocean, and in the atmosphere. Its lifetime, including atmospheric, oceanic, and soil sinks, is now computed at 0.7 years, but its calculated atmospheric budget is largely out of balance, with sinks outweighing sources by $\sim$40%. New findings continue to reveal previously unidentified sources, which seem gradually to begin closing the gap between calculated sources and sinks (Table 1). Anthropogenic emissions of CH_3Br are scheduled for phase-out by the year 2005 in developed countries and by 2015 in developing countries. However, the extent to which this will actually reduce the atmospheric burden of methyl bromide depends in part upon how the atmospheric budget is ultimately resolved. Finally, a question that will become more pressing with global change is: how will the fluxes of methyl bromide between the Earth s surface and atmosphere change in the future? A change in the sea-surface or soil temperature will certainly affect methyl bromide fluxes, as will changes in precipitation or land-use patterns. It is possible that such alterations of natural fluxes could outweigh today s direct anthropogenic emissions, but we cannot know until we understand the natural cycles of this important, ozone-depleting gas more fully.

Milankovitch, Milutin

(1879- 1958)

Milutin Milankovitch was a Serbian mathematician who specialized in astronomy and geophysics. He was born on 28th May 1879 in Dalj, Slavonia (part of Austro–Hungary until 1919; then part of Jugoslavia and now in Croatia). He died in Belgrade on 12th December 1958. He graduated as a doctor of technical sciences on 17th December 1904 from the Technical High School of Vienna. On the 1st October 1909, he was elected professor at the University of Belgrade where he lectured on Rational Mechanics, Theoretical Physics and Celestial Mechanics, until his retirement 46 years later. He was a member of the Serbian Academy of Sciences, Jugoslav Academy of Sciences and Arts, German Academy of Naturalists Leopoldine Halle and Italian Institute of Paleontology.

Milutin Milankovitch was a contemporary of Alfred Wegener (1880–1930) with whom he became acquainted through Vladimir Koppen (1846–1940), Wegener s father in law (*see* Wegener, Alfred, Volume 1). It is roughly between 1915 and 1940 that Milankovitch put the astronomical theory of the Pleistocene ice ages on a firm mathematical basis. His first book, written in French, dates from 1920, but his massive special publication of the Royal Serbian Academy of Sciences on *Kanon der Erdbestrahlung* was published in German in 1941 and was translated into English in 1969.

Milankovitch s main contribution was to explore the solar irradiance at different latitudes and seasons in great detail, to compute its long-term variations from the orbital parameters and to relate them in turn to the climate (*see* Orbital Variations, Volume 1). His theoretical investigation provided the basis for the core of his argument that under those astronomical conditions in which the heat budget around the summer solstice falls below average, so will summer melt, with uncompensated glacial advance being the result. The essential product of the Milankovitch theory is therefore his curve demonstrating how the intensity of summer sunlight varied over the past 600 000 years. This curve was used to identify the European ice ages reconstructed by Albrecht Penck and Eduard Bruckner, from which he concluded that these geological data constituted a verification of his theory.

Up to the 1960s, the Milankovitch theory was disputed as a result of discussions based on fragmentary geological records and because the climate was considered too resilient to react to such small changes as observed in the caloric summer insolation. Milankovitch was little disturbed by these different opinions, believing firmly that his theory was correct. In the late 1960s a systematic approach and use of modern techniques led to major discoveries, which progressively supported his essential concept, namely that orbital variations exert a significant influence on climate (Imbrie and Imbrie, 1979; Berger *et al.*, 1984; Berger, 1995).

Milutin Milankovitch wrote some 70 books and papers, including some on popular astronomy. He was involved in the reform of the Julian calendar, became even a writer and wrote his memoirs: not because I thought I was such an important person, but because I have lived in an historically interesting and turbulent period, and I described these events as a trustworthy witness. My work spanning some 30 years, has been closely connected with the work of other scientists who have used my results in their respective fields. The mutual collaboration has been documented with more than 600 letters and 100 publications. Therefore, these memoirs are, for a good part, the history of a branch of the sciences called Astronomical Theory of Climatic Changes . These memoirs were the basis of the unique

biography written in English on Milankovitch by his son (Milankovitch, 1995).

Modeling Regional Climate Change

Filippo Giorgi

Abdus Salam International Center for Theoretical Physics, Trieste, Italy

The determination of climatic changes at the regional scale is one of the central issues within the global change debate. Regional-scale information is needed to assess the impacts of climatic changes on the environment and society, and to determine suitable policies to react to such impacts. Despite the importance of this issue, the current uncertainties in the projection of regional climatic changes for the next several decades are still very high. This is due to the complexity of the processes that determine regional climate change and the need to develop more comprehensive modeling tools and research strategies to address this problem. This article discusses the basic processes that regulate regional climates and some of the modeling approaches developed to study regional climate change. The term climate change here refers to the climatic effects due to anthropogenic forcings for the coming decades (e.g., greenhouse gas and aerosol emissions). However, the modeling techniques discussed can be extended to any kind of regional climate study.

THE PROCESSES OF REGIONAL CLIMATE CHANGE

It is useful to provide an operational definition of regional scale, as different definitions are often implied in different research contexts. Here the term regional scale covers the relatively broad range of 10^3–10^7 km^2. The upper end of the range (10^6–10^7 km^2) is also commonly referred to as sub-continental scale, and phenomena occurring at broader scales are dominated by general circulation processes. The mid and lower end of the range (10^3–10^6 km^2) covers scales that are commonly referred to as mesoscale to synoptic scale, and are characteristic of the weather phenomena that affect our daily life. Scales finer than 10^3 km^2 are here referred to as local scale, while scales

coarser than 10^7 km^2 are referred to as large (or global) scale.

Following these definitions, the climate of a given region is determined by processes and interactions that occur at the global, regional and local scale. Large-scale processes and forcings regulate the general circulation of the atmosphere, which determines the sequence of weather events and regimes that characterize the climate of a region. Embedded within the large-scale circulation systems, regional and local forcings, along with mesoscale circulations, modulate the spatial and temporal structure of the regional climate signal. Examples of large-scale forcings that affect the global circulation are the solar radiation flux, the concentration of long-lived greenhouse gases, large scale snow and sea ice distribution, ocean–continent contrasts and continental scale topographical features. Examples of regional and local scale forcings are those due to complex topography, land use characteristics, inland bodies of water, complex coastlines, short-lived radioactive gases and aerosols, and regional snow and sea ice distributions.

In addition, because of the non-linear nature of atmospheric dynamics, processes occurring over given regions can influence the climate of distant regions through teleconnection patterns. This occurs, for example, in the El Niño Southern Oscillation (ENSO) and the North Atlantic Oscillation (NAO) phenomena, whereby regional anomalies in sea surface temperature and sea level pressure patterns can affect weather regimes over areas far from the source of the anomaly.

Finally, it is important to recognize that climate, both at the global and regional scale, is determined by atmospheric processes as well as complex interactions between different components of the climate system, i.e., the atmosphere, the hydrosphere, the cryosphere, the biosphere and the chemosphere. Processes within and among climate system components take place at a wide range of temporal scales and can be highly non-linear in nature.

The difficulty of modeling regional climate change is thus evident. The effects of climate system interactions, forcings and circulations at the global, regional and local scale need to be properly described, along with the teleconnection effects of regional forcing anomalies. This presents a formidable cross-disciplinary and multi-scaled scientific task that cannot be fully achieved by any individual modeling tool presently available, but requires the combined use of different modeling techniques.

MODELING REGIONAL CLIMATE CHANGE

Coupled Atmosphere–Ocean General Circulation Models (AOGCMs) are the most powerful tools available today to simulate long-term climate change. AOGCMs are three-dimensional numerical representations of the governing equations that describe the dynamics and physics of the coupled global atmosphere–ocean–sea ice system. State-of-the-art AOGCMs also include descriptions of land biosphere and atmospheric chemistry processes. For the simulation of climatic changes over centennial time scales, the model equations are numerically integrated over equivalent three-dimensional grids in which the distance between adjacent grid points determines the resolution at which processes can be explicitly represented. Processes occurring at sub-grid scales need to be expressed, or parameterized, in terms of quantities resolved by the model. The higher the model resolution, the more grid points are used in the numerical solution of the model equations, and the more computer power is necessary to integrate the model. Crudely speaking, an increase in horizontal resolution of a factor of two requires an eight-fold increase in computer power because, with increasing resolution, the integration time step must be reduced to preserve computational stability and accuracy. Therefore, computer resources are one of the factors that influence the resolution used in AOGCMs.

Despite the continuous development of increasingly powerful computing systems, the horizontal resolution of the atmospheric component of present-day AOGCMs is still relatively coarse, in the order of 300–500 km. This resolution is primarily due, in an indirect sense, to the long temporal scales involved in simulating the long-term changes in the ocean circulation, because of the very extensive computer resources that are then needed when integrating a coupled AOGCM for century time scales or longer (as is typically done in climate change experiments). Other factors limit the resolution of AOGCMs, such as the inclusion in the models of increasingly comprehensive descriptions of physical, chemical and biological processes and the effect that increasing resolution has on the AOGCM performance. While some aspects of model performance improve with increasing resolution, others deteriorate.

As a result, it can be expected that the standard atmospheric horizontal resolution of long-term AOGCM simulations may remain of the order of a few hundred km down to approximately 100 km for years to come. At these resolutions, it has been shown that AOGCMs can reproduce the fundamental characteristics of the general circulation of the atmosphere, and of large scale circulation features that affect regional climates, such as planetary wave patterns, storm tracks, jet streams and the Hadley circulation (e.g., IPCC, 1996, Chapter 5; *see* Model Simulations of Present and Historical Climates, Volume 1). AOGCMs have also shown encouraging performance in simulating important aspects of observed climate variability, such as related to ENSO or NAO (e.g., IPCC, 1996, Chapter 5).

On the other hand, resolution limitations prevent AOGCMs from capturing the fine scale signal that characterizes regional and local scale climate over many

regions of the world. As mentioned, this fine scale structure is caused by the effects of local and regional scale forcings which occur at sub-AOGCM grid scales and thus cannot be captured by AOGCMs. Lack of representation of these forcings can induce large errors in regional climate simulations by AOGCMs. An example can illustrate this point.

The Great Basin of the US, and especially its southern portion, is the driest region of the continental US and one of the driest in the globe. The Basin is enclosed by the Sierra Nevada range to the west and the Rocky Mountains to the east (Figure 1a). The dryness of the basin is caused by two primary factors. One is of large scale nature, i.e., the fact that the region lies to the south of the main Pacific storm track that impinges upon the northwestern US. The other is regional in nature, and is due to the precipitation shadowing effect of the Sierra Nevada mountains. As westerly moving systems cross the Sierra Nevada, air moving upslope cools down and condenses, generating clouds and precipitation in the upstream side of the range. Conversely, in the lee of the mountain range, downward moving air warms up, causing cloud evaporation and inhibiting precipitation over the southern Great Basin region (Figure 1b). As the maps indicate, the fine scale precipitation patterns observed over the western US are indeed caused by the complex topographic forcing over the region (Figure 1b).

One of the consequences of the coarse resolution of AOGCMs is that the surface topography seen by the model is highly smoothed. Over the continental US this results in merging the Rockies and the Sierras into one single mountain system centered just east of the Great Basin (Figure 2a). As a result, the southern Great Basin in a coarse AOGCM instead of lying in the lee of the Sierras and being shielded from precipitation, lies in the upslope of the model Rockies, thereby undergoing an upslope topographic enhancement of precipitation. Therefore, for the problem of simulating the climate of the Great Basin, while AOGCMs can capture the large scale aspects of it, e.g., the position

(a)

Figure 1 (a) Topography of the western United States; (b) average observed January precipitation over the western United States. Units are inches. (Reproduced from Giorgi *et al.*, 1992)

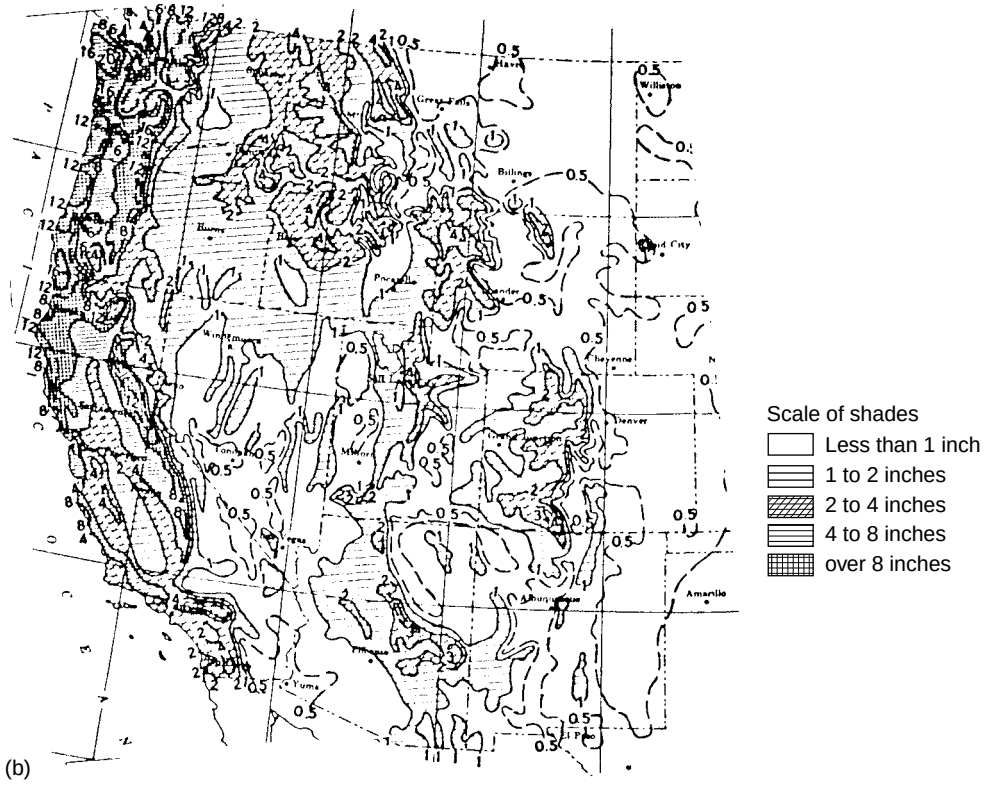

Figure 1 (*Continued*)

of the Pacific storm track, they entirely miss the aspects related to forcing by regional topographical features. With a topographic representation such as that of Figure 2(a), an AOGCM cannot capture the spatial detail of precipitation shown in Figure 1(b).

Various techniques have been developed over the last decade to enhance the regional information of AOGCMs, with the aim of describing at increased spatial resolution the effects of regional and local forcings. These are commonly referred to as regionalization techniques, and can be divided into three categories:

1. Use of high resolution and variable resolution atmospheric general circulation models (GCMs) in time slice experiments. With this technique, the atmospheric component of an AOGCM is run for pre-selected time periods, or slices (typically 10–30 years in length), with sea surface temperature forcing taken from the corresponding AOGCM simulation. Because only the atmospheric component is integrated for a limited period of time, a higher resolution can be reached (of the order of 100 km to date). In variable resolution models, the horizontal resolution is gradually increased over the region of interest (up to approximately 50 km to date).
2. Regional climate modeling. With this technique, a high resolution limited area model is used to simulate the climate of a region using large scale forcing meteorological fields from GCM simulations.
3. Statistical downscaling methods. Using this approach, statistical relationships are developed between large scale predictors and local/regional predictands using either observed or modeled data. These relationships are then applied to the output of AOGCM simulations to estimate changes in local and regional climate.

These techniques have different advantages and limitations that are discussed in a number of articles and references cited therein (Giorgi and Mearns 1991, 1999; Cubasch *et al.*, 1995; Deque *et al.*, 1995; IPCC, 1996, Chapter 6; Hewitson and Crane, 1996). It is beyond the purpose of this article to discuss all these techniques. Rather, for illustrative purposes we focus on one of them, i.e., the use of regional climate models, with the premise that many of the considerations presented also apply to the other regionalization techniques.

The Great Basin example given above has some historical significance. It is in order to simulate possible climatic changes over the Great Basin of the US that in the late 1980s a research group at the National Center for Atmospheric Research, in Boulder, Colorado, pioneered the use of limited area atmospheric models for climate applications (Dickinson *et al.*, 1989; Giorgi, 1990). When used

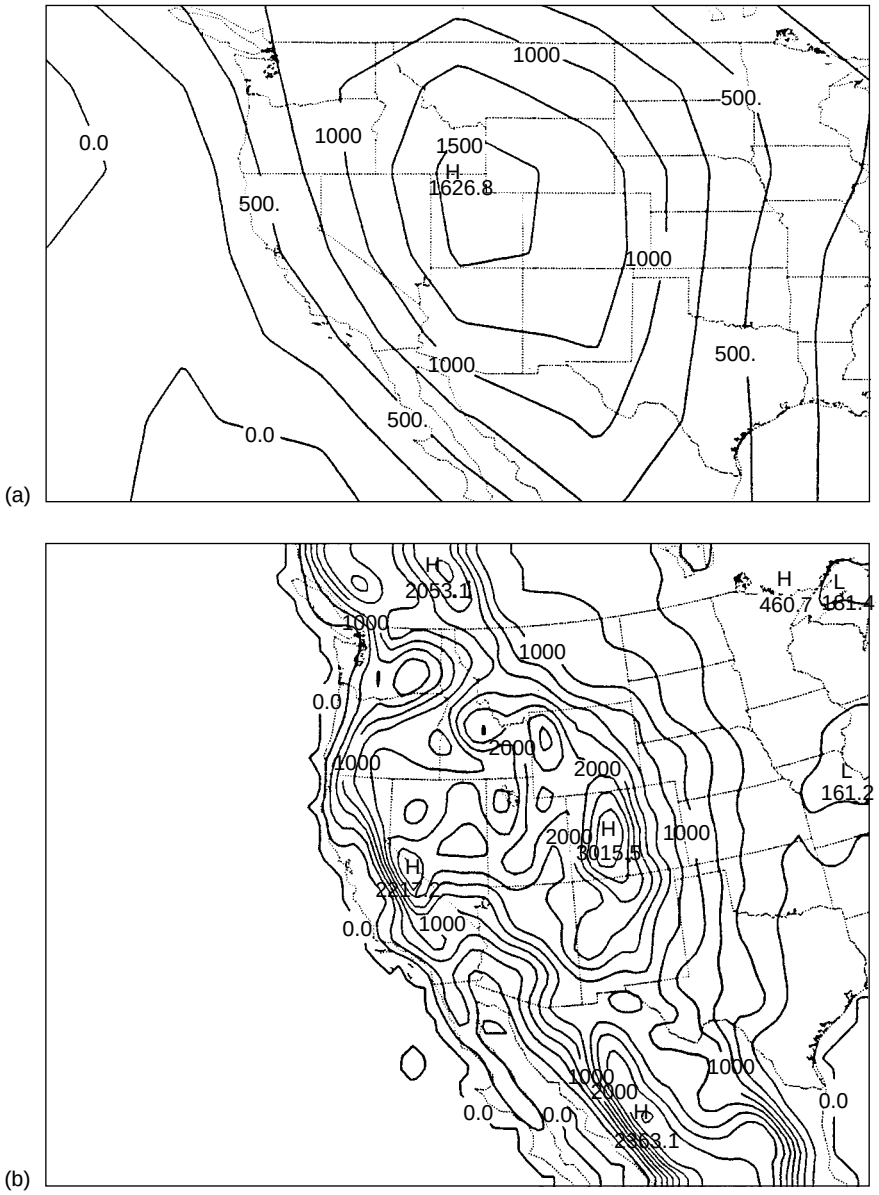

Figure 2 (a) Representation of the topography in western United States in a coarse resolution GCM (approximately 500 km grid size); (b) Representation of the topography in western United States in a RCM at 60 km grid size. Units are meters. (Reproduced from Giorgi *et al.,* 1992)

in climate studies, these models are usually referred to as regional climate models (RCMs). Essentially, RCMs are composed of the same set of equations as GCMs and describe the same physical processes, but they only cover limited area horizontal domains typically of 10^6 to $5 \times 10^7\,\mathrm{km}^2$ in size. As a consequence, for a given amount of computing power, an RCM can be run over a selected region with a much higher horizontal resolution than a GCM and can thus provide a more spatially detailed representation of the physical processes that affect regional climate. For the Great Basin example, Figure 2(b) shows the topographic representation of an RCM over the western US at a 60 km grid size. It is evident that the basic regional topographical features of the area are much better represented than in a coarse resolution GCM (Figure 2a).

RCMs require the provision of time-dependent meteorological conditions (wind components, temperature, water vapor and atmospheric pressure) at the lateral boundaries of the integration domain. In addition, they require the specification of sea surface temperature and initial meteorological and land surface conditions (e.g., soil moisture).

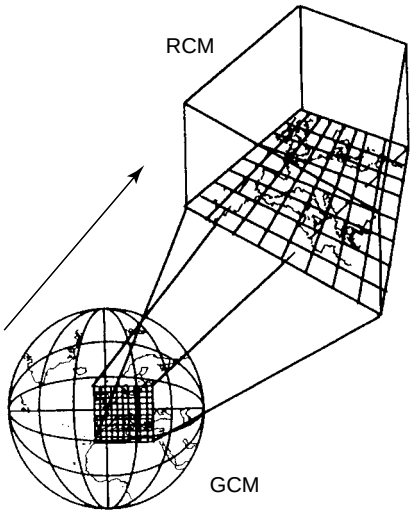

Figure 3 Conceptual representation of the one-way GCM–RCM nesting technique. See text for details. (Reproduced from Beniston, 1998)

These driving fields can, for example, be provided by observations or, for climate change studies, by the output of AOGCM (or more generally GCM) simulations. This technique is referred to as one-way nesting of an RCM within a GCM (Figure 3, Beniston, 1998). The term one-way derives from the fact that, while information from the driving GCM is supplied to the nested RCM, the feedback from the RCM fields to the GCM is not represented. The underlying strategy of this approach is that the GCM can provide the response of the general circulation to large scale forcings along with the teleconnection response to broad regional forcing anomalies. Having as input this information, the nested RCM can describe the effects of local and regional forcings on regional climate in a physically based way.

Limited area models have been used for many years in numerical weather prediction, and in the study of atmospheric phenomena such as extratropical cyclones, mesoscale convective complexes, tropical storms, sea breeze circulations. As a result, several advanced and widely tested limited area modeling systems are available as the end product of a multi-decadal experience in mesoscale modeling. These models can provide robust frameworks for the development of RCMs.

The relative simplicity of the one-way nesting methodology constitutes an important aspect of nested modeling. The method most commonly used to provide lateral boundary conditions to RCMs (the relaxation method) consists of smoothly blending the RCM model solution towards the forcing fields in a lateral buffer area of the domain. With several variants available, this method has proven to be effective in providing good consistency between forcing and simulated large scale fields, and in achieving little generation of boundary numerical noise.

Because RCMs only cover limited areas, they can reach relatively high horizontal resolutions. To date, the majority of RCM experiments utilize grid sizes of the order of 50 km. However, some experiments have been conducted at grid sizes of 10–20 km and even higher. When running an RCM at very high resolution it may be necessary to first run the RCM at an intermediate resolution and then use fields from this experiment to drive the very high resolution experiments. This multiple nesting prevents an excessively abrupt resolution transition from the GCM to the RCM.

It is important to understand the fundamental limitations of the nested RCM technique (Giorgi and Mearns, 1991, 1999). One is the lack of two-way feedbacks from regional scale circulations produced by the RCM to the large scale circulations. This limitation can be more or less important depending on the region under consideration. Another limitation is that the nested RCM cannot correct large errors present in the forcing GCM fields. Most RCM work has shown that the basic features of large scale circulations in an RCM are essentially dominated by the GCM forcing that, originating from the lateral boundaries, pervades the interior of the RCM domain reaching a dynamical equilibrium with the internal model solution. The role of the RCM is essentially to modulate the GCM signal by adding fine scale information generated by the internal high resolution model physical and dynamical forcings.

As an example, if the GCM has large errors in simulating the storm tracks that affect a region, the nested RCM will not be able to compensate for that error. It is thus of foremost importance that the driving GCM fields be of good quality, and indications are that the general circulation features simulated by the latest generation of AOGCMs are considerably improved compared to earlier ones. Various model intercomparison projects, the largest one being the Project to Intercompare Regional Climate Simulations (Takle *et al.*, 1999), have been recently organized to elucidate strengths and weaknesses of RCMs.

EXAMPLES OF REGIONAL CLIMATE CHANGE SIMULATIONS

A number of steps need to be taken before completing a nested RCM simulation of regional climate change. The first is to analyze the RCM behavior over the region of interest using observations as driving fields to simulate actual periods. The model results can then be compared with climate observations for the period of simulation. Fields from global analyses of observations produced, for example, by the European Centre for Medium-range Weather Forecasts or by the National Center for

Environmental Prediction can be used for this purpose. Experiments of this type are referred to as perfect boundary condition experiments, because the quality of the driving fields, although still not error-free because of deficiencies in the observing networks and analysis models, is the best available.

These experiments serve different purposes. One is to evaluate and optimize the model performance. In fact, systematic model errors revealed by perfect boundary condition experiments can be attributed primarily to deficiencies in aspects of the internal model physics and dynamics, so that these aspects can be suitably improved. Studies have shown that, when driven by good quality boundary conditions, RCMs can reproduce the observed structure of surface regional climate variables such as temperature and precipitation in terms of their average climatology, intra- and inter-seasonal characteristics, and inter-annual variability (Giorgi and Mearns, 1999).

Another primary purpose of these experiments is to select the most appropriate model domain and horizontal resolution. The choice of domain and resolution is an important and not trivial issue, as it depends on both physical and computational considerations. The model domain should be large enough to allow the RCM to develop its internal mesoscale circulations and to include processes and forcings that are important for the climate of the region. Similarly, the resolution should be sufficiently fine to appropriately describe such forcings and processes. On

Figure 4 Cold season precipitation over Great Britain. (a) Present day climate simulation with a driving GCM; (b) present day climate simulation with a nested RCM; (c) observations from the Climatic Research Unit (CRU) of East Anglia University. Units are mm day^{-1}. (Reproduced from Jones *et al.*, 1995)

the other hand, the computational requirements to run an RCM rapidly increase with domain size and model resolution, so that ultimately a compromise needs to be reached between physical and computational constraints. Once the model is fully tested and configured using perfect boundary condition experiments, the RCM can be run with driving fields from GCM simulations of present day climate and can be validated against climatological observations. It is important to identify systematic biases in the simulated present day climate by the nested GCM–RCM system because these are fundamental for a correct interpretation of the climate change simulations. GCM-driven simulations of present day climate are also important because they help to establish the added value of using RCM nesting. In GCM-driven experiments, the simulation period should be of sufficient length to produce robust climate statistics.

In general, the RCM performance in reproducing present-day climate in GCM-driven experiments tends to deteriorate compared to that of experiments driven by

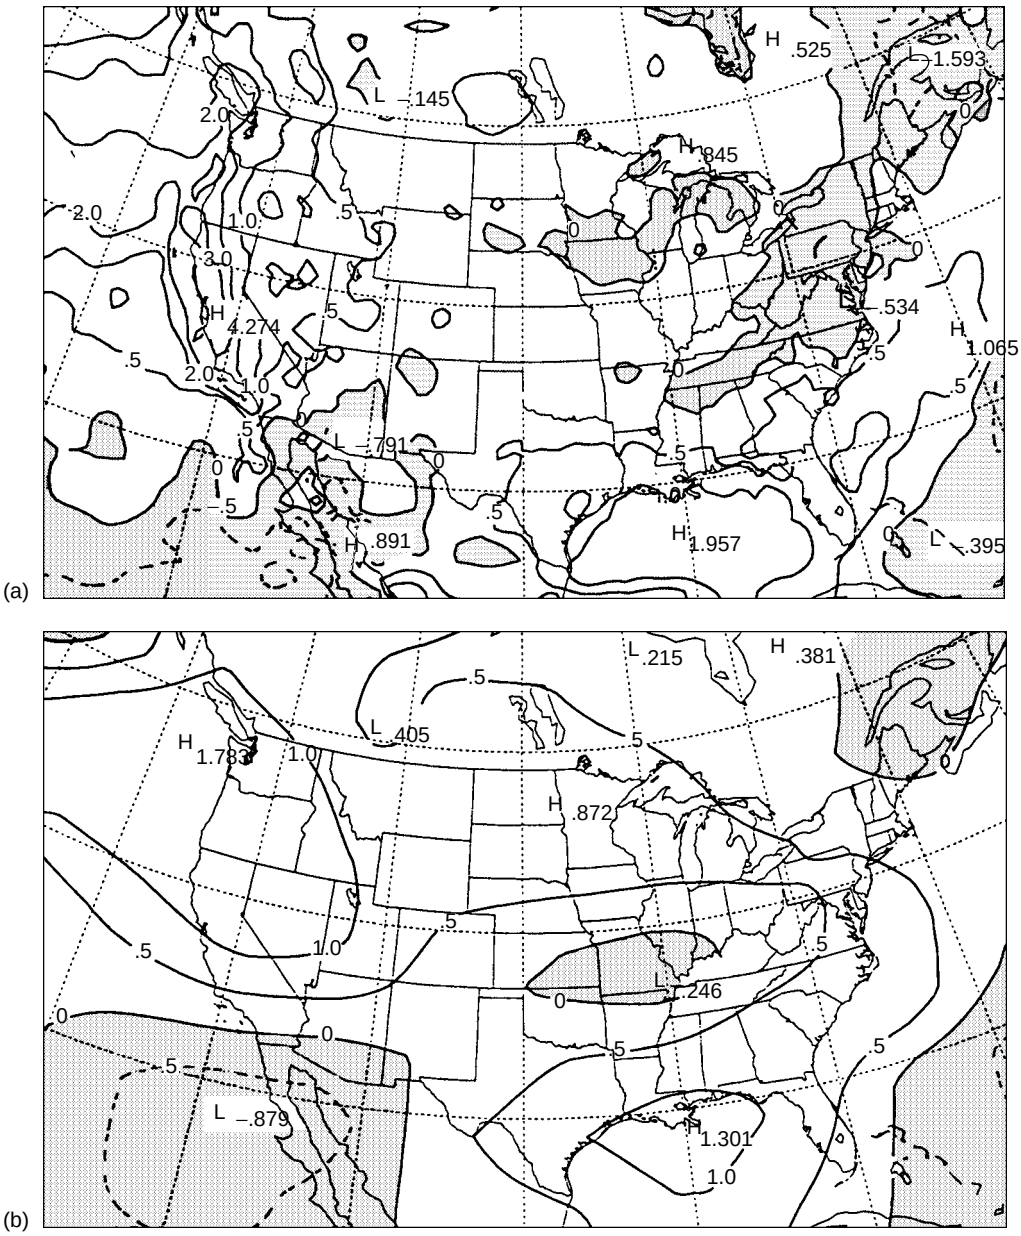

Figure 5 Cold season precipitation difference between climate conditions at doubling of greenhouse gas concentration and present day climate conditions over the continental United States as simulated with a nested RCM (a) and the driving GCM (b). Units are mm day^{-1}, and the contour intervals are at −3, −2, −1, −0.5, 0, 0.5, 1, 2, 3, mm day^{-1}. Shaded areas denote negative values. (Reproduced from Giorgi *et al.*, 1994)

observations, because errors in the large scale GCM forcing fields are transmitted to the RCM through the lateral boundary conditions. Compared to the driving GCMs, RCMs have been shown to enhance the simulation of spatial patterns of surface climate as forced by topography and other sub-GCM scale processes (IPCC, 1996, Chapter 6; Giorgi and Mearns, 1999). The increased resolution of RCMs also allows the simulation of a broader and more realistic spectrum of weather events, in particular as concerning higher order climate statistics such as daily precipitation intensity distributions and extreme events.

After systematic biases in the nested GCM–RCM modeling system are identified, we are ready to perform simulations for climate change conditions. In some circumstances it may be possible, and thus advisable, to further test the model performance by carrying out simulations for known climate conditions different from present, such as palaeoclimates. This can be an important test of the model, because future climate simulations are not directly verifiable.

To date, a wide range of regional climate simulations have been carried out (see for example Giorgi and Mearns, 1991, 1999; IPCC, 1996, Chapter 6; McGregor, 1997). Early experiments, in which the technique was still in its development stage, were typically of a few years in length, i.e., relatively short compared to the interdecadal time scales characteristic of the climate change issue. Nevertheless, these simulations allowed the development of the technique, and an understanding of first order effects. It is important to realize that a fundamental methodological step was taken when extending limited area model simulations beyond the several days length of weather prediction application. Several recent RCM simulations have reached lengths of 20–30 years, and a full 140-year RCM simulation of transient climate change has been recently completed.

A few examples are useful to illustrate the functioning of the nested modeling technique. Figure 4 (Jones *et al.*, 1995) shows a simulation of present day wintertime precipitation over Great Britain by a nested RCM and the driving GCM. Results are compared with high resolution observations. A substantial enhancement in the simulation of spatial precipitation detail by the RCM is evident. Figure 5 (Giorgi *et al.*, 1994) shows a simulation of wintertime precipitation change over the continental US in conditions of CO_2 doubling by a nested RCM and the corresponding driving GCM. It can be seen that the broad scale patterns of precipitation change in the two models are similar, for example, the location of broad regions of positive and negative change. This is because these broad scale signals are due to general circulation processes (e.g., shifts in the storm tracks) and are essentially regulated by the driving GCM. The fine scale structure of the signal, however, can be quite different in the two models. For the western US, which is characterized by complex topographical features, much of the precipitation increase simulated by the RCM is concentrated over the western coastal regions, while the GCM-simulated increase spreads much farther inland. This is because of the precipitation shadowing effect of the western US coastal ranges, which is better represented in the high resolution RCM than the low resolution GCM.

FUTURE PERSPECTIVES IN RCM RESEARCH

The use of RCMs (as well as other regionalization techniques) has filled an important gap in the spatial-temporal scale of climate modeling, i.e., that of fine spatial scales in conjunction with long temporal scales. This has opened the opportunity to a wide range of innovative applications, of which the simulation of regional climate change is only one.

Since the late 1980s, many RCM systems have been developed, employing a wide variety of model dynamical and physical frameworks, numerical techniques and methods of nesting. RCM applications have essentially covered all regions of the globe, and studies have ranged from paleoclimate and present day climate processes to multi-decadal future climate simulations. The use of RCMs for seasonal prediction has recently received considerable attention and will likely represent an important area of application of regional models. Multiple nesting has already allowed RCM resolutions of a few 10s of km, and it can be expected that, as computing power continues to increase, regional multi-decadal simulations at resolutions of less than 10 km will become feasible in the near future, i.e., that regional climate simulations reaching the local scale will be possible. Work on two-way coupling between GCMs and RCMs is also underway to examine the importance of representing regional-to-global feedbacks, although these feedbacks can be alternatively represented through the use of variable resolution AGCMs.

One of the research directions that offers the most promising and exciting perspectives of innovative research is the coupling of RCMs with other components of the climate system to generate regional climate system models (Figure 6, Giorgi, 1995), and research efforts in this direction have been initiated recently. In particular, regional coupled models can be used to study climate system interactions and feedbacks with the advantage that the coupling is accomplished at scales that are most consistent with relevant processes and available models (Giorgi, 1995). Finally, regional modeling can also be very useful for global modeling in different ways: by providing information on interactions at scales that global models will presumably reach in the future, and by helping

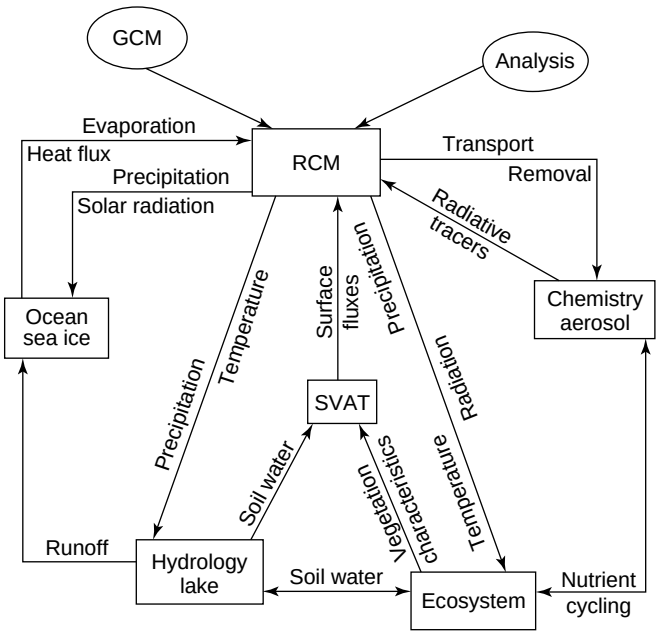

Figure 6 Conceptual design of a regional climate system model. A SVAT, or Surface–Vegetation Atmosphere Transfer scheme, is a model of land surface processes that can act as interface between different components of the climate system. (Reproduced from Giorgi, 1995)

in developing improved representations of dynamical and physical processes.

Molina, Mario J

(1943-)

Mario Molina is an atmospheric chemist and professor at the Massachusetts Institute of Technology (MIT) in Cambridge, MA. In 1995, he shared the Nobel Prize in Chemistry with Sherwood Rowland (*see* Rowland, F Sherwood, Volume 1) and Paul Crutzen (*see* Crutzen, Paul J, Volume 1) for their contributions to understanding the effects of chlorofluorocarbons (CFCs) (*see* Chloro uorocarbons (CFCs), Volume 1) on the chemistry of the stratosphere and the factors contributing to stratospheric ozone depletion (*see* Depletion of Stratospheric Ozone, Volume 1).

Professor Molina was born in Mexico City on March 19, 1943 to Roberto Molina Pasquel and Leonor Henriquez de Molina. His father was a lawyer who also taught at the National University of Mexico (Universidad Nacional Autonoma De Mexico, UNAM) and later served as Mexican Ambassador to Ethiopia, Australia, and the Philippines. Molina attended elementary school and high school in Mexico City, where he was fascinated by science, particularly chemistry. In 1960, following graduation from high school, he enrolled in the chemical engineering program at UNAM, with plans to become a physical chemist. After graduating in 1965, Molina enrolled at the University of Freiburg in Germany and received a postgraduate degree in 1967, having done research in the kinetics of polymerizations. He then returned to Mexico as an Assistant Professor at the UNAM and set up its first graduate program in chemical engineering. In 1968, he enrolled in the graduate program at the University of California (UC) at Berkeley to pursue studies in physical chemistry, using chemical lasers to investigate the distribution of internal energy in the products of chemical and photochemical reactions. Molina received his PhD in physical chemistry in 1972. While at Berkeley he also met Luisa Tan, who was a fellow graduate student and who later became his wife and scientific collaborator.

In the fall of 1973, Molina made a move that would set the stage for the development of his career in atmospheric chemistry. Leaving the UC Berkeley, he became a postdoctoral fellow in the group of Professor Sherwood Rowland at the UC Irvine. Offered a number of research options, Molina chose the task of finding out the environmental fate of certain very inert industrial chemicals – the CFCs – that had been accumulating in the atmosphere. CFCs had been introduced as refrigerants early in the 20th century, being safer and more efficient than earlier refrigerants, namely ammonia and sulfur dioxide. At that time, CFCs were thought to have no significant effects on the environment. Within three months of arriving at UC Irvine, however, Rowland and Molina had developed the CFC–ozone depletion theory, which explains how chlorine (Cl) atoms produced by the decomposition of the CFCs catalytically destroy ozone. The importance of this destruction mechanism became clear when they compared the emissions of CFCs to the amounts of nitrogen oxides that, based on studies a few years earlier by Paul Crutzen of the natural factors influencing stratospheric chemistry, were controlling ozone levels. With the possibility that the continued release of CFCs into the atmosphere would cause a significant depletion of the Earth s stratospheric ozone layer, which protects life at the surface from the highly energetic ultraviolet radiation from the Sun, Rowland and Molina contacted Professor Harold Johnston at UC Berkeley, who was a pioneer in studying the impact of the release of nitrogen oxides from the proposed supersonic transport aircraft on the stratospheric ozone layer. Johnston informed them that atmospheric chemists Ralph Cicerone and Richard Stolarski had arrived at similar conclusions concerning the catalytic properties of Cl atoms in the stratosphere, in connection with the release of hydrogen chloride, either from volcanic eruptions or from the ammonium perchlorate fuel planned for the space shuttle. The results of these studies were published in *Nature* in 1974 (Molina and Rowland, 1974), setting in motion a chain of events that led first to the curtailment of the use of CFCs in aerosol spray cans and as solvents, and later to radical reductions in global production of CFCs under the Montreal Protocol on the Protection of the Ozone Layer (*see* Ozone Layer: Vienna Convention and the Montreal Protocol, Volume 4). Even though the potential influence was realized in the 1970s, studies indicate it will take until the middle of the 21st century for CFC-induced Cl levels in the stratosphere to drop to levels that do not create ozone holes in the polar regions of the stratospheric ozone layer.

In 1975, Molina was appointed to the faculty of the UC Irvine, where he studied the spectroscopic properties of several unstable and difficult to handle compounds of atmospheric importance, including hypochlorous acid, chlorine nitrite, chlorine nitrate, peroxynitric acid, etc. In 1982, he joined the Molecular Physics and Chemistry Section at the Jet Propulsion Laboratory in Pasadena, CA, where he led a group conducting measurements and developing techniques for the study of newly emerging problems, particularly relating to the peculiar chemistry that is promoted by polar stratospheric clouds, some of which consist of ice crystals. They were able to show that Cl-activation reactions take place very efficiently in the presence of ice under polar stratospheric conditions. With his wife, they carried

out experiments with chlorine peroxide, a new compound that turned out to be important in providing the explanation for the rapid loss of ozone in the polar stratosphere. In 1989, Molina accepted a joint appointment in the departments of Earth, Atmospheric and Planetary Sciences and of Chemistry at MIT, where he has continued his research on global atmospheric chemistry issues. He was named MIT Institute Professor in 1997. Molina is a member of the US National Academy of Sciences, the Institute of Medicine, and the Pontifical Academy of Sciences. He has served on the US President s Committee of Advisors in Science and Technology, the Secretary of Energy Advisory Board, the National Research Council Board on Environmental Studies and Toxicology, and on the boards of US-Mexico Foundation of Science and other non-profit environmental organizations. In winning the Nobel Prize in 1995, Molina became the first Mexican–American to win a Nobel Prize and indeed the first Mexican-born Scientist to become a Nobel Prize Winner.

Monitoring Systems, Global Geophysical

Christopher N K Mooers
University of Miami, Miami, FL, USA

To help understand and assess the state of the Earth system, monitoring systems are used to observe (or sample) geophysical variability in a sustained, standardized fashion, as opposed to conducting one-time exploratory surveys or short-term observational experiments. Ideally, monitoring systems would sample a comprehensive set of geophysical variables to a uniformly high standard on a global basis; the observed data would be freely available to all concerned parties; and the data, or derived, high-order information products, would be well utilized by local, regional, and global decision-makers. This ideal remains to be ful lled in the perhaps not too distant future due to the onrush of technology, scienti c understanding, and societal need.

The Earth system is variable on space and time scales that depend upon the dynamics of the intrinsic and extrinsic processes producing natural variability. Convolved with natural variability is that due to activities of human society, usually termed anthropogenic variability. For Earth system management, it is important to be able to deconvolve the patterns of natural and anthropogenic variability in order to contemplate effective mitigating action of human-induced change. However, natural and anthropogenic variability may or may not be readily distinguishable depending upon whether their characteristic space and time scales and space- time patterns are similar or dissimilar, as dictated by the attributes of their forcing. Therefore, a close understanding of natural and anthropogenic processes is also often required to distinguish anthropogenic from natural variability.

Below, several general principles and issues of geophysical monitoring are discussed, some aspects of discipline-based geophysical monitoring are outlined, and a future outlook is conveyed for geophysical monitoring in support of the new global environmental ethic needed for sustainable Earth system management.

GENERAL CONCEPTS

Historically, geophysical monitoring systems have evolved from ancient astronomical observatories, record keeping by religious missionaries and imperial forces, and exploratory and expeditionary activities. Modern autonomous instrumentation facilitates systematic observations by large numbers of entities and at diverse locations and, with a modicum of effort, in a coordinated fashion. Understandably, monitoring systems, driven by particular societal needs or scientific opportunities, have developed on a disciplinary basis, and often on a national basis. However, this disciplinary and national partitioning of monitoring efforts may lead to lost opportunities and other inefficiencies as well as undermining a unified, comprehensive approach. Because economic or military advantage can be derived from monitoring certain geophysical variables (e.g., atmospheric winds and oceanic currents), the data accrue value, which leads to their treatment as proprietary, thereby undermining the principle of free exchange of geophysical data.

For enlightened stewardship of the Earth s environment, natural processes must be understood. This requires the use of the modern, combined approach of observations, experiments, theory, and numerical simulations (modeling). The most reliable and quantitative observations are obtained from scientific instrumentation. However, instrumental records, as opposed to anecdotal records or proxy (paleo) records, have begun to become available over only the past century or two. Hence, it is important to conduct process studies to understand the relationship between the

proxy (usually geochemical, biological (e.g., microfossil), or biogeochemical in nature) and instrumental records. With that understanding, the proxy records may be more fully interpreted (*see* Natural Records of Climate Change, Volume 1), and the instrumental records may be extrapolated backwards in time.

Because geophysical variables vary with spatial position, observations are generally required at numerous locations to form the basis for producing maps in the horizontal plane and transects in vertical planes. Because they also vary with time, time series of observations are required, too. Ideally, the data product consists of time sequences of maps and transects and plots in a coordinate plane defined by time and one spatial dimension (such diagrams are commonly called Hovmuller diagrams). To isolate the essential physics, it is frequently effective to examine geophysical variables in Fourier space for one or more of the four coordinates (three spatial dimensions plus time).

Exceptions to the previous remarks occur. For example, some monitoring strategies are focused on space–time events that may be restricted in space or time and have characteristic signatures (i.e., patterns). Such events can be targeted with a specific, tailored monitoring strategy (which can be termed a strategic sentinel), analogous in a very general fashion to the canary in the coal mine paradigm.

Enlightened stewardship of the environment also requires assessments of trends in geophysical variables to identify statistically significant departures from normal conditions. For this purpose, systematic observations need to be made routinely to specified accuracy and precision. Observations need to be sampled frequently enough in time and space to avoid aliasing from high temporal or spatial frequencies and over long enough durations and distances to avoid biasing from low temporal or spatial frequencies, respectively. One approach is to install temporally sampling sensors at various fixed sites and then connect these sensors into a network or observing system (e.g., *see* Air Quality, Global, Volume 1). Another approach is to use a platform; such as, an artificial satellite to convey remote sensing systems; the satellite can either be an Earth orbiting satellite which periodically repeats its ground track or a geostationary satellite which continuously views a fixed sub-domain of the Earth (*see* EOS (Earth Observing System), Volume 1).

Such routine, sustained, professional observational campaigns define geophysical monitoring, which is only interrupted due to a technical or some other kind of a disturbance, upgrading of the instrumentation, or implementation of an observing system redesign. These routine monitoring programs are usually carried out by governmental agencies. The governmental monitoring services generally provide documentation of sensor calibrations and network nodes (e.g., date of installation, geographical coordinates, and altitude relative to mean sea level); installation, operation, and maintenance of the sensor network; and data acquisition, transmission, quality control, archival, and distribution. Error estimates for the observations (e.g., those due to sensor noise) and the overall observing system network (e.g., those due to small scale (unresolved) geophysical noise) are byproducts of the calibration and monitoring activities that are essential for quantitative analysis of the results. With the advent of modern technology, network sensors and nodes have become electronic and automated, and data are typically telemetered from remote nodes to central sites in real time via landlines, radio links, communication satellites, or equivalent means.

Scientific researchers have several roles to play regarding monitoring systems. For example, they are often responsible for new sensor development. Similarly, they are often responsible for the design and advocacy of sensor networks, and the conduct of sampling experiments to determine the network s design parameters. Less commonly, they may create or assist in operating a monitoring system. Very commonly, researchers rank, along with environmental decision-makers, as prime users of the data sets derived from monitoring systems.

An interesting irony is that when a new observational capability bursts upon the scene, the data acquisition activities are seen as a source of exciting science. Once the sensing technology becomes proven, routine, and institutionalized, the data acquisition activities are viewed as routine monitoring, or even mindless monitoring. However, once the observing network has operated long enough to document at least a large fraction of one cycle of energetic, longer period variability, the data become highly valuable again for scientific research, and the monitoring system achieves heroic status. The only way to avoid the mindless monitoring appellation, is to keep research scientists engaged with the monitoring process, which requires support for critical investigations conducted with the monitoring data. Such scientific investigations also provide invaluable feedback on the performance of the monitoring system.

Another irony is that geophysical data are useful to the largest number of users, which includes managers and operators as well as researchers, when they are fresh; i.e., available in real time. Subsequently, their utility languishes until the data record becomes long enough to provide a useful historical and statistical perspective and then recognition and appreciation of the value of the historical data record greatly increases.

It is generally understood that it is impractical, or even impossible, to observe every geophysical variable of interest with sufficient accuracy and space–time resolution, and that dynamical models must be used for full field estimates. However, the models are very dependent upon the adequacy of observations for initial and boundary conditions,

forcing functions, and adjustment of internal values through data assimilation. In other words, the available observations are used to constrain the models; conversely, the models are used to interpolate and extrapolate dynamically the inevitably sparse observations.

These comments have only addressed a few aspects of the synergistic interchange between observations and models. For example, pure model simulations should be validated with observations to determine whether the model s verisimilitude is sufficient before attempting data assimilation. As another example, by sub-sampling a model simulation according to the template of a candidate observing system and carrying out various analysis protocols, models can be used to help assess the efficacy of the design of a candidate observing system network on an *a priori* basis.

Overall, the modern concept of geophysical monitoring systems includes the incorporation of models and observations to provide optimal field estimates that, in turn, can be analyzed and synthesized to produce higher order information products (replete with error estimates) than those based on observed or modeled variables alone. Additionally, a modern monitoring system includes a vital subsystem for information management that treats such functionalities as data acquisition, quality control, archival, retrieval, display, transmission, and distribution.

Given a geophysical monitoring system and a data archival strategy, a natural adjunct is the formation of a climatology for broad use that characterizes a variety of properties of the evolving data set in statistical and geophysical terms. Because numerous assessments for societal purposes and scientific analyses are likely to stem from a climatology, it is essential to document its attributes and understand its quality.

Having reviewed some of the general principles and issues associated with geophysical observing systems, attributes of the monitoring systems of several geophysical disciplines will next be considered. Of interest is their adequacy for fulfilling the needs of society in addressing stewardship issues associated with a sustainable Earth system, and in protecting its inhabitants from natural hazards by issuance of early warnings and otherwise mitigating their impacts.

STATUS OF GLOBAL GEOPHYSICAL MONITORING SYSTEMS

Global geophysical monitoring systems tend to be organized by scientific disciplines. Increasingly, however, scientific and logistical advantages in coordinating such efforts are being recognized. Hence, where possible, these synergistic arrangements or opportunities will be noted. The three fluid geophysical disciplines, namely meteorology, hydrology, and oceanography, will be addressed first because they have much in common. Then, the monitoring systems of the four solid earth geophysics disciplines; viz., seismology, geodesy, geomagnetism, and volcanology are addressed.

Meteorology

Probably the most advanced geophysical discipline in modern monitoring strategies is meteorology due to the everyday interest in forecasting the weather, and now short-term climate, by observing and modeling the atmosphere. Certainly, it is the most advanced in pioneering the assimilation of observations from a very diverse observing system into numerical models to make optimal estimates of atmospheric variables and for the initialization of those models to facilitate their use in the forecast mode. This task, and the infrastructure necessary to accomplish it, is typically termed operational meteorology. Beginning over a century ago, military, agricultural, and aviation applications provided the motive force for the development of operational meteorology, which now serves innumerable users, including the general public. A combination of observing systems is used, including ground stations to observe winds, wet and dry temperature, pressure, visibility, etc. radiosonde stations to observe vertical profiles of temperature and humidity; remote sensing radars for vertical profiles of winds; upper tropospheric winds and temperatures from commercial aircraft; and satellite imagers for surface temperature and clouds and sounders for vertical profiles of temperature. Most nations have national weather services that coordinate their operational meteorology activities through the World Meteorological Organization (WMO). WMO is a United Nations (UN) affiliated agency, which oversees, for example, the global telecommunication system (GTS) for aggregating and disseminating real time data reports and numerical model products as part of the World Weather Watch (WWW). *En passant*, the research meteorology (and hydrology and oceanography) community is also a beneficiary of the WWW data sets and relies on them to a significant degree.

Hydrology

Hydrological observing systems serve a variety of needs ranging from water resource management to study of climate issues ranging from droughts and floods to hazardous events such as flash floods and heavy and harmful precipitation. Such observing systems include rain gauges, stream gauges (for river flows), snow pack thickness, plus standard surface atmospheric variables. With so much in common with operational meteorology, operational hydrology is often conducted by the national weather services for real time hydrology, and is facilitated by WMO. Additional gauging and modeling are done by the engineering

and geological components of hydrology dealing with water resource management on a seasonal and longer-term basis. With the growing concern for climate and global change, the scientific issue of understanding the global water cycle has emerged as a priority, necessitating the use of new technologies such as satellite remote sensors for producing global, synoptic estimates of precipitation and ice cover.

Oceanography

Ocean observing systems serve the needs of mariners who navigate the ocean; the industrial entities involved in offshore operations (oil and gas extraction, waste disposal, fishing, aquaculture, and so forth); the environmental managers responsible for sustainable marine ecosystems and public health; plus those who are engaged in climate analysis and prediction. The systematic and cooperative acquisition of oceanic data by the maritime industry and navies of the world began in the 1850s, leading to bottom topographic charts of the seafloor and climatological atlases of ocean surface currents and atmospheric surface winds, for example. Despite this early start, operational oceanography has been slow to develop except in the context of several leading navies in recent times. However, today there exists an embryonic ocean observing system which is in the process of being upgraded through the Global Ocean Observing System (GOOS), a program of the Intergovernmental Oceanographic Commission (IOC), an agency of United Nations Educational, Scientific and Cultural Organization (UNESCO) (*see* Global Ocean Observing System (GOOS), Volume 2).

The principal elements of the *de facto* ocean observing system are the coastal sea level network, consisting of hundreds of telemetering coastal tide gauges that are non-uniformly distributed and biased toward the Northern Hemisphere; extensive, high quality marine lower atmospheric and upper oceanic data from dozens of merchant vessels in the Ships of Opportunity and Volunteer Observing Ship (VOS) programs; satellite-tracked, surface layer drifters for surface currents, temperature, and atmospheric pressure; and satellite infrared imagery from which sea surface temperature is determined. Rapidly emerging components for the *de facto* ocean observing system include the autonomous profiling (for temperature and salinity), telemetering Palace Floats, with 3000 to be deployed as the global ocean; Array for Real-time Geostrophic Oceanography (ARGO), which will also provide current estimates at their rest depth (circa 1 km) as well as at the sea surface; satellite radar altimeters, which determine the sea surface height with high precision and characterize jets and eddies; and satellite radar scatterometers that measure surface winds with high accuracy.

The international Global Ocean Data Assimilation Experiment (GODAE) program is under development; it aims to make ocean state estimates with global ocean models that assimilate Palace Float temperature and salinity profiles, altimetric sea surface heights, and so forth. The results will allow improvement of the design of GOOS and help facilitate the growth of operational oceanography. To obtain absolute values for sea surface heights measured from satellite radar altimeters, it is essential to have an accurate geoid; conversely, sea surface height variability due to ocean dynamics constitutes a noise source for geodetic measurements. Similarly, for coastal tide gauges to provide absolute sea levels for use in sea level rise studies, they must be connected to a geodetic grid to take into account vertical displacements due to long period tectonic motions and glacial rebounds. Thus, there are strong needs for coordination between oceanography and geodesy.

With the ocean system strongly forced by atmospheric and hydrologic processes on time scales of the order of a year or less, and with oceanic processes forcing the atmospheric and the hydrologic systems on longer time scales, there is an increasingly strong basis for cooperation between the fluid geophysics disciplines. Because of the societal concern for possible changes in the contemporary climate regime, and because of the inadequacies of the *ad hoc*, *de facto* monitoring systems currently used for climate change assessments, the international meteorological, oceanographic, and hydrological communities, under the leadership of WMO, are developing the Global Climate Observing System (GCOS), which is an intersection between WWW and GOOS, plus some enhancements (*see* GCOS (Global Climate Observing System), Volume 1).

Seismology

Driven by societal concern for earthquake prediction and nuclear weapons testing detection, as well as basic research, numerous arrays of seismometers have been established, some of which are of a regional nature, while others are of a global nature. Seismic wave propagation theory is sufficiently advanced that it can be used together with the seismic array data to estimate synergistically geophysical and geochemical information about the structure of the Earth s crust and mantle using inverse methods. Much of the seismological observing system is organized on a national basis, and some on an international basis. Frequently, arrays are operated by consortia of research institutions and/or agencies. Because two-thirds of the Earth s surface is covered by the ocean, it is essential to extend the seismological arrays from the continents to the deep sea for global coverage. For logistical and technological reasons, as well as some scientific reasons, this need is leading to a partnership between marine seismologists and those oceanographers concerned with developing and operating long-term seafloor observatories, as in the International Ocean Network (ION) program.

Geodesy

Geodesy is concerned with the accurate and precise shape of the Earth s surface (i.e., the geoid) and its temporal variation due to tectonic activity, which has innumerable societal applications ranging from accurate topographic mapping to property rights to land-use planning to flood control strategies, to name several. Hence, mapping the Earth s gravitational field and determining precisely the rate of rotation of the Earth (equivalently, the length of the day) are central tasks for geodesy (*see* Atmospheric Angular Momentum and Earth Rotation, Volume 1). The monitoring methods of geodesy include the use of networks of gravimeters, both in the stationary and portable modes. They also include the use of precise navigation systems; e.g., as the satellite based global positioning system (GPS) that utilizes radio signals whose propagation is perturbed by atmospheric effects, necessitating collaborations between geodesists and meteorologists. Conversely, the refracted radio signals can be used, through inverse methods, to estimate the thermal structure of the atmosphere. The methods of geodesy can be combined to provide precise positioning, in three space dimensions and time, of moving as well as stationary objects. Marine geodesists have been extending precise positioning to the seafloor and the ocean interior in recent years, making feasible programs such as ION, as mentioned above.

Geomagnetism

The geomagnetic field is highly variable in time as well as space due to solar–terrestrial interactions stemming from solar flares and involving ionospheric processes that affect radio propagation and electrical grids on the Earth s surface. Thus, a network of geomagnetic observatories, equipped with magnetometers, was initiated over a century ago to monitor geomagnetic storms in the ionosphere. With the use of upper atmospheric models, forecasting of ionospheric conditions is emerging as an operational capability, for which coordination with operational meteorology is essential. Magnetometer networks are being established on the seafloor, as well.

Volcanology

Volcanism is monitored by methods ranging from seismometers to synthetic aperture radar (SAR) imagery and GPS receivers to detect vertical movements of the surface for advanced warning of society as well as for basic research.

SUMMARY

Over the past two decades, with the rising concern for global sustainability issues, the maturing of enabling technologies; e.g., satellite remote sensing and numerical modeling, and the increasing scientific attention devoted to global processes, the new multidisciplinary field of Earth system science has emerged. Earth system science encompasses global geophysics, biogeochemistry, and marine and terrestrial ecology.

Earth system science aims to understand how the physical, chemical, and biological systems of the Earth cofunction (*see* The Earth System, Volume 1). Thus, global geophysics, geochemistry, and geo-ecology are beginning to share common interests and strategies for monitoring (both observing and modeling), including an abiding need for observed data. It is often possible for these disciplines to co-locate observing networks for mutual advantage, both logistically and scientifically, and to share platforms (e.g., satellites and seafloor observatories), information management systems, and other resources. In this spirit, the Global Terrestrial Observing System (GTOS) is being developed under the leadership of the United Nations Environmental Programme (UNEP), which adds terrestrial and marine ecology to the disciplinary mix (*see* Global Terrestrial Observing System (GTOS), Volume 2). At another level of integration, GOOS, GCOS, and GTOS are being linked through the Integrated Global Observing Strategy (IGOS).

As an entity in the International Council for Science (ICSU), the International Union of Geodesy and Geophysics (IUGG), through its seven constituent disciplinary associations, fulfills several roles in global geophysical monitoring (*see* IUGG (International Union of Geodesy and Geophysics), Volume 1). For example, it has promoted and fostered several disciplinary observing system networks through various permanent services. It was a leading coordinator for the International Geophysical Year (IGY) in 1957, that provided a one-time, integrated global geophysical survey (*see* IGY (International Geophysical Year), Volume 1). Above all, it periodically assembles geophysicists from the less developed and more developed countries to discuss scientific results based, in part, on data from the observing systems and to plan extensions of these systems. Such communications and collaborations play a crucial role in technology transfer from the geophysicists of the more developed countries to those from the less developed countries. In turn, the collegial relations so engendered help form the basis for access to the less developed nations for installation of monitoring sites to extend the global networks and fill data gaps. In 1999, IUGG adopted a resolution advocating the advance of Integrated Global Earth Monitoring Systems (IGEMS) by supporting the various observing system networks in existence and planned and promoting the free exchange of geophysical data. It can be anticipated that this new resolution will lead, in due course, to the IUGG playing a planetary stewardship role by assembling and promulgating global assessments on the state of the Earth system.

The future of global geophysical monitoring systems is strongly linked to the rising moral imperative (well represented in the deliberations of the United Nations Commission on the Environment and Development (UNCED), popularly known as the Earth Summit, Rio de Janeiro, Brazil, 1992) of understanding the global environment at a level firmly grounded in observations, as well as theory and modeling, such that increasingly reliable assessments and projections, with defensible error estimates, can be made about the state of the Earth system in support of Earth management protocols designed to achieve sustainability. If done well, the world community will then be able to move beyond the present confusion and uncertainty over the prospects for climate and global change and make more rational and timely decisions dealing with anthropogenic influences on the Earth system.

Monsoons

The term *monsoon*, believed to be of Arabic origin, refers to large-scale seasonally varying wind flows associated with major continental land masses and neighboring oceans. In summer, air over the land is heated, expands (so becomes less dense), rises, cools and spreads outward at high altitude. Near the surface, moist air flows in from the ocean to replace it, bringing clouds and rain as rising and cooling take place. In winter, the atmosphere over land areas cools, becomes more dense, subsides, warms as it is compressed, and dry currents flow from land to sea. The phenomenon is in essence a sub-continental scale version of the sea breeze/land breeze regime observed at coastlines around the world.

The largest and best known monsoon system is that centered on the Indian subcontinent, although monsoonal climates are also found in tropical regions of Australia, Africa, Central America and the southwestern US. In March and April the Indian sub-continent begins to heat strongly, with some of the highest surface temperatures of the year occurring by May. A large difference between land surface temperature and sea surface temperature results. As a consequence, the wintertime flows of dry air from the land to the ocean are replaced by moist winds coming in off the ocean due to the low pressure created over the land by the warm and rising air currents. A large low pressure system dominates Southwest Asia, while the Himalayas and Hindu Kush mountains trap warm air within the Indian ocean basin, preventing it from continuing north without rising and precipitating out its moisture. Intense winds blow from the southwest around the low pressure area and over the Indian Ocean, coinciding with the seasonal northward shift in the intertropical convergence zone (ITCZ). As the winds cross the Indian Ocean they pick up moisture that is released in tremendous convective storms (usually beginning in early June) as they pass over the sub-continent. Most of South Asia receives nearly all of its rainfall from the summer monsoon, with the months of May, June, and July being the wettest of the year. Variability in monsoon rainfall can make the difference between starvation and prosperity for millions. The Indian Meteorological Department issues regular forecasts of monsoon onset and precipitation based primarily on statistical methods calibrated by the long history of past events.

In the winter, a reverse process occurs. The land surface cools faster than the sea surface as a result of water s capacity to retain heat. The winds turn and carry continental air out over the ocean, the ITCZ retreats to the south, subsiding air dominates the Indian subcontinent, and dry conditions prevail.

This simple picture is but the most prominent feature of a complex circulation system that dominates a major portion of the planet. Other branches of the Asian monsoon control the seasonal precipitation of Southeast Asia and Southern China. Moreover, the strength and timing of the Asian monsoon is linked with the Pacific-wide Walker circulation associated with the El Niño/Southern Oscillation phenomenon (*see* El Niño and La Niña: Causes and Global Consequences, Volume 1). The latter connection offers some promise of improving predictions of the Asian monsoon.

Similar, though less intense, monsoonal circulations are found in West Africa, Australia, the southwestern US, and northern Mexico. In the context of a changing global environment, it is natural to expect changes in the massive monsoonal circulations. Indeed, Chinese investigators (Fu and Yuan, 2001) have identified connections between human-induced land-use changes over China, consequent changes in surface heating and evapotranspiration, and monsoon intensity. Future changes in global circulation associated with global warming may be expected to influence the timing and intensity of monsoons as well. Because the behavior of the Asian Monsoon is a major factor in life-support systems for millions of peoples in Asia (*see*, for example Fisheries: Pollution and Habitat Degradation in Tropical Asian Rivers, Volume 3; Indus Basin: a Case Study in Water Management, Volume 3), research into the effects of global environmental change on the behavior of the Asian monsoon is of highest research priority.

Mountain Climates

Roger G Barry
University of Colorado, Boulder, CO, USA

Mountain climates are highly variable spatially as a result of the combined effects of latitude, altitude, distance from the ocean, and local relief.

Mountain ranges occupy about 20% of the total land surface of the Earth. A mountain can be defined as terrain having a sufficient altitudinal range to cause vertical differentiation of climatic elements and vegetation cover. The common elements of mountain climates include:

1. reduced air density, pressure and oxygen availability with consequences for physiology and bioclimatology; about 50% of the population will experience some symptoms of hypoxia above 3 km altitude;
2. reduced vapor pressure;
3. vertical differences in mean temperature over 1 km in elevation equivalent to the gradient over about 1000 km distance poleward;
4. corresponding vertical/latitudinal differences in the duration of snow cover which increases nearly linearly with height;
5. solar radiation (including UV–B) increases of 5–15% km^{-1}, due to decreased attenuation by moisture and aerosols;
6. strong local climatic contrasts, termed topoclimates, as a result of slope orientation, topographic shading and air drainage.

The height, length and width of a mountain barrier determine its effects on airflow, clouds, precipitation and frontal systems over a range of scales. A high, broad barrier may block the airflow causing it to flow through gaps or around the mountains, thereby often creating local winds. The temperature conditions on an isolated mountain are closer to those in the free air than over an elevated plateau or mountain range where the terrain modifies the lower atmosphere through energy transfers and orographicaly-induced cloud cover.

Mountain climates are highly variable as a result of the basic controls of latitude, proximity to an ocean in the upstream direction of prevailing winds and weather systems, and relief. The imprint of latitude on mountain climates is evidenced by the diurnal and seasonal rhythms of solar radiation and temperature. High equatorial mountains experience summer every day and winter every night (Hedberg, 1964), whereas high latitude mountains have a polar night and summer midnight sun. An upwind ocean is crucial as a moisture source. In North America, the western Cordilleras have large annual precipitation totals, up to 80% of it falling as snow in the winter half year. Precipitation amounts decrease progressively inland, with exaggerated dry zones (rain shadows) in the interior valleys and basins, although western slopes of the successive ranges have augmented totals. In South America, the western slopes of the Andes in Peru and northern Chile are semi-arid because the winds are mostly from the east and the main moisture source is the Amazon Basin.

Wind speeds increase steadily with altitude in the mid-latitude westerlies but in the tropical easterlies there is little altitudinal change and winds may even decrease upward. Orography gives rise to local winds of dynamic origin (foehn, barrier winds) and thermodynamic origin (anabatic/katabatic up/down slope winds; mountain/valley winds, respectively, blowing from those directions). Altitudinal gradients of precipitation vary widely. In mid-latitudes, annual precipitation totals tend to increase with altitude on windward slopes up to about 3 km as the increase in wind velocity offsets the decrease in moisture content. Because evaporation also tends to decrease with altitude in extratropical latitudes, the runoff increases, with altitude, at a faster rate than the precipitation increases. In equatorial regions, the largest rainfall totals are usually on the lowest slopes and amounts decrease above. In the easterly trade winds, the maximum occurs on windward slopes between about 700 and 1200 m altitude, near the mean cloud base level. Some of the heaviest annual precipitation totals are recorded in mountain areas – 11 m $year^{-1}$ in the South Island of New Zealand Alps around 2000 m altitude, 11–12 m $year^{-1}$ around Cherrapunji (1300 m) in Assam from the southwest monsoon, and 12 m $year^{-1}$ at 1570 m elevation on Mount Waileale, Kauai, where the 4200 m summit receives less than 50 cm.

Mountain observatories in Europe especially provide century-long records of climatic data. Stations in the

Alps and Pyrenees indicate a mean annual temperature increase of about 1 °C per 100 years which at three stations exceeds that observed at lowland stations in western Europe. However, in central Europe the period 1930–1950 was warmest and, in eastern Europe and the Caucasus, there has been little twentieth century warming. For 30–70 °N most stations at elevations above 1500–2000 m show a diurnal asymmetry in warming trends with minimum temperatures for 1951–1989 increasing more than maximum temperatures, although in the Alps both maximum and minimum temperatures show an increase.

There has been widespread warming on tropical mountains during 1975–1990 as evidenced by a rise in the freezing level at radiosonde stations; this is particularly pronounced between 15 °N and 15 °S. This appears to be responsible for a dramatic shrinkage of tropical glaciers in South America and Irian Jaya although decreased precipitation is suggested for glaciers on East African peaks.

MSU (Microwave Sounding Unit)

The MSU was part of the atmospheric sounding instrument suite on nine National Oceanic and Atmospheric Administration (NOAA) polar orbiting spacecraft beginning with TIROS-N in December 1978 and ending with NOAA-14, launched in late 1994.

The MSU measures the intensity of microwave radiation emitted from atmospheric oxygen at four frequencies near the 60 GHz absorption band; 50.30, 53.74, 54.96 and 57.95 GHz. The intensity of the radiation is proportional to the temperature of oxygen and thus to that of the atmosphere. The emissions arise from broad vertical layers with approximate levels of maximum emissions being the surface, 6, 15 and 20 km for the four frequencies, respectively.

The MSU is a cross-track scanning instrument, with 11 Earth-views per 25.6 s scan. After each set of 11 Earth-views, the rotating antenna points to cold space and then to a hot target on board for calibration points. The temperatures of cold space (2.7 K) and the hot target (by embedded thermometers) are known and from this information, the representative temperature of the Earth-views may be calculated. Adjustments, however, are required to account for the effects of changing altitude, longitudinal drifting of the satellite orbit and instrument gain fluctuations. Once adjusted, the time series reveal exceptionally close agreement with independent measurements produced from weather balloons.

Several data products have been generated, including a low-mid tropospheric (surface to 8 km) and lower stratospheric (17–23 km) temperature series. For the period 1979–2000, the global mean low-mid troposphere indicated little trend either up or down while for the same period, the conventional surface temperatures indicated a significant increase (*see* Tropospheric Temperature, Volume 1). The lower stratospheric temperatures reveal significant cooling. Theoretical calculations have shown that these three distinct layers will respond differently to climate forcing and thus reveal varying trends.

JOHN R CHRISTY *USA*

Munk, Walter

(1917-)

Walter Munk, one of the great founding fathers of modern oceanography, was born in Austria in 1917. At age 14 he was sent to New York to be trained in the financial tradition of his maternal family. After 3 years in finances, he enrolled in the California Institute of Technology (Caltech) and graduated in applied physics in 1939.

Subsequently, he obtained a masters degree in geophysics from Caltech and was admitted to the PhD program at Scripps Institution of Oceanography, where, for some time, he was the only student under Harald Sverdrup, Scripps director. During World War II, he served for 18 months in the Field Artillery and the Ski Troops. Afterwards, he joined Sverdrup, Roger Revelle and Richard Fleming, the leading oceanographers of the time, at the US Navy Radio and Sound Laboratory. He finished his PhD dissertation in 1947 and joined Scripps Institution as assistant professor of geophysics. He has remained at Scripps ever since, becoming associate professor in 1949 and full professor in 1954. He served as director of the La Jolla Laboratory of the Institute of Geophysics and Planetary Physics in 1959–1982; retired as full professor in 1988 but was recalled to active duty in the same year.

Walter Munk is the author of 250 publications in international journals and volumes. He has contributed seminal papers in all his fields of interest, most often being the initiator of the field itself. In the period 1942–1950, his research focussed on wind waves, where he pioneered the first wind wave prediction model that was of crucial importance for the US Navy in maritime operations. He successively worked on the wind-driven ocean circulation, producing a series of fundamental papers that first explained how the surface currents of the ocean are driven by the wind stress field. In 1950–1960 his interest concentrated on the Earth s wobble and spin and, with Gordon MacDonald, he wrote an encompassing geophysical discussion of the rotation of the Earth which is a classic in the literature. Deep-sea drilling ventures, sun glitter and radar clutter, and the study of southern swell, surfbeats, edge waves, tsunamis and tides kept him busy through the 1960s. In the early 1970s his curiosity was attracted by internal waves, leading to the Garrett-Munk spectrum for internal waves, the explanation of which is still a challenge for oceanographers. In the last 15 years, Munk s major interest has been focussed on the exploration of the ocean interior through sound waves, inventing, with Carl Wunsch, the field of Ocean Acoustic Tomography, that has culminated with the Acoustic Thermometer of Ocean Climate (ATOC) Experiment (*see* Acoustic Thermometry, Volume 1).

Walter Munk is a member of all the major scientific societies including the US National Academy of Sciences, the Russian Academy of Sciences, and the Royal Society of London. He has received honorary degrees from the University of Bergen, Crete, Cambridge (UK) and more than 20 other national and international medals and awards, including the National Medal of Science in 1983 from President Reagan. In 1999 he was awarded the prestigious Kyoto Prize in Basic Sciences.

PAOLA MALANOTTE-RIZZOLI *USA*

Munn, Robert Edward (Ted)

(1919-)

Robert Edward Munn was born July 26th, 1919 in Winnipeg, Manitoba, Canada. Armed with a BA in Mathematics from McMaster University in 1941, Munn joined the Meteorological Division of the Canadian Department of Transport. After 7 months of courses at the University of Toronto learning how to forecast the weather, he was posted to Gander, Newfoundland in 1943 where he was part of a team that forecast for transatlantic flights and North Atlantic operational patrols.

In 1948 Munn moved to the Public Weather Office in Halifax where he published his first paper, *A Survey of the Persistence of Precipitation at Halifax*. In 1956 he became an air pollution research meteorologist in Windsor, Ontario, seconded to the Canada–US International Joint Commission. While there he earned a PhD from the University of Michigan in 1961 on intermediate-range Lagrangian diffusion modelling, and published his first book, *Descriptive Micrometeorology*.

In 1959 Munn became head of the new Micrometeorology Section in Transport Canada s Meteorological Branch in Toronto. He published extensively throughout the 1960s and 1970s on air pollution, turbulence and micro- and meso-scale meteorology, lake-breeze studies and urban heat-island effects. In 1971 Munn founded *The International Journal of Boundary-layer Meteorology* and served as editor in chief for more than 25 years. Over the years he managed to combine journal editorship with his many other duties by setting aside the early morning hours from 5 to 7.30 for editing and proof reading. He was editor in chief for Scientific Committee on Problems of the Environment (SCOPE) John Wiley Environmental Monographs from 1979–1998 and is currently a member of five journal editorial boards (*see* SCOPE (Scienti c Committee on Problems of the Environment), Volume 4).

Munn spent 6 months as a visiting professor at the University of Stockholm in 1971. He remained with the Atmospheric Environment Service (AES) (now known as the Meteorological Service of Canada (MSC)) until 1977 when he retired at age 58, having given 35 years to public service, and began a new career, as an Associate at the Institute for Environmental Studies at the University of Toronto. He became increasingly interested in environmental policy, risk assessment and sustainable development during the period

from 1977 to 1985. He made good use of his experience in evaluating and synthesising scientific research results and served as an interpreter of these results for the broader, non-scientific audience of policy makers. Munn was a visiting scientist at Chelsea College, University of London in 1979.

Between 1985 and 1988 he served as Leader of the Environment Program and deputy director at the International Institute for Applied Systems Analysis (IIASA) in Laxenburg, Austria. On his return to the Institute for Environmental Studies in 1989 Munn focused on long-term global change and global environmental issues, contributing frequently to interdisciplinary syntheses. Munn was one of the principal editors of the United Nations Environment Programme (UNEP) 1992 book: *The World Environment 1972- 1992*. He was editor for a 1996 monograph on Policy Making in an Era of Global Environmental Change for the Royal Dutch Academies of Engineering and International Council for Science (ICSU), and advisor to the United Nations Conference on Environment and Development (UNCED) and ICSU on an important project to define environmental issues in the next millennium.

In addition to his extensive editorial work, Munn has published or edited 20 books and monographs, authored more than 200 papers and received numerous international and national fellowships, awards, medals and prizes, including: Fellow of the Royal Society of Canada; Fellow of the American Meteorological Society (AMS); Fellow of the American Association for the Advancement of Science; and Fellow of the Canadian Meteorological and Oceanographic Society; the Frank A. Chambers Award of the Air Pollution Control Association; the Paterson Medal (highest Canadian award for meteorology); 1998 AMS Award for Outstanding Achievement in Biometeorology; and most recently 1999 AMS Award: The Walter Orr Roberts Lectureship.

His latest challenge is as editor in chief of this John Wiley *Encyclopedia of Global Environmental Change*. Despite his heavy workload he is always relaxed, never seems to be rushed, spends lots of time at galleries and concerts and, somehow, gets everything done.

DOUGLAS WHELPDALE *Canada*

N

Natural Climate Variability

Michael Ghil
University of California, Los Angeles, CA, USA

Climate varies on all time scales, from one year to the next, as well as from one decade, century or millennium to the next. The complex nature of this variability is a major obstacle to the reliable identi cation of global changes brought about - in the past, present or future - by the presence and activities of humanity on this planet.

This article discusses observed climate variability on various time scales, paleoclimatic, interdecadal to centennial, seasonal to interannual, and intraseasonal. Key ideas to explain the observed variability are presented, and some of the models used to explore these ideas are mentioned. Finally, we discuss brie y the implications of these ideas for the detection and prediction of climate change.

Climate variations happen on all time scales, as well as on all spatial scales, from the regional to the global. As an example, the oceanic El Niño (*see* El Niño and La Niña: Causes and Global Consequences, Volume 1) phenomenon is most pronounced in the tropical Pacific off the coast of Peru, but the associated Southern Oscillation in the atmosphere has far-reaching, nearly global implications. The combined El Niño/Southern Oscillation (ENSO) (*see* El Niño/Southern Oscillation (ENSO), Volume 1) variability has a seasonal component, hence the name El Niño, due to its preference for appearing first at Christmas time. It also has a quasi-biennial component, with a characteristic recurrence time of 2–2.5 years, and a low-frequency one, with a recurrence of 4–5 years. The interaction of these three distinct modes of variability renders the evolution of sea-surface temperatures across the tropical Pacific fairly irregular. An additional cause of the irregularity observed in these temperatures lies in the frequent weather perturbations that affect the ocean s surface.

Natural climate variability includes in general, as it does in the ENSO example above, three types of phenomena.

1. Variations that are directly driven by a purely periodic external force, like the diurnal or the seasonal cycle of insolation, are the easiest to understand and predict. The diurnal variations are due to the rotation of Earth on its axis, the seasonal ones to its revolution around the Sun. They bring about the temperature and precipitation variations between day and night and between summer and winter, respectively. On much longer time scales, multiply periodic (often called quasi-periodic) variations in Earth s orbit around the Sun affect the intensity of the solar radiation that reaches the Earth s surface.
2. Variations due to the non-linear interplay of feedbacks within the climate system are harder to understand and to predict than the previous ones. For instance, a temperature drop within the system will increase the amount of snow and ice, and thus lead to further cooling; this is the so-called ice-albedo feedback, explored in some detail by energy-balance models (*see* Energy Balance Climate Models, Volume 1). On the other hand, the increase of trace-gas concentrations in the atmosphere, such as that of carbon dioxide (CO_2), will increase surface temperatures through the greenhouse effect (*see* Projection of Future Changes in Climate, Volume 1). This temperature increase will release even greater amounts of trace gases from the upper ocean or, on the contrary, trap them in terrestrial vegetation. Each climate feedback can enhance or countervail the effect of another feedback (*see* Climate Feedbacks, Volume 1). The distinct feedback mechanisms identified so far in the climate system are numerous and complex. Their number and complexity contribute significantly to the difficulty of reliably detecting human-induced climate change (*see* Climate Change, Detection and Attribution, Volume 1).
3. Variations associated with random fluctuations in physical or chemical factors are hardest to predict in detail for any length of time. These factors can be external to the climate system itself, such as aerosol loading due to volcanic eruptions (*see* Volcanic Eruptions, Volume 1). They can also be internal to the system, such as weather fluctuations. The latter are known to be unpredictable on the longer time scales of seasons

to millennia. Still their averaged effect over these time scales may result in heat-transport variations between the equator and the poles.

The periodically driven variations – in the absence of any other source of variability – are themselves purely periodic and thus highly predictable. A single sudden change imposed on the system, whether in the solar irradiance received at the top of the atmosphere, in the atmosphere s reflectivity or opacity, or in other forcings or parameters of the system, has a relatively simple effect, conceptually speaking, on such a periodic variation.

A sudden impulse, as described in the previous paragraph, can change, for example, either the mean about which hemispheric temperature oscillates or the amplitude of the oscillation or both. Such a change would thus be easily detectable, speaking again in relative terms, when compared with one that a sudden impulse would cause in the other two types of variations, those resulting from the interplay of non-linear feedbacks (Lorenz, 1963) or those produced by stochastic forcing (Hasselmann, 1976). The characteristics of the latter two types of variations may be affected by an imposed change in diverse and complicated ways, ways that may be hard to distinguish from those of a spontaneous change within the system (*see* Chaos and Predictability, Volume 1).

An artist s rendering of climate variability on all time scales is provided in Figure 1(a). It is meant to summarize our knowledge of the relative power S, i.e., the amount of variability in a given frequency band, between f and $(f + \delta f)$; here frequency f is the inverse of period T, $f = 1 \bullet T$, and δf indicates a small increment. This power spectrum is not computed directly by spectral analysis from a time series of a given climatic quantity, such as (local or global) temperature; indeed, there is no single time series that is 10^7 years long and has a sampling interval of hours, as the figure would suggest.

Instead, Figure 1(a) represents a composite of information obtained by analyzing the spectral content of many different climatic series. The figure reflects the three types of variability mentioned earlier: sharp lines that correspond to periodically forced variations, at one day and one year; broader peaks that arise from internal modes of variability; and a continuous portion of the spectrum that reflects stochastically forced variations, as well as deterministic chaos. The latter represents the irregular variations that result from the deterministic interplay of non-linear feedbacks.

Between the two sharp lines at one day and one year lies the synoptic variability of mid-latitude weather systems, concentrated at 3–7 days, as well as intraseasonal variability, i.e., variability that occurs on the time scale of 1–3 months. The latter is also called atmospheric low-frequency variability. This name refers to the fact that the variability in question has lower frequency, or longer period, than the so-called baroclinic instability of large-scale atmospheric flow that gives rise to the development of weather systems. The periods associated with intraseasonal variability exceed even the duration of these weather systems complete life cycle, from their birth in the storm tracks off the east coasts of the major landmasses to their decay further to the east, across an entire ocean basin. Intraseasonal variability comprises phenomena such as the 40–50-day Madden-Julian oscillation of winds and cloudiness in the tropics, as well as the alternation between episodes of zonal and blocked flow in mid-latitudes. Both of these phenomena involve exchanges of angular momentum

between the atmosphere, the oceans and the land: as the winds speed up, the Earth rotation slows down, and vice-versa (Ghil and Childress, 1987; Ghil and Robertson, 2000).

Immediately to the left of the seasonal cycle in Figure 1(a) lies interannual, i.e. year to year, variability. This variability is dominated by ENSO-related phenomena and involves the interaction of the seasonal cycle with internal modes of variability of the ocean-atmosphere system in the tropical Pacific (Philander, 1990; Neelin *et al.*, 1998). Additional forms of interannual and interdecadal variability in higher latitudes are associated with the North Atlantic Oscillation, the Pacific Decadal Oscillation, and the Arctic Oscillation (*see* Arctic Oscillation, Volume 1; North Atlantic Oscillation, Volume 1; Pacific Decadal Oscillation, Volume 1).

The emphasis of climate research in the second half of the 20th century has shifted farther and farther to the left in the composite spectrum of Figure 1(a). It has proceeded from the study of weather systems in the 1950s and 1960s to that of intraseasonal variability in the 1970s and 1980s and on to interannual variability in the 1980s and 1990s. The greatest excitement – among scientists as well as the public – is currently being generated by interdecadal variability, namely climate variability on the time scale of a few decades, i.e., the time scale of an individual human's life cycle.

This progression of interest towards longer and longer time scales is due to two complementary causes. First, the non-linear feedbacks between different components of the climate system that affect the longer-term interactions pose a greater challenge to the scientific community. Second, the greater scientific challenge goes hand in hand with humanity's increasing desire to predict and eventually control its environment farther and farther into the future (National Research Council, 1995).

Clearly, controlling our environment is predicated upon the ability to understand and predict it first. Thus, weather prediction can be performed with the same accuracy now for 3–5 days as it was for 12–24 hours in the 1960s, due to the very substantial progress in understanding and modeling weather phenomena over the last 40 years. We have learned to carry out predictions of certain climate variables over certain areas, with some useful skill, for up to six months in advance. This skill is a result of considerable advances in understanding ENSO and modeling coupled ocean-atmosphere interactions over the last 20 years. It is reasonable, therefore, to attack now the even more challenging problems of understanding and predicting climate variability for the next decade and century.

Prediction is greatly facilitated by regularity. Thus, the prediction of sea-surface temperatures on seasonal to interannual time scales is helped by the near-repetition of warmer temperatures in the eastern tropical Pacific every boreal winter, as well as roughly every second year, and every fourth or fifth year. The positive interference of the quasi-biennial mode (2–2.5 years) with the low-frequency mode (4–5 years) yields major warm and cold events, but the episodes of mutual reinforcement between modes still occur rather irregularly. This irregularity precludes, at present, greater certainty in predictions for 6 months or longer (Neelin *et al.*, 1998).

The power spectrum shown in Figure 1(b) is based on the longest instrumentally measured record of any climatic variable, the 335 year long record of Central England temperatures. It represents an up-to-date blow-up of the interannual to interdecadal portion of Figure 1(a). The broad peaks are due to the climate system's internal processes: each spectral component can be associated, at least tentatively, with a mode of interannual or interdecadal variability. Thus the rightmost peak, with its period of 5.2 years, can be confidently attributed to the remote effect of ENSO's low-frequency mode. The 7.7-year peak is currently believed to capture a North Atlantic mode of variability that arises from the Gulf Stream's interannual cycle of meandering and intensification (Moron *et al.*, 1998; Speich *et al.*, 1998). The two interdecadal peaks, near 14 and 25 years, are also present in global records, instrumental as well as paleoclimatic. They seem to be associated with oscillatory modes in the global oceans' thermohaline circulation (*see* Ocean Circulation, Volume 1) and its coupling to the atmosphere above (Ghil and Robertson, 2000).

Finally, the leftmost part of Figure 1(a) represents paleoclimatic variability. The information summarized here comes exclusively from proxy indicators of climate. These indicators include coral records and tree rings for the historic past, and marine-sediment and ice-core records for the last two million years of Earth history, known as the Quaternary. During the Quaternary era, large ice sheets were present on the planet, especially in its Northern Hemisphere. This era is therefore termed an ice age, when compared to such ice-free epochs of the past as the Cretaceous.

Ice ages occupy on the whole no more than about one tenth of documented Earth history. Their main interest lies in the fact that natural climatic variability is higher during an Ice Age than during more benign geological times. The Quaternary represents an alternation of warmer and colder episodes, called glaciation cycles. This cyclicity is manifest in the broad peaks present in Figure 1(a) between roughly 1 kyr and 1 Myr. Of these, the three peaks near 20 kyr, 40 kyr and 400 kyr reflect quasi-periodic variations in Earth's orbit. These orbital variations (*see* Orbital Variations, Volume 1) are due to the perturbing forces exerted by Jupiter and the other planets on Earth's otherwise purely periodic, Keplerian motion around the Sun. They represent, respectively, variations in precession, obliquity and eccentricity, three parameters that are used to describe Earth's secularly varying orbit.

The large 100-kyr peak continues to puzzle paleoclimatologists. It has been attributed variously to an internal mode

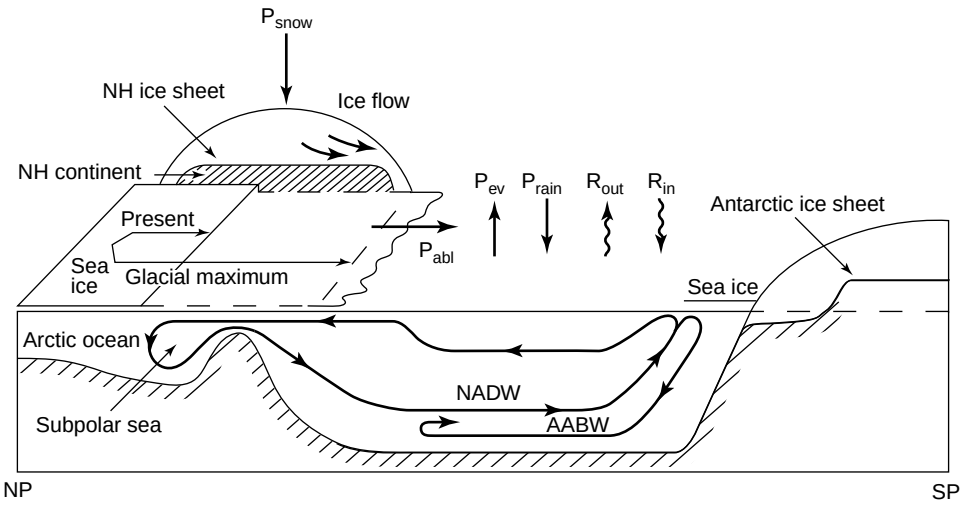

Figure 2 Schematic diagram of the Atlantic Ocean's thermohaline circulation and of the radiative, hydrologic and cryospheric processes likely to affect it (after Ghil *et al.*, 1987)

of the climate system, to the system s resonant response to small eccentricity variations or to a combination tone between orbital frequencies (Ghil and Childress, 1987). In the latter theory, the dominant 100-kyr peak corresponds to the non-linearly resonant amplification of a difference tone between the two distinct precessional lines at 19 kyr and 23 kyr. Certain climate simulations from the geological past attribute a critical role to natural changes in CO_2 levels, both in the initiation of the Quaternary as a whole and in generating the 100-kyr peak during the Late Pleistocene, i.e., the last one million years (*see* Climate Model Simulations of the Geological Past, Volume 1).

The peak at 6–7 kyr was predicted theoretically in the early 1980s as an internal oscillatory mode due to the interplay between the positive ice-albedo feedback and the negative precipitation-temperature feedback. In this theory, when coupling an energy-balance model with an ice-sheet model, global temperature drops as ice mass increases. The temperature drop diminishes the evaporation in low latitudes and hence the ice accumulation in high latitudes; this in turn decreases the ice extent and allows temperatures to rise again. Heinrich events (*see* Heinrich (H-) Events, Volume 1) were discovered in the late 1980s and found in the 1990s to have a near-periodicity of 6–7 kyr, as predicted by this theory (Ghil, 1994).

The peak at 2–2.5 kyr is associated with the names of W Dansgaard and H Oeschger and was discovered in Greenland ice cores (*see* Dansgaard- Oescheger Cycles, Volume 1). It seems to arise from the alternative intensification and weakening of the Atlantic s thermohaline circulation, as represented in Figure 2. Both the region of formation of North Atlantic Deep Water (NADW) and its flux (i.e., its mass transport per unit time) vary in a fairly irregular manner, but with a millennial-scale mean

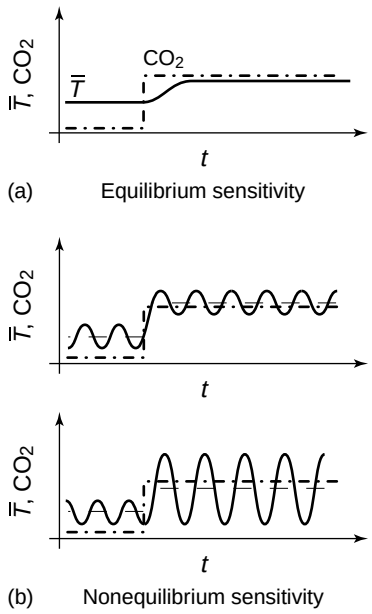

Figure 3 Climate sensitivity for (a) an equilibrium model and (b) a nonequilibrium, oscillatory model: as a forcing parameter (atmospheric CO_2 concentration, dash-dotted line) changes suddenly, global temperature (heavy solid) undergoes a transition. In (a) only the mean temperature (still heavy solid) changes; in (b) the oscillation's amplitude can also decrease (upper panel), increase (lower panel) or stay the same, while the mean (light dashed) adjusts as it does in panel (a)

periodicity. They are associated with variations in sea-ice cover, as well as in temperature and precipitation over the adjacent land areas.

What are the implications of the natural variability described so far on our understanding of global climate

Box 1 Computations of the climate's equilibrium sensitivity are often based on the linear, scalar ordinary differential equation

$$c\dot{\theta} = \lambda\theta + Q \qquad \bullet 1 \bullet$$

where θ is global temperature and

$$\dot{\theta} \equiv \frac{d\theta}{dt}$$

is its rate of change with time t.

Here

$$\lambda = \sum \lambda_i \qquad \bullet 2 \bullet$$

is the sum of the (linear) feedbacks λ_i, positive or negative, and

$$Q = \sum Q_j \qquad \bullet 3 \bullet$$

is the sum of the (positive or negative) forcings Q_j, also called source (or sink) terms (see Ghil and Robertson, 2000, and references therein). Typically, Q_j might include absorption by greenhouse gases (positive forcing) and reflection by aerosols (negative forcing).

If climate change during the industrial era were truly governed by simple linear mechanisms, according to Equations (1–3) above, it would be fairly smooth. Provided that only gradual increases in aerosols and greenhouse gases were at work, it would look schematically like the light solid line in Figure 4. In fact, the observed temperature variations in the Northern Hemisphere looked, again schematically, like the heavy solid line in the figure. The difference between the two curves, light and heavy, is due to the presence of natural variability, as well as to that of variable natural forcings, like volcanic eruptions and solar-irradiance variability.

This difference implies that the actual climate system's evolution is more complex than that dictated by a linear response to simple forcings. To simulate and predict this complex evolution requires the use of a set of non-linear (ordinary or partial) differential equations, depending on time t and on a set of parameters μ:

$$\dot{X} = F \bullet X \bullet t \bullet \mu \bullet \qquad \bullet 4 \bullet$$

Here X is a vector of state variables that describes the atmosphere, ocean and other climate subsystems. The components of the right-hand side vector F give the rates of change of the components of X. The vector F depends on the state X itself, time t (in the form of time-dependent forcing), and the parameter set μ. This set includes but is not limited to those present in the former scalar equation; typical parameters are those that determine the strength of various (non-linear) feedbacks and the net insolation at the top of the atmosphere.

Gradual changes in μ can lead to sudden changes in system behavior, from steady state to purely and multiply periodic, and on to chaotic and fully turbulent; these changes are called bifurcations. As a result, the system's predictability can change dramatically.

change? If no variability whatsoever were present, i.e., if the climate system were in equilibrium, external changes would result in a simple shift of this equilibrium (see Figure 3a). The ratio of the amount of this shift, in global mean temperature say, to the equivalent change in irradiance at the top of the atmosphere say, is usually defined as climate sensitivity (*see* Climate Sensitivity, Volume 1). The actual forcing change under consideration might be in carbon dioxide concentration or in atmospheric opacity due to aerosol loading or in the mean distance between Earth and Sun (see Box 1 for details).

Figure 3(b) shows how the response of the system would be modified if the system were undergoing periodic oscillations, either as the result of purely periodic forcing or due to an internal mode that is purely oscillatory. In this case, a shift in the mean would be accompanied by a change in the oscillations amplitude, increasing or decreasing it. In fact, for a non-linear system, a change in an external parameter can lead from the system s being in equilibrium to its undergoing self-sustained oscillations, i.e., as a result of global change the system might be destabilized and become oscillatory.

The climate system s behavior, however, is much more complicated than being in equilibrium or in a state of purely periodic oscillations. Thus, the effects of natural or anthropogenic changes in the system s forcing or parameters, including but not restricted to net insolation, cannot be measured by a single quantity like climate

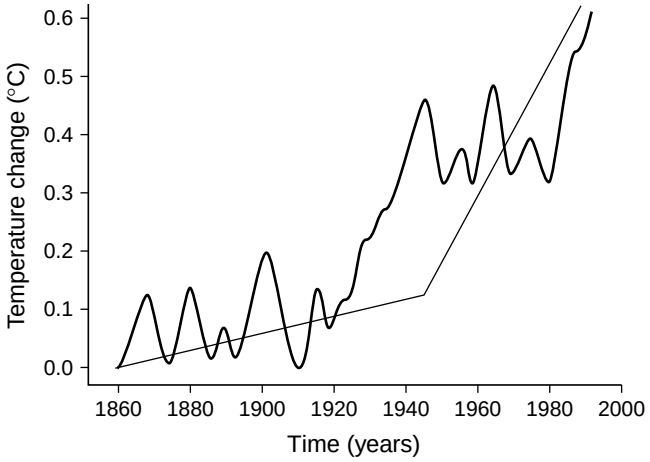

Figure 4 The role of natural variability in climate-change detection and attribution: equilibrium response of global temperatures to changes in aerosols and trace gases (light solid line) vs. observed temperature variations (heavy solid)

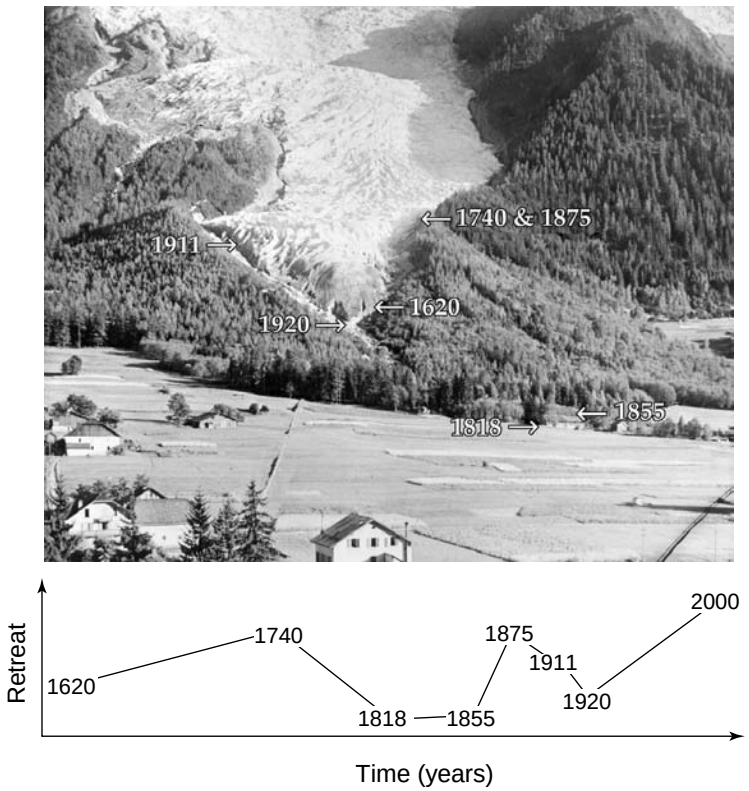

Figure 5 Retreats and advances of an alpine glacier over the last 300 years (upper panel courtesy of Musée Alpin–Les Amis du Vieux Chamonix)

sensitivity. Resonances may lead to the amplification of certain oscillatory modes and the entire behavior of the system may change, becoming more or less predictable. The situation we are confronted with is illustrated schematically in Figure 4. The figure highlights the discrepancy between a simple response to human-induced forcings and the temperature variability recorded during the last century-and-a-half (see Box 1 for explanations).

A simple example of the difficulties in assessing human-induced climate change in the past, and hence predicting it for the future, is given in Figure 5. Valley glaciers in France s Chamonix Valley, and elsewhere in the Alps, have been retreating recently. This retreat, however, is far from unprecedented, as the figure shows. Is the present retreat reversible – as it was in the latter part of the 18th century or the early part of the 20th – or is it not?

Natural Records of Climate Change

John S Perry[1] and Thompson Webb, III[2]
[1]*Alexandria, VA, USA*
[2]*Brown University, Providence, RI, USA*

Climate scientists study records of past climates to better understand natural climate variations and the signi cance of human-induced changes to global and regional climate. Of great importance, data on past climatic variations provide information about a rich array of natural experiments from which insights can be gained into the mechanisms that determine and can change the climate. Data on past climates can also be used to validate explanatory and predictive models of the climate system.

Instrumental records provide information about the climate for only the past century and a half, and for much of this time, station data provide uniform and dense coverage over only a few subcontinental areas. Because of these limitations, the earlier climatic (i.e., paleoclimatic) record must be pieced together by other means. Fortunately, many organisms and natural processes are affected by the climate and have left records that can be deciphered and calibrated to provide proxy records of climate. Historical records also contain many direct and indirect observations about climate. By taking advantage of these non-instrumental sources of climate information, research in many areas of the Earth and life sciences has led to an increasingly comprehensive and reliable base of information describing the history of Earth's climate.

INTRODUCTION

If the Earth had from its birth been covered with a dense network of modern automatic weather stations (perhaps operated by the Martian Weather Service), then the study of past climates would be a simple exercise in arithmetic and bookkeeping. However, such is far from being the case. Even today, with satellites peering at the Earth from all angles, its surface is only incompletely and imperfectly observed. Frustratingly large blank areas persist in global maps of weather observations. As we look back in time, these blanks rapidly become larger, and the coverage of reliable quantitative instrumental data rapidly shrinks to a sparse network of cities and sailing routes. If we seek to look back some hundreds of years, we soon precede the invention of thermometers and barometers and find only a handful of careful observational records from China and the Greco-Roman Empire.

The reconstruction of past climates therefore cannot rely on official observers who used thermometers and carefully filled out observation forms. Other sources of information have to be found and utilized. Through clever analysis, natural records that have long been accumulating can be used to reconstruct past conditions. Rocks have eroded under rain, wind, and ice sheets and glaciers. Dunes, wadis (dry streambeds), and lake deposits grew or waned as deserts advanced and retreated. Glaciers and rivers flowed or shrank. Plants and animals and their associated communities flourished, died, evolved, or migrated as the climate became more or less favorable for their growth. Even atmospheric composition has changed; for example, oxygen was produced as life first evolved (which in turn allowed the UV-absorbing stratospheric ozone layer to form) and then and later the amount of carbon dioxide and other greenhouse gases changed in concentration.

Many of the processes affected by and affecting past climates have left their traces in the world of today, much as even the most careful criminals leave clues at the scene of their crimes. Paleoclimatologists act much like detectives and forensic pathologists in seeking to reconstruct descriptions of past climates. Fortunately, many of the indirect clues left in the Earth s vast storehouse can be related quantitatively to climate variables. Such clues serve as substitutes for the unavailable instrumental records and have therefore been termed *climate proxies*. For example, the width and density of the annual rings in ancient wood yields information on past growth rates, which depended in turn on the temperature and precipitation when the ring formed hundreds and even thousands of years ago. Reliable quantitative data on the geographic distribution of plant, animal, and human populations of the past can also provide valuable insights into past climatic conditions. For example, during the Last Glacial Maximum 21 000 years ago, spruce trees like those growing in central Canada today grew in Kentucky and southern Ohio.

Paleoclimatic data can also aid in the interpretation of recent variations and changes in climate. For example, knowledge of the climate patterns that accompanied past warm periods can suggest how particular climatic features may change as temperatures rise, and may offer useful insights about the specific climate patterns that could accompany global warming (e.g., US/USSR, 1990). The responses of past animal and plant populations to times of rapid climate change may also indicate how rapidly they can adapt to change. Past climate states can also serve

as natural experiments for testing the reliability of the numerical models of the Earth system that are used to predict the future course of climate. Such natural experiments can be selected from times with higher and lower concentrations of greenhouse gases, altered values of seasonal solar radiation, lower and higher sea levels, and more and less abundant ice extent. The ability of models to explain the climates of the past also tells us something about their reliability as guides for projecting climates of the future (Joussame and Taylor, 2000).

The list of data sources employed as paleoclimate observations is long and growing (Ruddiman, 2000). Bradley (1999) broadly categorizes the potential sources of information as: (1) historical documents; (2) geomorphological features such as dunes, glacial moraines, and river terraces; and (3) cores from ice sheets, glaciers, marine sediments, lake sediments, peat deposits, soils, rocks, trees, cave formations, and corals as providing the natural archives in which data on past climates are preserved. Some of these archives, such as rocks, span billions of years with relatively coarse resolution whereas others, such as tree rings, corals, and annually laminated sediments, provide annual records over hundreds to thousands of years. Other articles in this volume touch upon a number of these sources of information; here, we include an illustrative list and provide some information about their interpretation and availability.

HISTORICAL INFORMATION

Historical documents (i.e., written records) contain a wealth of information about past climates and some of the factors (such as volcanic eruptions) that have caused them to change (Bradley and Jones, 1995). Observations of weather and climatic conditions can be found, among other sources, in ships logs, farmers diaries, travelers accounts, newspaper articles, court and church records, and other written material (Lamb, 1982). For example, the dates of ice breakup in harbors, lakes, and rivers have often been recorded for centuries, as have the dates of first and last frosts, flowering, and harvest (*see* Phenology, Volume 2). Tax records indicate when highland farms were flourishing, abandoned, or even covered by glaciers as some Norwegian farm fields were at times during the Little Ice Age extending roughly from 1450–1850 AD (Grove, 1988). Shipping records indicate both weather conditions and the market conditions for weather dependent crops. Reports on the brilliance of past sunsets, especially when available from many locations, can tell of the timing and approximate magnitude of major volcanic eruptions. Even paintings contain clues about the prevailing climate of their period, such as the Breughel paintings of ice covered canals in the Netherlands. When properly evaluated, historical data can yield both qualitative and quantitative information about past climate.

TREE RINGS

Tree rings provide an annual record of local climate during the life of the tree (Fritts, 1976). Many trees are hundreds of years old, and a few live thousands of years. Moreover, much ancient wood is preserved in arid areas, in the beams of buildings and ruins, or petrified, for example, in wetlands. The rings of a tree record the influence of the environment on its growth over the tree s lifetime. In a tree, the cells that will become wood or bark, the cambium, grow in a light layer during late spring/early summer, changing to a dark layer in later summer/early fall. A light and dark ring pair thus represents one year in temperate latitudes. These annual rings can be counted to provide an exact chronology, and because there is more growth under good conditions, the growth patterns can be studied to determine the conditions a tree lived through, such as forest fires, drought, insect attack, or floods. The rings of a tree may be studied in either a cross section of the trunk or a cut of a fallen tree, or in a core taken from a living tree. By matching tree ring sequences from a series of overlapping wood samples, continuous chronologies of climate can be developed extending many centuries to thousands of years into the past. For example, rings from Douglas fir and bristlecone pine yield a continuous record of over 8000 years in the western United States. Quantitative relationships are derived between recent tree ring variations and observed climate; these relationships are then employed to estimate past climatic conditions from ancient trees. In addition to their scientific value, such data have important practical applications because they enable climatologists and hydrologists to extend the instrumental record of precipitation and river flow to produce more representative and reliable statistics for design of dams and irrigation projects.

CORALS

Corals build their hard skeletons from calcium carbonate, a mineral extracted from seawater. Because of variations in growth rates related to temperature and cloud cover conditions, the skeleton formed in the winter has a different density than that formed in the summer. Thus, corals exhibit seasonal growth bands much like those observed in trees. The carbonate contains oxygen and the isotopes of oxygen, as well as trace metals, may be used to determine the temperature of the water in which the coral grew (Dunbar *et al.*, 1996). These temperature recordings can then be used to reconstruct climatic conditions during that period of time that the coral lived. Many corals grow only in shallow waters, and raised terraces of these coral deposits provide definitive indications of past sea levels in coastal regions, such as Barbados and New Guinea, although care must be taken to account for tectonic uplift (*see* Isostasy, Volume 1). The decay of natural radioactive

elements incorporated into the coral permits the age of coral to be determined. Because of the amount of information that can be derived from contemporary and fossil corals, much research attention is being devoted to such studies, and a network of coral cores from all around the world is being established. Data derived from corals has been particularly valuable in studying the variability of the El Niño/Southern Oscillation (ENSO) over time (Dunbar *et al.*, 1996).

FOSSIL POLLEN

Wind pollinated plants produce millions of durable pollen grains to allow for the inefficiency of the fertilization process, and many of these grains end up in lakes and bogs where they are well preserved in the sediments or peats. Palynologists collect cores of these sediments. The cores can be radiocarbon dated and treated with strong acids and bases to dissolve away the sediments, leaving a dated residue rich in pollen. Samples of the residue are then spread on microscope slides. The distinctive shape of each microscopic grain allows each to be counted and identified to the level of genus or family (and sometimes even the species). After 300 or more grains are counted in each sample, the pollen data are then used to estimate the percentage of each taxon present in the sample. From the types of pollen found in each sample, inferences can then be made about the vegetation that produced the pollen and the climatic conditions that allowed the vegetation to grow.

Time series of pollen data covering the last 10 000 or more years are available from all continents excepting Antarctica. The maps of past vegetation and climates constructed from these data show the changing patterns of vegetation since the Last Glacial Maximum for Europe and North America. These maps have been used to check the past climates simulated by climate models for each 3000–5000 year interval over the past at 21 000 years ago. For example, Huntley and Webb (1988) provide descriptions of the interpretive methods and vegetation history for Australia, New Zealand, Eurasia, and North America. Wright *et al.* (1993) used pollen data to reconstruct the climate changes of the past 21 000 years (i.e., since the Last Glacial Maximum) and also to check the results of climate model simulations of these climates.

ICE SHEETS AND GLACIERS

Moraines mark the extent of past ice sheets and glaciers, and, when accurately dated, can be used to construct the size and equatorward or downward extent of these flowing bodies of ice. The growth of the Laurentide and Scandinavian ice sheets to heights of 1–3 kilometers during the Last Glacial Maximum ultimately lowered sea levels by over 100 m. Although the successive advances and retreats of continental ice sheets can wipe away evidence of earlier glaciations, carved landscapes and the rebound rates of formerly glaciated lands can give indications of the mass, flow rates, and duration of such ice masses (Peltier, 1994).

ICE CORES

In mountain glaciers and polar ice caps, snowfall has been accumulating for centuries and millennia. The annually varying deposits of snow gradually become squeezed into thinner and thinner layers of ice as snow continues to accumulate. Layers of ash from dated volcanoes, lead deposited during Greek and Roman times, correlations with climatic variations recorded in other media, and other techniques (in addition to simply counting) can be used to confirm the ages of the various layers.

Drilling as much as 4 km downward through these ice masses, glaciologists have extracted ice cores that can be analyzed for clues about climatic conditions as far back as 420 000 years ago. These ice cores contain dust and tiny bubbles of air entrained in the snowfall from which the ice originated. The isotopic composition of the water making up the ice and the chemical composition of the entrained air can be used to reconstruct the past climatic conditions of the area and the past composition of the atmosphere. The ratio of oxygen isotopes in the ice indicates the temperature at which the snow was formed. The layers of ice and snow that make up glaciers and ice sheets thus form a natural archive of local, regional, and global environmental information (Bradley, 1999; Ruddiman, 2000).

Extensive drilling programs have been conducted in Greenland, Antarctica, and a number of mountain glaciers. Analyses of the ice and the material trapped in it indicate both natural and human made environmental variations over the time period during which the ice has accumulated. Ice core records now extend over time scales up to hundreds of thousands of years. Cores recording conditions going back thousands of years show how the concentration of carbon dioxide has increased from pre-industrial levels of 280 ppmv to current levels of over 360 ppmv, thus revealing the effects of human activities and the burning of fossil fuels. The core extracted at the Vostok station in Antarctica extends back 420 000 years, and reveals swings in temperature and atmospheric carbon dioxide concentration during the last four glacial/interglacial cycles. Such records thus provide powerful evidence for a linkage between carbon dioxide and climate (see Figure 1).

LAKE SEDIMENTS

Large amounts of sediment accumulate in lake basins of the world each year. Most of the sediments come from algae and other plankton that grow in the lake waters each year. Soil, leaves, seeds, and pollen grains also wash into

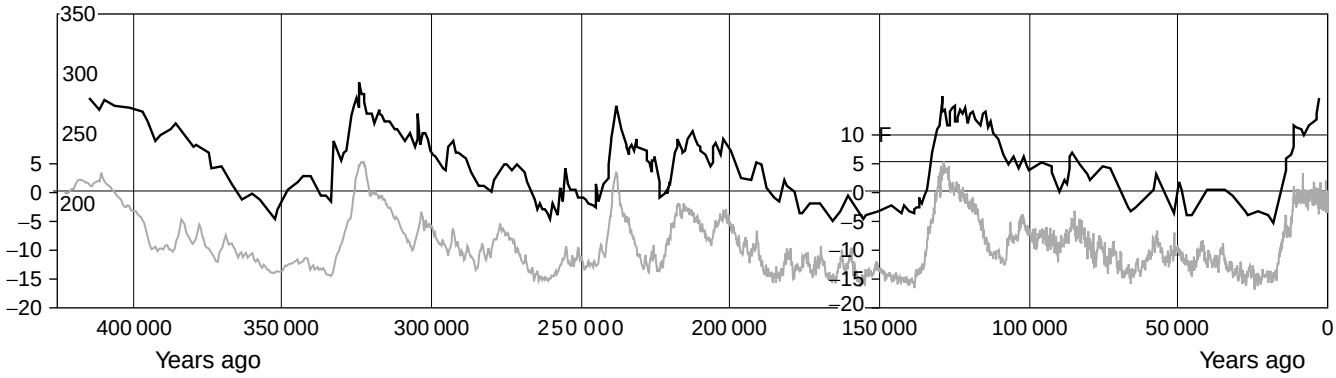

Figure 1 Changes in the global average concentration of carbon dioxide and the local surface air temperature have been reconstructed for the past 420 000 years using information derived from an ice core drilled at the Vostok station in Antarctica (Petit *et al.*, 1999). The local temperature record is derived from measurements of oxygen-18 isotope concentrations in the water frozen as snow. The record shows a series of long-term variations in the lower tropospheric temperature (above the inversion layer) that is similar to changes in solar radiation caused by changes in the Earth's orbit around the Sun. For most of past 420 000 years, temperatures in Antarctica (and by implication the globe) have been lower than recent values. Independent geological evidence indicates that glacial ice amounts peaked on Northern Hemisphere continents during these cold periods, most recently about 20 000 years ago. The very brief warm periods coincide with interglacial periods over the world's continents, with the Eemian interglacial of about 120 000 years ago being the last warm period until the present interglacial started about 10 000 years ago. In the absence of human influences on the climate, models of the advance and retreat of glaciers that include representations of changes in the Earth's orbit, natural variations in atmospheric composition, effects of climate change on land cover, sinking and rising of land areas due to the presence or absence of glaciers, and other factors suggest that the Earth would not return to glacial conditions for many thousands of years (Berger *et al.*, 1999). These studies also suggest that global-scale glaciation would be unlikely if the carbon dioxide concentration is above about 400 ppmv

rivers and lakes. These sediments accumulate millimeter by millimeter, forming a record of the history of environmental conditions in the watershed that feeds the lake. The high organic content of most lake sediments allows for radiocarbon dating back to 40 000 years or more. During the current interglacial of the last 11 500 years, mid-latitude lakes have accumulated sediments at average rates of 70 cm per 1000 years, which is about an order of magnitude faster than sediments are accumulating in the oceans.

In some lakes, the contents and color of sedimentary layers can vary with the seasons and striations are evident. These striations, called varves, are found in both contemporary lakes and in ancient lake sediments that have been converted into sedimentary rock. They allow for studies with annual resolution.

Lakes can often be viewed as giant rain gauges whose water levels record the changing moisture conditions of the watershed and region. Former shorelines can appear like bathtub rings around lakes that are now at lower levels than they were in the past. The Great Salt Lake in Utah is such a lake today. The changing shorelines indicate that the lake was many meters higher when Lake Bonneville existed during the last glacial period. Evidence of changes in the salinity of lakes is another clue to changes in moisture balance. Changes in the composition of diatoms and other plankton can also indicate moisture and water level changes. Continental maps of past lake level changes provide a strong test of climate simulations of past climates (Wright *et al.*, 1993).

OCEAN SEDIMENTS

Billions of tons of sediment accumulate on the seabeds of the world each year. Part of this rain of sediment consists of the remains of tiny zooplankton and algae that inhabit the near surface layers, and the excrement of other organisms that eat them. Just as on land, the particular mixture of plants and animals is dependent on the temperature and other variables, and some species even provide additional clues by, for example, changing which way they coil depending on the temperature. The remains of other bottom living (or benthic) organisms that derive sustenance from the downward flow of detritus can provide clues to deep ocean conditions, which in turn provides clues about the surface climate.

These sediment layers accumulate very slowly, sometimes only a few centimeters per thousand years, but they provide a record of Earth s climate history going back many millions of years. Because the accumulation rate is typically very slow, time markers are based on radiometric dating, on changes in isotope ratios (which can indicate, for example, the amount of glacial ice), and on the alignment of ferromagnetic particles that record reversals in the Earth s magnetic field (the last of which occurred about 700 000 years ago).

Ocean sediment records are particularly useful at deriving long histories of climatic conditions (*see* Earth System History, Volume 1). For example, the international Climate: Long-range Investigation, Mapping and Prediction (CLIMAP) project employed deep sea sediment cores to reconstruct the global pattern of sea surface temperature changes at the peak of the last glaciation, now dated at 21 000 years ago. Mathematical techniques were applied to derive quantitative estimates of surface temperatures from the relative proportions of different species of foraminifera, diatoms, and radiolaria in samples taken from the cores. Spectral analysis of the changes in marine plankton during the last 400 000 years was key to showing that variations in the Earth s orbit pace the glacial interglacial cycles (*see* Imbrie, John, Volume 1).

OTHER DATA SOURCES

This selection of data sources represents only a sampling of the numerous techniques employed to reconstruct the Earth s climatic history. For example, the sedimentary rocks that constitute much of the Earth s crust reveal much information about the chemistry and climate of the periods in which they were deposited. The rise and fall of global sea level as the great ice sheets waxed and waned is recorded in coastal terraces; for example, on Barbados, coral reefs grew during high sea stands and have left terraces as the ocean level fell. The fortuitous slow uplift of the island itself left these terraces as a sort of strip chart recording of glacial/interglacial history. Indeed, virtually any biological organism that has left discernible traces may be investigated as a proxy indicator of climate. For example, European caves inhabited by owls for thousands of years preserve on their floors layers of the tiny bones of the small rodents on which the owls subsisted. Changes in the relative numbers of various species have been correlated with changes in climatic conditions.

CONCLUSION

The billions of years of the Earth s history before the invention of thermometers left no giant filing cabinets of observations. However, the Earth and its inhabitants did leave for us a wealth of records of other kinds. These natural records of past climates vary greatly in their accuracy and resolution, and require great diligence and skill to acquire and interpret. However, they provide powerful searchlights into the obscurity of the past. They permit us to build remarkably detailed pictures of climates very different from our own; pictures that can help us to understand the processes determining the climate of today and to improve our capability to predict the climate of the future (see Ruddiman, 2000; Bradley, 1999; Crowley and North, 1991).

Nitrous Oxide

Nitrous oxide (N_2O) is a radiatively and chemically active gas that is present in the atmosphere in trace amounts.

Nitrous oxide is a natural component of the atmosphere and is a primary source of nitrogen oxides in the stratosphere, where they have an important effect on the concentration of stratospheric ozone. Nitrous oxide is emitted to the atmosphere by a variety of biological sources in the water and soils and also is created as a by-product of atmospheric chemical processes involving the breakdown of ammonia (NH_4) (itself a biological product). Estimates of emissions from these natural sources are approximately 10 teragrams of nitrogen (TgN) per year, with an uncertainty of about 50%. Ice core records indicate that the pre-industrial concentration of nitrous oxide in the atmosphere was approximately 285 parts per billion by volume (ppbv), implying a total atmospheric burden of about 1380 TgN. Dividing the burden by the natural flux gives an atmospheric lifetime of about 140 years, which is in reasonable accord with estimates of the rate of chemical destruction, which give a lifetime in the range of about 120–150 years.

In addition to the natural sources of nitrous oxide, there are sources from human activities. The primary sources are estimated to be agricultural soils (largely as a result of fertilizer application), cattle and feedlots, industrial sources, and biomass burning. Total human-induced emissions are estimated to be about $7\,\mathrm{TgN\,yr^{-1}}$ from natural sources. Consistent with the augmentation of natural emissions, observations indicate that the atmospheric concentration of nitrous oxide has increased to about 315 ppbv. The concentration is slightly higher in the Northern Hemisphere than in the Southern Hemisphere, which is consistent with the human-induced sources being larger in the Northern Hemisphere. As fertilizer is applied more widely, and as climate changes soil conditions, the emissions from human activities are likely to change, and the newest emission scenarios generally project nearly constant or rising emissions during the 21st century. Because of the long lifetime, the nitrous oxide concentration is therefore projected to continue to rise due to human activities.

The increase in the nitrous oxide concentration of about 30 ppbv to date has created a radiative forcing of about $0.15\,\mathrm{W\,m^{-2}}$, which is about equivalent to the contribution from the most important of the chlorofluorocarbons and about 10% of the effect of the rising concentration of carbon dioxide (CO_2). Because nitrous oxide is so closely associated with the production of food and because it has a relatively small influence compared to carbon dioxide, the focus of efforts to limit greenhouse warming has been less intense on nitrous oxide, although it is included in the basket of gases created by the Kyoto Protocol. Nonetheless, there have been efforts to reduce industrial emissions of nitrous oxide as a contribution to the overall effort to limit global warming.

North Atlantic Oscillation

Christof Appenzeller
Swiss Federal Office of Meteorology and Climatology, Zurich, Switzerland

The North Atlantic Oscillation (NAO) is a large-scale uctuation in atmospheric mass and heat that strongly affects the climate of the North Atlantic sector and its surrounding continents. Its impact is strongest in the winter season. During a positive NAO phase the mean westerly winds are increased and the European winters are milder than normal whereas in the western Atlantic cold conditions prevail. In a negative phase the opposite occurs. A remarkable feature of the NAO is its long-term variability, with a tendency towards a more positive phase over the last 30 years. This upward trend in NAO accounts for a good part of the observed surface warming over Eurasia and also contributes to the Northern Hemisphere warming (Hurrell, 1996).

The NAO is defined in terms of an index (Hurrell, 1995) that represents a normalized pressure difference between the high latitude low pressure region centered near Iceland and the high pressure region in the subtropical Atlantic (Figure 1). A large pressure gradient between these two centers indicates stronger than average westerlies across the North Atlantic. This leads to increased flow of relatively warm and moist oceanic air towards the European continent, which in turn leads to warmer winter temperatures in Eurasia and colder conditions over the western Atlantic. Also wetter conditions occur over Iceland and Scandinavia and drier ones over Southern Europe. During negative phases of the NAO, the mild westerlies are reduced and Europe experiences a cold, more continental winter climate. The cold European winters of the 1960s as well as the relatively cold winter of 1995–1996 were associated with negative phases of the NAO, while the warm winters of the late 1980s accompanied positive phases.

NAO-like climate fluctuations can be observed in a large number of key environmental parameters and many of these show distinct changes in recent decades. Examples are changes in storm track intensity and location, in the temperature of the polar stratosphere and the strength of the Earth s ozone shield, in the intensity of ocean convection in the Labrador and Greenland–Iceland sea and its implication for the Gulf stream system, in sea ice cover over the northern North Atlantic and Arctic ocean, in retreat and advances of Scandinavian and Alpine Glaciers, in marine and terrestrial ecosystems such as the distribution of fish and the length of the growing season over Europe. See for example Uppenbrink (1999), and Marshall *et al.* (2000) for further information.

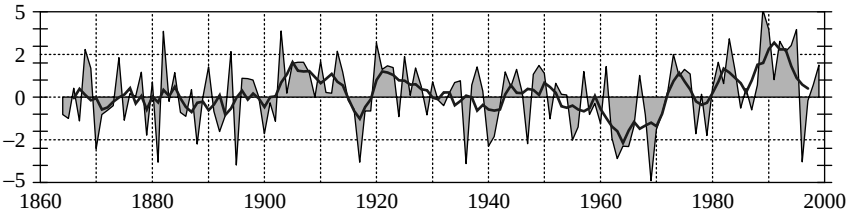

Figure 1 Winter NAO index based on the observed pressure difference between Iceland and Portugal. Data are a December to March average and each station is normalized relative to the period 1864 to 1983. The thick line is a 5 year running average. (Data provided by the Climate Analysis Section, NCAR, Boulder, CO, see also Hurrell (1995))

The NAO index shows both inter-annual and decadal fluctuations. A distinct trend towards more positive NAO values occurred in the decades from 1970 to 1990, with the highest value on the instrumental record occurring in winter 1988–1989. Such decadal climate variability can substantially mask or enhance a human-induced warming trend and can make the detection of the global warming more difficult. Reconstructed NAO indices using paleoclimatic indicators suggest that prolonged positive and negative NAO phases have occurred in the past (Appenzeller *et al.*, 1998). In addition the NAO index took a deep dive in the winter 1995–1996 although it has since returned to more average values. Hence, the fluctuations over the last decades could simply be due to natural variability. On the other hand, numerical as well as observational studies have shown that external climate forcing such as human-made greenhouse gases can affect natural climate variability in a non-linear way, e.g., Palmer (1999). If this is the case the positive NAO trend might be a consequence of global change.

Although the NAO seesaw of cold–warm winters between Iceland and Northern Europe has long been known, a comprehensive knowledge of the mechanisms responsible for this climate oscillation is still lacking. Some modeling and observational evidence supports the idea that the NAO can occur as a purely internal atmospheric process. While such variations could explain the observed coherent spatial structure, it is unlikely that they are a source of energy for the observed variability on multi-annual or longer time scales. Low frequency variability could also be occurring due to coupling of the atmosphere with the underlying ocean. There are clear indications that the temperatures at the surface as well as in the uppermost ocean layer are varying with the NAO. Coupled interaction with the wind-driven gyre circulation or the large-scale thermohaline circulation can also result in NAO-like variability. Hence, the sensitivity of the middle-latitude atmosphere to changes in surface boundary conditions, such as the sea surface temperature in the North Atlantic, the extent of sea-ice or some land property seems to have a controlling effect.

On the other hand, it has been suggested that the NAO should be considered as a sub-part of a more hemispheric pattern referred to as Northern Hemisphere annular mode (NAM) or Arctic oscillation (AO) (*see* Arctic Oscillation, Volume 1). These ideas point in particular to the role of the stratosphere within the climate system. If this is the case chemical and dynamical processes that affect the stratospheric circulation such as volcanic eruptions, ozone depletion or greenhouse gases might also be affecting the NAO long-term variability.

Ocean Circulation

Lynne D Talley

Scripps Institution of Oceanography, University of California, La Jolla, CA, USA

Ocean circulation is one of the major elements of climate, moving heat, freshwater, nutrients and dissolved gases. Ocean circulation at the largest spatial scales and long time scales contains many elements that are in common in the different oceans. Understanding the processes that drive these different elements has progressed a long way and is essential for verifying climate models. The ocean circulation is forced (1) by the winds, through a thin frictional layer called the Ekman layer and through the response of the interior ocean to mass convergences and divergences in this layer, and (2) by heating and cooling that change the temperature and processes that change the amount of fresh water and hence the salinity. The first type of circulation is wind driven and the second is the thermohaline circulation.

The prevailing, large-scale winds of the Earth are trades (easterlies) in the tropics, westerlies at mid-latitudes. The wind-driven ocean circulation that results contains subtropical gyres around ocean high pressure regions and subpolar gyres around low pressure regions. These gyres are asymmetric, with strong western boundary currents (velocities of about $1\,m\,s^{-1}$*) that extend to great depth and relatively weak currents elsewhere. With increasing depth, each subtropical gyre shrinks poleward and westward towards its western boundary current. Shallow eastern boundary currents are created by local upwelling along eastern boundaries, driven by equatorward winds. In the tropics, the trade winds drive westward surface flow and create a strong and very thin eastward-flowing undercurrent on the equator. At the latitude of Drake Passage, between South America and Antarctica, the ocean is open all the way around the Earth. The westerly winds here create the strong, deep-reaching eastward flowing Antarctic Circumpolar Current.*

Except in the strong western boundary currents and the Antarctic Circumpolar Current, the deep flow is driven by thermohaline forcing, in which dense waters are made in isolated locations at high latitudes and spread through the oceans via relatively strong deep western boundary currents, which differ in mechanism and often direction from the wind-driven western boundary currents. Abyssal flow away from the deep western boundary currents is dominated by topography, and is often found to move parallel to the topography, with low pressure in the center.

Ocean currents transport heat from the tropics to the poles. Most of the heat is lost at mid-latitudes, where vigorous western boundary currents bring warm water to the latitude of cold, dry air outbreaks from the continents. This part of the heat transport is associated with the shallowest, wind-driven part of the subtropical gyre circulations (Talley, 1999), where the thermohaline circulation, forced by heating and cooling, is overshadowed by the wind-driven circulation. The deep thermohaline circulation is asymmetric, with deep water formation only in the northern North Atlantic and its adjacent seas and along the margins of Antarctica. No deep water is formed at the sea surface in the North Pacific or northern Indian Ocean. The global thermohaline circulation thus consists of two intersecting cells, one with sinking in the North Atlantic and the other with sinking in the Antarctic.

INTRODUCTION

The circulation of the ocean has been of practical interest to fishermen, traders and navies for as long as humans have gone to sea. As knowledge about ocean currents and capabilities to observe it below the surface grew, curiosity about currents below the sea surface resulted in increasingly detailed descriptions of the ocean as a three dimensional fluid. These observations have led to an improved understanding of the processes that govern the circulation. In this day of concern about the Earth s climate and our burgeoning ability to understand and model it with ever better computer resolution and power, knowledge of ocean circulation is as essential as knowledge of atmospheric circulation and the biosphere. In this article, the basic circulation patterns as we understand them now are described briefly including some historical perspective on this knowledge, followed by a section describing the physical processes that we understand to govern the circulation. In the last section, ideas about the role of ocean circulation in climate are presented.

Fluid flows, including those of the ocean circulation, are continuous and turbulent, and contain a wide range of behaviors from very small waves to the global circulation that is described here. Thus approach them in a simplified way, focusing on the time and space scales for considering the potential for and character of global environmental change. What is described here is often called the *general circulation*, meaning that it is the circulation at the largest space scales and longest time scales. Most elements of the general circulation are nearly unchanging in time within a given major climate regime; while given currents may be somewhat stronger or weaker in different seasons or years, or found in a slightly different location, the currents are always present in some form. Thus, we can hope to understand the underlying reasons for their existence in the present interglacial state and therefore be able to surmise the circulation patterns in other major climate regimes. Based on our understanding of the oceans, we have learned that, even with the massive climate shifts associated with glacial/interglacial switches, the basic elements of the ocean circulation would not have changed, with western boundary currents, wind driven gyres, eastern boundary currents, tropical circulation, and thermohaline circulation driven by dense water formation. However, strengths, depths, and horizontal positions of ocean currents would have shifted with large-scale shifts of wind patterns and changes in the relative strength of thermohaline forcing in each ocean basin. The circulation with quite different ocean geometry resulting from shifting continents can also be surmised given understanding of the processes that govern the present circulation.

The space scales of the ocean circulation range from about 100 km, which is the width of a strong current like the Gulf Stream off the east coast of North America, to several thousand kilometers, which is the width of the gyres that extend across each ocean basin, to global scale. Speeds of horizontal currents range from less than a centimeter per second in some areas of the deep ocean and far from the ocean sides to about $100\,\mathrm{cm\,s^{-1}}$ ($1\,\mathrm{m\,s^{-1}}$) in the strongest currents such as the Gulf Stream. Because the ocean depth averages around 5 km, and is at most about 10 km, the vertical circulation is limited and is in fact so much slower than the horizontal circulation that it is almost impossible to measure. Nevertheless, this very weak vertical circulation can be important for connecting the layers of the ocean, particularly for the circulation forced by water density changes.

Ocean currents are geostrophic (see section on processes below), like the large-scale atmospheric patterns that are associated with high and low pressure centers (*see* Atmospheric Motions, Volume 1). The force due to the difference in pressure pushes water from high to low pressure. However, because the Earth rotates, the water turns to the right in the Northern Hemisphere, and therefore circulates clockwise around high pressure centers and counterclockwise around lows; this tendency is due to the Coriolis acceleration (*see* Coriolis Effect, Volume 1). In the Southern Hemisphere, the water turns to the left and hence flows counterclockwise around lows, etc. High pressure at the sea surface in the ocean is due to water being piled up there, so the sea surface is slightly higher, up to one meter, than in the low pressure regions. Most surface height differences that drive the ocean circulation are much smaller, on the order of 5–10 cm. Spatial atmospheric pressure variations are too small to drive ocean circulation.

The ocean s circulation is forced almost exclusively at the sea surface by the winds and by changes in water density resulting from heating, cooling, evaporation and precipitation. These forcings create the high and low pressures through flows that are not geostrophic. We refer to the first type of forcing as *wind forcing*. The second is often called *buoyancy forcing*, because making water denser makes it less buoyant, or *thermohaline forcing*, because it results from changes in temperature and/or salinity (*see* Thermohaline Circulation, Volume 1). The ocean circulation can be reasonably well separated into portions that result from wind and from thermohaline forcing. Wind driven circulation is mainly confined to ocean basins while some parts of the thermohaline circulation extend from one end of the ocean to the other. Wind forcing dominates the surface circulation and creates the strongest currents, carrying the largest volumes of water, but thermohaline circulation dominates in the deep ocean. The wind driven and thermohaline circulations are of course connected with each other; a given water parcel will be subject to both forcings. The elements of the circulations are described in the next two sections. Our understanding of how the circulation is forced is described in more depth in the section on physical processes.

SURFACE CIRCULATION

The circulation at the ocean s surface is mainly produced by the winds. Mapping attempts have been made throughout the history of navigation, with a major growth in description and insight in the 17th century in the wake of global navigation. An excellent review, replete with reproductions of the significant charts of surface circulation, can be found in Peterson *et al.* (1996). The first to make the connection between winds and ocean currents was the German physician Varen (1622–1650), followed by the first global mapping and description of mid-latitude subtropical gyres in each ocean by the Dutch scholar Vos (1618–1689). Production of various schemes of surface circulation blossomed in the 19th century, with various degrees of realism, following invention of the chronometer and ability to determine longitude. Sobel (1995) provides a popular account of the British government s quest to solve the problem of measuring longitude, and the nearly unrewarded success of British clockmaker John Harrison in his lifelong work on the marine chronometer, a precise clock that worked even on moving and rolling ships.

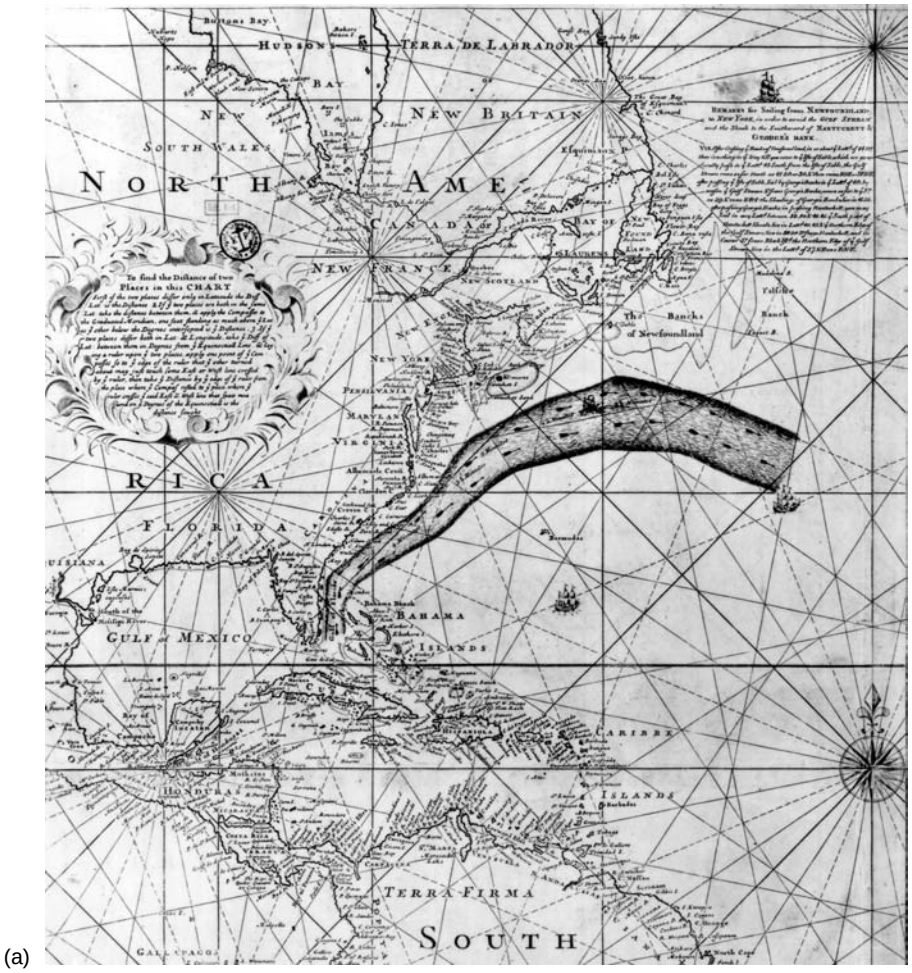
The strongest currents that are part of the general circulation are about $1\,\mathrm{m\,s^{-1}}$, or about 2 knots ($1\,\mathrm{knot} = 1$ nautical mile $\mathrm{h^{-1}}$). Tidal currents can exceed this, but are not found at this strength in the open ocean (*see* Tides, Oceanic, Volume 1). Currents of this strength can impact the progress of ships. An early map of the Gulf Stream (Figure 1a) was produced by Benjamin Franklin for the mail service from Britain to America, based on observations by his cousin Captain Timothy Folger, who was a whaling captain based in Nantucket. The original map was unearthed in an archive in Paris (Richardson, 1980) and is remarkably accurate, unlike a miscopied version that had been widely circulated and which placed the Gulf Stream in the wrong location (*see* Franklin, Benjamin, Volume 1).

The surface circulation for the globe has been summarized in schematic form by Schmitz (1996), and is reproduced here with some changes (Figure 2). Each of the largest ocean basins (North and South Atlantic, North and South Pacific, Indian) has a subtropical gyre, in which the currents circulate clockwise in the Northern Hemisphere and counterclockwise in the Southern Hemisphere. These gyres extend all the way from the western to the eastern boundary. The subtropical gyres are driven by westerly winds at mid-latitudes and easterly trade winds equatorward of about 30 °latitude. The communication of this forcing to the general circulation is roundabout and is described in the section on physical processes below.

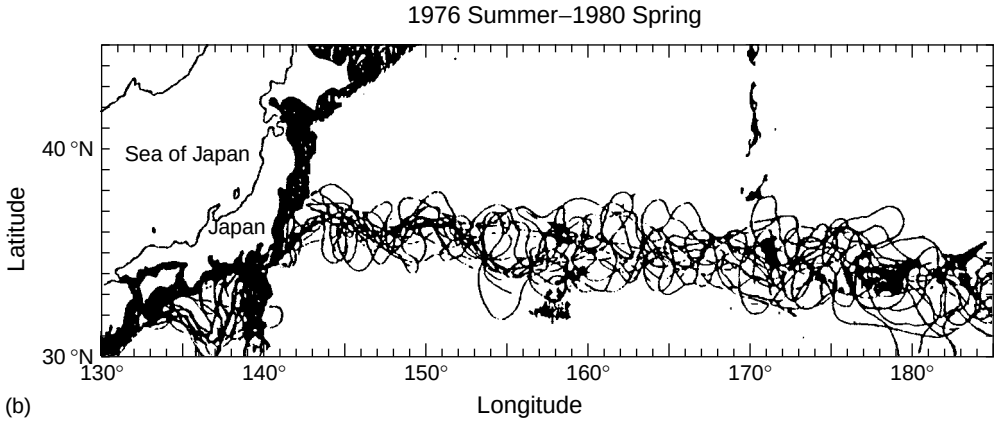
The subtropical gyres are asymmetric; the currents at the western boundaries are much stronger in all oceans than anywhere else in the gyres. These western boundary currents are the fastest currents in the ocean circulation. (Some tidal and strait flows are faster.) The western boundary currents include the Gulf Stream (North Atlantic), the Kuroshio (North Pacific), the Brazil Current (South Atlantic), the East Australia Current (South Pacific) and the Agulhas Current (Indian). All of these subtropical western boundary currents carry warm water away from the tropics towards the cooler regions at mid-latitudes; each loses a tremendous amount of heat during the process. In fact, the ocean s total heat loss is dominated by the losses in these western boundary currents. (The ocean s total heat gain is dominated by input from the Sun in the tropics.) As can be seen from the Franklin Gulf Stream chart (Figure 1a) and the modern satellite image of the Gulf Stream (Figure 1c), the Gulf Stream separates from the coast at North Carolina and moves out into the open ocean, remaining a strong current for a long distance out to sea. This behavior is characteristic of all of the other western boundary currents as well, in that all of them flow strongly along the boundary, then separate and flow offshore as strong and narrow currents for about 1000 km.

Western boundary currents are approximately 100 km in width, even after they separate from the coast and flow out to sea. After the currents leave the coast, they retain their width, but they also meander widely before they finally lose their energy. The meanders fill a wide swath, which for the Gulf Stream is almost exactly the envelope shown in the Franklin/Folger chart (Figure 1a). The meandering paths of the Kuroshio are shown in (Figure 1b). The meanders are about the same length and fill about the same envelope most of the time but are very dynamic, with a time-scale for change of two to four weeks. The meanders pinch off regularly both north and south of the current axis to form rings, which are 100–200 km across (e.g., Gulf Stream rings seen in Figure 1c). The rings that form on the north side of the current contain water from the south, warm side of the current and so are called *warm core rings*, while rings on the south side contain cold water and are called *cold core rings*. The rings generally migrate westward and sometimes rejoin the current.

All of the western boundary currents extend to the ocean bottom when they are along the boundary. The western boundary is not a vertical wall but is rather the continental slope between the land and the abyssal ocean. Before the separation point, the boundary current rides along the slope, not in the deepest water. After separation, the boundary currents flow out into the deeper part of the ocean and many of them then extend down to the ocean bottom at 4000–6000 m due to their tremendous energy. The highest speeds are always at the ocean surface, with decay to very low speeds at depth, reflecting the source of the western boundary currents as part of the wind driven circulation.



(a)



(b)

Figure 1 (a) Map of the Gulf Stream, produced by Benjamin Franklin based on information from Captain Timothy Folger, and rediscovered in a Paris archive by Richardson (1980). (b) Meanders of the Kuroshio after it separates from the Japanese coast (Mizuno and White, 1983). (c) Shown as a bright red band, the Gulf Stream is about 27 °C (~80 F) in this sea surface temperature image of the western North Atlantic during the first week of June 1984. There is a large temperature difference between the Gulf Stream and the surrounding waters and so the current and it meanders and rings are visible in sea surface temperature. This image is based on data from NOAA-7 Advanced Very High Resolution Radiometer (AVHRR) infrared observations. Warmer hues denote warmer temperatures. (Courtesy of O. Brown, R. Evans and M. Carle, University of Miami, Rosenstiel School of Marine and Atmospheric Science, Miami, Florida.)

(c) 
Figure 1 (*Continued*)

While every ocean has a subtropical gyre with a western boundary current, each western boundary current has its own peculiarities, arising from the shape or existence of the western boundary and its intersection with the part of the wind pattern that dictates the separation point (see the section on physical processes below). The Brazil Current of the South Atlantic is the most canonical, following a single boundary until the separation point. The North Pacific s Kuroshio is nearly as simple, although it is complicated along the western boundary because of the numerous island chains and marginal seas. In the North Atlantic, there are actually two subtropical western boundary currents: the Gulf Stream, which we have discussed, and the North Atlantic Current, which is in a sense a continuation of a portion of the Gulf Stream, with the coast of Newfoundland as its western boundary because the winds dictate that the subtropical gyre should extend as far northward as Newfoundland. In the South Pacific, the East Australia Current flows southward to the latitude of New Zealand and then shoots straight eastward across the Tasman Sea to the northern tip of New Zealand, where it then recommences its southward flow for a short distance as a western boundary current before separation. In the Indian Ocean, the Agulhas flows southward to the Cape of Good Hope and would keep going if Africa extended farther south because the wind pattern does not dictate a separation until farther south. So the Agulhas essentially runs past the western boundary and makes a tremendous loop south of Africa back towards the east into the Indian Ocean. This is called the Agulhas retroflection. The retroflection is highly unstable and large rings of Indian Ocean water are produced at the place where it curves back. These rings move westward into the South Atlantic and are a major source of Indian Ocean water for the Atlantic Ocean.

The strength of the western boundary currents is related to the strength of the wind forcing that drives the subtropical gyres. A useful measure of the strength of a current is the total amount of water that it transports, which means looking for the maximum depth and horizontal extent of the current and computing the net flux of water. The transport is the sum (integral) of all of the velocities through a chosen area. The usual unit for ocean transport is the Sverdrup, where 1 Sverdrup $= 1 \times 10^6\,\mathrm{m^3\,s^{-1}}$, which is velocity times area. Subtropical western boundary currents typically carry 60–100 Sverdrups. All of this water must be returned equatorward in the interior of the ocean, away from the boundary, and then rejoin the western boundary current.

Most of the area of the subtropical gyres is occupied by the broad, slow eastward flow on the poleward side of the gyre, broad, slow equatorward flow all the way across the ocean, and broad, slow westward flow on the equatorward side of the gyre. The eastward flows are sometimes referred to as the west wind drift; in the Northern Hemisphere they are also referred to as the North Atlantic Current and the North Pacific Current. The westward flows in both Northern Hemisphere oceans are called the North Equatorial Current, not because they are along the equator but because they are on the tropical side of the gyres. The westward flows in the Southern Hemisphere oceans are called the South Equatorial Current in each ocean. The eastward and westward slow flows are divided at the sea surface by a narrow front called the Subtropical Front, which is at around 30 °latitude.

An important feature of the upper ocean subtropical circulation, called *subduction*, is associated with the density structure of the ocean, in which density increases with depth, and surface density increases with distance from the equator, that is, surface water is warmest in the tropics and colder at higher latitudes. When the warm surface water flows poleward in the western boundary current, it is subjected to intense cooling. The water that emerges from the separated western boundary current is then cooler than the water to the south. This emerging water circulates back towards the south, but when it does so, it encounters warmer surface water. The warming rate at the surface is not large enough to change the temperature and density of this equatorward flow, and so it submerges beneath the lighter surface layers. This process occurs for all waters that enter the subtropical gyres and that must make their way back towards the tropics. The submerging process was named subduction by Luyten *et al.* (1983) who were the first to fully describe the process and provide a theory for it.

Each subtropical gyre has an eastern boundary current as well as a western boundary current. All eastern boundary currents are significantly weaker and much shallower than western boundary currents. In snapshot observations, eastern boundary currents often resemble a string of highly time dependent eddies, with weak flow moving around and between the eddies. Eastern boundary currents are important for the ocean s biological productivity because they are driven by winds that cause upwelling of nutrient rich waters from about 100 m depth, below the sunlit euphotic zone where most ocean life occurs. The upwelled water is also cool, and is responsible for foggy coastal conditions in the eastern boundary regions. The simple theory for eastern boundary currents is included in the section on physical processes below. The eastern boundary currents are: Canary Current (North Atlantic), California Current (North Pacific), Benguela Current (South Atlantic), Peru Current (South Pacific) and the Leeuwin Current (Indian). Alone among the eastern boundary currents, the Leeuwin Current flows poleward, against the flow of the subtropical gyre.

A second major feature of the surface circulation that occurs in most ocean basins is a subpolar gyre. These are counterclockwise circulations found in the North Atlantic and North Pacific, and clockwise circulations in the Weddell

Sea (Atlantic sector of the Antarctic) and Ross Sea (Pacific sector of the Antarctic). The subpolar gyres are driven by westerly winds that are strongest at the subtropical/subpolar gyre and weaker at higher latitudes. The Northern Hemisphere subpolar and subtropical gyres are separated from each other by a narrow front, called the Subarctic or Subpolar Front. The Antarctic region is open to ocean circulation all the way around Antarctica, at the latitude of the maximum westerly winds. A major current, the Antarctic Circumpolar Current, flows eastward around Antarctica at this latitude. Its maximum speeds are about half those of the Gulf Stream. The subpolar circulations in the Southern Hemisphere are south of the Antarctic Circumpolar Current, and are separated from the subtropical circulations by the two main fronts of the Antarctic Circumpolar Current, called the Subantarctic and Polar Fronts (*see* Southern Ocean, Volume 1).

The subpolar gyres, like the subtropical gyres, are asymmetric, with strongest circulation at the western boundary. Subpolar circulation extends more vigorously throughout the gyre to the ocean bottom than does subtropical circulation, and so there tend to be focused currents along all boundaries in subpolar gyres, but the western boundary currents are the strongest. The western boundary current in the Weddell Sea is the simplest, flowing northward along the Antarctic Peninsula. The Ross Sea gyre is less confined by a western boundary and part of the flow continues westward west of the Ross Sea along the coast of Antarctica. The North Atlantic s subpolar gyre has two western boundaries, one along Greenland and the other along Labrador. There are western boundary currents in each of these areas, called the East Greenland Current and the Labrador Current. The North Pacific s subpolar gyre has a leaky boundary due to the many island chains. The main western boundary current is the Oyashio, which flows southward along the southern part of the Kuril Islands and along the coast of Hokkaido before it separates and flows eastward. The western boundary current in the Bering Sea and along the Northern Kuril Islands is referred to as the East Kamchatka Current because it mainly flows along the coast of Kamchatka. There is also a western boundary current along the coast of Sakhalin within the Okhotsk Sea, called the East Sakhalin Current. And finally, the shape of the Gulf of Alaska (the area of the eastern subpolar gyre surrounded by Alaska and Canada) allows a weak western boundary current called the Alaskan Current along the Alaska Peninsula and the eastern Aleutian Islands.

The third major surface circulation feature is the complex circulation in the tropics, which is described separately in the section on tropical circulation, including its vertical structure, which is also complex. At the sea surface, the Pacific and Atlantic tropical circulations include a North Equatorial Current (which was already mentioned as being part of the subtropical gyre circulation and which is not close to being on the equator, but rather is a westward flow north of 10 °N), the North Equatorial Countercurrent (eastward flow at about 5 °N), and the South Equatorial Current (westward flow at the surface on the equator and in the Southern Hemisphere).

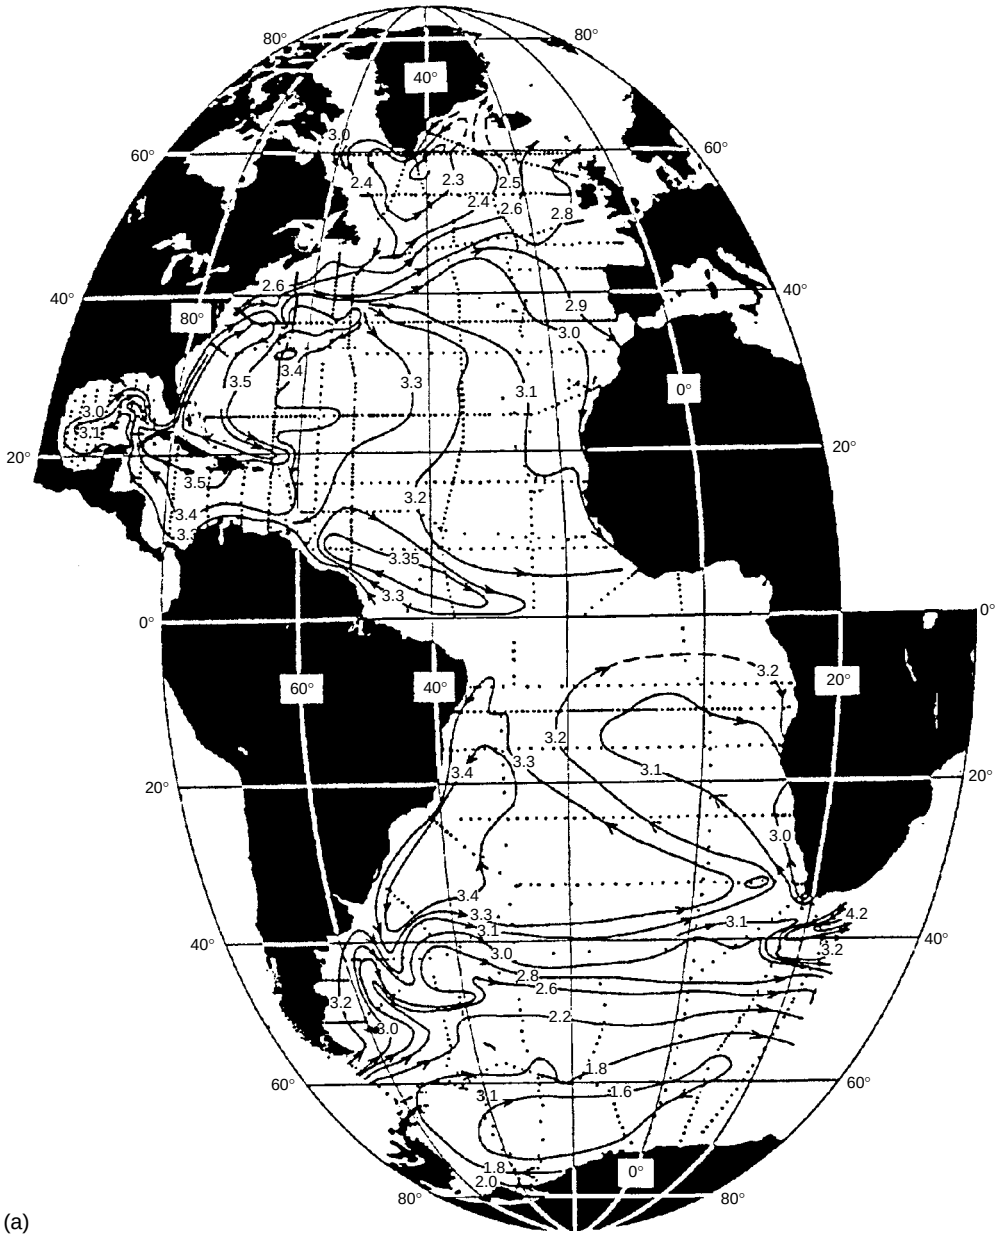
The surface circulation in the tropical Indian Ocean is the most complex of all of the general circulation patterns because it responds to the strong seasonal monsoonal winds, which reverse direction. West of India, in the Arabian Sea, the circulation is clockwise (around a high pressure center) during the southwest monsoon in late summer, i.e., like a normal Northern Hemisphere subtropical gyre. The northward flowing western boundary current is called the Somali Current. During the Northeast Monsoon, which occurs in late winter, the wind blows from the land to the sea and the Arabian Sea circulation is counterclockwise around a low. The Somali Current then reverses direction and flows southward.

Finally for the surface circulation, the connections between basins and gyres are shown in Figure 2. The most important connecting currents for the global ocean circulation are the westward flow from the Pacific to the Indian Ocean through the Indonesian passages, the northward flow from the Pacific to the Arctic through Bering Strait, and the connection of Agulhas Current waters into the South Atlantic s circulation. These flows are not necessarily part of the wind driven circulation, but are part of the shallow portion of the thermohaline circulation, described below.

THE MID-DEPTH CIRCULATION

The surface circulations described in the previous section do not extend unchanged to depth. One major change with increasing depth is that current speeds of the general circulation generally decrease considerably. This is most true for currents that are driven by the winds. There is another part of the circulation that is driven by high latitude cooling and resulting deep convection. These currents, although weak in comparison with the surface flows of western boundary currents such as the Gulf Stream, may be strongest close to the ocean bottom. A second major change is that the gyre circulations shift and shrink with depth. A third major change is that topography becomes more important in steering the flows (most apparently for the abyssal circulation described in the section on deep circulation). And fourthly, the equatorial circulation has a large amount of vertical structure (see section on tropical currents below), differing in this way from circulation outside the tropics.

The mid-depth circulation of the Atlantic and Pacific Oceans, from Reid (1994, 1997) is depicted in Figures 3(b) and 4(b). For comparison, Reid s maps for the surface

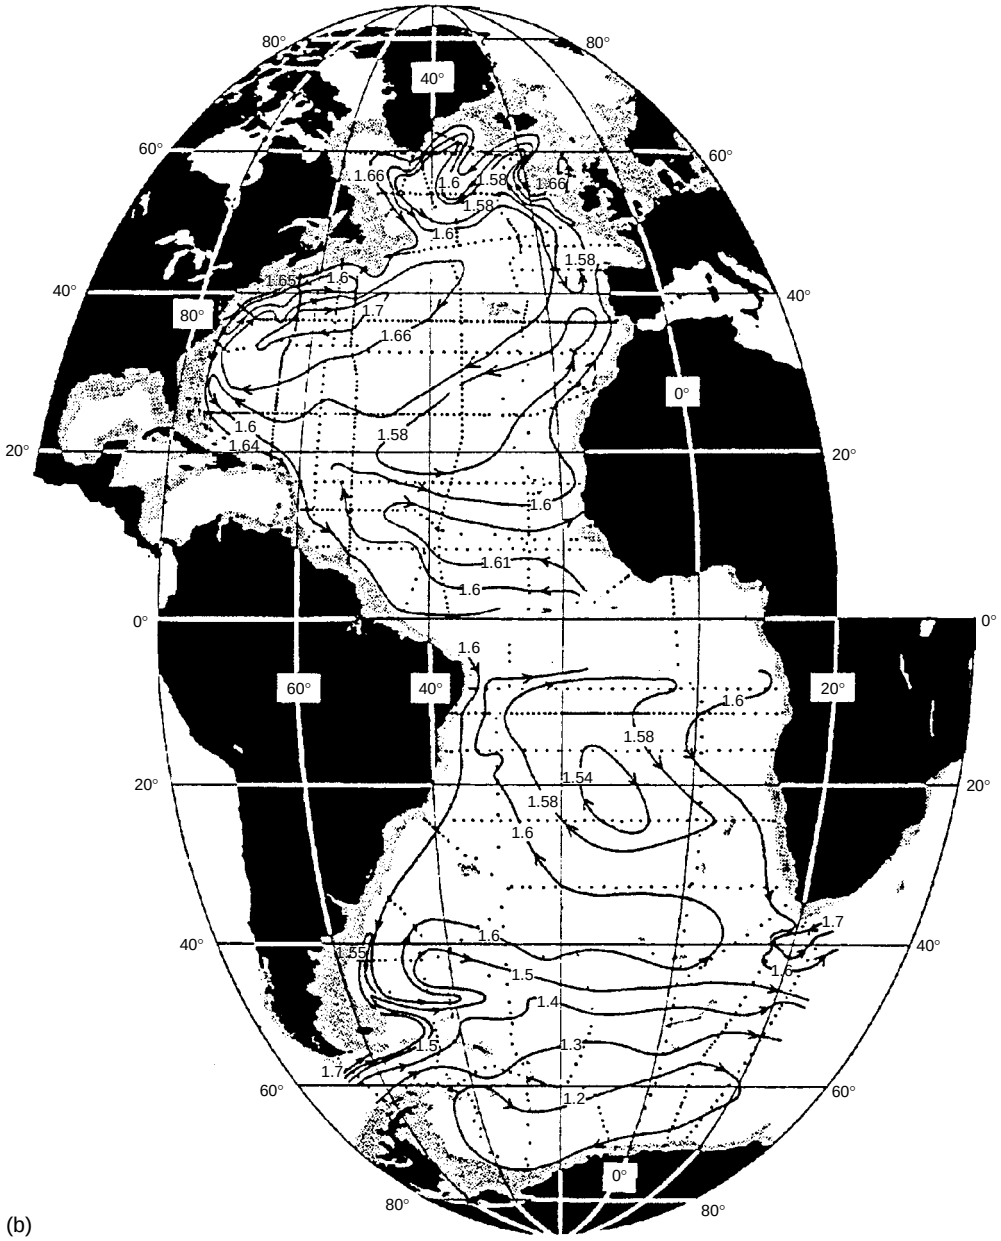


(a)

Figure 3 Depictions of the circulation of the Atlantic Ocean at the (a) sea surface, (b) at 1500 m depth, and (c) at 4000 m depth (all from Reid, 1994). The contoured quantity in each map is called the streamfunction. Where the contoured surface is high is the high pressure region described in the text. The general circulation follows the contours, that is, with flow around the highs and lows. The strength of the currents is proportional to the distance between the curves; the closer they are the stronger the current

circulation are included because the circulations in Figure 2 were schematic. As of now there is no product like those of Figures 3 and 4 for the Indian Ocean, but many of the comments made here about the subsurface circulation apply also to the Indian Ocean.

The subtropical gyres of all of the four basins (North and South Atlantic, North and South Pacific) in Figures 3 and 4 can be seen to have contracted significantly towards the western boundary and also poleward. This contraction begins just below the sea surface, as can be seen in Reid (1994, 1997), where by 200 m depth, the gyres are already considerably smaller than the surface gyres. What is constant with increasing depth in these gyres is the position of the western boundary current and that the gyres remain asymmetric, with the western boundary current still the most vigorous part of the flow.



(b)

Figure 3 (*Continued*)

The subpolar gyres of the North Pacific and North Atlantic also change with depth. According to Reid (1997) the North Pacific s subpolar gyre becomes more strongly confined to the north, with the subtropical gyre shifting farther north with increasing depth. The North Atlantic s subpolar gyre is not very different at 1500 m than at the surface, although the flow is more strongly constrained by topography because the Mid-Atlantic Ridge encroaches on the northern side of the gyre. The Weddell Sea gyre at 1500 m is about half the strength of the surface Weddell gyre, but with no change in location or horizontal extent. The clockwise Ross Sea gyre is not strongly defined at any level in Reid (1997) in that a western boundary current is not indicated, possibly due to lack of observations. However, the clockwise flow is apparent and is little changed in location at 1500 m compared with the surface.

The Antarctic Circumpolar Current is at about the same location at 1500 m as at the sea surface.

Outside the surface intensified gyres, weaker gyre, which, have no parallels at the sea surface appear at 1500 m in Reid s (1994, 1997) analyses. Most of these gyres have not been studied carefully or mapped outside this particular set of studies. Direct observations of flow in most mid-latitude regions, using either current meters or drifting floats, show

(c)

Figure 3 (*Continued*)

that currents are dominated by time dependent eddies rather than by the very slow broad flows depicted in Figures 3 and 4. The primary exception to this eddy dominance is in the tropical region where the flows are nearly due east-west and somewhat faster than in the mid-latitudes (Davis, 1998).

Because the mid-depth circulation outside the tropics is so weak, the most useful measures of its impact and direction may be the total amounts of water moving from one latitude to another, as summarized in the section on global thermohaline circulation.

THE DEEP CIRCULATION

Near the ocean bottom, the topography of the ocean bottom significantly affects the circulation, because the mid-ocean ridges and island chains have larger and larger

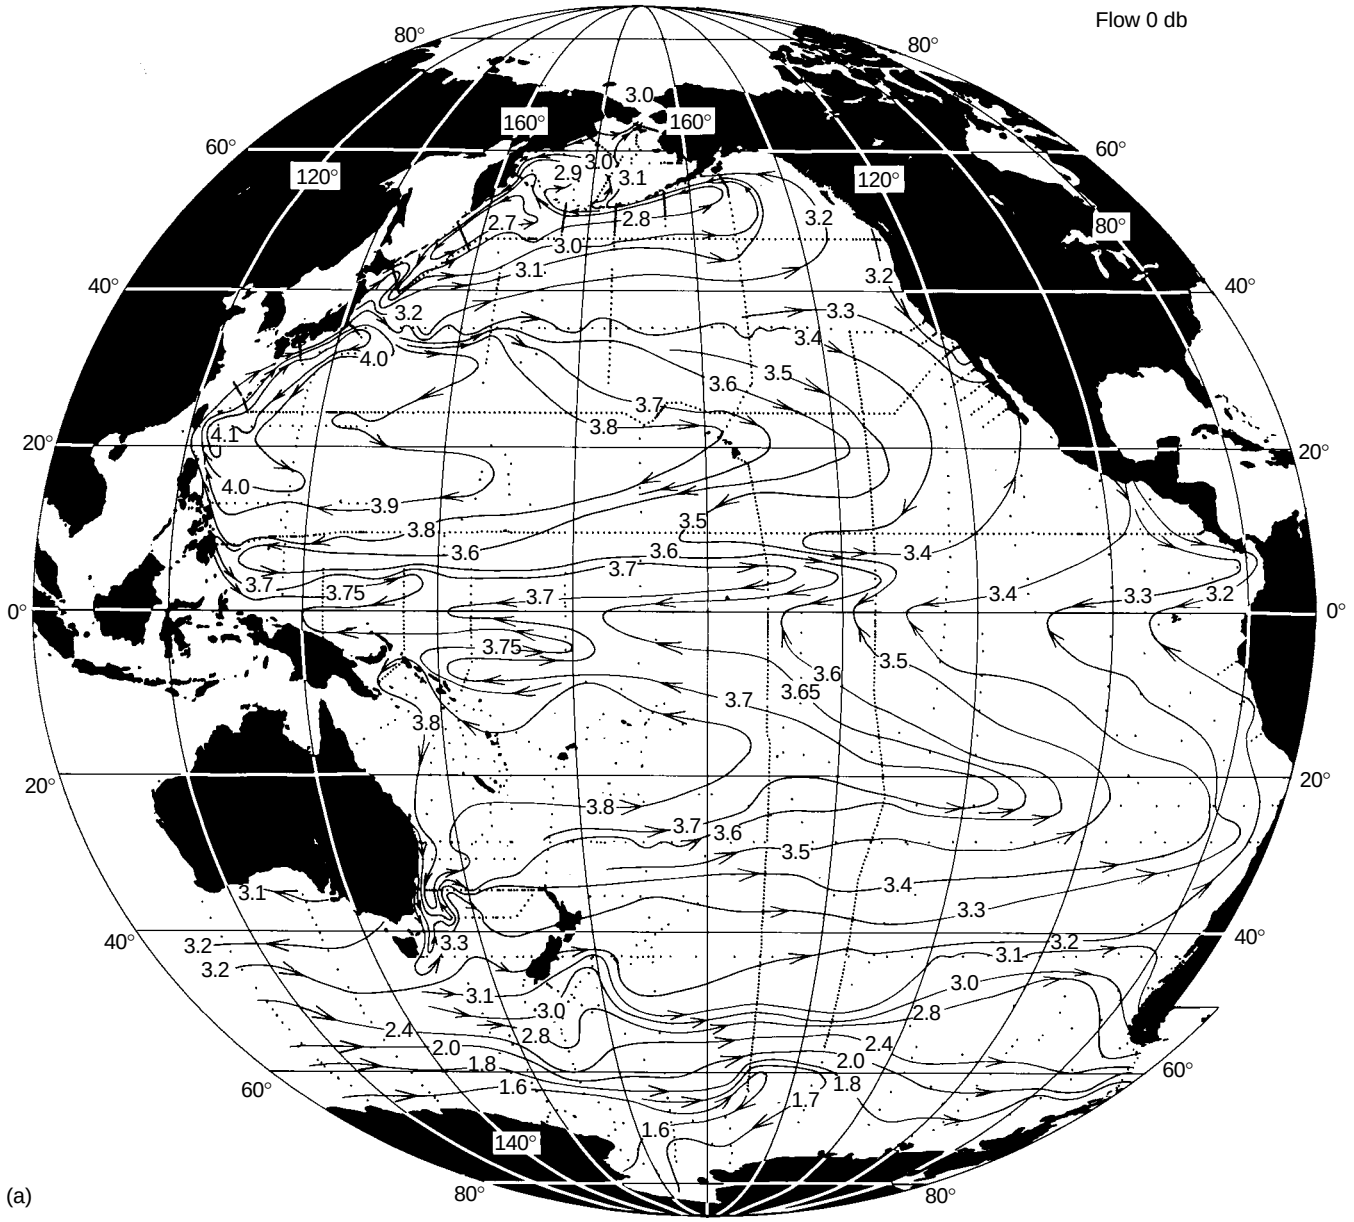


Figure 4 Depictions of the circulation of the Pacific Ocean at the (a) sea surface, (b) at 1500 m depth, and (c) at 4000 m depth, all from Reid (1997). The contoured quantity in each map is the streamfunction. Where the surface is high is the high pressure region described in the text. The general circulation follows the contours, that is, with flow around the highs and lows. The strength of the currents is proportional to the distance between the curves; the closer they are the stronger the current

cross-sections. As seen in Figures 3(c) and 4(c) from Reid (1994, 1997) the subtropical gyres shrink all the way to the western boundary and separation region, where the most vigorous surface currents are found and which therefore penetrate to great depth. The subpolar circulations reach to the ocean bottom, but must wind their way around the various topographic obstacles, particularly in the North Atlantic. The Weddell Sea gyre shrinks to the westernmost part of its basin.

The most significantly different aspects of the abyssal ocean s circulation are concentrated western boundary currents that have nothing to do with the surface intensified gyre s western boundary currents. The clearest of these deep western boundary currents in Figures 3(c) and 4(c) is a southward flow along the western boundary of the Atlantic, extending from the northern subpolar region to South America to about 40 °S. This deep flow was first detected by Wust (1935), although an explanation for

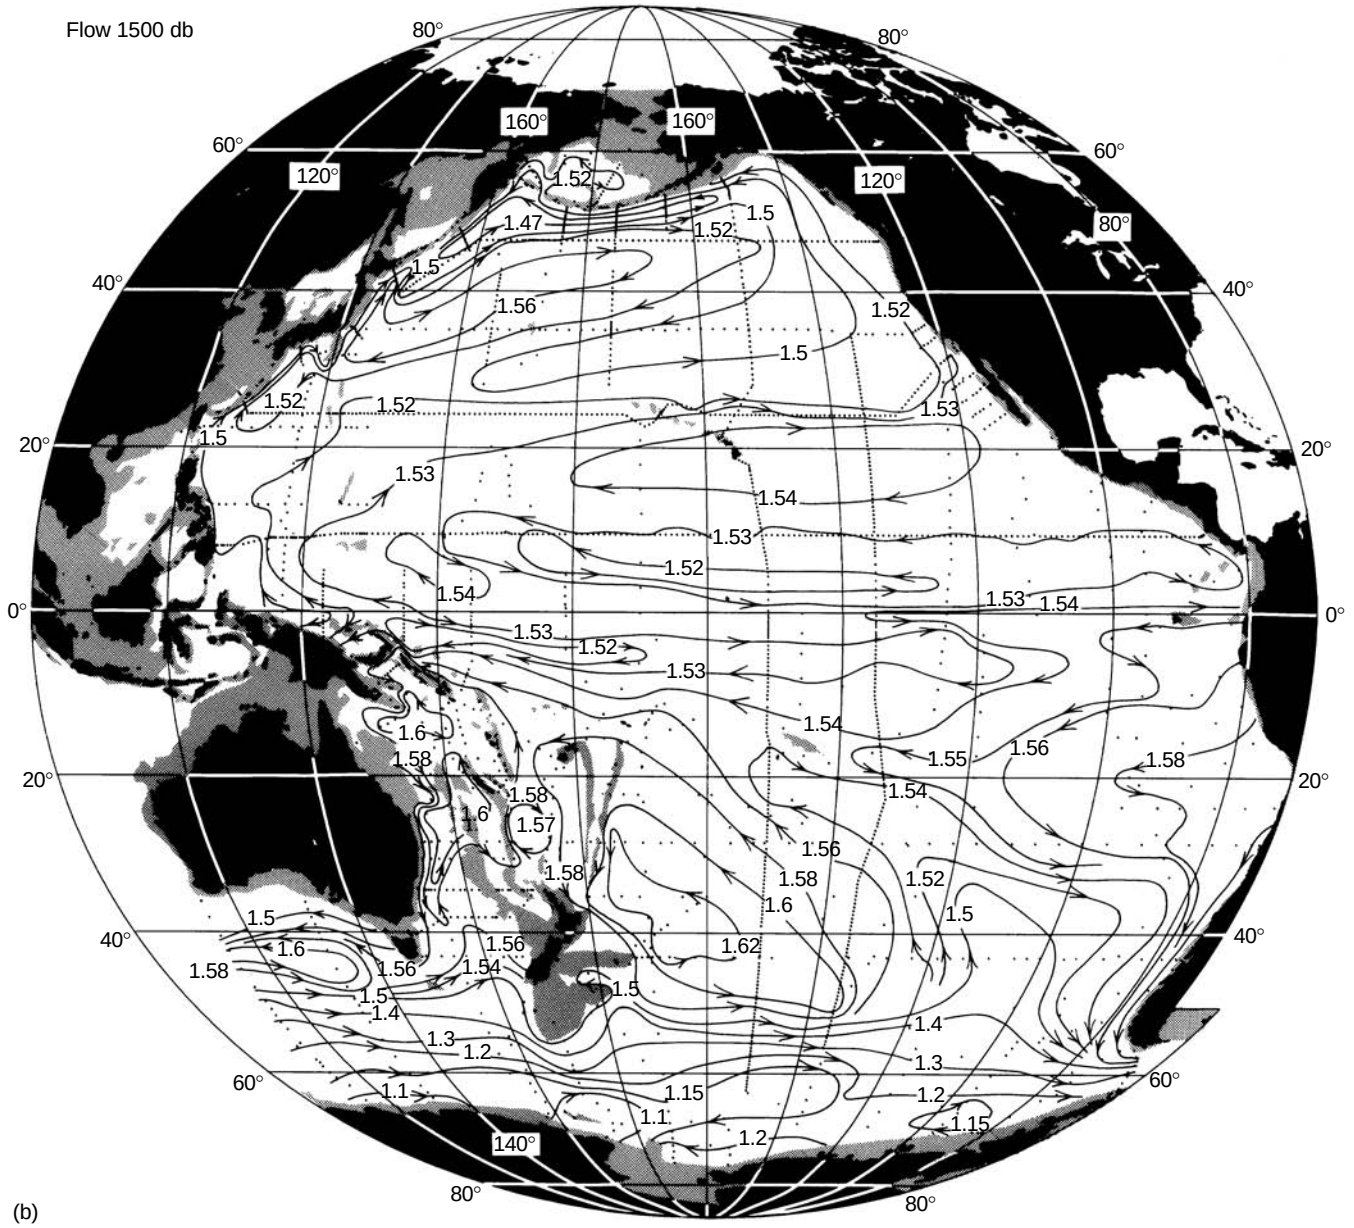

Figure 4 (*Continued*)

its existence did not come along until the early 1960s (Stommel and Arons, 1960). The deep western boundary currents are the most obvious and measurable part of the deep thermohaline circulation, in which deep waters are formed at high latitudes and spread via the boundary currents and very slow interior flow to fill the whole of the deep oceans below about 1500 m depth.

A deep western boundary current flows northward in the Pacific Ocean (Figure 4c), bringing deep water from the Antarctic (of both North Atlantic and Antarctic origin) to the deep South Pacific, across the equator and into the deep North Pacific.

In mid-latitude regions of the Atlantic and South Pacific, the deep flow that is not associated with the deep extension of the subtropical gyres or with the deep western boundary currents tends to be centered around low pressures (counterclockwise in the Northern Hemisphere and clockwise in the Southern Hemisphere), as shown by Reid in the maps reproduced in Figures 3(c) and 4(c).

THE TROPICAL CIRCULATION

The surface circulation in the equatorial Pacific and Atlantic is westward, and is directly connected to the westward

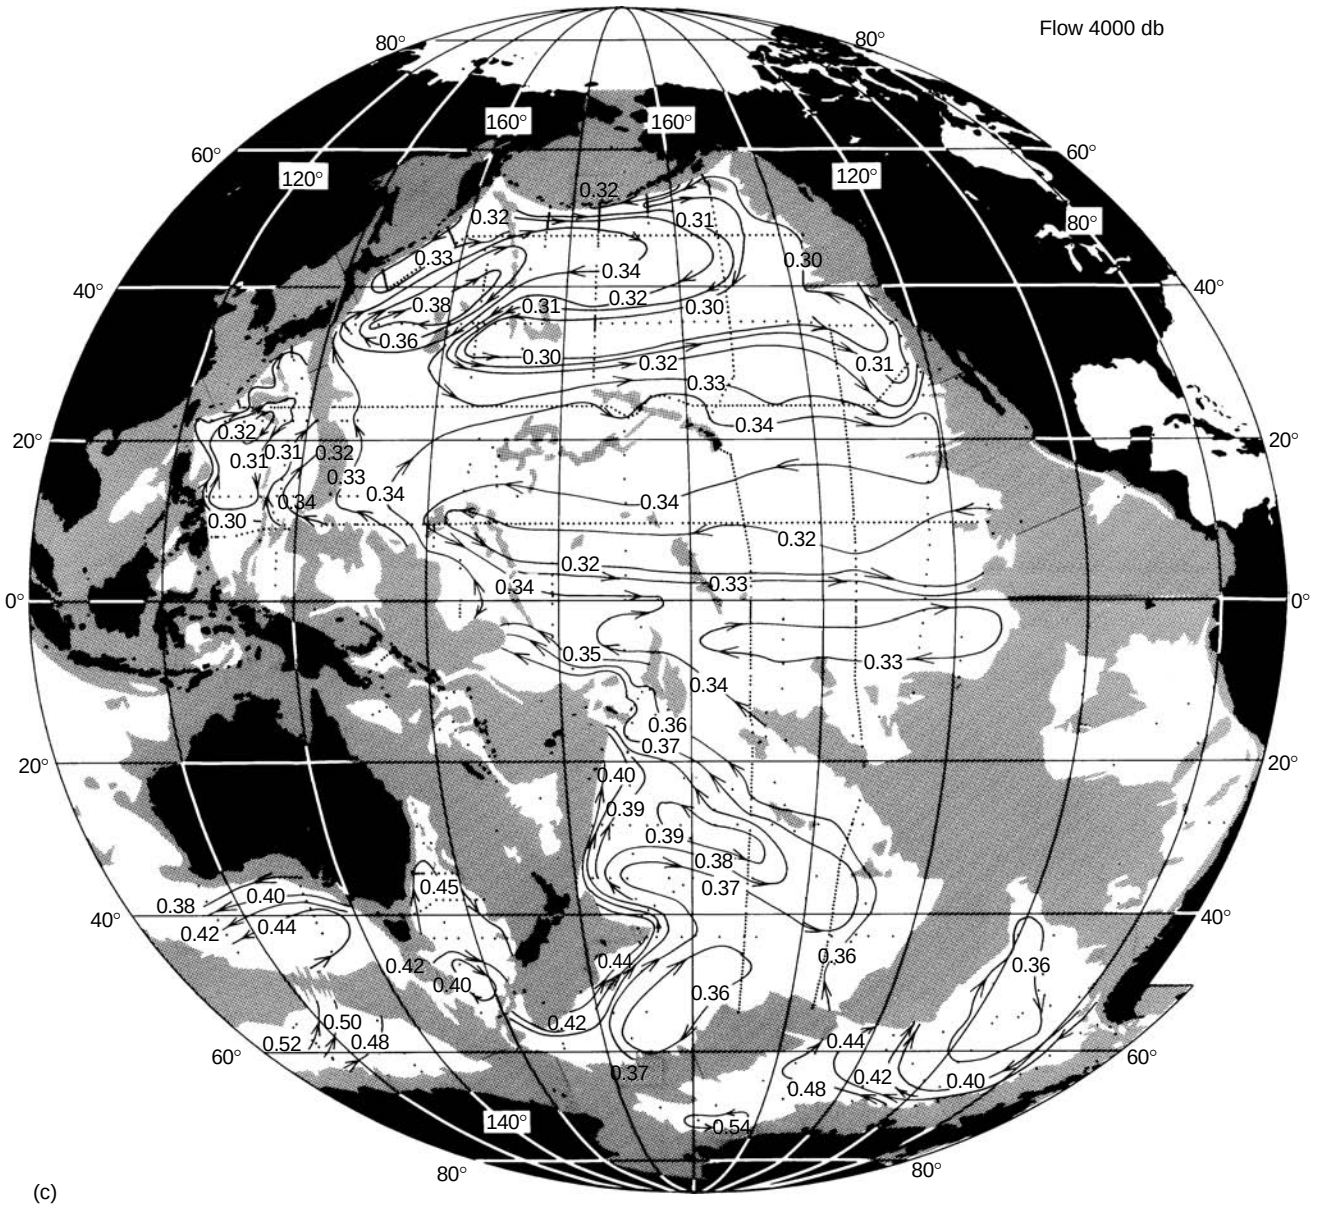

Figure 4 (*Continued*)

flow of the Southern Hemisphere subtropical gyres. The westward surface flow is separated from the Northern Hemisphere subtropical gyres by a narrow and strong eastward flow at about 5 °N, called the North Equatorial Countercurrent. This current probably reaches very deep into the ocean. It is the southern side of a very long and narrow counterclockwise circulation. The Southern Hemisphere does not usually have an equatorial countercurrent because the trade wind pattern is different from the Northern Hemisphere. The difference lies in the average position of the Intertropical Convergence Zone north of the equator, which creates the North Equatorial Countercurrent (*see* Intertropical Convergence Zone (ITCZ), Volume 1).

North of the North Equatorial Countercurrent lies the North Equatorial Current, which is also the westward flow of the subtropical gyre and which was mentioned in the section on surface circulation. The North Equatorial Current flows westward to the western boundary and splits into the northward western boundary current for the subtropical gyres (Gulf Stream and Kuroshio) and into a southward flow for the long, narrow clockwise tropical gyre (Antilles Current in the North Atlantic and Mindanao Current in the North Pacific).

The westward equatorial surface flow is driven by the trade winds (easterlies). When the trade winds weaken or even reverse, the flow of water westward at the equator

weakens or reverses and upwelling weakens or stops. In the Pacific, this is the case during an El Niño (*see* El Niño and La Niña: Causes and Global Consequences, Volume 1). In the Indian Ocean, this change in the trade winds happens twice a year during the transitions between monsoons; when the winds are from the west along the equator, the equatorial surface flow becomes strong and eastward and is referred to as the Wyrtki Jet.

Immediately below the surface currents, the flow directly on the equator is eastward and very strong (greater than $1\,m\,s^{-1}$, that is, even stronger than the Gulf Stream). The strong flow is centered around 150 m depth, and is shallower to the east. It is no more than about 100 m thick and is confined to within 1 °latitude from the equator. This continuous flat ribbon of flow (100 m thick by 200 km wide) is called the Equatorial Undercurrent.

Below the Equatorial Undercurrent, the equatorial currents have complicated structure in the vertical. Immediately below the undercurrent, the flow is westward and is called the Equatorial Intermediate Current. This current extends down to about 900 m depth. Between 900 and 1800 m, the flow reverses direction every 150 m. These are referred to as the stacked jets. Finally at the bottom on the equator is a layer several thousand meters thick that flows eastward (Firing, 1987).

The subsurface flow just north and south of the equator is eastward, down to at least 400 m (Figure 5). These flows are called the North and South Subsurface Countercurrents, or the Tsuchiya Jets. They sometimes appear to be slightly deeper poleward extensions of the Equatorial Undercurrent.

THE GLOBAL THERMOHALINE CIRCULATION

The circulations at individual levels shown in the previous three sections provide a view of the complex horizontal flows that transport waters around the basins. It is difficult from these views to discern the throughputs of water that connect the basins and oceans. However when the ocean s properties are viewed along cross-sections from top to bottom and, say, from the northernmost to the southernmost part of each hemisphere, it is clear that there must be connections between the ocean basins. For instance, north–south cross-sections of salinity through the middle of each ocean in the article on salinity patterns (*see* Salinity Patterns in the Ocean, Volume 1) show that waters can be detected for a long distance from their high or low salinity sources. These properties are carried by the circulation. The circulation that carries water properties from one wind driven regime to another is the thermohaline circulation.

The thermohaline circulation is driven by cooling, evaporation and salinization through sea ice formation, which increases density, and by heating and precipitation, which decrease density. The thermohaline circulation is much weaker than the wind driven circulation and so it is difficult to see its effect on currents in the upper ocean where the wind driven circulation is vigorous. In the deep ocean, the permanent circulation, particularly when quantified by transports of currents carrying water from one region to another, is dominated by thermohaline forcing.

Cooling is probably the most significant of the various processes in driving a discernible, easily quantified circulation. This is because deep convection created by cooling is localized to well-defined regions of the oceans, and produces waters that are injected below the depth of the vigorous part of the wind driven circulation. References to global thermohaline circulation usually mean this mechanism of driving circulation. While cooling at mid-latitudes in the separation regions of the wind driven western boundary currents is enormous, the associated convection is not deep. The cooled waters are not dense enough to penetrate below the thermocline. It is nearly impossible to quantify how much circulation is associated with mid-latitude cooling because the circulation above the thermocline is strong and associated mainly with wind driving. Mid-latitude cooling is, however, an important part of the global heat budget (poleward heat transport), resulting in a shallow overturn, with somewhat cooler waters returning towards the equator, to be heated and returned poleward in the western boundary current.

Evaporation is large in the subtropical gyres, under the atmospheric high pressure zones (*see* Salinity Patterns in the Ocean, Volume 1). As with mid-latitude cooling, the effect of the evaporation can be seen almost exclusively in changes of properties and in calculations of net freshwater transport into the evaporation regions, but not in the effect of evaporation on the circulation itself. On the other hand, brine rejection associated with sea ice formation also increases salinity and is a significant, measurable thermohaline process in producing denser water because it is localized, like high latitude deep convection driven by cooling (*see* Sea Ice, Volume 1).

Globally the heating of the Earth balances cooling. Most heating is in the tropics. This means that deep waters cooled at high latitudes must eventually be heated and returned to the surface. This process is probably distributed over most of the oceans, with deep waters gradually warming by downward mixing of heat until the water parcels rejoin the surface circulation and move to the cooling regions. The upwelling rates are very low and regions of larger and smaller upwelling have yet to be well determined.

Precipitation s role in the thermohaline circulation is mostly to inhibit convection. A large-scale example is the subpolar North Pacific, where the surface layer is relatively fresh due to local precipitation, large amounts of runoff from the coast of North America and sea ice melt in the Bering and Okhotsk Seas. The result is a surface layer that cannot convect through the resulting halocline even when

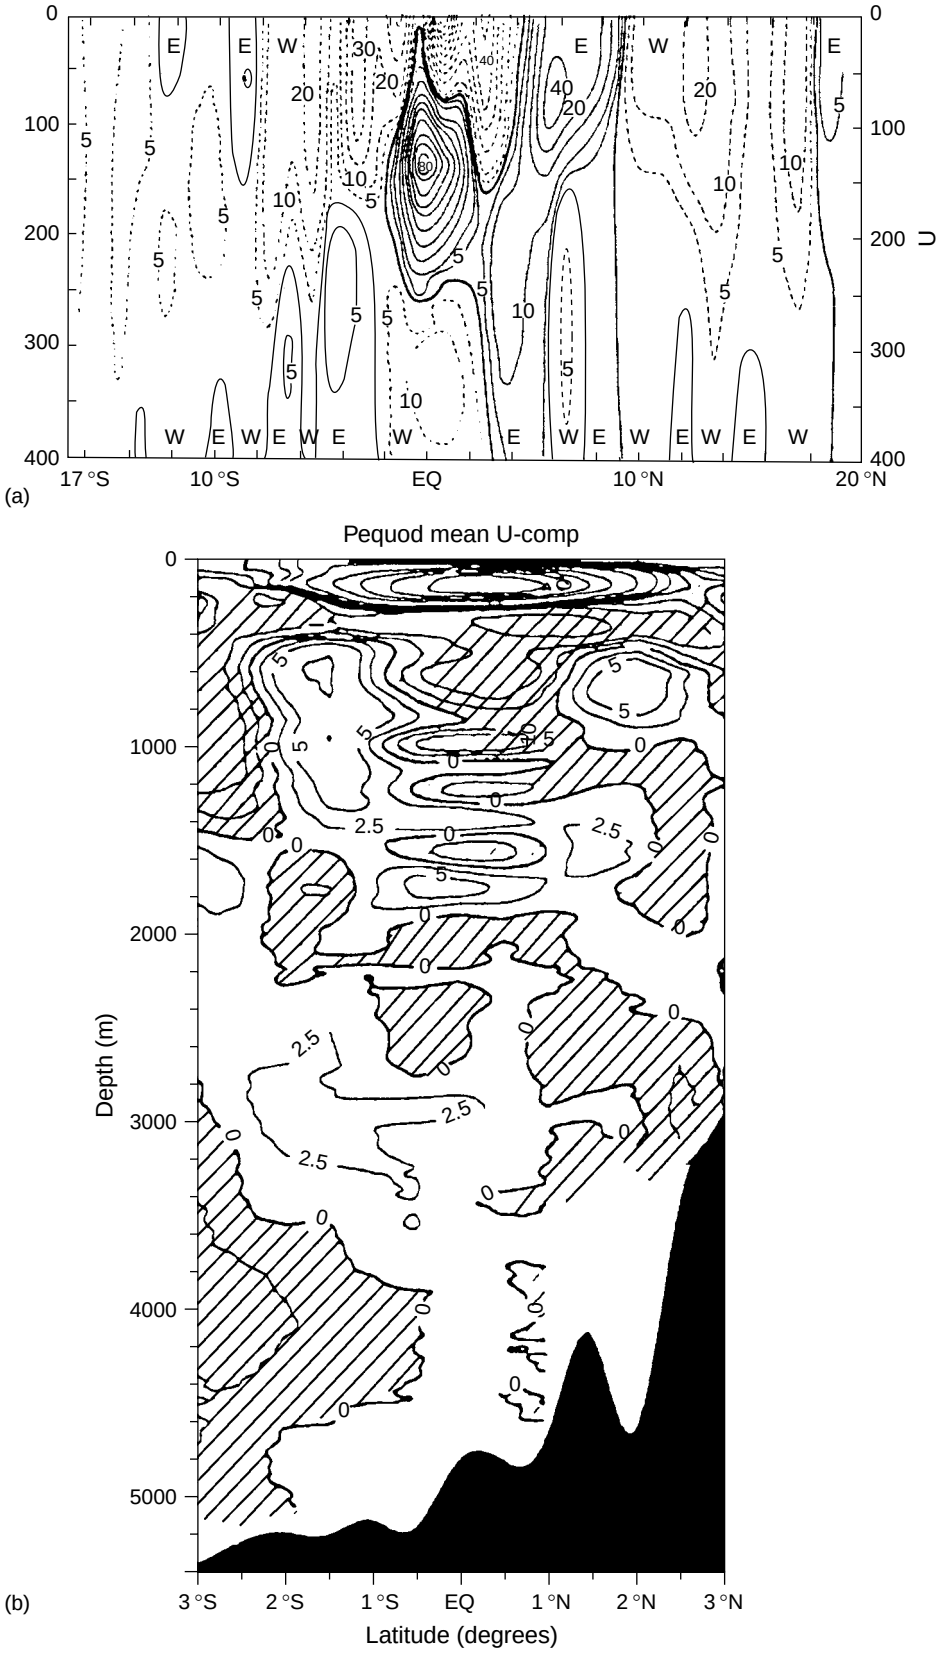

Figure 5 East–west circulation within several degrees of the equator in the central Pacific, based on Wyrtki and Kilonsky (1984) for the upper 1000 m and Firing (1987) for the full water column

the surface temperature is reduced to the freezing point. There are also well-documented events of large (hundreds of square kilometers) patches of low salinity at the sea surface in the subpolar North Atlantic that can inhibit the usual convection as they move slowly counterclockwise with the wind driven circulation (Dickson *et al.*, 1988).

Because the thermohaline circulation is weaker than the wind driven circulation and because it inherently involves overturning, a common way to quantify it is to compute how much water in different layers is transported into and out of given areas. A common choice is to calculate how much water flows northward/southward across an east–west section that goes completely across an ocean basin. For instance, transports are often calculated at 24 °N in the Atlantic and Pacific, where there are data sets that go from coast to coast. To be most meaningful, oceanographers divide the water column up into layers associated with surface waters, thermocline water, and various intermediate and deep layers. The resulting transports can show water moving northward across that latitude in say the uppermost, warm layer, and returning southward in a deep, but not bottom layer.

Transport calculations were introduced above for the wind driven circulation. It was seen above that the wind driven western boundary currents carry about 50–100 Sverdrups. The global thermohaline circulations described here carry about 15–20 Sverdrups, which is considerably less than the wind driven circulation. However, the thermohaline circulation is important because it connects all regions of the global ocean.

The recognizable elements of the thermohaline circulation are the deep western boundary currents, which were mentioned in section 4 in reference to Figures 3(c) and 4(c). The pattern of flow that fills in the interior of the basins from the deep western boundary currents is strongly affected by topography.

There are two global thermohaline circulations involving deep convection at high latitudes: the North Atlantic Deep Water (NADW) and the Antarctic Bottom Water (AABW) cells (Figure 6). These two global overturning circulations are interconnected. Smaller thermohaline cells are more connected with the wind driven circulation and quite complex (see Schmitz, 1995) and will not be described here. NADW and AABW are water masses, that is, particular types of waters that can be recognized by their special properties, such as a salinity maximum (for NADW) or extreme cold temperature (AABW). Because thermohaline circulation involves transformation of surface waters into something else, it is often and perhaps most easily described in terms of the plethora of recognized water masses. Besides the NADW and AABW, we will introduce several other water masses that are associated with the overturning circulations of these two.

The NADW global overturning has sometimes been referred to as the global conveyor belt (Broecker, 1991), referring to its extent from the northern North Atlantic to the Pacific Ocean via the Antarctic, its upwelling, and its return of warm water through the Indonesian archipelago, across the Indian Ocean and back up into the Atlantic (*see* Ocean Conveyor Belt, Volume 1). The actual NADW cell has considerably more detail and many additional elements (Worthington, 1976; Schmitz and McCartney, 1993; Reid and Lynn, 1971; review in Talley, 1996). The NADW cell is depicted reasonably well by Schmitz (1995, 1996) (Figure 6).

The deep water in the NADW cell is formed in the northern North Atlantic. There are three northern North Atlantic sources. First is localized deep convection in the Nordic Seas, which lie north of the sills connecting Greenland, Iceland and Scotland. The renewed Nordic Seas water is dense and plunges over the sills into the subpolar North Atlantic; the most important pathway is through Denmark Strait between Greenland and Iceland. This dense Nordic Sea overflow water (NSOW) reaches the bottom of the northern North Atlantic and flows westward and southward, following the continental slope. The second source is localized intermediate depth convection in the Labrador Sea, between Labrador and Greenland. This area is part of the subpolar North Atlantic. The convected LSW fills the mid-depth of the Labrador Sea and is moved eastward out of the Labrador Sea to fill the subpolar North Atlantic and southward along the continental slope, just above the Nordic Seas water. Together the LSW and Nordic Seas overflow water form the deep western boundary current in the North Atlantic. At mid-latitudes these waters are joined by those from the third source, which is the Mediterranean Sea. Within the Mediterranean, deep convection driven by heat loss and evaporation creates a dense, very saline water that flows back into the North Atlantic, plunging down over the sill at the Strait of Gibraltar and filling intermediate depths at mid-latitudes. This MOW is recognized by its high salinity (*see* Salinity Patterns in the Ocean, Volume 1). The MOW joins the deep western boundary current in the tropics and together the renewed North Atlantic waters flow southward into the South Atlantic as the NADW. By the time they reach the southern South Atlantic, the individual sources of the NADW have mixed together and cannot be recognized; the NADW becomes a generally saline and well-oxygenated water mass.

NADW in the South Atlantic joins the Antarctic Circumpolar Current and flows eastward towards the Indian Ocean. As the NADW is carried eastward in the Antarctic Circumpolar Current, its high salinity gradually becomes fresher through mixing with other waters, but it remains recognizable as a salinity maximum all the way through the Indian and Pacific Oceans. Some of the high salinity water flows northward into the Indian and Pacific Oceans,

and is one of the two major components of the deep water for these oceans. In the Indian Ocean, the northward flow of deep water occurs in three regions, separated by mid-ocean ridges. In the southwestern Indian Ocean, a branch of NADW flows northward into the region east of the Agulhas. In the Pacific Ocean, the main northward flow is just east of New Zealand, in the deep western boundary current described in the section on tropical circulation. This deep flow fills the South Pacific and moves northward through the Samoan Passage into the tropics and then into the North Atlantic.

Where does NADW upwell to eventually complete the circuit back to the northern North Atlantic? This is a very difficult question to answer. Within the North Atlantic, by computing net transports across sections from coast to coast, one can show that the northward warm flow is in the Gulf Stream and is mostly in and above the thermocline. The calculations become more difficult the more removed they are from the North Atlantic. What is clear is that there is no wholesale upwelling in the Pacific Ocean that feeds the warm westward flow through the Indonesian archipelago, as depicted in Broecker (1991) (*see* figure in Thermohaline Circulation, Volume 1). In the Antarctic Circumpolar Current, NADW is joined by bottom waters formed in the Antarctic. These flow together into the deep Indian and Pacific Oceans and both upwell into older deep water layers (between 1500 and 3000 m depth) in those oceans. The IDW and PDW re-enter the Antarctic Circumpolar Current and dilute the NADW there. South of the Antarctic Circumpolar Current, these mingled deep waters upwell to near the surface, only to have some portion convected or salinified through brine rejection to become

deep and bottom waters in the Antarctic (the second major global overturning cell).

Some of the upwelled deep waters might also take part in formation of the thick mixed layer waters just north of the Antarctic Circumpolar Current. These thick mixed layers vary in properties around Antarctica, becoming colder and fresher eastward from South America until reaching their most extreme values just west of Chile (McCartney, 1977). The thick mixed layers in general are called Subantarctic Mode Water (SAMW). The coldest, freshest SAMW is modified by intermediate depth convection just west of Chile and becomes a fresh intermediate water called Antarctic Intermediate Water (AAIW). AAIW fills all of the Southern Hemisphere oceans north of the Antarctic Circumpolar Current, by spreading northward by the broad subtropical gyre circulations. SAMW, which is warmer than AAIW, also spreads northward from the Antarctic Circumpolar Current, via the subtropical gyre circulations.

SAMW and AAIW have three sources: water that flows southward in the Southern Hemisphere s subtropical gyre western boundary currents, water from south of the Antarctic Circumpolar Current that is pushed northward across the current, and upwelling from the underlying deep waters, most likely as the SAMW and AAIW circulate around the subtropical gyres.

Schmitz (1995) shows an upwelling of deep water to intermediate water within the subtropical gyres and then a conversion of intermediate waters to warm upper waters, primarily in the eastern South Pacific and eastern South Atlantic. Many of the conjectures about upwelling are, however, based on mass balances that have significant errors. What Schmitz s (1995) schematics and budgets do clearly show is that the global thermohaline system is fairly complicated.

The second major global overturning circulation is that of AABW (or Lower Circumpolar Deep Water, CDW), with formation of this water in localized regions in the Antarctic (Orsi *et al.*, 1999). Two primary sources of AABW have been found in the Weddell Sea and in the Ross Sea. Both of these areas have clockwise subpolar-type gyres, as described in the first section. Formation is through brine rejection, which occurs during formation of sea ice (*see* Salinity Patterns in the Ocean, Volume 1; Sea Ice, Volume 1). A third distributed source has been found along the Antarctic coast south of Australia (Rintoul, 1998), also presumed to be brine rejection in coastal areas. AABW spreads northward to the Antarctic Circumpolar Current through the gyre circulations south of the current. From the Antarctic Circumpolar Current, it enters the deep Atlantic Ocean as a northward flowing deep western boundary current, beneath the southward flowing deep western boundary current that carries NADW. AABW is the bottom water of the South Atlantic and also of the North Atlantic, extending as far north as Bermuda. By the time it reaches Bermuda, it all upwells into the NADW layer above it, and the bottom waters north of this region are NADW.

In the Indian and Pacific Oceans, AABW flows northward along with the high salinity NADW core that is also within the Antarctic Circumpolar Current. Oceanographers usually do not refer to these cores as AABW or NADW, because they are significantly diluted by the old deep waters from the Indian and Pacific Oceans, which themselves are formed from upwelled AABW and NADW. Throughout its path, AABW upwells into the deep water layer above it, and so it does not fill the northern reaches of either the Atlantic or Pacific Oceans.

What is the warm water return path to the AABW source? As mentioned above, the water that is found at the surface in the Antarctic regions where AABW is formed, is upwelled deep water from the Antarctic Circumpolar Current.

The magnitude of the currents associated with the NADW and AABW overturning circulations is about $5\,\mathrm{cm\,s^{-1}}$. The total transport of NADW out of the North Atlantic is 15–20 Sverdrups. The transport of AABW into the Antarctic Circumpolar Current is not as well measured, but is between 10–30 Sverdrups.

PHYSICAL PROCESSES THAT CREATE THE GENERAL CIRCULATION

Up to this point, the circulation of ocean waters has been described without much mention of the physical processes that oceanographers consider to be central. These are described here. The preceding sections could have been couched in these physical process terms, much as is the description of global circulation and water masses in a recent text by Tomczak and Godfrey (1994) and in a review of what is known about Pacific circulation with emphasis on comparison with theory (Talley, 1995). The central concepts for ocean circulation are: geostrophy, Ekman transport, Sverdrup transport, western boundary current theory, subduction, abyssal circulation theory, and equatorial circulation theory. These are not a complete set of the important concepts, but serve as a framework for much of what was described in the previous sections. Reasonable descriptions of these processes without extensive mathematical formulations can be found in texts such as Tomczak and Godfrey (1994).

A basic tenet for general circulation, which has very large spatial scales except in boundary currents, and long temporal scales, is that friction (viscosity) is very weak. Molecular-scale diffusion is indeed extraordinarily weak compared with the diffusion and friction that would be needed to have any impact on the general circulation. The ocean does have some frictional responses, including the Ekman transport and western boundary current formations described below. Because we observe these behaviors, which occur only in boundary layers at the sides of the

ocean where flow changes rapidly with distance or depth, and because we also observe that most of the ocean acts as if there were no friction, we conclude that something like friction must be acting near boundaries. Based on where the pseudo-frictional behavior occurs, we empirically conclude that small-scale turbulence, and possibly eddies up to a scale of a few kilometers, create something like friction and diffusion for the general circulation.

The most central concept for the general circulation is *geostrophy*, which is a balance between the force resulting from differences in pressure and the Coriolis force resulting from the Earth s rotation (*see* Coriolis Effect, Volume 1). Geostrophic flows in the Northern Hemisphere are always exactly to the right of the pressure difference force, while in the Southern Hemisphere they are always exactly to the left. All general circulation flows, except in the very surface layer (top 50 m) and right on the equator, are geostrophic. Tests of geostrophy using direct current measurements have borne this out. The pressure differences, especially for the upper ocean circulation, arise from differences in sea surface height, which allows more water mass to appear in one place than another. The difference in sea surface height across the strongest currents such as the Gulf Stream are no more than about 1 m and height difference for weaker currents are much smaller. This cannot be measured directly with today s technology. Therefore, we have no direct knowledge of the absolute pressure difference between two points. What we can construct though from the ocean s density distribution is how the pressure differences change with depth, which means that the velocity changes with depth. For instance, for a wind driven circulation such as the Gulf Stream, the velocity is highest at the sea surface, which means that the largest pressure difference is at the surface. Velocity decreases with depth, which has implications for the density distribution with depth, resulting in density surfaces that tilt across the current (see the textbook descriptions). We then must somehow measure or guess the true pressure difference at one reference depth. This is done in many ways, all of which require intensive work.

The second central concept is of *Ekman transport*, which is the flow driven directly by the winds in the surface layer. The winds push on the water through friction, and the frictional flow in the very top layer (say 1–2 m) is conveyed through friction to the next layer and so forth. This downward conveyance of the frictional driving dies out with depth, and vanishes around 50 m. Because of the Earth s rotation, each layer is driven slightly to the right of the one above in the Northern Hemisphere (left in the Southern Hemisphere). If the total flow in this 50 m thick layer, which was first described by Ekman (1905), is added up, the net flow is exactly to the right of the wind (Northern Hemisphere). This net flow is the Ekman transport and is how the wind directly forces the ocean.

Ekman transport has immediate consequences for the ocean when winds blow along a coast. If, as along California, they blow from the north in the Northern Hemisphere, then the Ekman transport is offshore (i.e., to the west), which results in upwelling at the coast to fill in waters pushed westward by the Ekman transport. The upwelled water comes from about 100–200 m depth and brings with it significant nutrients and colder water, as described in the first section. The offshore transport also causes the sea surface to be slightly lower at the coast than offshore, which results in a geostrophic flow along the west coast of North America, creating the California Current, which is the eastern boundary current described in the first section.

In the middle of the oceans, in places where the winds vary with position, the Ekman transport also varies with position. This results in upwelling if the Ekman transport has to be supplied (Ekman divergence), or downwelling if it has to be removed (Ekman convergence). In subtropical gyres, which are driven by westerly (west to east) winds on the higher latitude side and trade winds (east to west) on the lower latitude side, Ekman transport is towards the equator on the higher latitude side and towards the pole on the lower latitude side. This results in downwelling in the gyre. Subpolar gyres on the other hand are characterized by upwelling, which explains their much higher surface nutrient content and hence much higher productivity than subtropical gyres. The biology in surface waters uses up whatever food is available in a short time, and the dead parts and fecal pellets that fall below the surface layer provide nutrients back into the water through bacterial decay.

The surface circulation described in the first section was the purely geostrophic circulation, based on pressure differences and Coriolis acceleration. Ekman transport is not geostrophic, and is superimposed on top of the geostrophic flow. Thus, the surface circulation, as described here, is really more like the true circulation about 50 m below the sea surface, assuming only small changes in the pressure difference force between the surface and 50 m.

The third concept for general circulation is *Sverdrup transport*. This is the reaction of the full water column to Ekman convergence or divergence. When there is Ekman convergence, and hence downwelling, it is as if the whole water column is being squashed. Because the water column is effectively rotating because the Earth is rotating, squashing will cause its rotation rate to flow (much like a spinning ice skater who extends her arms and slows). The rotation rate change is accomplished by the movement of the water column to a different latitude, with slower spinning being towards the equator and faster spinning towards the poles. This response to the winds/Ekman transport was theorized by Sverdrup (1947). Sverdrup transport is geostrophic, i.e., the forcing that causes the northward or southward movement is very small, so that what we actually observe is that

the pressure field is set up to produce geostrophic flow in the correct direction.

Because the average wind patterns for the globe are east–west, the mid-ocean Sverdrup transport tends to be all northward or almost all southward at a given latitude. Therefore Sverdrup transport can work only if there are north–south boundaries along which the flow can return in a narrow boundary current that has different physics from the Sverdrup transport. Support for the Sverdrup transport idea lies in the existence of the subtropical and subpolar gyres, in which flow is equatorward over most of the ocean in Ekman convergent regions, and poleward in Ekman divergent regions. This requirement for boundaries explains why the ocean does not exhibit a clear Sverdrup transport response to the winds in the Antarctic where there is no land (at the latitude of Drake Passage), and why the atmosphere which obeys the same physical laws as the ocean does not exhibit Sverdrup transport.

Narrow western boundary currents are required to return the Sverdrup transport back to its original latitude, to close the mass balance (because there are no holes in the ocean). These boundary currents are always on the western side of the ocean. This is because they are removing energy (or rotation changes) put in by the large-scale winds through the Sverdrup transport. The physics of the boundary currents that dictates that the currents must be on the western side is friction (or viscosity), which can act if there are large changes in flow in a short space scale. In a subtropical gyre of the Northern Hemisphere for instance, the winds put in negative rotation (reducing the rotation), with the response that the water moves equatorward. The water must move back poleward to complete the gyre. This is only possible if there is a source of positive rotation. Friction acting on boundary current at the western wall can input positive rotation because the current will have no velocity at the wall, and maximum velocity at some distance offshore (about 50–100 km). This difference in velocity (zero at the wall and maximum offshore) will thus create positive rotation (think of a paddle wheel sitting in the flow next to the wall) and can balance the Sverdrup transport forcing. The theory of frictional western boundary currents was introduced by Stommel (1948) and Munk (1950) (*see* Munk, Walter, Volume 1). A frictional boundary current on the eastern wall however would have negative rotation with zero velocity at the wall and maximum poleward velocity offshore and so cannot balance the Sverdrup transport forcing. Like Sverdrup transport and unlike Ekman transport, the flow in western boundary currents is almost geostrophic i.e., the frictional part, while important in determining the direction and shape of the flow, is still much weaker than geostrophy, and so it is possible to use estimates of the horizontal changes in pressure to compute the speed of the currents.

Eastern boundary currents are of a completely different nature from western boundary currents, and were explained above when Ekman transport was introduced. They are the geostrophic flow that goes with the coastal upwelling created by offshore Ekman transport (equatorward if there is upwelling and poleward if there is downwelling). Upwelling is very shallow because the ocean is strongly stratified and it is not possible to bring very dense water all the way up to the surface, and so eastern boundary currents are also very shallow.

Returning to the interior circulation of the ocean gyres, we consider again the topic of subduction. As already explained, subduction is a phenomenon in the subtropical gyres in which the cooler surface waters from the higher latitudes in the gyre must be moving equatorward because of the Sverdrup transport. In the steady state ocean circulation, the surface waters are warmer and lighter towards the equator. Because there is no whole scale heating at the sea surface that would change the cooler water into exactly the right warmer waters, the cooler waters subduct beneath the warmer ones. Subduction is the main mechanism for setting the vertical temperature (and salinity) structure in the subtropical gyres, down to the depth of the coldest/densest water that outcrops at the highest latitude of the subtropical gyres. This latitude is around $40-55^{\circ}$ depending on the wind patterns in each of the ocean basins. The subducted waters typically reach no deeper than about 500–1000 m in the centers of the subtropical gyres.

Part of the deep ocean circulation (i.e., the thermohaline part) is driven by sinking of cold, dense water at high latitudes and upwelling of these waters elsewhere. Abyssal circulation theory, introduced by Stommel and Arons (1960), explains the current structure that results from isolated sinks of water, the spread of these waters to fill the oceans, and a general upwelling to return the cold water back to the upper ocean. The latter process must be accompanied by downward diffusion of heat, of course, but is not included explicitly in the Stommel/Arons theory. The crux of their theory is that most of the ocean is responding to the general upwelling, because the sinking is so localized (for the ocean now this would be in the Nordic Seas and the Antarctic). If the upwelling is uniform, i.e., the same size everywhere in the ocean, and if the ocean had a flat bottom, then the upwelling acts on the deep ocean like Ekman divergence, acting to create Sverdrup transport in the wind driven ocean circulation. That is, the response is for the water columns to move poleward (slowly) because their rotation rate is being increased by the upwelling.

There must of course be a connection between the sources of dense water at high latitudes and all of this upwelling and poleward flow. Stommel and Arons showed that the connection is through deep western boundary currents, called deep because this mechanism has to do with circulation in the deep layer fed by the high-latitude

sinking. Because the actual deep ocean is far from flat bottomed, and because the upwelling itself very likely is not uniform (although we do not yet know what its distribution is), the slow poleward flow of the Stommel/Arons theory is not really observed. However, the deep western boundary currents that connect all of the sinking and upwelling together are clearly observed and are the primary evidence that something like their mechanism is at work. Again, as for Sverdrup transport and wind driven western and eastern boundary currents, the abyssal circulation driven through this sinking and upwelling is basically geostrophic.

The equatorial circulation is a special topic because geostrophy breaks down at the equator. The breakdown is apparent because the Coriolis force has one sign in the Northern Hemisphere (flow is to the right of the pressure difference force) and the opposite sign in the Southern Hemisphere (flow to the left of the pressure difference). Right on the equator, the Coriolis force vanishes. Flow directly on the equator responds directly to the pressure difference force and flows from high pressure to low pressure (instead of being geostrophic). The surface frictional flow on the equator is pushed in the direction of the winds (rather than at right angles as in Ekman transport). In the Pacific and Atlantic, the equatorial winds are almost always easterlies (trades), and blow the surface water to the west. In the Indian Ocean, the winds reverse seasonally and sometimes blow the surface water to the west and sometimes to the east. Because all of these oceans have side boundaries at the equator, the wind blown water piles up at the boundary. This creates a sea surface height difference between the western and eastern parts of the oceans. In the Pacific and Atlantic, the water is piled up at the western boundary. This creates a pressure difference force that drives water back towards the eastern boundary. The flow created by this pressure difference force is the equatorial undercurrent.

A small distance away from the equator (within 30 km), the Earth s rotation begins to assert itself on the equatorial circulation. Ekman transport (at right angles to the wind forcing) begins to assert itself and flow also begins to respond geostrophically to pressure differences. The Ekman response to the prevailing trade winds in the Pacific and Atlantic is transport away from the equator both north and south of the equator. This creates upwelling in the equatorial region, which is important for setting sea surface temperature there and hence has a direct impact on climate (see section below).

There are many additional aspects to ocean circulation theory at the equator, including reasons for the existence of such very complicated vertical structure, but there is not room here to go into them because explanations require introducing the very large-scale waves that adjust the ocean circulation to changes in forcing.

THE ROLE OF OCEAN CIRCULATION IN CLIMATE

The ocean affects the atmosphere and hence the Earth s climate by directly heating and cooling the atmosphere. The ocean also affects climate through its effect on the Earth s albedo, which is how strongly the Earth reflects solar radiation back to space, and by its role in greenhouse gas cycles. Climate change also has an expression in the ocean through changes in temperature and salinity distributions, largely due to circulation changes, which in turn affect biological distributions in the ocean.

The circulation, temperature and salinity changes that are associated with present day climate fluctuations, particularly those centered at mid to high latitudes such as the North Atlantic Oscillation and the Arctic Oscillation, are linked to only small perturbations to the general circulation (*see* Arctic Oscillation, Volume 1; North Atlantic Oscillation, Volume 1). The tropical climate fluctuations such as El Niño are associated with relatively larger changes, but even these are only large at the sea surface, with only small changes to the deeper tropical circulation. During the much longer glacial cycles, the circulation can be significantly perturbed, but the basic physical elements described in the section above remain intact even if altered.

Ocean circulation thus affects climate through its influence on sea surface temperature, ice formation, and the upwelling/downwelling that affect greenhouse gas sequestration. The ocean s surface temperature distribution is a major forcing factor for the atmosphere, particularly in the tropics where atmospheric convection to great heights occurs. The ocean has a central role in the tropically centered climate cycle of El Niño (*see* El Niño and La Niña: Causes and Global Consequences, Volume 1). Sea surface temperature in the equatorial oceans is affected by the depth of the thermocline there, by the extent to which there is upwelling of colder waters from below the thermocline, and by east–west circulation that moves warm and cold waters around. The normal trade wind forced Pacific Ocean circulation, with surface waters pushed to the west and upwelling driven mainly by Ekman transport away from the equator, results in warm temperatures in the west and cold in the east. When the trade wind strength is reduced, and winds in the western Pacific even reverse, upwelling is reduced and warm water surges to the central Pacific. This reduces the temperature difference between the western and eastern equatorial regions, which in turn changes the strength and shifts the location of the atmosphere s tropical convective cell (the Walker circulation). This shift in the atmosphere further reduces the trade winds hence the cycle has positive feedback. Similar feedbacks between the ocean and atmosphere are being explored for the tropical Atlantic and Indian Oceans.

Within the lowest layer of the atmosphere the ocean has a major impact on local climate, as clearly seen in coastal

regions. Water has a much larger heat capacity than air, which means that water temperature changes in response to gain or loss of a given amount of heat are much smaller than air temperature changes. Ocean temperatures vary within a much smaller range than air temperatures. Coastal climates have much smaller extremes than inland climates because of this relative oceanic stability.

At mid and high latitudes, the direct feedback of the ocean s surface temperature on climate is less marked because deep atmospheric convection is a tropical phenomenon. The general surface temperature difference from equator to pole, much of which is due to the ocean, drives the atmosphere s Hadley circulation with rising air in the tropics and sinking air at mid-latitudes. The large heat loss from the ocean (heat gain by the atmosphere) within the subtropical western boundary current separation regions affects the major storm tracks. Several climate modeling studies have suggested the importance of mid-latitude ocean temperature distributions in the mid-latitude decadal climate oscillations (e.g., Latif and Barnett, 1994). The lure of using ocean circulation to explain these variations is in the match of the time scale of the oscillations to the time scale of the upper ocean circulation. This takes a decade or two depending on ocean width, with the Pacific width and time scales about twice those of the Atlantic. Mid-latitude temperature distributions are affected by the strength of the western boundary currents, by sequestration of temperature anomalies through subduction in the subtropical gyres with reemergence of the anomalies either in the tropics or at the western boundary, and by westward, slow propagation of large-scale planetary waves that carry information about the ocean s thermocline depth and hence upper ocean temperature distribution.

The ocean s various thermohaline circulations help to redistribute the Earth s heat, with the oceans carrying about one-third to one-half of the Earth s heat from the tropics to the poles and the atmosphere carrying the remainder. Where circulation is dominated by wind driving, such as in the North Pacific, almost all of the heat is carried in the shallow wind driven circulation, and is associated with subduction. Where circulation also has a major thermohaline component, and if the thermohaline component is associated with temperature changes of more than about 5 °C, both the wind driven and thermohaline circulations are important for heat transport. Such is the case in the North Atlantic, where there is both major heat loss in the Gulf Stream separation region, associated with the wind driven subtropical gyre, and heat loss in the eastern subpolar gyre and in the Nordic Seas, associated with the deep thermohaline overturning. Warmth is carried northward by the ocean circulation, and the cooled waters return southward in both the subducted upper layers of the subtropical gyre and in the intermediate and deep waters formed farther north.

Changing sea ice distributions (*see* Sea Ice, Volume 1) may have a stronger effect on climate than mid-latitude sea surface temperature changes, through both the much larger temperature contrast between the ice and water than between different waters and by the role of ice in the Earth s albedo (reflectivity). Sea ice distributions are affected to some extent by ocean circulation. A marked example is in the Nordic Seas between Greenland and Norway and north of Iceland, where warm northward flowing North Atlantic waters keep the eastern part of the Nordic Seas ice-free all year round. An increase in the flow would decrease the sea ice area and move the ice edge. During glacial periods, sea ice extended much farther equatorward and the atmospheric circulation would have had significantly different strength as a result.

Within the ocean, climate change, including interannual and decadal variations as well as much longer time scales, has a demonstrable effect on local biological productivity and species distribution. In the North Atlantic for instance, observed changes in temperature in the subpolar gyre over the past 100 years have had major consequences for fisheries, particularly spawning grounds which depend on temperature (Dickson *et al.*, 1988). In the North Pacific, El Niño changes the temperature distribution of the tropical and eastern boundary regions, including flow of warmer waters poleward along the eastern boundaries, which brings tropical species to higher latitudes, and which reduces the efficiency of local upwelling and hence reduces nutrient supply to the local fisheries.

At the western boundary of the North Pacific, the position of the subpolar western boundary current separation (that is, maximum southward intrusion of Oyashio waters) is carefully monitored by Japanese fisheries agencies because of the profound impact of presence or absence of the nutrient rich Oyashio waters. Within the subpolar North Pacific, the position of the subarctic front also has a large impact on fisheries, because of the large-scale upwelling of the subpolar gyre north of the front. The latitude at which the subpolar and subtropical gyre circulations split in the eastern North Pacific impacts the paths followed by returning spawning salmon. (North of Vancouver Island the fish belong to Canadian fisherman and south of Vancouver Island they belong to US fisherman.) Many other examples of how ocean and circulation changes impact biota abound, including in paleooceanographic studies, in which changes in marine species are used to reconstruct past ocean circulations.

The role of the ocean circulation in climate was the main subject of the international World Ocean Circulation Experiment (WOCE), whose field study phase was 1991–1998, and which has sponsored major advances in general circulation modeling and ocean data assimilation (*see* WOCE (World Ocean Circulation Experiment), Volume 1). Because it was recognized that the general circulation, as it exists today, is central to climate, much of WOCE dwelt on describing and modeling the present ocean circulation. WOCE results have been reported in several thousand scientific publications, and

have been summarized in a recent book (Siedler *et al.*, 2001). The WOCE data sets and model advances will be used for decades to come to continue to advance understanding of the general circulation and to provide necessary checks for climate models, which couple all of the relevant systems; atmosphere, ocean, land, and biology.

Ocean Conveyor Belt

The global-scale thermohaline circulation of the world ocean has been termed the *ocean conveyor belt*, because it forms a continuous loop carrying water and its properties around the world (Gordon, 1986; Broecker, 1991), see Figure 1. A description may conveniently begin in the

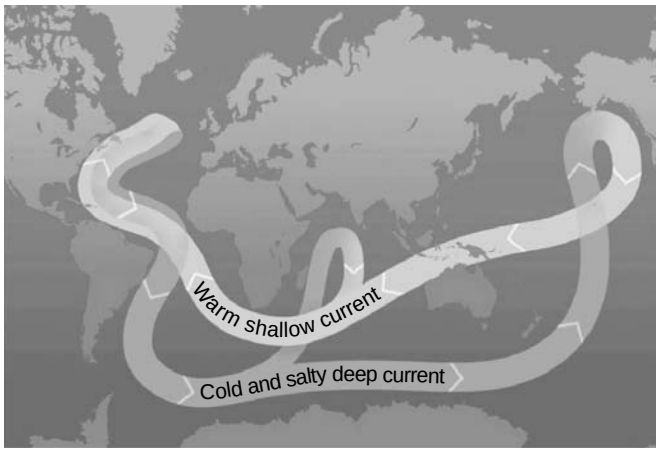

Figure 1 The ocean plays a major role in the distribution of the planet's heat through deep sea circulation. This simplified illustration shows this *conveyor belt* circulation, which is driven by differences in heat and salinity. Records of past climate suggest that there is some chance that this circulation could be altered by the changes projected in many climate models, with impacts to climate throughout lands bordering the North Atlantic. (Redrawn from Broecker, 1991)

North Atlantic, where the well-known Gulf Stream carries northward relatively warm and salty surface waters that are formed, in large part, in the Mediterranean and the subtropical Atlantic Ocean. In the sea between Norway and Greenland, Arctic winds cause evaporation and chilling. The heat and moisture transferred to the air warm Europe and provide its precipitation, particularly during the winter. The waters are also made saltier as a result of brine rejection during ice formation (*see* Ocean Circulation, Volume 1; Salinity Patterns in the Ocean, Volume 1).

The resulting cold, salty, and therefore dense water sinks to become an immense southward-flowing stream of North Atlantic deep water. Because of the Earth s rotation, this deep-ocean current hugs the western edge of the Atlantic basin, running southward under the northward moving Gulf Stream that occupies the upper ocean layer. The cold, deep water continues to flow southward into the South Atlantic, where it joins with even colder, dense, oxygen-rich water sinking from the seas bordering Antarctica to form a pool of circumpolar deep water (*see* Southern Ocean, Volume 1).

Two branches of the global circulation emerge from this Antarctic abyss. One branch flows northward along the eastern coast of Africa to mix with the waters of the Indian Ocean. The other continues around the eastern coast of Australia and then northward, eventually mixing upward with surface waters in the tropical and North Pacific. The surface waters in the Pacific Ocean then move equatorward, then westward, driven by the trade winds through the Indonesian Archipelago, across the South Indian Ocean, around the Cape of Good Hope, and ultimately back into the equatorial Atlantic, where the waters are taken up by the Gulf Stream and begin another round the world, thousand-year excursion.

Because of the heat provided to Europe in the North Atlantic region and the nutrients carried upward as deep waters rise in the tropical and North Pacific, variations in the strength and path of this conveyor system could have major implications for regional and global climates. During glacial periods, as ice covered the North Atlantic, the Gulf Stream shifted location and moved across the Atlantic toward France, thereby contributing to the chilling and glaciation of northern Europe. There is also emerging evidence that a sudden slowdown in the thermohaline circulation contributed to the return of glacial conditions to Europe during the Younger Dryas about 11 000 years ago (*see* Younger Dryas, Volume 1). It has been suggested that the slowdown occurred because of a sudden release of glacial meltwaters just before the Younger Dryas, and that these waters freshened the North Atlantic and thereby stopped the downward push by dense, salty waters that drives the global thermohaline circulation.

That the thermohaline circulation has changed in the past has raised questions about how it might change in the future (e.g., Calvin, 1998). In contrast to the freshening mechanism that caused the Younger Dryas, it is suggested that future freshening could result from the sharp increase in high-latitude precipitation (and ensuing increased river runoff) that are projected as the world warms, and from an increase in the rate of glacial calving from Greenland. Many of the coupled ocean–atmosphere model simulations of potential climate change during the 21st century project a slowing down of the thermohaline circulation (Cubasch and Meehl, 2001), with some indication that the likelihood and magnitude of the reduction in strength increase as the rate of change in carbon dioxide concentration increases. Such a slowdown would reduce the amount of warming over Europe and the North Atlantic. While no models currently show a complete collapse of the thermohaline circulation during the 21st century, there is a possibility that such a flip-flop could occur at later times if the emissions of greenhouse gases continue to grow at high rates.

Ocean Drilling Program

The *Ocean Drilling Program* (ODP) is an international partnership of scientists and research institutions organized to explore the evolution and structure of Earth. ODP provides researchers around the world with access to a vast repository of geological and environmental information recorded far below the ocean surface in seafloor sediments and rocks. By studying ODP data we gain a better understanding of Earth s past, present, and future.

The drill ship, *JOIDES Resolution*, is the centerpiece of the ODP. With this ship, ODP can drill cores (long cylinders of sediment and rock) in water depths up to 8.2 km. Built in 1978 in Halifax, Nova Scotia, the drill ship was originally a conventional oil drilling ship. She was refitted in 1984 and is now equipped with some of the world s finest shipboard laboratories. The ship s complement for each cruise is a mixture of 30 scientists from around the world, 20 engineers and technicians, and a crew (including drilling personnel) of 52.

Each year JOIDES Resolution departs on six scientific expeditions, each approximately 2 months in length. Every expedition has specific scientific goals chosen through a careful review process. The research ship has drilled in the Atlantic, Pacific, Indian, and Arctic Oceans. Since January 1985, ODP has recovered more than 160 000 m of cores. Upon completion of an expedition, the cores are transported to one of four repositories for curation, storage, and future research. ODP scientists are able to use these repositories much as the general public uses a library. For further information, see http://www.oceandrilling.org.

Ocean Observing Techniques

Robert A Weller

Woods Hole Oceanographic Institution, Woods Hole, MA, USA

Ocean observations are essential to understanding the ocean's role in climate, particularly how it transports and stores heat, freshwater, and carbon dioxide (CO_2). The principal observations being made are of temperature, salinity, and ocean currents. Vertical pro les and time series are collected using pro lers and moorings so that the transport and storage of heat and freshwater by the ocean can be determined. Additional observations are made of chemical tracers, nutrients, and other quantities to elucidate biological, chemical, and geological as well as physical pathways and processes in the ocean. To date, the ocean has been sparsely sampled, and an international effort is underway to institute comprehensive global ocean observations.

Several characteristics of the ocean guide our choice of what to measure and of the methods chosen when making observations in support of understanding and predicting change in the ocean and how that change impacts the global climate system. First, the ocean is a large reservoir, covering about 70% of the Earth s surface, with great capacity to store and transport heat and climatically important compounds such as carbon dioxide (CO_2). Second, the entire oceanic volume is not, however, in immediate contact with the atmosphere. Generally, a shallow, warm and buoyant layer several tens to one hundred meters thick is found at the surface. This plays an important role in short-term atmosphere–ocean interaction while also insulating the interior of the ocean. Third, the ocean has a complex, three-dimensional circulation that impacts global climate over a wide range of time scales (*see* Ocean Circulation, Volume 1). Horizontal flows in the surface layer can be strong, up to several meters per second, and can move warm water from the tropics to higher latitudes. Surface water can also be exchanged with water in the interior, sinking rapidly in some locations when strongly cooled by the atmosphere, but more typically moving much more slowly along three-dimensional pathways that take several years to exchange surface water with intermediate depths and up to hundreds of years to reach the deepest basins. Finally, the ocean is a challenging environment for observations. Seawater is corrosive. Biofouling and vandalism damage instrumentation. Much of the ocean is remote and seldom visited, and the radio telemetry that we rely on in space exploration cannot be used. Because radio waves do not penetrate, oceanographic remote sensing is largely limited to the use of sound and instruments placed deep in the ocean have had to record their data for later recovery.

The upper ocean has been the focus for most observations, in part motivated by the potential for improvements in weather prediction as well as climate models and also because of ease of access. Observations of the intermediate and deep regions are not routine and have been made mainly during oceanographic research programs. The majority of ocean observations to date have been of the physical variables, temperature and salinity, and of the ocean currents.

Ocean temperature is measured primarily to determine how much heat the ocean stores in what locations and also to combine the temperature with salinity to determine the

density of seawater. Temperatures range as high as about 33 °C at the sea surface under strong sunlight and in low wind and can be as cold as 1–2 °C in the deep basins. The sea surface temperature (SST) provides a measure of the ocean s thermal forcing of the atmosphere and a key surface boundary condition for numerical models of the atmosphere. Observations of the temperature and thickness of the surface mixed layer provide a measure of the heat stored in the ocean that can readily be released to the atmosphere. SST is measured globally to an accuracy of about 0.5 °C using satellite observations of infrared radiation from the sea surface calibrated by and merged with direct measurements by drifting buoys, moored buoys, and merchant ships. These *in situ* measurements have been found to be essential to the interpretation of the satellite data.

Vertical profiles of temperature in the upper ocean are collected from some of the same merchant ships (volunteer observing ships, VOS) that volunteer to drop expendable temperature profilers (known as expendable bathythermographs, XBTs), typically to 750 m depth. Research ships also drop XBTs, which are accurate to about 0.1 °C. To obtain more accurate measurements, oceanographers lower the more precise, reusable profilers, conductivity, temperature, and depth (known as CTDs) down as far as the ocean bottom. Temperature accuracy is 0.005 °C, and the conductivity measurement allows salinity to be determined. Time series of temperature at one point can be collected from moorings, of either a surface buoy or a subsurface buoy. These moored instruments record their data internally, with sampling as frequently as every minute. Such moorings are recovered by a research ship months to years after deployment in order to collect the data and recover the instruments for reuse. Recently efforts have been made to also get some of the data from moorings back more rapidly, and instruments are being developed to transmit temperature data up the mooring line, to be relayed via satellite from the surface buoy or from a buoyant data capsule that floats to the surface.

Salinity and temperature are needed to compute the density of seawater. The temperature and salinity of seawater are also useful as tracers to track the movement of the water. Salinity is more difficult to measure, and the most precise measurements made with CTDs achieve an accuracy of about 0.005 practical salinity units, psu (*see* Salinity Patterns in the Ocean, Volume 1) when the CTD is calibrated with water samples drawn from the ocean when the profile is collected. Many of the same techniques used for measuring temperature can also be used. Expendable profilers (XCTDs) are used less frequently than XBTs due to their greater cost. CTDs deployed from research ships have collected much of the historical salinity data. In recent years, new salinity sensors have led to underway surface salinity observations from merchant ships and the deployment of salinity sensors on moorings. These new, more stable salinity sensors will also be used on a new generation of instruments known as Lagrangian profilers. These profilers are autonomous; they will be released around the world and allowed to drift. They have an internal pump and piston that allows them to change their own density and dive from the surface to about 1500–2000 m depth. They remain there for 1–2 weeks, then become more buoyant and rise to the surface, where temperature and salinity data collected on the way down and the way up are relayed back via satellite and where the float s position is determined by the global positioning system (GPS).

Measurements of ocean currents are needed to understand how and where the ocean transports heat, salinity and water mass (referred to as freshwater). Ocean current measurements also help us understand the dynamics of the ocean and provide benchmarks for developing ocean models. Ocean currents can be measured by tracking drifters. This is commonly done in the surface layer, where a small float little influenced by the surface wind has a large drogue at 15 m depth and where the drifters positions can be tracked by satellite. It is also done by using sound to track floats ballasted to remain at a fixed depth. Ocean currents in the interior of the ocean are often measured by current meters attached to moorings as shown in Figure 1. Acoustic techniques have been developed that use the Doppler shift of sound reflected from moving particles to measure ocean currents. Acoustic Doppler current profilers (ADCPs) mounted to look down from ships and on moorings can obtain velocity profiles over depth ranges of 100–1000 m. In the interior of the ocean, the geostrophic flow (where the pressure gradients are balanced by the Coriolis force) can be calculated from temperature and salinity profiles made using CTDs. A new class of instruments, called moored profilers, combines the measurement capabilities of a CTD with a current meter. These instruments measure salinity, temperature, and velocity as they move up and down along mooring cables.

Additional observations useful for climate studies are of tracers and of quantities involved in biological, chemical, and geological pathways and processes. Helium/tritium and other isotopic ratios are measured, and when there is a well-defined source, provide tracers to better understand the slow, three-dimensional circulation of the ocean. Nutrients (phosphate, silicate) and dissolved oxygen are measured using water samples collected at various depths during research cruises, adding to the evidence used to determine these slow pathways. Efforts are increasing to more routinely measure dissolved CO_2 and particulate fluxes of carbon in the ocean.

The major challenges for understanding the ocean s role in climate are first to adequately sample the global ocean

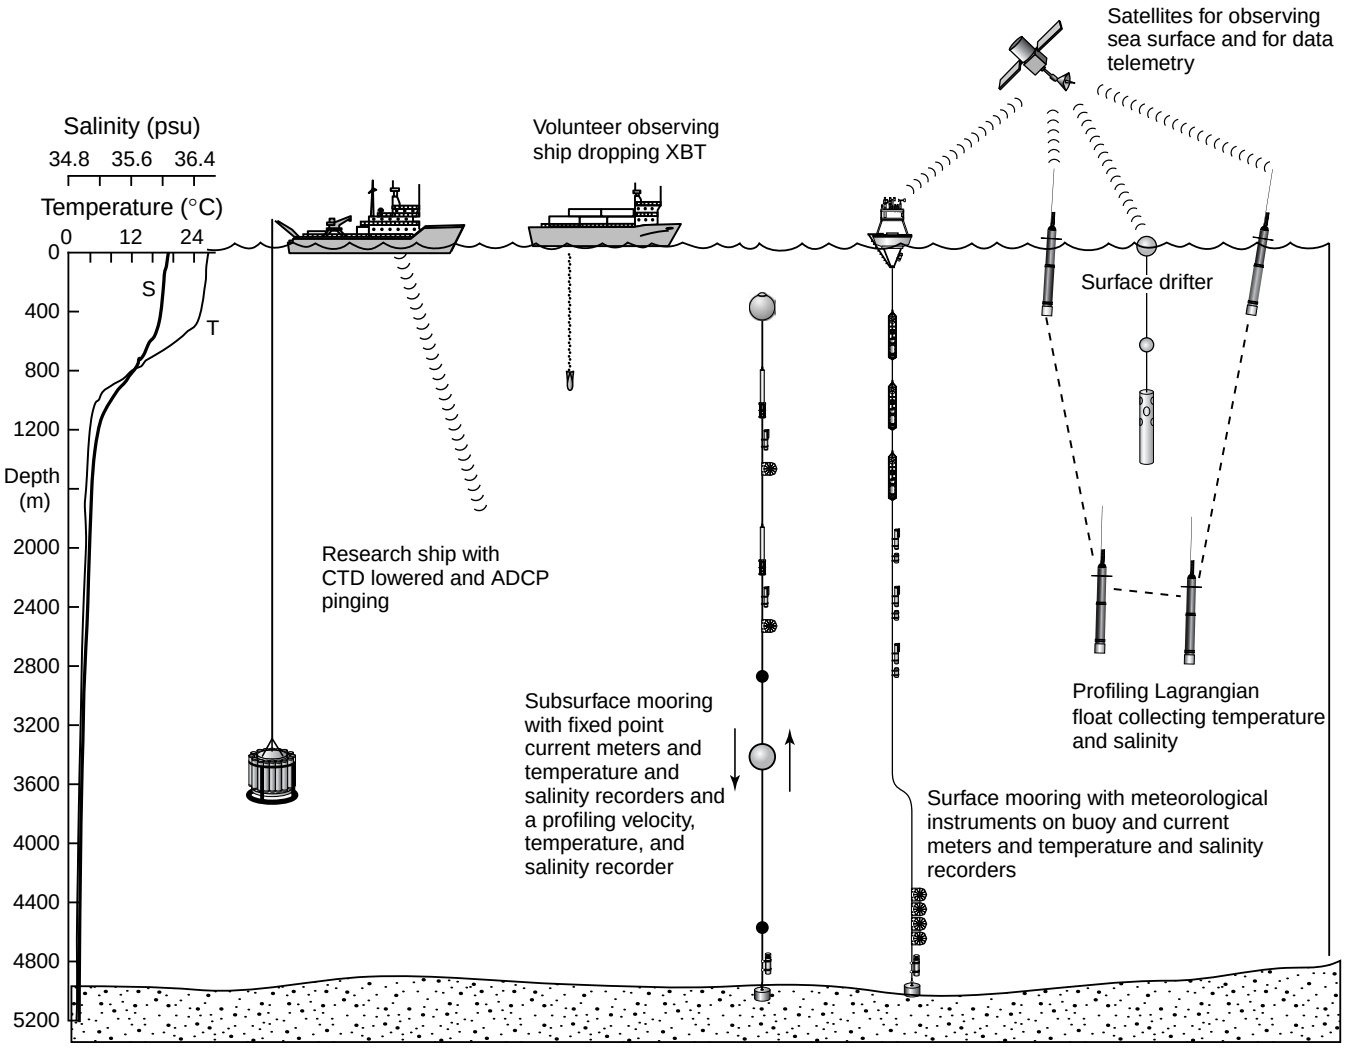

Figure 1 Typical mid-North Atlantic temperature and salinity profiles to the left and various oceanographic sampling techniques to the right. Research ships lower CTDs to obtain accurate temperature and salinity profiles. Research ships also have hull-mounted acoustic Doppler current profilers (ADCPs) to measure ocean currents in the upper ocean. Voluntary observer ships (VOSs) from the merchant fleet drop XBTs to obtain temperature profiles. Subsurface and surface moorings anchored to the bottom can be equipped with current meters to measure ocean currents and salinity and temperature records. Drifting buoys that float on the surface can be fitted with drogues to measure shallow currents and SST. New floats that can dive to 1500–2000 m are being used to collect temperature and salinity profiles that are relayed back via satellite

and second to understand the processes that govern change in the ocean and its role in the climate system. Comprehensive global observations of the ocean are not yet routine. Only a handful of oceanographic time series span more than a decade. As a result, we have a very sparse data base for detecting and attributing changes in ocean temperature and salinity that might result from combinations of natural and anthropogenic variability in the hydrologic cycle, the surface heating of the ocean or changing patterns of surface winds. The need to develop ongoing, operational ocean measurements is one of the motivations for the Global Ocean Observing System (GOOS) now being designed. Present plans call for the deployment of moorings at fixed points and 3000 Lagrangian profilers to obtain new observations to complement the present satellite and VOS measurements. Measurements of acoustic travel time between the fixed moorings may be used to provide integral measures of change in the temperature of the ocean. Efforts will increase to add additional biological, chemical, and geological sensors. New research programs, such as the Climate Variability and Predictability program (CLIVAR) sponsored by the World Climate Research Programme, are being developed to make the more detailed measurements needed to resolve and understand the processes.

Oceanography

Broadly defined, *oceanography* comprises the scientific study of all aspects of the ocean, which covers about 70% of the planet s surface. Thus, oceanography is inescapably a huge field of science. Some of the areas of study involved illustrate its diversity: ocean bottom geographic features (depths, volcanoes, trenches, oceanic plateaus, fracture zones, ridges and basins), plate tectonics, chemical composition of ocean water (salt content, carbon dioxide (CO_2) levels, density, etc.), interaction between the ocean and the atmosphere (Coriolis effect, weather systems, hurricanes, monsoons, cyclones, El Niño, etc.), ocean climates, ocean currents, waves, tides, chemical cycling in the ocean, plankton and sediments, and all the diverse varieties of marine life. The interactions between global environmental change and the oceans vividly demonstrate this diversity. For example, understanding the global carbon cycle and its modifications by human activity requires understanding of ocean chemistry (shaped by ocean basin geology, river runoff, etc.), biological processes, turbulent exchange between ocean and atmosphere, and ocean circulation on time scales from days to millennia.

Oceanography has been defined by one oceanographer (Chamberlin, 2001) as an interdisciplinary science aimed at understanding the relationships between physical, geological, chemical and biological processes in the sea. Oceanography therefore involves:

- mathematics and physics – to understand ocean circulation and climate;
- chemistry – to understand the carbon cycle and cycling of other elements;
- biology – to understand marine life and natural resources; and
- geology – to understand records of past climate and the development of the oceans.

Thus, a number of subdisciplines may be identified:

- chemical oceanography: study of the chemical composition and quality of water, and the chemical processes taking place in the ocean;
- geological oceanography: study of the geological and geophysical, and surface and subsurface characteristics of ocean basins and coastal margins;
- marine biology: study of life processes in marine environments; and
- physical oceanography: study of the physical and dynamical properties and processes of the ocean.

Because of the vastness of the ocean, and the difficulty of observing its depths, oceanography is uncommonly dependent on large and expensive observing platforms and systems, and on advanced data processing and computing facilities. Fleets of specialized oceanographic vessels are maintained by many nations to sound the ocean depths, assay its chemistry, and inventory its life. Buoys, both surface and subsurface, free-floating and moored, are increasingly being employed in ocean-wide networks. Satellites provide detailed measurements of sea-surface temperature, wind stress and waves, and indicators of biological activity. Because of the dynamic characteristics of ocean circulation, modeling its circulation requires immense computational power, while huge data archives are needed to manage the vast amounts of data currently being acquired. Thus, very much like space exploration, oceanography demands collaborative work by multi-disciplinary teams employing large and complex observational and research facilities.

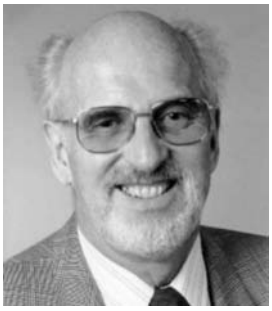
Oeschger, Hans A



(1927- 1998)

Hans A Oeschger was a Swiss physicist and paleoclimatologist. His career included: PhD University of Bern, 1955; Venia Docendi, University of Bern, 1962; vice-president of the Swiss National Academy of Sciences, 1975–1981; and Dean of the Faculty of Science, University of Bern, 1978–1979. Professor Oeschger s honors include the Harold C Urey Medal from the European Association of Geochemistry, the Seligman Crystal from the International Glaciological Society, the Tyler Prize for Environmental Achievement, and the Roger Revelle Medal from the American Geophysical Union.

Hans Oeschger trained as an experimental physicist at Eidgenoessische Technische Hochschule (ETH) Zurich. He was greatly influenced by his mentor, Fritz Houtermans, at the University of Bern to follow a career in isotope geochemistry. Houtermans inspired him to reach out beyond the traditional boundaries of physics and, intrigued by Libby s work with the isotopes of carbon and hydrogen, he and Oeschger established a radiocarbon laboratory, the Laboratory for Low Level Counting and Nuclear Geophysics. During his 40-year tenure as a researcher and professor, and together with the splendid team of colleagues that he assembled at the Physics Department at the University of Bern, Professor Oeschger pioneered the application of the techniques of modern physics to the investigation of the Earth System. He and his colleagues developed many innovative techniques for measuring radiocarbon on very small samples of carbon, oxygen isotopes, and radiocarbon dating of ice.

On a visit to La Jolla in 1958, Oeschger interacted with scientists just developing the field of environmental geochemistry. David Keeling had just begun carbon dioxide (CO_2) measurements on Mauna Loa and Hans Suess and Oeschger made the first radiocarbon measurements on bicarbonate samples in water from the deep Pacific Ocean. Oeschger realized the great potential of natural radioactive and stable isotope studies for many scientific fields. With Johannes Geiss he analyzed the radioactivity in meteorites and later also in lunar samples. With Hugo Loosli, he succeeded in measuring the radioactive isotopes ^{37}Ar, ^{39}Ar, and ^{81}Kr in atmospheric samples. The measurements of ^{37}Ar provided information on underground nuclear weapon testing. ^{39}Ar was employed as a tracer for deep ocean circulation and ^{39}Ar and ^{81}Kr analyses helped to determine the age of underground water. With Uli Siegenthaler, he modeled bomb-^{14}C and fossil fuel CO_2 uptake by the ocean using a box diffusion model; and with W Berner and Bernhard Stauffer he made the first measurements of the CO_2 content of glacial age air trapped in ice cores.

In the late 1970s, Oeschger became interested in the issue of the increasing concentration of atmospheric CO_2 and its consequences for global environmental change. He realized the importance of knowing the preindustrial concentration prior to the direct atmospheric measurements that had only recently begun. At a meeting in Austria, Oeschger and Chet Langway found a common interest in the potential of natural ice of known age as an archive for atmospheric gasses and for information on other Earth System phenomena. Together with Willi Dansgaard, a collaboration evolved to sample the world s great ice sheets. They successfully drilled to bedrock at the Dye3 Station in south Greenland and recovered ice samples dating back into the Eemian (*see* Eemian, Volume 1) of the last interglacial. This was the fore-runner of the more extensive deep drilling projects, Greenland Ice Core Project (GRIP) and Greenland Ice Sheet Project 2 (GISP2), at the summit of the Greenland ice sheet in the early 1990s and the recovery of the suite of deep cores from the Russian Vostok Station in Antarctica under the leadership of Claude Lorius.

The drilling techniques and analytical methods that were devised by Oeschger and his colleagues enabled them to establish a history of variation on greenhouse gas concentration, providing an unprecedented reconstruction of climate change over the past 150 000 years, and demonstrating the reality of the abruptness of some past changes in climate. These results stimulated further studies on the mechanisms of climate change, the relationship of climate to Earth s carbon system and inter-hemispheric climate coupling during glacial–interglacial cycles.

Because Oeschger understood that the Earth must be seen as a complex system controlled by its biogeochemical systems, he was instrumental in establishing the International Geosphere–Biosphere Programme (IGBP) to assess the consequences of the human impact on the Earth System. In emphasizing the importance of paleoinformation, he led the way in initiation of the Past Global Changes (PAGES) project, which was charged with producing a quantitative understanding of the Earth s past environmental history and defining the envelope of natural environmental variability.

Oeschger transformed paleoclimatology into a quantitative science that today has a central and essential position within the global change sciences. His career exemplifies innovative research, but he was also a strong advocate for science on the service of society; he considered our planetary environment as his personal responsibility.

Orbital Variations

André Berger

Institut d'Astronomie et de Géophysique G. Lemaître, Louvain-la-Neuve, Belgium

The amount of incoming solar radiation received at any point on the Earth has an annual periodic variation caused by the Earth's elliptic translation motion around the Sun. In addition, the seasonal and latitudinal distributions of this solar radiation have a long-period variation caused by the so-called secular variations in the astronomical elements. These are: the eccentricity, e, *a measure of the shape of the Earth's orbit around the Sun; the obliquity,* ε, *the tilt of the equator on the Earth's orbit; and the climatic precession,* $e \sin \tilde{\omega}$, *a measure of the distance from Earth to Sun at the summer solstice (*$\tilde{\omega}$ *being the longitude of the perihelion measured from the moving equinox). As determined from celestial mechanics, the secular variations of these elements of the Earth's orbit and rotation are due to the gravitational perturbations which the Sun, the other planets, and the Moon exert on the Earth. These astronomical elements form the basis of any astronomical theory of paleoclimates for explaining the quaternary glacial- interglacial cycles (*see *Quaternary, Volume 1). Actually, the long-term variations of the incoming solar radiation are pacing climatic changes at time scales of tens to hundreds of thousands of years. The exceptional strength of the 100-kyr cycle requires some non-linear ampli cation through feedback mechanisms related to the albedo, water vapor and isostatic rebound, in particular.*

Astronomical computations allow reconstruction of past (and prediction of future) variations with a good accuracy. The short-term variations of the astro-climate elements (e, ε, $e \sin \tilde{\omega}$) have been computed for the past few millennia (Loutre *et al.*, 1992) using one of the classical secular planetary theories built for the ephemerides by Bretagnon (Paris) and used in astronomical observations (another well-known expression was calculated by Simon Newcomb in 1898 for the eccentricity as a function of time). Spectral analyses of these astronomical parameters for the past 5000 years show periodicities ranging from 2.67 to 250 years. Particularly significant for the eccentricity and climatic precession are the periods of 2.67, 3.98, 5.93 and 11.9 years. Obliquity shows, in addition, periods of 29 and 18.6 years, the last one arising from the nutations related to the Moon and well known in the theory of the Earth s tides. The amplitude of the induced variations in the incoming solar radiation are, however, quite small, reaching a maximum of $0.2\,\mathrm{W\,m^{-2}}$ at these frequencies.

For the long-term variations over the last few million years, the equations for the motion of the planets around the Sun, for the precession, and for the obliquity are integrated, and their numerical solutions are expressed in trigonometrical form as quasi-periodic functions of time:

$$e = e^* + \sum E_i \cos\bullet\lambda_i t + \varphi_i\bullet \qquad \bullet 1\bullet$$

$$\varepsilon = \varepsilon^* + \sum A_i \cos\bullet\gamma_i t + \zeta_i\bullet \qquad \bullet 2\bullet$$

$$e \sin \tilde{\omega} = \sum P_i \sin\bullet\alpha_i t + \eta_i\bullet \qquad \bullet 3\bullet$$

where the amplitudes P_i, A_i, E_i, the frequencies α_i, γ_i, λ_i and phases η_i, ζ_i, φ_i are given in Berger (1978).

In the term $e \sin \tilde{\omega}$, the amplitude of $sin\tilde{\omega}$ is modulated by *eccentricity*, and the envelope of $e \sin \tilde{\omega}$ is given exactly by e because the frequencies of e originate strictly from combinations of the frequencies of $\tilde{\omega}$. Figure 1 shows the long-term variations of these three astronomical parameters over the past 200 000 years and the next 130 000 years.

Over the past 3×10^6 years, the eccentricity of the orbit varies between near circularity ($e = 0$) and slight ellipticity ($e = 0\bullet07$) at a period with a mean of about 100 000 years. The most important terms in the series expansion occur, however, at 413 000, 95 000, 124 000, 99 000, and 131 000 years (in decreasing order of amplitude). The tilt of the Earth s axis varies between about 22 and 25° at a period of nearly 41 000 years. Although this period corresponds in Equation (2) to the amplitude that is by far the largest, there are two other important terms, one with a period of 54 000 and one with 29 000 years.

As far as *precession* is concerned, two motions must be considered. The first is the axial precession, in which the torque of the Sun, the Moon, and the planets on the Earth s equatorial bulge causes the axis of rotation to wobble like that of a spinning top. The net effect is that the North Pole describes a clockwise circle in space (provided the *nutations* – the terms with small amplitude and much smaller periods – are neglected), with a period of about 25 800 years corresponding to the period of the vernal equinox against a fixed reference point. The second is related to the fact that the elliptical figure of the Earth s orbit is itself rotating counter-clockwise in the same plane, leading to an absolute motion of the perihelion with a period, measured relative to the fixed stars, of about 100 000 years (the same as that of the eccentricity).

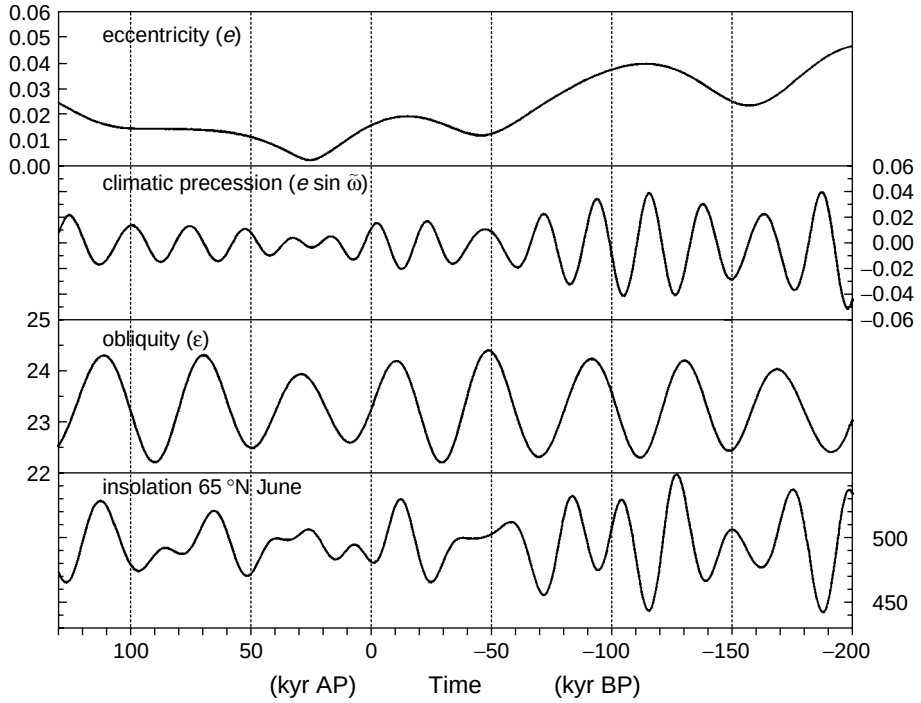

Figure 1 Long-term variations of eccentricity, climatic precession, obliquity and June insolation at 65 °N from 200 000 years ago to 130 000 years in the future (Berger, 1978). This latitude is taken as a typical example. According to Milankovitch (*see* **Milankovitch, Milutin**, Volume 1), it is indeed a key latitude where most of the ice sheets develop in the Northern Hemisphere. Time is going from the right (the past 200 kyr) to the left (the next 130 kyr) according to the geological tradition. The very particular future behavior of the orbital parameters and insolation can lead to an exceptionally long interglacial lasting up to 50 kyr AP, even if humans were not having an influence. In a scenario where the CO_2 concentration reaches 750 ppmv within the next two centuries as a result of human activities, the Greenland ice sheet might melt after 6 kyr, the human influence on the global climate disappearing only after 50 kyr AP (Loutre and Berger, 2000)

The two effects together result in what is known as the climatic precession of the equinoxes, a motion mathematically described by $\tilde{\omega}$, and in which the equinoxes and solstices shift slowly around the Earth s orbit relative to the perihelion with a mean period of 21 000 years (this period actually results from the existence of two close periods of 23 000 and 19 000 years).

Therefore, while today the winter solstice occurs near perihelion, some 11 000 years ago it occurred near aphelion. Moreover, because the lengths of the seasons vary in time according to Kepler s second law, the solstices and equinoxes have occurred at different calendar dates during the geological past. Presently in the Northern Hemisphere, the longest seasons are spring (92 days, 19 h) and summer (93 days, 15 h); fall (89 days, 20 h) and winter (89 days) are definitively the shortest. In about 1250 AD spring and summer had exactly the same length as fall and winter because the winter solstice was occurring at the perihelion. About 4500 years from now, the Northern Hemisphere spring and winter will have the same shorter length and, consequently, summer and fall will be equally long.

The combined influence of changes in e, ε, and $e \sin \tilde{\omega}$ produces a complex pattern of insolation variations. A detailed analysis of the daily solar irradiance (Berger *et al.*, 1993) shows that it is principally affected by variations in *precession*, although the *obliquity* plays a more important role as latitudes increase, mainly in the winter hemisphere. At the equinoxes, insolation for each latitude is only a function of precession. At the solstices, both precession and obliquity are present, although precession dominates for most latitudes.

Changes in incoming solar radiation caused by changes in tilt are the same in both hemispheres during the same local season: an increase of ε leads to an increase in insolation in the summer hemisphere and to a decrease in the winter hemisphere. Because the strength of the effect is small in the tropics and maximal at the pole, an increase in obliquity tends to amplify the seasonal cycle in the high latitudes of both hemispheres simultaneously.

The precession effect can cause warm winters and cool summers in one hemisphere while doing the opposite in the other. For example, portions of the present winter in the Northern Hemisphere receive as much as 10%

more insolation than they did 11 000 years ago, when the perihelion occurred in the Northern Hemisphere summer.

The spectral power of the long-term variations of different insolation parameters depends on the type of parameters considered. For example, the total energy received during any astronomical season for a given latitude is only a function of obliquity (as a consequence of the second law of Kepler). This implies that the total amounts of energy received at a given latitude in the Northern and Southern Hemispheres during the same season, are exactly out of phase, but in phase if the local season is considered. If the mean irradiance is considered, precession again starts to play an important role depending upon the latitude (this is because the length of the astronomical seasons is only a function of precession).

Many other insolation parameters can be elaborated (like the latitudinal gradient and the seasonal contrasts), all displaying a spectrum with different precession and obliquity powers. In particular, the total energy received by the Earth over a full year varies according to the eccentricity only, being maximum for an elongated orbit and minimum for a circular one. In the intertropical regions, because the Sun passes overhead twice a year, precession can lead there to a cycle about 10 kyr long.

But the theoretical frequencies in Equations (1)–(3), are not stable in time (Berger *et al.*, 1998). For eccentricity, the 400-kyr period is weak before 1 Myr BP, it strengthens starting around 900 kyr BP and is particularly strong over the next 400 kyr, when the components in the 100-kyr band will be exceptionally weak. This 400-kyr cycle plays a very important role because the amplitude of precession is modulated by eccentricity. Minima corresponding to this 400-kyr cycle being very low ($e \sim 0$), insolation remains about constant during these times, allowing the other factors to become more important. For *obliquity*, the main period is quite stable, but the spectra of the amplitude and frequency modulations display significant power at 191 and 97 kyr. (Obliquity is the angle between the equatorial plane and the plane of the orbit of the Earth around the Sun (the ecliptic). It is also the tilt of the Earth axis of rotation at an angle, presently $23^{\circ}27'$, away from a vertical drawn to the plane of the orbit.) However, these modulations explain very little (less than 2%) of the variance of insolation (at 65°N in June, for example) over the last million years. On the other hand, the ice ages themselves might have had an influence on the astronomical parameters (Peltier and Jiang, 1994). The waxing and waning of the ice sheets might indeed have altered the Earth s dynamical flattening and so the axial tilt. However, this ice sheet effect is partly cancelled by viscous compensation in the mantle, so that the net effect remains unknown.

For pre-Quaternary times in the Cenozoic, the chaotic nature of the orbital motion of the planets in the solar system limits the possibility of obtaining an accurate solution over more than 35–50 Myr (Laskar, 1999). For earlier times, sensitivity analyses of the astronomical frequencies has suggested (Berger *et al.*, 1992) that the shortening of the Earth–Moon distance and of the length of the day would induce a shortening of the fundamental periods for obliquity and climatic precession. Over the last half-billion years, these periods would accordingly change, respectively, from 54 to 35, 41 to 29, 23 to 19 and 19 to 16 thousand of years. Over such remote times and earlier, the obliquity of the Earth s orbit might have been chaotic with very large variations.

The orbital hypothesis was first quantitatively formulated by the Serbian astronomer Milutin Milankovitch in the 1920s and 1930s (*see* Milankovitch, Milutin, Volume 1) to explain the Quaternary s long-term climatic variations. He argued that insolation changes in the high northern latitudes during the summer season were critical to the formation of continental ice sheets. During periods when insolation in the summer was reduced, the snow of the previous winter would tend to be preserved – a tendency that would be enhanced by the high albedo of the snow and ice fields. Eventually, the effect of this positive feedback would lead to the formation of ice sheets.

A simple linear version of the Milankovitch model would therefore predict that the total ice volume and climate over the Earth would vary with the same regular pattern as the insolation. This means that the proxy record of climate variations would reflect those frequencies of the astronomical parameters that are responsible for changing the seasonal and latitudinal distribution of incoming solar radiation. Investigations during the past 20 years have indeed demonstrated that the 19 000, 23 000, and 41 000 year periodicities actually occur in long records of the Quaternary climate (Hays *et al.*, 1976), that the climatic variations observed in these frequency bands are linearly related to the orbital forcing functions, and that there is a fairly consistent phase relationship among insolation, sea–surface temperature, and ice volume (Imbrie *et al.*, 1992). The geological observation of the bipartition of the precessional peak that was confirmed to be real in astronomical computations (Berger, 1978), was one of the first and most impressive of all tests for the Milankovitch theory. The same investigations, however, identified the largest climatic cycle as 100 000 years, at least over the last 1 million years. Because the eccentricity signal is very weak in the insolation, it cannot be related to orbital forcing by any simple linear mechanism. Actually, the variance components centered near this 100 000-year cycle seem to be in phase with the eccentricity cycle, but its exceptional strength requires some non-linear amplification by the glacial ice sheets themselves, involving mechanisms such as ice albedo feedback and isostatic rebound of the lithosphere, by the carbon dioxide atmospheric concentration, or by the oceanic circulation. It might also be that other astronomical parameters

must be looked for, like the inclination of the Earth s orbit on a reference plane or the axial tilt although careful analysis shows that that is much less probable (Ridgwell *et al.*, 1999).

For the last few millions of years, for which a reasonably reliable astronomical solution exists, the orbital parameters provide a clock with which to date old sediments with a precision several times greater than permitted by physical techniques. Instead, for the last 2–3 tens of millions of years, the climatic cycles are used to create a time scale by assuming that the observed quasi-cyclicity is a response to astronomical forcing (Shackleton *et al.*, 1999). Finally, careful analysis of much older proxy records (even hundreds of millions of years ago) reflects also the astronomically induced climatic variations.

Ozone Depletion Potential (ODP)

Ozone depletion potentials (ODPs) provide a relative measure of the cumulative impact on stratospheric ozone from trace gas emissions, and are used by policymakers to examine the relative effects on ozone from chlorofluorocarbons (CFCs), halons, and other halocarbons. The ODP concept is also used to evaluate the potential effects of possible replacement compounds. Emissions of gases containing chlorine, bromine, or iodine can particularly affect stratospheric ozone (but not the emissions of water-soluble gases like hydrochloric acid, which would likely be washed out of the atmosphere and not reach the stratosphere). Chlorine, bromine, and iodine react extremely efficiently with ozone in catalytic processes, and these atoms can destroy thousands of ozone molecules if they reach the stratosphere. The ODP concept arose as a means of determining the relative ability of a chemical to destroy ozone. If a compound does not contain chlorine, bromine or iodine, then it is less likely to affect the stratosphere. Exceptions could occur if the compound can achieve such significant use that it would become a source of stratospheric nitrogen oxides, hydrogen oxides, or sulfuric particles.

The ODP of a gas is defined as the integrated change in total ozone per unit mass emission of the gas, relative to the change in total ozone per unit mass emission of CFC-11, one of the gases of most concern to ozone change. As a relative measure, ODPs are subject to fewer uncertainties than estimates of the absolute percentage of ozone depletion caused by different gases. As a result, ODPs are an integral part of national and international considerations on ozone-protection policy, including the Montreal Protocol and its amendments, and the United States Clean Air Act. Table 1 shows ODPs for several of the gases of most concern to ozone depletion. Replacement compounds like hydrochlorofluorocarbons (HCFCs) and hydrofluorocarbons (not shown because their ODPs are close to zero) have much smaller ODPs than the CFCs and halons.

Table 1 Steady-state ODPs[a]

Gas	Formula	ODP
CFCs		
CFC-11	CCl_3F	1.0
CFC-12	CCl_2F_2	0.82
CFC-113	CCl_2FCClF_2	0.90
CFC-114	$CClF_2CClF_2$	0.85
CFC-115	CF_3CClF_2	0.40
Bromocarbons		
Methyl bromide	CH_3Br	0.37
Halon-1301	CF_3Br	12.0
Halon-1211	CF_2ClBr	5.1
HCFCs		
HCFC 22	$CHClF_2$	0.034
HCFC-123	CF_3CHCl_2	0.012
HCFC-124	CF_3CHClF	0.026
HCFC-141b	CH_3CCl_2F	0.086
HCFC-142b	CH_3CClF_2	0.043
HCFC-225ca	$CF_3CF_2CHCl_2$	0.017
HCFC-225cb	$CClF_2CF_2CHClF$	0.017
Others		
Carbon tetrachloride	CCl_4	1.20
Methyl chloroform	CH_3CCl_3	0.11
Methyl chloride	CH_3Cl	0.02

DONALD J WUEBBLES *USA*

Ozone Hole

The term *ozone hole* arose in the media following the discovery in 1985 of the large stratospheric ozone depletion that has been occurring during the springtime (September–November) over much of the Antarctic continent since the late 1970s. Joseph Farman and colleagues first documented this rapid springtime decrease in Antarctic ozone over their British Antarctic Survey (BAS) station at Halley Bay, Antarctica. These analyses were confirmed by satellite data and it was soon found that decreases in the total ozone column were greater than 50% compared with historical values observed by both ground-based and

satellite techniques. Measurements have found 60–90% decreases in monthly average ozone amounts between 12 and 20 km, for the springtime period, relative to pre-ozone-hole levels, with essentially all the ozone at these altitudes destroyed at times. Since 1992, the Antarctic ozone holes have been the biggest (in areal extent) and the deepest (in terms of minimum amounts of ozone overhead), with ozone being locally depleted by more than 99% between about 14 and 19 km in October (*see* Stratosphere, Ozone Trends, Volume 1). There is no indication yet that the magnitude of the Antarctic ozone hole has peaked or begun to decline.

The cause of the ozone hole is as follows:

- Air over the Antarctic becomes extremely cold during the winter as a result of the lack of sunlight over the polar region and because of greatly reduced mixing of the lower stratospheric air over this region with air outside this region.
- During the winter, a circumpolar vortex, also called the *polar winter vortex*, forms which isolates the air in the polar region from that outside of the region as a result of a stratospheric jet of wind circulating between approximately 50 °S and 65 °S.
- The extremely cold temperatures inside the vortex lead to the formation of clouds in the lower stratosphere (from roughly 12 to 22 km), called *polar stratospheric clouds*.
- Reactions occur on the cloud particles that convert less reactive forms of chlorine and bromine gases to much more reactive ones that then can react to destroy ozone.
- When daylight starts to occur over Antarctica in the early spring, this chlorine and bromine is available to react with and destroy ozone. The ozone destruction continues until the polar vortex breaks up, usually in November.

In recent years, it has been discovered that these processes also occur in the Northern Hemisphere, although the weaker strength of the arctic polar vortex generally has resulted in much smaller ozone depletions. However, total ozone column reductions of up to 25% and local destruction of ozone of 70% were discovered during the 1999–2000 winter and early spring.

P

Pacific–Decadal Oscillation (PDO)

Nathan J Mantua
University of Washington, Seattle, WA, USA

The Paci c (inter) Decadal Oscillation (PDO) is an El Niño-like oscillatory pattern of climate variability centered over the Paci c Ocean and North America. Over North America, PDO variations are most energetic in the boreal winter and spring. The PDO has considerable in uence on climate-sensitive natural resources in the Paci c and over North America, including the water supplies and snow pack in some selected regions in North America, and major marine ecosystems from coastal California north to the Gulf of Alaska and the Bering Sea. In fact, it was sheries scientist Steven Hare that coined the term Paci c Decadal Oscillation (PDO) in 1996 while researching connections between Alaska salmon production cycles and Paci c climate (Hare, 1996).

Three main characteristics distinguish PDO from El Niño/Southern Oscillation (ENSO): rst, 20th century PDO events persisted for 20- 30 years, while typical ENSO events persisted for 6 to 18 months; second, the climatic ngerprints of the PDO are most visible in the North Paci c/North American sector, while secondary signatures exist in the tropics, while the opposite is true for ENSO; and third, the mechanisms that cause PDO are not currently known, while causes for ENSO are relatively well-understood (Mantua et al., *1997; Zhang* et al., *1997).*

From a societal impacts perspective, recognition of PDO is important because it shows that normal climate conditions can vary over time periods comparable to the length of a human's lifetime.

Typical surface climate anomaly patterns for warm and cool phases of the PDO are shown in Figure 1. In warm PDO phases (Figure 1a), sea surface temperatures (SSTs) tend to be anomalously cool in the central North Pacific coincident with anomalously warm SSTs along the west coast of the Americas. For October–March, warm PDO sea level pressure (SLP) anomalies vary in a wave-like pattern. Low pressures over the North Pacific cause enhanced counterclockwise winds over the North Pacific, and high SLP over western North America and the subtropical Pacific cause enhanced clockwise winds in those regions. PDO circulation anomalies extend through the depth of the troposphere, and are well expressed as persistence in the Pacific North America (PNA) teleconnection pattern described by Wallace and Gutzler (1981) (*see* Paci c- North American (PNA) Teleconnection, Volume 1). Cool PDO climate anomalies are simply opposites of those for warm PDO phases (Figure 1b).

Tracking PDO variations is typically done with indices constructed from observed Pacific SST and SLP patterns. A representative pair of PDO indices are shown in Figure 2

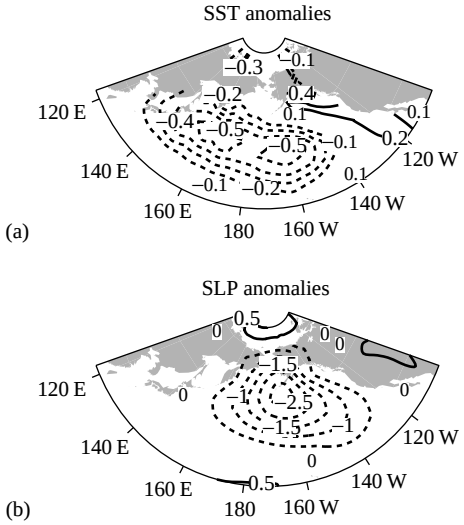

Figure 1 Warm phase PDO surface climate anomalies: (a) sea surface temperature anomaly pattern, dashed contours depict cooler than average temperatures, while solid contours reflect warmer than average temperatures, contour interval is 0.1 °C; (b) atmospheric SLP anomaly pattern, dashed contours depict lower than average SLPs, while solid contours reflect higher than average pressures, contour interval is 0.5 h Pa

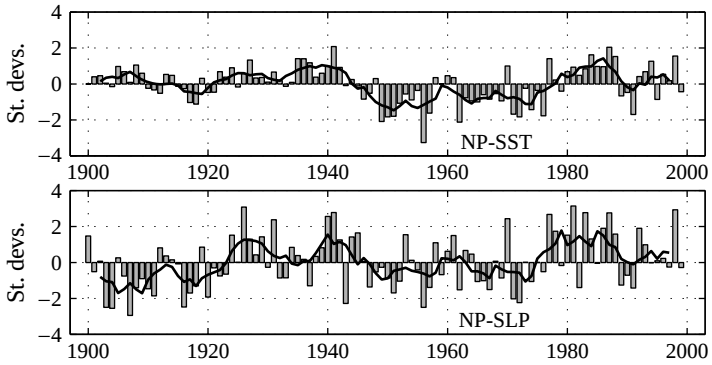

Figure 2 October–March averaged PDO indices based upon projections of observed North Pacific SST and SLP patterns onto those shown in Figure 1. Positive values indicate warm phases of PDO, while negative values indicate cool phases of PDO. Index values are normalized for the entire period of record shown. Solid curve shows a 5-year running average for each time series. October–March averages are used because year to year PDO fluctuations are most energetic during these months

(see Trenberth and Hurrell, 1994; Mantua *et al.*, 1997). When SSTs are anomalously cool in the interior North Pacific and warm along the Pacific Coast, and when SLPs are below average over the North Pacific, the two indices have positive values, indicating warm phase PDO conditions. A notable feature of the indices is their tendency for year to year persistence, with positive/warm or negative/cool index values tending to prevail for 20–30 year periods. However, within the 20–30 year regimes there are several short-lived sign reversals in the indices, including three year reversals from 1959–1961 and again from 1989–1991. Note that these (and other) indices depict two full PDO cycles in the 20th century: cool PDO regimes prevailed from 1890–1924 and again from 1947–1976, while warm PDO regimes dominated from 1925–1946 and from 1977 to (at least) the mid-1990s (Mantua *et al.*, 1997; Minobe, 1997). Minobe (1999) has shown that 20th century PDO fluctuations were most energetic in two general periodicities, one from 15–25 years, and the other from 50–70 years.

The North American climate anomalies associated with PDO are broadly similar to those connected with El Niño and La Niña, though generally not as extreme (Latif and Barnett, 1996) (*see* El Niño and La Niña: Causes and Global Consequences, Volume 1). The warm phase of PDO is correlated with anomalously warm and dry winter/spring conditions in the northern half of North America and anomalously wet conditions over the southern US and Northern Mexico (El Niño-like). The cool phase of PDO is correlated with the opposite (La Niña-like) climate patterns over North America. PDO variability is strongly expressed in regional snow pack and stream flow anomalies, especially in western North America (see Cayan, 1996; and Mantua *et al.*, 1997), and appears to influence summer rainfall and drought in the US (Nigam *et al.*, 1999). A summary of major climate anomalies associated with PDO is given in Table 1.

Combining PDO and ENSO information may enhance the skill of empirical North American climate forecasts. Empirical studies suggest that ENSO influences on North American climate are strongly dependent on the phase of the PDO, such that the canonical El Niño and La Niña patterns of North American climate anomalies are most likely to occur during years in which ENSO and PDO

Table 1 Summary of Pacific and North American climate anomalies associated with extreme phases of the PDO

Climate anomalies	Warm phase PDO	Cool phase PDO
Ocean surface temperatures in the northeastern and tropical Pacific	Above average	Below average
October–March northwestern North American air temperatures	Above average	Below average
October–March Southeastern US air temperatures	Below average	Above average
October–March southern US/Northern Mexico precipitation	Above average	Below average
October–March Northwestern North America and Great Lakes precipitation	Below average	Above average
Northwestern North American spring time snow pack and water year (October–September) stream flow	Below average	Above average

extremes are in phase (i.e., with warm PDO coincident with El Niño, and cool PDO coincident with La Niña, but not with other combinations) (Gershunov and Barnett, 1998).

Important changes in Northeast Pacific marine ecosystems have been correlated with the PDO (Francis *et al.*, 1998). For example, warm PDO phases have favored high salmon production in Alaska and low salmon production off the west coast of California, Oregon, and Washington states. Conversely, cool PDO eras have favored low salmon production in Alaska and relatively high salmon production for California, Oregon, and Washington (Hare, 1996; Hare *et al.*, 1999).

Causes for the PDO are not currently known. Some climate simulation models produce PDO-like oscillations (e.g., Latif and Barnett, 1994), although often for different reasons (NRC, 1998). The mechanisms giving rise to PDO will determine whether skillful PDO climate predictions for up to one or more decades into the future are possible. Even in the absence of a theoretical understanding, PDO climate information improves season-to-season and year-to-year climate forecasts for North America because of its strong tendency for multi-season and multi-year persistence.

Much controversy exists over how PDO works, and how it might best be monitored, modeled and predicted. The stakes in PDO science are high, as an improved PDO understanding offers sharper views of future climate than those now provided by ENSO science alone.

Pacific–North American (PNA) Teleconnection

Yochanan Kushnir

Columbia University, Palisades, NY, USA

*The PNA pattern is the dominant atmospheric teleconnection pattern in the western half of the Northern Hemisphere. The PNA in uence is largest during the boreal winter (December, January, and February) when it extends from the eastern seaboard of Asia, across the North Paci c and North America to the western North Atlantic (see Figure 1). It is weaker during fall and spring and least in uential in the boreal summer months. The PNA displays a wide range of time scales, from month-to-month variability to multidecadal undulations that bear relevance to the broader issue of climate change. It is most frequently associated with the El Niño/Southern Oscillation (ENSO) phenomenon and is viewed as the latter's extratropical arm (*see *El Niño/Southern Oscillation (ENSO), Volume 1).*

The PNA is generally depicted in terms of its corresponding mid-tropospheric, monthly, geopotential height variations. These form a chain of four large-scale, oval-shaped elements. The most prominent of the four is centered

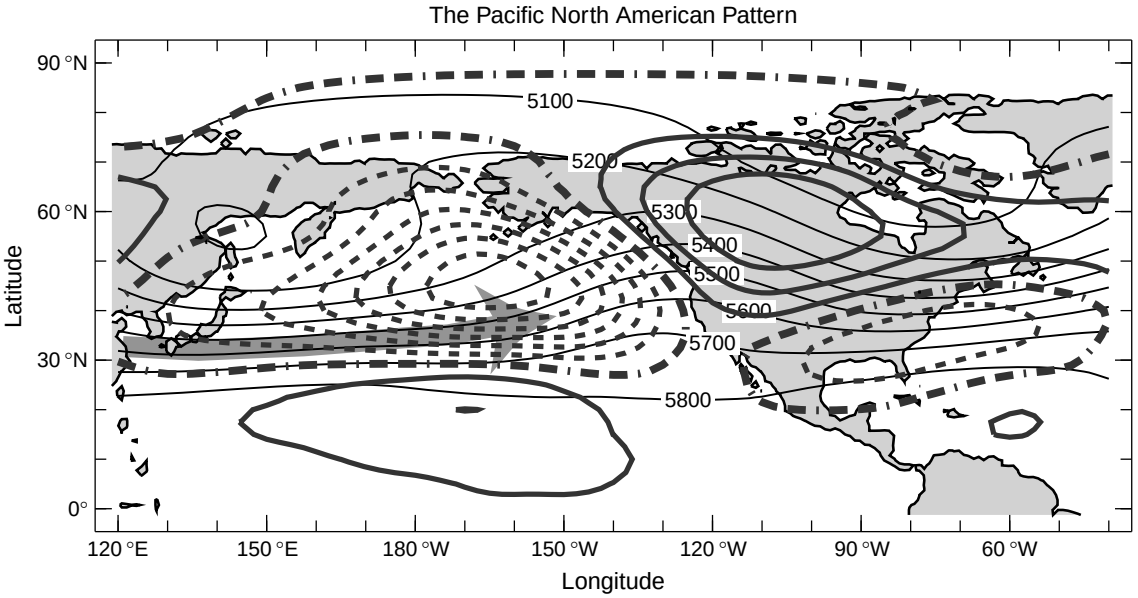

Figure 1 A map of the western sector of the Northern Hemisphere, showing the averaged difference between winters (December–February) in which the PNA was in its positive phase and winters with a negative phase of the phenomenon. The PNA pattern is depicted by thick contours, drawn every 20 m with positive contours solid, negative contours dashed, and the zero line dot dashed. The composite is based on the PNA index as defined in Wallace and Gutzler (1981). (Data available from http://tao.atmos.washington.edu/data_sets/pna). The index values for the winters of 1959–1997 were sorted and the average of the 10 most negative index years was subtracted from that of the 10 most positive. The PNA composite is superimposed on the normal, wintertime, 500 hPa geopotential height field (thin black contours every 100 m). The thick gray arrow over the Pacific Ocean depicts the mean position of the jet stream

in the vicinity of the Aleutian Islands and influences the entire northern North Pacific Basin. To the south lies a much weaker, yet significant, tropical center. Geopotential height fluctuations in these two centers are anti-correlated (varying out of phase with one another) and form a seesaw straddling the mean position of the Pacific subtropical jet stream. The third PNA element overlays western Canada and the northwestern US and also varies out of phase with the main North Pacific center. The fourth element lies over the southeastern half of North America and varies in-phase with the Aleutian center and out of phase with the American Northwest one. The significance of these locations and their respective phases are in their relation to the normal atmospheric circulation (see Figure 1). They represent a variation in the waviness of the atmospheric flow in the western half-hemisphere and thus the changes in the north–south migration of the large-scale Pacific and North American air masses and their associated weather.

References to an atmospheric connection between the Pacific and North America appear in the literature for more than half a century. Wallace and Gutzler (1981) gave a detailed historical account of these early studies and introduced the term PNA in their seminal work on Northern Hemisphere teleconnections. The PNA has been associated with significant variations of surface air temperature and precipitation over North America. The spatial pattern of these effects reflects changes in air-mass movement and in the paths of wintertime storms. When the PNA is in its positive phase (with pressure lower than normal over the North Pacific and higher than normal over Canada) winter temperatures are higher than normal in Alaska, western Canada, and the northwestern US. Positive PNA winters are also associated with cooler conditions in eastern Mexico and the southeastern US. Alaskan winters tend to be drier than normal when the PNA is positive, while northern California and Florida are wetter than normal.

The pioneering work of Bjerknes (1969) on the nature of El Niño and its observed global links was one of the first to divulge the origins and physical mechanisms of the PNA. In the ensuing years this work was extended and the PNA links to El Niño explained as the dynamical atmospheric response to equatorial Pacific sea surface temperature variations and the associated shifts in the massive tropical convection centers (see for example, Rasmusson and Wallace, 1983). However, significant PNA variability exists even in the absence of ENSO, as is evident from observations and climate model experiments that do not include sea surface temperature variability. Non-ENSO variability in variations in the PNA pattern is most probably related to non-linear processes in the atmosphere in which various scales of motion interact with one another (particularly weather disturbances with the more permanent part of the circulation). Thus, while advances in ENSO prediction provide hope for predicting the PNA and its climatic

impacts, such forecasts will have to remain probabilistic in nature, reflecting the random, unpredictable element of midlatitude variability.

Changes in surface winds and air mass movement over the North Pacific Ocean associated with PNA variability have a profound impact on the temperature and circulation of the upper ocean layer and consequently on the distribution and abundance of fish species and other marine life (Mantua *et al.*, 1997). These oceanic effects have been studied extensively in recent years in connection with the multi-decadal component of PNA variability (Trenberth and Hurrell, 1990; Zhang *et al.*, 1997). The existence of such slow components in climate variability is important not only because of their direct impacts but also because of their significance to climate change detection and attribution (IPCC, 1990, 1996).

PAGES (Past Global Changes)

PAGES is the International Geosphere–Biosphere Programme Project charged with providing a quantitative understanding of the way the Earth System has changed during the geologically recent past, in response to both natural processes and human activities. Coordination of the PAGES project, which evolved during the 1990s, is undertaken by an international office located in Bern, Switzerland and jointly funded by the US and Swiss National Science Foundations.

One of the central tasks of PAGES, through the organization of coordinated national and international scientific efforts, is to obtain and interpret high quality paleoclimatic records and thereby provide the data essential for the assessment and validation of predictive climate models. PAGES provides an essential framework for the integration and intercomparison of ice, ocean and terrestrial paleo-records and encourages the creation of consistent analytical and data base methodologies in paleoscience.

The responsibility of PAGES goes beyond paleo-climate to include, for the geologically recent past, reconstruction of all the major physical, chemical and biological processes that, through their interactions, regulate the total Earth System. Increasingly, as we approach the present day, this implies a major concern with the role of human activities as an integral component. A more complete understanding of the Earth system as it has changed through time, at both global and regional level, is crucial to providing a robust scientific basis for sustaining human societies in the future. PAGES, therefore, works to identify and elucidate those aspects of past environmental change that are of the greatest significance for human societies. It seeks to promote and coordinate the broad and diverse area of research that extends knowledge of our changing environment back beyond the short, recent period for which we have direct observations or instrumental records.

Further information on the organization of the project, its personnel, priorities and products, can be obtained by consulting its website: http://www.pages.unibe.ch/.

FRANK OLDFIELD *Switzerland*

Paleoclimate

see Earth System History (*Opening essay*, **Volume 1**)

Paleoclimatology

Paleoclimatology is the study of past climates that predate measurement by standard meteorological instruments. The

realm of inquiry stretches from the last century back to the origin of the Earth, 4.5 billion years ago, and starts with the changing composition of the atmosphere as life evolved (*see* Carbon Dioxide Concentration and Climate Over Geological Times, Volume 1). When did photosynthesis begin and when did oxygen concentrations become high enough that an ozone layer could form and absorb ultraviolet radiation? Atmosphere, biosphere, and lithosphere interactions were central to these developments. Paleoclimatologists also use data, models, and theoretical reasoning to study what past climates were like, when and how they changed, and what caused the changes (*see* Earth System History, Volume 1). Hypotheses about the causes of past changes in climate have abounded. However, recent advances in dating, data, data analysis, and modeling have led to information about past climates that is accurate and precise enough that hypotheses can be thoroughly tested, rejected or refined, working toward a well-substantiated and self-consistent experimental and theoretical explanation. Imbrie and Imbrie (1986) provide record of this evolution in paleoclimatic research by tracing early 19th century ideas about ice ages through to the funding of major international, interdisciplinary programs that characterized a significant share of late 20th century research into past climates.

Central to the advances that have been made were the improvement in dating methods and the proliferation of data sets that contain climatic information. Data in terms of geochemical records and numbers and types of fossils come from ice cores, marine, lake, and cave sediments, soils, rocks, and trees (Bradley, 1999) (*see* Natural Records of Climate Change, Volume 1). Tax records, and geomorphological patterns (e.g., glacial moraines and ancient shorelines) on the Earth s surface also provide information. The data are then interpreted in terms of past changes in ice volume, vegetation, plankton abundance, animal distributions, carbon dioxide concentrations, wetland extent, permafrost, and sand-dune formation – all of which are indicative of past changes in climate (Crowley and North, 1996). Through synthesis and modeling, paleoclimatologists have constructed time series and maps of past climates. In an iterative process, these data are being used to test simulations of past climates by climate models, while the model results are being used to help explain the patterns in the data (*see* Climate Model Simulations of the Geological Past, Volume 1).

Paleozoic

The *Paleozoic* era lasted 350 million years (Ma), beginning 570 Ma before present (BP) at the end of the Precambrian and ending with the start of the Mesozoic at 220 Ma BP (Matthews, 1984). The Paleozoic era contains six periods. In order, from earliest to latest, they are: the Cambrian, Ordovician, Silurian, Devonian, Carboniferous (subdivided into the Mississippian and Pennsylvanian), and Permian, in order from earliest to latest. The lower (older) boundary with the Precambrian marks the beginning of hard-bodied organisms that yield the first fossil remains, while the upper (younger) boundary with the Triassic marks one of the major extinction events in Earth s history. The term Paleozoic was coined by Adam Sedgewick based on sedimentary units in Wales, but modified by John Phillips based on fossil assemblages (Prothero, 1990). The paleogeography during the Paleozoic went through major transitions, from circum-equatorial continents, including the supercontinent Gondwanaland (Africa, South America, India, Antarctica, and Australia), to the pole-to-pole supercontinent Pangaea. The transition from Gondwanaland to Pangea required Gondwanaland to pass over the South Pole, and North America, Europe, and Siberia to shift to the Northern Hemisphere (Matthews, 1984). The polar position of Gondwanaland resulted in two major glaciations during the Paleozoic. The first glaciation was the Ordovician–Silurian in Northern Africa and the second the Permo–Carboniferous glaciation in South Africa, Australia, South America, India, and Antarctica. Prior to the first glaciation, high sea levels are indicative of high atmospheric carbon dioxide (CO_2) concentrations (related to tectonic activity) and a period of relative warmth. During the late Paleozoic, the existence of Pangea led to an arid, continental climate (Crowley, 1991). Coal formation in the US and Europe peaked during the late Paleozoic (Crowley, 1991) and the uplift of the Appalachians also began during the Ordovician.

Parameterization

The term *parameterization* refers to a formula that is used to represent the effect of processes that are too small to be explicitly included in a model because they occur at scales smaller than the model grid-point spacing. Parameterizations are necessary because, on the one hand, physical quantities in nature vary continuously in three dimensions, while on the other hand, computers are capable of storing the values of model variables at only a finite number of grid points. The spacing between the points of the model grid is the *spatial resolution*. The typical resolution that can be used in a climate model is hundreds of kilometres in the horizontal. Many important elements of the climate system (e.g., clouds, turbulent eddies in the atmosphere and ocean, irregularities in the land surface) have scales much smaller than this. An example of a parameterization would be a formula used to compute the fraction of a grid box in an atmospheric model that is filled with cloud based on the average relative humidity of the box and the direction and magnitude of vertical air motion (high relative humidity or strong upward motion should lead to greater cloudiness). Both of these parameters would be computed by the atmospheric model on the grid-point array, and are in effect being used to diagnose what should be happening between the grid points. Parameterizations are usually developed based on an intuitive, physical understanding of the key driving variables combined with empirical (observed) relationships. However, because the empirical relationships or physical principles that underlie parameterizations are not rigorously derived from fundamental principles, the observed correlation might not be applicable if the underlying conditions change i.e., as the climate changes. For this reason, the use of parameterizations introduces uncertainties in the climatic changes predicted by climate models. All climate models, no matter how complex and how fine the resolution, rely on parameterizations, because there will always be some processes that cannot be explicitly represented (*see* Climate Feedbacks, Volume 1).

Past Global Changes (PAGES)

see PAGES (Past Global Changes) (**Volume 1**)

Perfluorocarbons (PFCs)

Per uorocarbons (PFCs) are compounds containing only fluorine and carbon. The normal state of these compounds at standard temperature and pressure ranges from gases to liquids and waxes to solids. Very few of these compounds occur naturally in the environment. Only the gaseous PFCs are involved in the global environmental change issue: global climate change. These gases are very resistant to decomposition, with photolysis and ion reactions in the mesosphere being the only significant loss processes. Since transport to these altitudes is slow, the atmospheric lifetimes of PFCs are thousands of years. Due to a combination of the long lifetime and strong infrared absorption, atmospheric emissions of gaseous PFCs make disproportionately large contributions to global climate change with global warming potentials (GWPs) over 5700 (*see* Global Warming Potential (GWP), Volume 1). Intentional production of gaseous PFCs is generally for use in very specialized applications such as the manufacture of semiconductors. The semiconductor industry uses CF_4, C_2F_6 and C_3F_8 in both the plasma etching of thin films and in plasma cleaning chemical vapor deposition tool chambers because of their unique characteristics. Perfluoromethane (CF_4) is the most abundant PFC in the atmosphere with a 1995 concentration of about 80 ppt. Current anthropogenic emissions of this gas are more than 1000 times larger than natural emissions. However, because of the extremely long lifetime of CF_4, over 50 000 years, about half of the current atmospheric burden is of natural origin. The largest anthropogenic source of CF_4 is a result of unintended production during the manufacture of aluminum. PFCs are among the compounds listed for control under the Kyoto Protocol to the United Nations Framework Convention on Climate Change (*see* Ozone Layer: Vienna Convention and the Montreal Protocol, Volume 4).

MACK MCFARLAND *USA*

Permafrost

Gunter Weller
University of Alaska Fairbanks, Fairbanks, AK, USA

Permafrost, or perennially frozen ground, is de ned as ground that is continually at a temperature below 0 °C for a

period of two years or more. It is therefore directly related to climate, and it can be highly sensitive to climate change. Permafrost is characteristic of the polar regions, and underlies approximately 25% of the land areas of the Northern Hemisphere; it is widespread in Alaska, Canada, Russia, Mongolia, China, as well as Antarctica. It also exists offshore along the arctic coasts as a remnant from the last ice age, when the global sea level was lower and the offshore regions were exposed to lower air temperatures. In addition, it occurs in some high mountains in lower latitudes and also on Mars and possibly other planets.

OCCURRENCE AND DISTRIBUTION

Figure 1 shows the distribution of permafrost in the Northern Hemisphere. Brown *et al.* (1997) have produced a map with greater detail. The distribution of permafrost is not controlled by climatic factors alone but also by geologic, hydrologic, topographic and botanical features. Where thick, insulating vegetation or peat layers protect the underlying soil from the Sun s direct rays, or on north-facing slopes, the upper permafrost boundary is close to the surface. The annually thawed top layer of the ground is called the active layer. It is a few decimeters thick in the high Arctic, but can be over 1 m thick in the sub-Arctic. Since the ground is frozen, allowing no groundwater discharge, the overlying tundra or boreal forest is often waterlogged, even in areas with low precipitation.

PERMAFROST TYPES AND FEATURES

Permafrost is classified as discontinuous, continuous, sporadic and mountain, and sub-sea permafrost, as shown in Figure 1, depending on its regional distribution and thickness. Discontinuous permafrost is patchy and relatively thin and extends south to about 50° latitude in China and in Canada s Hudson Bay area; often there are islands of thawed ground surrounded by permafrost. Continuous permafrost is extensive in aerial coverage, has no permafrost-free patches, except under deep lakes and river channels, and is thick. Known permafrost thicknesses range from about 1500 m in Siberia to less than 1 m at the southern boundary of the discontinuous or sporadic permafrost zone. The largest extent of mountain permafrost is on the Tibetan Plateau but it is also widespread in other alpine areas. Sub-sea permafrost is widespread on the Siberian and North American continental shelves in shallow water.

Permafrost terrain can often be recognized by geometrically arranged regular features on the surface, which are produced by freezing and thawing processes. This is called patterned ground and resembles large polygons, from a meter to many meters across, separated from one another by shallow troughs. Another feature is the *thermokarst*, which is an irregular depression in the ground where ice masses in permafrost terrain have thawed due to a warmer climate. *Pingos* are surface blisters or ice mounds, reaching tens of meters in height and upwards of 150 m across, which result as ice forms and expands during the re-freezing of thawed sediments. They are often located in old lakebeds and may take hundreds of years to form.

THE ROLE OF PERMAFROST IN HUMAN ACTIVITIES

One of the major obstacles to human settlement in and development of the high-latitude regions is ice-rich permafrost. The regions underlain by permafrost, with considerable amounts of ground ice, pose unusual and serious engineering problems related to the design, construction and maintenance of roads, pipelines, airfields, houses and other structures. The construction of the 1300-km long Trans-Alaska hot-oil pipeline, for example, required elevating the pipelines above ground in permafrost terrain and keeping

the support structures for the pipe artificially frozen. These problems require special engineering techniques, procedures, and materials to minimize disruption of the natural environment, but also to provide the most economical and sound methods of development.

Large amounts of ground ice are often present in the form of ice wedges and massive layers of ice lenses (Figure 2). Ice wedges form as contractions in the soil, which, on freezing and cooling, produce cracks that eventually fill with water and freeze. This process is repeated over long periods of time with subsequent expansion of the ice wedges and displacement of the surrounding frozen sediments and soils. Their presence is of paramount importance because thawing of this ice can cause subsidence, loss of soil strength, and other disastrous effects on man-made structures. Some of the biggest permafrost problems have been observed in Russia where apartment blocks, built from 1950 to the present, have begun to collapse because the climatic warming experienced since then has weakened the bearing capacity of the permafrost on which the buildings stand. Russian engineers expect most of these structures, of which there are hundreds in cities like Yakutsk, Vorkuta and Tiksi, to fail in the next 30 years if present climate trends continue.

EFFECTS OF CLIMATE CHANGE ON PERMAFROST

Permafrost is very sensitive to climate change and its profile of temperature with depth can indicate the past climatic history of the site. For example, borehole temperature measurements in continuous permafrost in Alaska have shown temperature increases of $2-4^{\circ}C$ over the past century (Lachenbruch and Marshall, 1986). Since the ground temperatures in the discontinuous permafrost zone are close to the melting point of ice, this permafrost is particularly susceptible to changes, and a small temperature rise could thaw all of it over times ranging from decades to centuries.

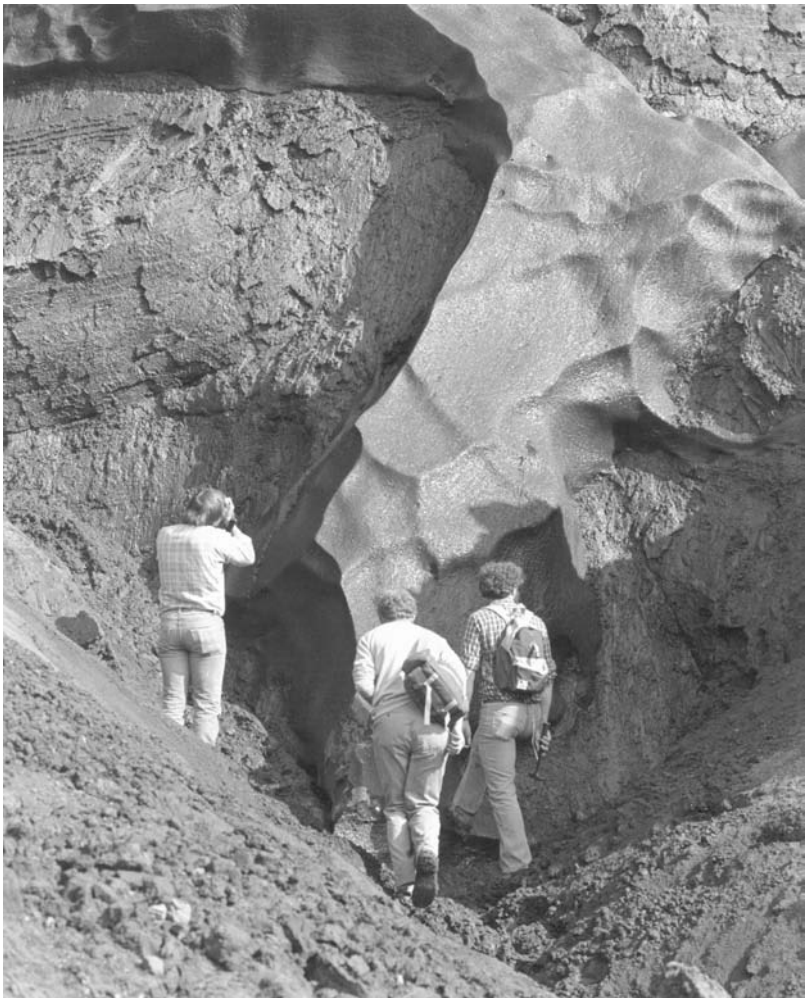

Figure 2 Massive ice wedges in permafrost terrain near Fairbanks, Alaska, exposed by gold mining operations. (Geophysical Institute photo, University of Alaska Fairbanks)

Table 1 Projected impacts due to a 3 °C warming of permafrost (modified from Weller and Lange, 1999)

	Continuous permafrost terrain			Discontinuous permafrost terrain		
Feature/parameter	Low	Moderate	Severe	Low	Moderate	Severe
Thaw lakes	X					X
Coastal processes		X				X
Eolian activity	X			?←	X	
Vegetation		X→	X	X→	X	
Active layer thickness	X					X
Permafrost thawing	X					X
Thaw settlement	X					X
Slope instability		X				X
Erosion		X				X
Solifluction		X				X
Engineering impacts		X				X

Temperature increases in the Arctic in recent decades have already reduced the volume of permafrost by thawing. In some areas, this has led to major erosion problems and landslides, for example in the Mackenzie River. Permafrost thawing has also caused major landscape changes from forest to bogs, grasslands and wetland ecosystems in Alaska. Table 1 summarizes some of the expected changes for a 3 °C temperature rise. *Soli uction* in permafrost terrain is the process of slow downward flow of water-saturated soil on slopes, which is promoted by the permafrost trapping snow and ice melt within the surface layer making it more fluid.

Photochemical Reactions

Douglas Kinnison

National Center for Atmospheric Research, Boulder, CO, USA

Photochemical reactions are reactions that are initiated by the absorption of a photon and that lead to the formation of new chemical species. These reactions are of particular importance because they are the link between the energy provided by solar radiation and the chemical composition of the atmosphere. Interestingly, for example, photochemical reactions driven by solar radiation are essential to the formation of the stratospheric ozone layer, which is essential to life on Earth because it screens out most solar UV-radiation.

Photochemical reactions occur in several different ways. In a photodissociation reaction, a photon splits apart a molecule:

$$AB + h\nu \longrightarrow AB^* \longrightarrow A + B \qquad \bullet 1 \bullet$$

The asterisk (*) represents an intermediate excited state of the *AB* molecule. There are also other photochemical processes, in addition to photodissociation, that can be described as photochemical reactions or photochemically driven, e.g.,

excitation:

$$A + h\nu \longrightarrow A^* \qquad \bullet 2 \bullet$$

insertion:

$$A^* + B \longrightarrow AB \qquad \bullet 3 \bullet$$

abstraction:

$$A^* + B \longrightarrow C + D \qquad \bullet 4 \bullet$$

dissociative excitation:

$$A^* + CD \longrightarrow A + C^* + D \qquad \bullet 5 \bullet$$

In the above examples, *A* through *D* species could be an atom or molecule.

The most important type of photochemical reaction in atmospheric chemistry is photodissociation (*see* Stratosphere, Chemistry, Volume 1; Troposphere, Ozone Chemistry, Volume 1). For example, the nitrogen dioxide (NO_2) molecule absorbs solar radiation in the visible and near ultraviolet region:

$$NO_2 + h\nu \longrightarrow NO_2^* \qquad \bullet 6 \bullet$$

If the wavelength of the photon is less (shorter) than approximately 420 nm, the photon has sufficient energy to exceed the bond strength of the NO_2 molecule and stimulate creation of nitric oxide (NO) and atomic oxygen (O) in its ground electronic state (^{3}P):

$$NO_2 + h\nu \longrightarrow NO_2^* \longrightarrow NO + O \bullet {}^3P \bullet \qquad \bullet 7 \bullet$$

This reaction, followed by the reaction of O(^{3}P) with molecular oxygen (O_2) is the source of *in situ* produced ozone (O_3) in the troposphere. Another example of a photochemical reaction that is important in atmospheric chemistry is:

$$O_3 + h\nu \bullet \lambda \bullet \ 310\,\text{nm} \bullet \longrightarrow O \bullet {}^1D \bullet + O_2 \qquad \bullet 8 \bullet$$

The products of the O_3 photolysis induced by radiation with wavelengths shorter than 310 nm are electronically excited oxygen atom (O(^{1}D)) and molecular oxygen (O_2). O(^{1}D) is a very important species and reacts with numerous chemical constituents in the atmosphere, e.g., O(^{1}D) plus H_2O is the primary process for forming hydroxyl radical (OH) in the troposphere; $O \bullet {}^1D \bullet + N_2O$ is the primary processes for forming nitrogen oxides in the stratosphere.

The additional energy of the absorbed photon above the bond dissociation energy is distributed as electronic, vibrational, rotational, and translational energy of the product molecules (and/or atoms).

In order to assess the atmospheric importance of any photochemical reaction, one must derive the photochemical rate (*see* Depletion of Stratospheric Ozone, Volume 1; Stratosphere, Chemistry, Volume 1; Troposphere, Ozone Chemistry, Volume 1). In the NO_2 example given above, the photochemical rate or change in the concentration of NO_2 with time is (e.g., in units of molecules $\text{cm}^{-3}\,\text{s}^{-1}$):

$$\frac{-\text{d}[NO_2]}{\text{dt}} = j[NO_2] \qquad \bullet 9 \bullet$$

The concentration of NO_2 is designated with square brackets (in units of molecules cm^{-3}). The rate constant is designated as j and has units of s^{-1} and is commonly termed the *photolysis rate coef cient* or *photolysis frequency*. This rate constant is the integral over all wavelengths for the following terms:

$$j = \int_\lambda F \bullet \lambda \bullet \sigma \bullet \lambda \bullet \phi \bullet \lambda \bullet \text{d}\lambda \qquad \bullet 10 \bullet$$

where F is the flux of photons (quanta $\text{cm}^{-2}\,\text{s}^{-1}\,\text{nm}^{-1}$) within the wavelength region, $\text{d}\lambda$ (nm); σ is the absorption cross-section of the molecule (cm^2 molecule^{-1}) within the same wavelength region; and ϕ is the primary quantum yield of the photochemical process (molecules quanta^{-1}) also within the same wavelength region. The primary quantum yield is defined as:

$$\phi_i = \frac{\text{number of excited molecules following the pathway for process } i}{\text{total number of photons absorbed}} \qquad \bullet 11 \bullet$$

For example, the nitrate radical (NO_3) absorbs light in the visible region of the solar spectrum:

$$NO_3 + h\nu \bullet 600 \bullet \ \lambda \bullet \ 700\,\text{nm} \bullet \longrightarrow NO_3^* \qquad \bullet 12 \bullet$$

This electronically excited NO_3 molecule then follows one of two photochemical pathways, with primary quantum yields given as ϕ_1 and ϕ_2:

$$NO_3^* \longrightarrow NO_2 + O \qquad \phi_1 \qquad \bullet 13 \bullet$$

$$NO_3^* \longrightarrow NO + O_2 \qquad \phi_2 \qquad \bullet 14 \bullet$$

By definition, the sum of all primary quantum yields is unity for all photochemical and photophysical processes. An example of a photophysical processes is fluorescence:

$$NO_3^* \longrightarrow NO_3 + h\nu \qquad \phi_3 \qquad \bullet 15 \bullet$$

For additional information on both photochemical and photophysical processes, see Atkins (1990) and Finlayson-Pitts and Pitts (2000).

Planetary Boundary Layer

Roger A Pielke, Sr

Colorado State University, Fort Collins, CO, USA

The planetary boundary layer (PBL) is the layer of the atmosphere immediately above the Earth's surface through which turbulent eddies of air, generated at the surface, extend. The atmosphere above the PBL is called the free atmosphere. These eddies vertically mix heat, water vapor, and atmospheric trace gases such as carbon dioxide, methane and radon. These turbulent air motions can be caused by surface heating, which produces convective turbulent fluxes, and/or by the shearing stress of the wind as it blows over the surface. The shearing stress produces what are called mechanical turbulent fluxes.

The depth of the PBL, in a cloud free atmosphere, can reach 5 km or more over regions of the Earth with strong surface heating and a temperature change with altitude that does not significantly suppress vertical mixing (Figure 1). This temperature change (called the lapse rate) has a value close to the adiabatic lapse rate of $-1\,^{\circ}\mathrm{C}$ per 100 m. At some height within the troposphere, there will be a layer of air that has a lapse rate that decreases less rapidly with altitude, and could even increase with altitude for a short distance. The height at which this first occurs is referred to as the base of the temperature inversion. This height corresponds to the top of the PBL.

When deep cumuliform clouds (cumulonimbus clouds) are present, the depth of the PBL can extend to the tropopause. In the tropical regions, this corresponds to altitudes of 17 km and higher. Cumulonimbus clouds, therefore, are a mechanism by which surface conditions can be rapidly transported through the entire depth of the troposphere. The PBL is generally subdivided into the convective boundary layer, the neutral boundary layer, the stable boundary layer, and the disturbed boundary layer. The *convective boundary* occurs when surface heating dominates the vertical turbulent mixing. It most often develops during daylight over land, where the ground surface is strongly heated by the Sun and over oceans when cold air blows over warmer water.

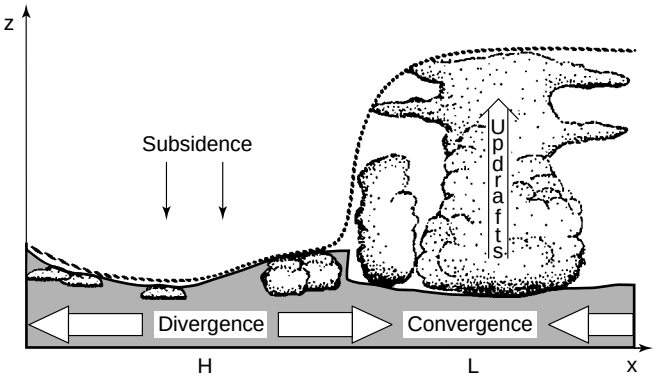

Figure 1 Schematic of synoptic-scale variation of boundary layer depth between centers of surface high (H) and low (L) pressure. The dotted line shows the maximum height reached by surface modified air during a one-hour period. The solid line encloses the shaded region, which is most studied by boundary-layer meterologists. (Reproduced from Stull (1989) by permission of Kluwer Academic Publishers)

Among the major characteristics of the surface that influence the convective PBL are its roughness, albedo, and conductance of water vapor. The partitioning of the convective heat flux into its sensible and latent turbulent heat components directly affects the boundary layer, because only sensible heating directly forces the vertical turbulent mixing. Latent convective fluxes result from the evaporation of water vapor from the soils or water surfaces, and from the transpiration of water vapor through the stomata of leaves. This latent flux is passively transported by the turbulence generated by the sensible heating of the surface until condensation and/or deposition of some of the water vapor occur. The latency of the heat is realized when this condensation and/or deposition occurs. This heat release can then directly affect vertical turbulent mixing. We see this effect visually in the bubbly, cauliflower form of cumulus clouds.

The *neutral boundary layer* occurs when there is no surface heating, but the winds are strong enough to continuously generate turbulence through shearing stresses at the surface. There is a shearing stress at the surface, because the wind speed is zero at that level, yet non-zero just above the surface. Under this condition, the wind change with altitude in the lowest 10% of the PBL is accurately represented as a linear function of the natural logarithm of the height above the surface. This wind profile is called the logarithmic wind profile.

The *stable boundary layer* develops when the vertical turbulent mixing is caused by the shear-generated turbulent fluxes. The turbulent heat flux, however, will actually be towards the surface when this mixing occurs, because the

surface is cooler than the overlying air. A stable boundary layer will tend to suppress shear generated turbulence.

The stable boundary layer commonly occurs on light-wind, clear nights, so that it is also referred to as the *nocturnal boundary layer*. Cooling by radiation is typically an important aspect of a stable boundary layer. This cooling can actually be strong enough to completely suppress vertical mixing. Such a boundary layer is then referred to as a *radiation boundary layer*. Vertical turbulence can also occur intermittently in a stable boundary layer, because the shearing stress periodically becomes large enough to generate turbulence, despite the stabilizing influence of the vertical temperature profile. A radiation boundary layer is also called a *very stable boundary layer*. The boundary layer itself can be decomposed into two layers. These layers are most clearly defined for the convective boundary layer and the neutral boundary layer. In the lower 10% of the boundary layer, wind direction changes little with altitude and can be generally ignored. This layer is called the *surface layer*. Above this layer to the top of the planetary boundary is called the *transition layer*. As you ascend within the transition layer, the atmospheric structure is approaching that of the free atmosphere. The transition layer is also referred to as the *Ekman layer*. The Ekman layer is a mathematical derivation used to explain the approach of the wind to its free atmospheric value, because the frictional effect of the surface becomes smaller with altitude (see Figure 2).

When adjacent regions of the Earth s surface have different characteristics, PBLs of different depths can occur. When the wind blows from one surface type to another, a transition boundary layer will occur that has properties of the new surface in the lowest levels, but properties of the older surface above. The region below the interface between these two regions of the boundary layer is called the *internal boundary layer*.

The physics governing the boundary layer for slowly varying weather conditions over relatively homogeneous, flat surfaces on Earth for clear or shallow cloud conditions is reasonably well understood. The modeling of weather and climate almost always uses parameterizations of the PBL that were developed from observations made over such simple landscapes. Our understanding of the boundary layer in more complex landscapes, in disturbed weather, and for rapidly changing weather conditions, however, remains poor.

In the context of environmental change, any anthropogenic or natural effect that alters the Earth s surface will immediately and directly alter the structure and dynamics of the PBL. Anthropogenic effects include landscape changes, such as the conversion of a tropical forest to grassland. Such changes in the boundary layer, through its effect on cumulonimbus convection, can influence the global atmosphere circulation (e.g., Chase *et al.*, 2000). Natural effects include snow accumulation and melt, as discussed for example in Liston (1999).

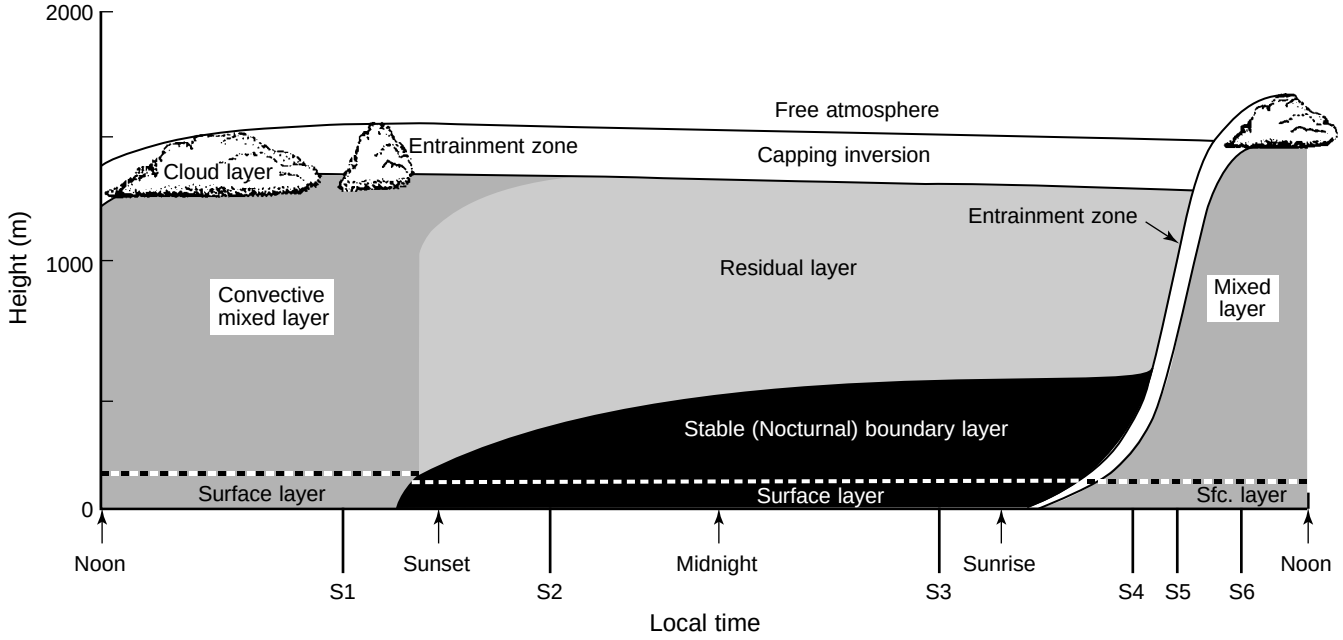

Figure 2 The boundary layer in high pressure regions over land consists of three major parts: a very turbulent mixed layer; a less turbulent residual layer containing former mixed layer air; and a nocturnal stable boundary layer of sporadic turbulence. The mixed layer can be subdivided into a cloud and a subcloud layer. Time markers are indicated by S1–S6. (Reproduced from Stull (1989) by permission of Kluwer Academic Publishers)

Plate Tectonics

W Brian Simison
University of California, Berkeley, CA, USA

The evolutionary history of our planet's varied environments is intricately tied to the processes and products of plate tectonics. Over great spans of time, the movement and deformation of the Earth's crust has brought different environments together to form new environments and separated other environments to evolve in isolation. Environments have been lifted from low to high elevations during the formation of mountains. Volcanic activity has wiped out vast environments and simultaneously laid down rich soils for the formation of new ones. The moving continents have in uenced global weather patterns, which in turn have affected the global distribution of environments. All of these scenarios are products of plate tectonics and part of the evolutionary history and global environmental change of our planet.

Plate tectonics is the primary process controlling the geographic distribution of continents and oceans and the geological dynamics of the ever-changing Earth. It is also the mechanism responsible for many geological features and events, including earthquakes, volcanoes, geysers, mountains, hot vents, island arcs, and the distribution of mineral resources.

Our understanding of plate tectonics is still developing; prior to 1960, very little was known about the processes controlling the planet s surface. The first to suggest that the surface of the planet was not static was Alfred Wegener (1880–1930) (*see* Wegener, Alfred, Volume 1). While examining maps and globes, Wegener noticed that the continents seemed to fit together like a puzzle. In 1912, he proposed that the continents were once united into a single protocontinent, which he called *Pangaea* (meaning all lands), and that over time they drifted apart.

There were many well-known geological and paleontological clues supporting his hypothesis. The best-known geological evidence was the observation that ancient gouges left by glaciers, known as *striae*, were very similar along the matching shorelines of Africa and South America. Wegener s hypothesis could explain this observation by placing the two continents together during an ancient ice age, thus permitting glaciers to cross the now separated margins of the continents and leave similar striae on their coasts. Well-documented paleontological evidence indicated the presence of the same fossilized plants and animals on different continents. Several hypotheses had been proposed to explain this observation; among the most popular of that time was the idea that land bridges spanned the vast oceans, thereby permitting plants and animals to cross the oceans. Wegener s hypothesis of continental spreading, however, provided an alternative explanation for the occurrence of similar fossils separated by great seas.

Wegener also argued that his hypothesis could account for the formation of the planet s mountain ranges and the differences in their apparent ages. The theory of mountain formation, or *orogenesis*, being discussed during his time was the Contraction theory, which suggested that the planet was once a molten ball and in the process of cooling, the surface cracked and folded upon itself to create mountains. The big problem with this idea was that all mountain ranges should be approximately the same age, and this was known not to be true. Wegener s explanation suggested that as the continents moved, the leading edge would encounter resistance, and thus compress and fold upwards, forming mountains near the leading edges of the drifting continents. The Sierra Nevada Mountains on the Pacific coast of North America and the Andes on the coast of South America were cited as examples. Wegener also correctly suggested that India drifted northward into the Asian continent, thus forming the Himalayas.

While his ideas elegantly explained many geological phenomena, Wegener did not have a viable mechanism that could move continents across the surface of the planet. This kept the scientific community from accepting his ideas. In 1929, just as Wegener s theory was being dismissed, Arthur Holmes elaborated on one of Wegener s many hypotheses; the idea that the mantle undergoes thermal convection. This idea is based on the property of heating fluids from below: the density of a heated fluid will decrease and therefore rise to the surface where it cools and subsequently sinks. This repeated rising and sinking results in a circulating current that could provide the necessary force to move continents. Arthur Holmes suggested that this thermal convection was like a conveyor belt and that the upwelling pressure could break apart a continent and force the fragmented continent to ride the convection currents in opposite directions.

Unfortunately, there was very little evidence that the surface of the planet was riding on a swirling sea of fluid

rock. However, scientists began documenting features of the ocean floor and discovered mid-oceanic ridges; parallel to the ridges were symmetrical bands of alternating geomagnetic polarity (Figure 1). Scientists have since learned that the Earth periodically undergoes reversals of its magnetic fields, where the geomagnetism that pulls the compass needle towards the North (magnetic) Pole suddenly switches to the South (magnetic) Pole. Geomagnetic direction is permanently recorded in rock as it cools from a molten to solid phase. Scientists studying the sea floor noticed that the geomagnetic bands along the mid-oceanic ridges formed parallel patterns of varying widths and that these patterns formed mirror images on either side of the ridges. This and other clues led R Deitz (1961) and Harry Hess (1962) to publish similar hypotheses based on mantle convection currents, now known as sea floor spreading. Their idea was the same as that proposed by Holmes over 30 years earlier, but now there was much more evidence to further develop and support the idea.

Our current understanding of plate tectonics involves four main features:

1. the Earth s surface is covered by a series of crustal plates;
2. the plates are continually moving, with their ocean edges continually spreading from the mid-oceanic ridges, their landward edges sinking at the plate margins, and the descending edges being reabsorbed in the mantle;
3. crustal plates ride convection currents in various directions;
4. the source of heat driving the convection currents is radioactive decay deep in the Earth s mantle.

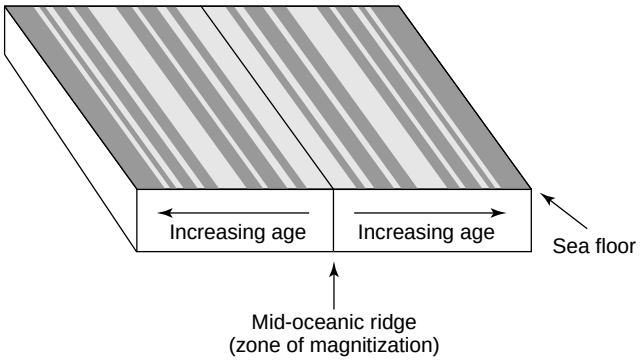

Figure 1 This figure demonstrates the effects of periodic magnetic polar reversals along mid-oceanic ridges. The dark stripes represent the ocean floor generated during *reversed* polar orientation and the lighter stripes represent the polar orientation we have today. Notice that the patterns on either side of the line representing the mid-oceanic ridge are mirror images of one another. Molten rock is extruded at the mid-oceanic ridge and hardens with the current geomagnetic direction. The stripes represent older and older rock as they move away from the mid-oceanic ridge. Geologists have determined that rocks found in different parts of the planet with similar ages have the same magnetic characteristics

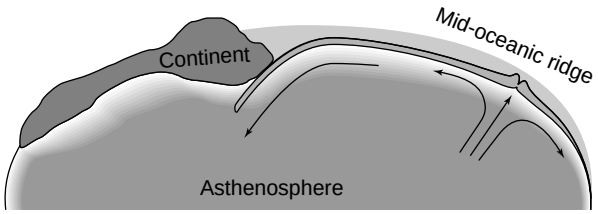

Figure 2 A cross-section of the Earth revealing a continental plate, an oceanic plate, an ocean and the asthenosphere. The arrows indicate the convection patterns of the fluid asthenosphere underneath the solid plates or lithosphere. These circulating convection currents are responsible for the movement of the plates

Underneath the Earth s crust (the *lithosphere*: a solid array of plates (*see* Lithosphere, Volume 1)) is a malleable layer of heated rock known as the asthenosphere, which is heated by the radioactive decay of elements such as uranium, thorium, and potassium. Because the radioactive source of heat is deep within the mantle, the fluid asthenosphere circulates as convection currents underneath the solid lithosphere. The asthenosphere is the source of lava released by volcanoes, the source of heat that drives hot springs and geysers, and the source of raw material that creates the mid-oceanic ridges and forms new ocean floor. Magma continuously wells upwards at the mid-oceanic ridges (Figure 2, arrows), producing currents of magma flowing in opposite directions that generate the forces pulling the sea floor apart at the mid-oceanic ridges. As the ocean floor is spread apart, cracks appear in the middle of the ridge, allowing molten magma to surface through the cracks to form the newest ocean floor. As the ocean floor moves away from the mid-oceanic ridge, it encounters continental plates that drive it back into the asthenosphere, where the plate edge is melted and returns to a heated state.

The large-scale effects of plate tectonics are important determinants of the global environment, with mountains affecting global weather, ocean basins affecting sea levels, shape of continents determining geography, and continental dynamics affecting the evolution of biological diversity.

Pleistocene

Pleistocene refers to the ice age that was the geologic epoch prior to the present Holocene within the Quaternary Period, which is part of the Cenozoic Era. The Pleistocene began 1.5–1.6 Ma and ended with the start of the Holocene, 10 000 years ago (Berggren and Couvering, 1978).

Polynyas

Polynyas are large, persistent areas of open ocean surrounded by sea ice or sea ice and land. They are larger, less elongated, and less ephemeral than the channels of open water known as *leads*, which form where the drift of the sea ice locally diverges. They tend to recur seasonally in the same place – sometimes every year, sometimes very irregularly.

Coastal polynyas commonly form in regions where wind blowing from land (often ice covered) forces newly forming sea ice away from the shore. In the polar winter, the heat loss from the open water to the cold atmosphere may be a hundred times greater than that through the surrounding sea ice. The latent heat released by the freezing of the new ice helps replenish that lost heat, allowing the polynya to remain unfrozen. At the same time, salt rejected in the freezing increases the salinity of the water and hence its density. The denser water sinks; consequently, coastal polynyas, particularly around Antarctica, contribute importantly to the generation of the bottom waters of the world s oceans.

A second mechanism of polynya formation is the upwelling of relatively warm, deeper water. Such upwelling may be caused by the interaction of ocean currents with features of the submarine topography.

Polynyas are important to climate because, together with leads, they produce the bulk of the heat and water vapor exchange between the ocean and the atmosphere in regions of sea ice cover. They are also the loci of strong biological activity, like the marginal sea ice zone around the outer edges of the ice pack.

A particularly large (several hundred square kilometers), mysterious polynya formed in the Weddell Sea near Antarctica for several austral winters during the 1970s. Its cause was probably a combination of atmospheric and oceanic circulation patterns, but marine expeditions to study it were largely unsuccessful because the polynya never reappeared after 1978. A more reliable polynya known as North Water forms annually at the northern end of Baffin Bay, west of Greenland. It too results from a combination of the two mechanisms. North Water exerts a pronounced effect on the regional climate.

Polynyas, because they are delicately balanced between competing oceanic and climatic processes, are likely to respond sensitively to environmental change. Thus they may act both to amplify changes and to provide early evidence, through their own alterations, of those changes.

Prediction in the Earth Sciences

Michael C MacCracken

Lawrence Livermore National Laboratory, Livermore, CA, USA

The great Danish physicist Neils Bohr once commented that "Prediction is very dif cult, especially about the future" (also sometimes attributed to Mark Twain and, later, to Yogi Berra). Although there is some public understanding that the existing pattern of the weather allows for prediction of how

the weather will evolve over the coming few days, there is little understanding of the basis for or accuracy of longer-term prognostications. Indeed, the notion that scientists can make statements about what is likely to happen 100 or more years into the future can seem overly presumptuous if recognition is not given to the careful ways that scientists use words to convey their views about the possibility/probability of future happenings.

In public discussion about weather and climate, the words prediction, forecast, projection, and scenario are often used almost interchangeably, as if their meanings are synonymous. However, the scientific community researching global change generally uses these words quite carefully, with each word having a distinctive meaning and significance. These differences and meanings are important to understand because they convey an important set of assumptions underpinning their usage.

Although there is not universal agreement, distinctions of the following types are often made:

- A *prediction* is usually a probabilistic statement that something will happen in the future based on conditions that are known today and assumptions about the physical processes that will determine these changes. A prediction generally assumes that future changes in factors other than those being predicted will not have a significant influence on what is to happen. In this sense, a prediction is most influenced by the initial conditions, that is, on the current conditions that are known through observations. Thus, a weather prediction indicating a major snowstorm will develop over the next few days is based on the state of the atmosphere today (and its conditions in the recent past) and not on unpredictable changes of other potentially influential factors that serve as boundary conditions, such as how ocean temperatures or human activities may change over the next few days. A prediction is made probabilistic by accounting for various types of uncertainties, for example, in the accuracy of observations, in the chaotic state of the atmosphere, etc. (*see* Chaos and Predictability, Volume 1). For decision-makers, what is important is that a prediction is a statement about an event that is likely to occur no matter what they do (i.e., policymakers cannot change tomorrow s weather).
- A *forecast* is generally more specific and more routinely prepared than a prediction, often being made by a particular person (or group) or with a particular technique or representation of current conditions. Whereas a prediction might suggest that there is a 70% chance of rain in the area, an example of a forecast would be a statement by a particular weather forecaster (or forecasting group) that it is expected to rain in the mid-afternoon tomorrow in a particular community. Basically, a general prediction is being made more specific using best judgment of some type. For a decision-maker, the credibility of the forecast depends critically on the credibility of the forecaster (and the forecasting technique). For many forecasters, this can be evaluated because there is a history of their records of success and failure. For example, weather forecasts are made every day, so statistics on their performance can be developed and evaluated. The recent development of ensemble forecasts (i.e., drawing upon, in a probabilistic way, an assembly of a set of forecasts that are each based on a separate technique or set of initial conditions) is a means of transforming a forecast into a prediction.
- A *projection* is usually a probabilistic statement that it is possible that something will happen in the future if certain conditions develop. In contrast to a prediction, a projection specifically allows for significant changes in the set of boundary conditions that might influence the prediction. As a result, what emerges are conclusions of the type if this happens, then this is what is expected. The simplest type of projection is to extrapolate into the future assuming all of the boundary conditions remain the same or the same trends prevail. For projections extending well out into the future, however, this is often a poor assumption, so scenarios (or story-lines) are developed of what could happen given various assumptions and judgments (see below). For example, the Intergovernmental Panel on Climate Change (IPCC, 2001) recently projected a range of possible temperature increases for the 21st century that calculations indicated would result in the event that the world followed a number of plausible story-lines concerning population and economic growth, energy technologies and emissions, and demographics and international relationships – while also assuming no agreements to limit emissions due to concerns about climate change. By considering how the resulting changes in atmospheric composition would affect the climate using seven different climate models, each with its own particular climate sensitivity (the temperature change that would result from a CO_2 doubling; *see* Climate Sensitivity, Volume 1), the projections of climate change accounted, to a reasonable extent, for a wide range of possibilities of both societal development and climate behavior. This is clearly a projection of what could happen if certain assumed conditions prevailed in the future; it is neither a prediction nor a forecast of what will or is likely to happen, especially given knowledge of what these projections portend. For a decision-maker, a projection

is thus an indication of a possibility, and normally of one that could be influenced by the actions of the decision-maker (*see* Projection of Future Changes in Climate, Volume 1).

- A *scenario* is a set of conditions describing how the future may evolve based on a set of assumptions. While the climate system depends on many rigorous physical laws, there are no such laws governing societal behavior and occurrences such as the invention of new technologies, the choices that lead to war and peace, the prevalence and intensity of diseases and cures, and the growth of the world population. Most important, society also evolves as a result of thinking about the future, perhaps the most unique aspect of human and societal capabilities. To provide a basis for taking advantage of human insight and in recognition that many relevant parameters can vary within such wide ranges that specific predictions are not possible, scenarios are used to envision possible alternative futures, hypothesizing that various factors could turn out in particular ways without predicting that this will occur. Because we cannot know what will happen, scenarios are constructed that describe the possible evolution of relevant parameters in a manner that is detailed, internally consistent, and scientifically sound. Usually, an envelope of possible futures (or scenarios) is designed that allows exploration or illustration of important issues that can enable scientists and decision-makers to think logically about the future. Another important reason for considering such a set of alternative futures is so that policymakers can conduct analyses and design management strategies that do not, for example, foreclose options or lock society into a particular, possibly adverse outcome. For example, one particular scenario might assume world population will reach a particular level, renewable energy sources will become less expensive and more available at a certain rate, the economy will grow at a certain rate, the world s nations will cooperate in sharing technologies, etc. Another scenario might be constructed with a different combination of expectations. For a planner, a set of scenarios is about possibilities, and the frequent shortcoming is in not being imaginative enough. It is for this reason that many such efforts are either too limited, or have resulted in such large ranges of possibilities that the resulting projections at first seem inconclusive. However, it is just this type of outcome that can help decision makers consider the wide range of possible futures (*see* Futures Research, Volume 5; Scenarios, Volume 5).

While scientists generally tend to use these words quite carefully, this is not always the case when the media report on science. For example, in the early 1990s, a survey of scientists was widely reported to indicate that many scientists had low confidence in predictions for the 21st century. This was taken by some to mean that scientists did not believe in the greenhouse effect. However, the result of the survey is not at all surprising given how prediction is defined and generally understood by scientists – of course, scientists cannot offer a definitive indication about what will happen in the 21st century because it depends on energy technologies and political decisions as well as how the climate will respond. However, without contradicting the survey results, the Intergovernmental Panel on Climate Change can report that there is an international consensus among most members of the scientific community on its projections of a temperature rise during the 21st century if emissions follow the projected emissions scenarios.

While these differences in terminology may seem subtle, they are essential for understanding the confidence to have in conclusions and to consider how they can be responsibly used. Outside the scientific community – for example in military and financial planning – preparing scenarios and then using them to explore their impacts on related parameters by constructing projections is a widely used approach. In such studies, it is understood that these are projections of what could happen if a particular situation developed, not predictions of what will happen. Although everyone would like to have reliable (and verifiable) predictions, the complexities of society and climate are such that we are forced to rely on projections if we want to use our capability for understanding the Earth system to look forward into the future in a useful way; otherwise we are limited to advancing forward blindly because we can only rely with certainty on mindless extrapolations of changes that have been observed in the past.

Q

Quasi–Biennial Oscillation (QBO)

Kevin Hamilton
University of Hawaii, Honolulu, HI, USA

Observations and theory of the Quasi-Biennial Oscillation (QBO) in the stratospheric circulation are reviewed. The QBO is a cyclic variation with slightly irregular periods averaging about 28 months. It appears most clearly in observations of the prevailing winds in the tropical stratosphere, but has signi cant effects on stratospheric temperature and circulation in the extratropics as well. The QBO also has a major impact on the interannual variation in stratospheric ozone, which must be considered when evaluating possible anthropogenic effects in the observed ozone record.

The prevailing east–west winds near the equator at heights between about 18 and 40 km are observed to undergo a remarkable oscillation from strong easterlies (up to about 30 m s^{-1} at some levels) to strong westerlies (about 20 m s^{-1}) with a mean period of about 28 months. This so-called QBO is by far the dominant component of interannual variability in the tropical stratospheric circulation and has a significant influence on variability of temperature and wind in the extratropical stratosphere as well. The variations in atmospheric circulation associated with the QBO significantly influence the ozone layer. The QBO variations in total column ozone can be as much as 6% of the mean value. Thus, QBO effects need to be accounted for when evaluating observed ozone trends.

The first information on the winds at high altitudes near the equator was obtained in 1883 when the dust cloud produced by the explosive eruption of Mount Krakatoa (in modern-day Indonesia) was observed to travel westward around the equator at a fairly constant speed of about 33 m s^{-1}. It was reasonably inferred that the winds near the equator at the heights estimated for the dust cloud (about 20–40 km) were steady easterlies of about 30 m s^{-1}. In the first half of the 20th century a few scattered balloon observations of stratospheric winds were taken at different times and locations near the equator. These sometimes showed the presence of easterlies but also sometimes westerlies. These puzzling results were reconciled at the time by assuming that the Krakatoa easterlies were a broad current in which thin ribbons of meandering westerlies were imbedded. In the 1950s, the first regular daily balloon observations of stratospheric winds and temperatures were begun at several stations near the equator. By 1960 enough data existed for R Reed (University of Washington) and, independently, R Veryard and R Ebdon (United Kingdom Meteorological Office) to determine that the monthly-mean winds in the tropical stratosphere in fact had very little geographical variation around the equator, but had a strong temporal variation, with prevailing easterlies at any height replaced by westerlies roughly every other year. Initially it was thought that the oscillation might have a period of exactly 2 years, but subsequent observations have shown that the QBO is somewhat irregular from cycle to cycle, but with an average period of about 28 months.

Figure 1 shows a long time series of monthly-mean values of the east–west (zonal) component of the wind at 50 hPa (approximately 21 km) computed from regular daily balloon observations at Singapore (1.3 °N). The presence of the QBO is obvious, and this oscillation utterly dominates any other aspect of variability in the record (such as the annual cycle, high frequency month-to-month variability or very long term trends). While the oscillation has been fairly stable through the almost 50 years for which there are detailed observations, Figure 1 also shows some modest irregularity from cycle to cycle. In particular, the period of the oscillation appears somewhat variable, with some anomalously long cycles (e.g., 1966–1969) and short cycles (e.g., 1971–1972). The variations in monthly-mean zonal wind observed at other stations close to the equator are very similar. Thus, the QBO can be thought of as an oscillation in the zonally averaged flow (i.e., the circulation averaged around latitude circles).

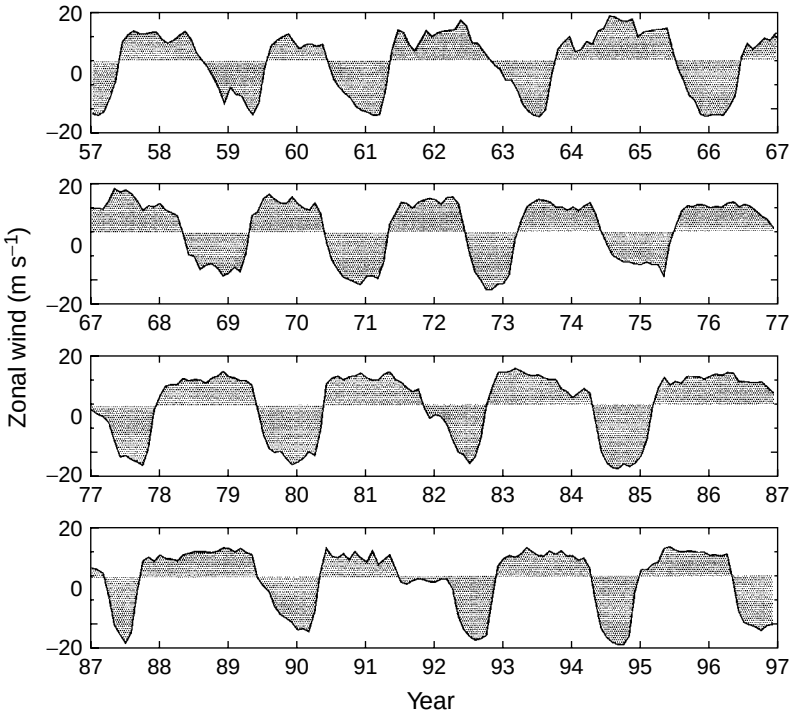

Figure 1 Monthly-mean values of the east–west wind for 40 years (January 1957 through December 1996) measured at 50 hPa at Singapore (1.3 °N, 103.9 °E). Positive values denote westerly winds

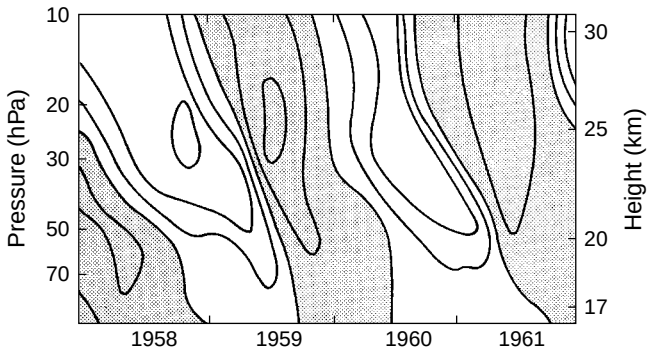

Figure 2 Height–time section of the monthly-mean east–west wind measured at Canton Island (2.8 °S, 171.7 °W) for a period of four years. The contour interval is 10 m s^{-1} and shading denotes westerly wind. Results shown for the height range 17–30 km

The QBO in zonal wind also has an interesting height structure. Figure 2 shows contours of the height–time evolution of the monthly-mean zonal wind over 4 years as measured at Canton Island (2.8 °S). At any level the oscillation between easterlies and westerlies is quite apparent, but the changes do not occur simultaneously at all heights. In fact there is a clear downward progression of the wind reversals at a rate of between 1 and 2 km month^{-1}. This is a consistent feature in each cycle of the QBO that has been observed. The oscillation is strongest near about 30 hPa (• 24 km), and has a large amplitude (generally greater than 20 m s^{-1} peak to peak) over a broad height region (about 20–40 km). Below 20 km the amplitude drops off rapidly and the QBO is not seen clearly in the troposphere. Similarly, above 40 km the QBO amplitude drops strongly, although the QBO is now known to have subtle influences at higher altitudes, particularly in terms of modulating higher-frequency components of the circulation.

Associated with the QBO in zonal wind are oscillations in zonal-average temperature and in the circulation in the meridional plane (i.e., the north–south and vertical wind components). The variations in temperature have been measured by daily balloons and from remote sensing instruments on satellites. The temperature QBO is as large as 8 °C, peak to peak. The QBO in the vertical wind is too small to be directly observed, but it has effects on stratospheric composition. In fact a quite strong QBO in tropical stratospheric ozone concentration is observed. The QBO in total integrated column ozone amounts has a peak to peak amplitude of about 6% of the mean column at the equator. The maximum in the ozone column at low latitudes is coincident with the maximum westerly wind at 50 hPa, clearly showing the strong connection between dynamical and ozone QBOs. The QBO is a very important component of natural variability and must be taken into account when evaluating possible

long-term trends in observed ozone, as well as temperature and wind.

The observed amplitude of the QBO in zonal wind drops off roughly exponentially with latitude in both hemispheres and has only half its equatorial amplitude at about 12° latitude. However, the QBO does appear to have at least some influence on the extratropical stratosphere, although these effects can only be seen as statistical effects in long observational records. In particular, the Northern Hemisphere polar stratosphere tends to be warmer (and the circumpolar vortex weaker) on average in winters when the equatorial QBO in the lower stratosphere is in its easterly phase. It is thought that the correlation with the equatorial QBO can explain about 25% of the interannual variance observed in the high latitude stratosphere. The effects of the stratospheric QBO on aspects of tropospheric circulation have also been investigated. While the possible tropospheric connections remain somewhat controversial, the phase of the QBO (which itself is reasonably predictable for months or even years) has been used as an input into long-term weather forecasts.

In the now standard theory for the QBO, developed initially in 1968 by R Lindzen (University of Chicago) and J Holton (University of Washington), higher frequency (periods of hours to days) wave motions excited by moist convection in the tropical troposphere act as catalysts transferring zonally averaged zonal momentum between different layers of the atmosphere. When a broad spectrum of waves is allowed to interact in this manner with the mean flow, the result can be a long-period oscillation of the zonally averaged flow with the downward progression characteristic of the observed QBO. Random variations in the strength of the convectively forced waves may then be invoked to explain the cycle to cycle variability seen in the QBO record. This model of the QBO has been used as a basis for speculation concerning long-term anthropogenic modification of the QBO. The effects of increasing greenhouse gas concentrations could include modifications to the convective forcing of high-frequency waves in the tropics and to the propagation and dissipation characteristics of the waves in the stratosphere. All these changes should have effects on the properties of the QBO. Continued monitoring of the QBO for possible long-term trends may provide evidence for anthropogenic effects on the atmosphere.

Quasi–Decadal Oscillation

Lon L Hood
University of Arizona, Tucson, AZ, USA

A 10- 12 year oscillation of the heights of constant-pressure surfaces in the Northern Hemisphere lower stratosphere was rst reported by Karin Labitzke of the Free University of Berlin (Germany) and Harry van Loon of the National Center for Atmospheric Research (Boulder, CO, USA) in the late 1980s. In addition to this meteorological quasi-decadal oscillation, a similar decadal oscillation of total column ozone exists with a global mean amplitude of 1.5- 2.0%. Like the meteorological oscillation, the quasi-decadal oscillation of total ozone is approximately in phase with the solar cycle (ozone maxima tend to coincide with solar activity maxima) and maximum amplitudes of the ozone oscillation occur near 30° latitude in both hemispheres. Current general circulation models that account for known direct effects of solar ultraviolet variability (changes in ozone production, radiative heating, upper stratospheric winds) as well as indirect dynamical interactions are able to simulate qualitatively several characteristics of the observed quasi-decadal oscillation. However, signi cant quantitative differences remain.

A current issue in global environmental research is the extent to which solar variability can influence climate change on time scales ranging from decades to centuries. In particular, it is important to determine the relative contributions of increasing solar energy output and increasing emissions of human-induced increases in greenhouse gas concentrations in producing the observed surface temperature rise of the past century. Although numerical atmospheric circulation models represent a useful means of estimating the climatic effects of solar forcing, it is essential that these models be tested and validated observationally. One means of testing Sun-climate models may be provided by the *Quasi-decadal Oscillation*, an observed temporal cycle of stratospheric and tropospheric meteorological parameters that correlates approximately with the Sun s 11-year activity cycle.

A 10–12 year oscillation of the heights of constant-pressure surfaces in the Northern Hemisphere lower stratosphere was first reported by Karin Labitzke of the Free University of Berlin (Germany) and Harry van Loon of the National Center for Atmospheric Research (Boulder, CO) in the late 1980s (*see* Stratosphere, Temperature and Circulation, Volume 1). As shown in Figure 1, correlations of 30 mb heights with the solar 10.7 cm radio flux (a ground-based proxy for solar ultraviolet variability)

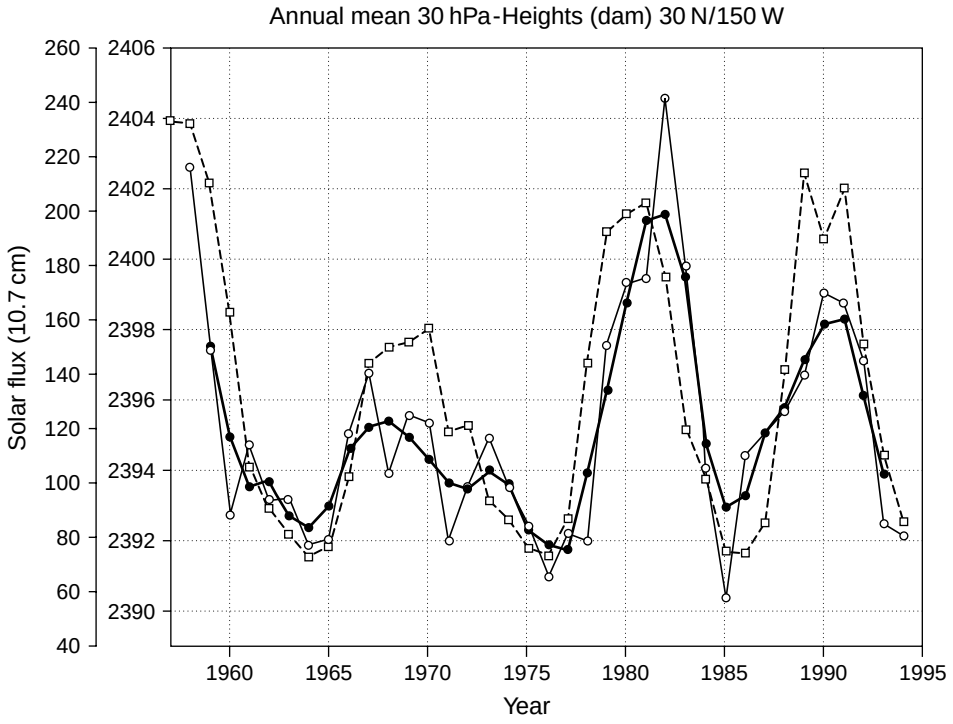

Figure 1 Time series of annual mean 10.7 cm solar flux (open squares), annual mean 30 mb height at 30 °N 150 °W (open circles), and a 3-year running mean of the 30 mb heights for each year (heavy solid line) (K Labitzke, private communication). The heights are in decameters (dam). (Reproduced by permission of *Tellus*)

can be quite high near 30 °N latitude. A similar correlation is present in the Southern Hemisphere with maximum amplitude near 30 °S latitude in winter. Because the heights of constant-pressure surfaces are determined in part by the temperature at lower levels, some evidence also exists for an 11-year solar cycle signal in temperature records for the lower stratosphere and upper troposphere of the Northern Hemisphere.

In addition to the meteorological quasi-decadal oscillation, a decadal oscillation of total column ozone exists with a global mean amplitude of 1.5–2.0%. Because most of the ozone column is in the lower stratosphere and the ozone lifetime there is much longer than dynamical time scales, total ozone is a sensitive measure of circulation changes in this part of the atmosphere. Like the meteorological oscillation, the quasi-decadal oscillation of total ozone is approximately in phase with the solar cycle (ozone maxima tend to coincide with solar activity maxima) and maximum amplitudes of the ozone oscillation occur near 30 °latitude in both hemispheres.

Solar-related energy inputs that could be involved in producing the quasi-decadal oscillation include total irradiance changes (which penetrate directly to the troposphere), changes in solar ultraviolet flux (which affect the production rate of ozone and are largely absorbed in the stratosphere), and changes in energetic particle fluxes and shorter wavelength radiation (which primarily affect the upper atmosphere above the stratopause). Because total irradiance changes are relatively small (about 0.1% from solar minimum to maximum) and the observed oscillation has a maximum amplitude in the lower stratosphere, changes in solar ultraviolet flux, which reach amplitudes of 6–7% near 200 nm wavelength, are considered to be the most likely forcing mechanism. However, indirect effects of solar variability on the upper atmosphere can not yet be eliminated as a significant contributor.

Current general circulation models that account for known direct effects of solar ultraviolet variability (changes in ozone production, radiative heating, upper stratospheric winds) as well as indirect dynamical interactions are able to simulate qualitatively several characteristics of the observed quasi-decadal oscillation. However, significant quantitative differences remain. For example, the observed ozone decadal oscillation differs markedly in latitude and altitude dependence from the simulations of the present climate by existing models. This suggests that an important element of the solar forcing process is not included in the models.

Recent work indicates that a full understanding of the quasi-decadal oscillation, and, by implication, a full understanding of how solar variability affects climate, requires a more detailed investigation of how solar variability may affect another atmospheric oscillation, the quasi-biennial oscillation (QBO) of zonal wind in the equatorial lower

stratosphere (*see* Quasi- Biennial Oscillation (QBO), Volume 1). Specifically, statistical studies suggest that this roughly 2-year oscillation, which is driven internally by upward propagating equatorial wave disturbances originating in the troposphere, may be modulated slightly by the solar activity cycle. Because the equatorial QBO strongly influences stratospheric dynamics on a global scale, any solar-induced perturbation of the QBO would imply dynamical effects in the lower stratosphere and upper troposphere that are not currently accounted for in climate model simulations of solar interactions. Previous work has documented that the QBO influences the occurrence of major mid-winter warmings in the polar zones of the Northern Hemisphere such that they occur primarily during the easterly phase of the QBO. However, as first noted by Labitzke during the 1980s, major mid-winter warmings also occur during the westerly QBO phase under solar maximum conditions. This results in an effective solar cycle variation of January and February mean lower stratospheric temperatures on a decadal time scale when the data are separated according to the phase of the QBO. Recent studies suggest that the westerly phase of the QBO wind oscillation itself in the equatorial lowermost stratosphere (near 50 mb) tends to be shorter in duration near solar maxima than near solar minima. The mechanisms by which solar variability is apparently able to modulate the equatorial QBO have not been fully established. Until these issues are resolved, the ability of current general circulation models to accurately simulate the solar-induced component of climate change will remain limited.

Quaternary

The *Quaternary Period* is the geologic period following the Pliocene, beginning 1.5–1.6 Ma. The Quaternary consists of the Pleistocene and Holocene epochs (*see* Holocene, Volume 1; Pleistocene, Volume 1). The Pleistocene was a period encompassing many glacial-interglacial cycles; the Holocene is the current interglacial period. The Quaternary Period has been marked by repeated cycles of Northern Hemisphere glaciations, which began prior to the start of the Quaternary around 2.5 Ma. The glaciations became more intense starting 700 000 years ago, changing from 41 000 year cycles to 100 000 year cycles (Webb and Bartlein, 1992). The glacial-interglacial cycles appear to be driven by changes in the latitudinal-seasonal pattern of insolation reaching the top of the Earth s atmosphere (caused by cyclic changes in the Earth s orbit around the Sun) and by other internal feedback mechanisms of the climate system (*see* Orbital Variations, Volume 1). Other factors that distinguish the Quaternary are repeated latitudinal climate displacements and changes in oceanic circulation and sea level. Originally the Quaternary was thought to be correlated with the first hominids, but their appearance is now thought to extend back into the Pliocene. The name *Quaternary*, originally used by Marcel De Serres, was coined by Paul Desnoyers (1829) based on nearly horizontal, relatively unconsolidated younger strata in lowland regions, although the term was also earlier used by Lyell to refer to beds containing fossils of relatively young age (Berggren and Couvering, 1977). The term *alluvium*, referring to recent loose and unconsolidated sediments (Werner) and *diluvium*, referring to sediments resulting from the noachian flood (Buckland), are also associated with Quaternary sediments (Prothero, 1990). More robust definitions of the start of the Quaternary (Pliocene-Pleistocene boundary) are based on the Calabrian Formation in Italy, as well as on certain index fossils (Berggren and Couvering, 1977).

Radiative Forcing

L D Danny Harvey

University of Toronto, Toronto, Canada

Surface and tropospheric temperatures are tightly coupled by non-radiative heat exchanges (namely, by sensible and latent heat fluxes). However, the coupling between the stratosphere and troposphere is rather weak. Thus, if the solar luminosity were to change, or the concentration of greenhouse gases or aerosols were to change, the surface and tropospheric temperatures would respond together, while the surface–troposphere system and stratosphere would respond more or less independently of each other. The net energy gain or loss from the surface–troposphere system is given by the net radiation at the tropopause. For this reason, when climatic change is driven by changes in net radiation, the changes in the surface temperature are driven by changes in the net radiation at the tropopause, not at the surface or at the top of the atmosphere. This change in net radiation is called the radiative forcing, because it is what forces or drives the change in surface climate. The radiative forcing involves the change in the net downward flux of solar energy at the tropopause, the change in the upward emission of infrared radiation at the tropopause, and the change in the downward emission of infrared radiation from the stratosphere.

The change in net radiation at the tropopause before any temperatures are allowed to change is called the *instantaneous radiative forcing*. As stratospheric temperatures change in response to the perturbation in the stratospheric radiative energy balance, the downward emission of infrared radiative energy will change, which will alter the subsequent change in the tropospheric and surface temperatures. Of course, any change in surface–troposphere temperatures will also alter the radiative balance of the surface–troposphere system (by changing the upward emission of infrared radiation), but such changes are part of the feedback which determine the ultimate response of the surface and troposphere. Because the stratosphere responds quickly (within months) and independently of the surface–troposphere system, the effect of any changes in stratospheric temperatures should be included when computing the radiative forcing. This gives the *adjusted radiative forcing*.

In the case of a doubling of the atmospheric concentration of CO_2, the global mean instantaneous forcing, as computed by a variety of researchers, is about 4.0–4.5 W m^{-2} (Cess *et al.*, 1993). Of this, about 1.5 W m^{-2} – or 40% – is due to extra downward emission from the stratosphere. This extra downward radiation causes the stratosphere to cool at the same time as the surface and troposphere warm. The cooling of the stratosphere in turn reduces the downward emission of radiation from the stratosphere by about 0.5 W m^{-2} (for a doubling of CO_2), thereby offsetting part of the initial increase in downward emission caused by the

increase in CO_2. Hence, the global mean adjusted radiative forcing for a CO_2 doubling is $3.5–4.0\,W\,m^{-2}$. On the other hand, the increase in downward radiation at the surface is only about $1.4\,W\,m^{-2}$ in the global mean, but the surface temperature change does not depend on the direct surface forcing. These flux changes, and the associated changes at the top of the atmosphere, are shown in Figure 1. Note that, before adjustment of stratospheric temperatures, the reduction in upward radiation at the top of the atmosphere is considerably less than the forcing at the tropopause, whereas after adjustment, the two are the same.

Table 1 lists the instantaneous and adjusted direct radiative forcings for changes in the concentration of selected greenhouse gases. The instantaneous and adjusted radiative forcings are almost identical in all cases except for CO_2, where the adjusted forcing is about 7% smaller than the instantaneous forcing, and for depletion of stratospheric O_3, where the two forcings differ in sign.

The size of the difference between the instantaneous and adjusted radiative forcings is a direct reflection of the extent of adjustment in stratospheric temperature that occurs. The main energy balance in the stratosphere (in the global mean) is between absorption of ultraviolet radiation by O_3 and emission of infrared radiation by CO_2. Thus, an increase in CO_2 concentration cools the stratosphere, causing the adjusted forcing to be smaller than the instantaneous forcing. Because O_3 is the prime gas responsible for heating the stratosphere, a decrease in stratospheric O_3 causes a large cooling of the stratosphere and a reduction in downward radiation that more than offsets the extra penetration of solar radiation. This in turn changes the sign of the surface–troposphere forcing from positive to negative. A more extensive analysis, explaining the reasons for the differences between CO_2 and other well-mixed gases, is presented in Chapter 10.1 of Harvey (2000).

Table 1 Instantaneous and adjusted direct radiative forcings for changes in the concentration of selected greenhouse gases and for a change in solar luminosity, as summarized by Harvey (2000)[a]

Forcing mechanism	Instantaneous forcing ($W\,m^{-2}$)	Adjusted forcing ($W\,m^{-2}$)
CO_2: 300 → 600 ppmv	4.63	4.35
CH_4: 0•28 → 0•56 ppmv	0.53	0.52
N_2O: 0•16 → 0•32 ppmv	0.96	0.93
CFC-11: 0 → 1 ppbv	0.21	0.22
CFC-12: 0 → 1 ppbv	0.26	0.28
SF_6: 0 → 1 ppbv	0.56	0.62
Stratospheric O_3: 50% reduction	0.26	−1.23
Solar luminosity: 2% increase	4.48	4.58

[a] The forcings for greenhouse gases have an uncertainty of ±10–15%.

To summarize, the surface and troposphere respond as a tightly coupled system to any of the factors that alter the Earth s radiative energy balance. To a good approximation, this coupled response is governed by the change in net radiation at the tropopause, after accounting for any adjustments in stratospheric temperatures that might occur. The adjustment in stratospheric temperature is particularly important in computing the radiative forcing due to changes in stratospheric ozone and to a lesser extent for changes in CO_2.

Cosmogenic nuclides *are radioactive and stable nuclei found in the Earth, moon and meteorites. They are produced by energetic particles from outside the solar system called* cosmic rays*. Amounts and ratios of radionuclides can be used to derive a great deal of information about Earth system history and solar activity.*

The most widely studied cosmogenic nuclides (with their half-lives) are: ^{3}He (stable), ^{7}Be ($t_{1/2} = 53$ days), ^{10}Be ($t_{1/2} = 1{\cdot}5 \times 10^{6}$ years), ^{14}C ($t_{1/2} = 5730$ years), ^{21}Ne (stable), ^{26}Al ($t_{1/2} = 7{\cdot}0 \times 10^{5}$ years), ^{36}Cl ($t_{1/2} = 3{\cdot}0 \times 10^{5}$ years). Because they are produced only in the atmosphere or outer layers of solid bodies in the solar system, cosmogenic nuclides are especially useful for studying surface processes. Thus far they have been used to study the timing of glaciations, to assess past solar energy output, to trace the mixing of the atmosphere, to determine how fast mountains erode, to estimate earthquake recurrence intervals, to investigate the rate of climate change, and to probe many other environmental processes. Their ability to help determine both the rates at which Earth system processes occur and the dates of events in the Earth s history makes cosmogenic nuclides extremely valuable tools in Earth science research.

The employment of cosmogenic nuclides in terrestrial environmental studies was at first limited by their extreme rarity in nature. However, developments in noble gas mass spectrometry and accelerator mass spectrometry during the last two decades improved measurement sensitivity to the point that as few as a million atoms of a cosmogenic nuclide could be accurately determined. With this remarkable increase in sensitivity, it became possible to use cosmogenic nuclides to address a number of open problems in the Earth and environmental sciences. A brief and selected survey of both the technique and the application of cosmogenic nuclides in the Earth sciences follows.

^{14}C is the most widely used cosmogenic nuclide. It is produced primarily via the exothermic ^{14}N(n,p)^{14}C reaction between cosmic ray–derived neutrons and atmospheric nitrogen. ^{14}C produced in the atmosphere rapidly equilibrates with volatile carbon species so that the ^{14}C/C ratio in the atmosphere is nearly homogeneous. Once ^{14}C containing carbon is incorporated into plant material, no further chemical exchange occurs and thereafter the ^{14}C content decreases slowly with time due to radioactive decay with a half-life of 5730 years. The age of organic material can therefore be determined by comparing the ^{14}C content of plant carbon with the ^{14}C content of atmospheric carbon. In practice, corrections must be made for variations in the atmospheric content of radiocarbon due to small changes in the cosmic ray flux and due to exchange between the atmosphere and other carbon reservoirs. These corrections can be made by measuring the ^{14}C content in samples whose age is otherwise known, e.g., in tree rings whose age has been determined by direct counting. First used to date cultural artifacts from the last 50 kyr, ^{14}C has now found wide application to dating such natural events as the timing of climate change recorded in marine and terrestrial sediments and the change in ocean circulation over time (*see* Younger Dryas, Volume 1).

^{10}Be and ^{36}Cl are produced in the atmosphere through cosmic ray interaction with atmospheric oxygen and argon, respectively. When deposited in glaciers by snowfall, these nuclides record the cosmic ray flux at the time the snow fell. Ice cores from polar regions contain a record of the cosmogenic nuclide content of the atmosphere for hundreds of thousands of years in the past. The effectiveness with which the solar magnetic field shields the Earth from cosmic rays waxes and wanes with overall changes in solar activity. This fact has allowed the ice core record to be used to derive past solar energy output in the period long before instrumental measurements began to be made. For example, the historic cold period in the 17th and 18th centuries, known as the *Little Ice Age*, was a time with very low sunspot activity and with elevated ^{10}Be and ^{36}Cl in ice cores. Similar periods of elevated cosmogenic nuclide content occur throughout the ice core record and are being used to investigate the possibility that variations in solar output may have had an effect on climate.

The atmosphere also contains ^{7}Be, a short-lived isotope of beryllium, that has been combined with ^{10}Be to probe atmospheric mixing. Because ^{10}Be and ^{7}Be are produced with a fixed ratio in the atmosphere and because ^{7}Be has a half-life which is of the same order as the atmospheric mixing time, the ratio of these nuclides has been used to date air masses and to trace the exchange of air between the troposphere, below, and the stratosphere, above.

Cosmogenic nuclides are also produced in rocks at the Earth s surface, even though the flux of cosmic rays decreases a thousand-fold by the time they reach the bottom of the atmosphere. By measuring the concentrations of the radioactive nuclides ^{10}Be–^{26}Al–^{36}Cl and the stable nuclides ^{3}He and ^{21}Ne, geologists have been able to determine the length of time a rock has spent at the Earth s surface. This dating technique – cosmogenic nuclide surface exposure dating – has been applied to a number of problems in geochronology which were previously intractable: direct dating of glacial moraines, fluvial terraces, debris flows, and lava flows. These ages have been important in determining the timing of advances

and retreats of mountain glaciers and in understanding how these regional events relate to global climate change recorded in marine sediments and ice cores.

The field of earthquake studies has also benefited from the application of cosmogenic nuclide surface exposure dating. There is much interest in determining the recurrence interval between earthquakes, a parameter important in assessing the seismic risk to a particular area. ^{14}C in organic material collected from displaced formations in trenches can often be used to determine the timing of fault motion. When organic material is lacking, as is often the case in arid regions, or when fault motion occurred before the $\sim$40 kyr time limit accessible with ^{14}C, surface exposure dating of features which have been offset by earthquake motion such as alluvial fans or moraines has been used to determine slip rates. Several such studies have focused on the uplift of the Tibetan plateau. This method is now being extended to western North America and other regions in the world.

Even subtle questions such as why some hills are covered with soil while others consist of exposed bedrock can be approached using cosmogenic nuclides. The surface of the Earth is constantly changing due to competition between landform displacement and erosion. The rates of these processes have been very difficult to determine. Because the concentration of cosmogenic nuclides in a rock depends on erosion as well as on the exposure time, cosmogenic nuclide concentrations in surface rocks have provided clues to help understand why some landscapes erode quickly and others are more stable, to determine what controls the conversion of bedrock to soil, and to study the rate at which cobbles migrate along stream catchments.

Radiosondes

Walter F Dabberdt

National Center for Atmospheric Research, Boulder, CO, USA

The radiosonde is an expendable balloon-borne electronics and sensor package that routinely measures the variation with altitude of temperature, humidity and pressure from the ground surface to heights up to about 30 km (a pressure altitude of about 11 hPa). When the device also measures winds, it is more correctly referred to as a rawinsonde, although the term radiosonde is commonly applied to both. In some cases, the balloon alone is tracked by either optical or radar techniques in order to measure only winds. This type of balloon is known as a pilot balloon or simply a pibal. The height pro le of these important meteorological parameters constitutes an upper-air sounding. In 1999, there were 100 operational radiosonde stations in the US that made a daily average of 182 soundings. In the continental US, an average distance of 315 km separates radiosonde stations. In 1999, there were 992 radiosonde stations worldwide that made an average of 1209 soundings each day, while an additional 65 pibal stations made 576 wind soundings daily. The number of soundings are down considerably from their peak values in 1988 of 1660 and 964, respectively. Since 1957, all stations make their soundings at the same times, 00Z and 12Z (Greenwich Mean Time or universal standard time), although many stations outside the US have reduced soundings to once per day due to budgetary constraints. Countries launching operational radiosondes are members of the World Meteorological Organization's World Weather Watch program; as such, they freely share their sounding data with each other. Shortly after an operational upper-air sounding is completed, a standard data message is prepared and made available to all nations using the Global Telecommunications System. The message is transmitted in a universal format that reports conditions at various standard or so-called mandatory (pressure) levels, as well as at signi cant levels, which represent levels where prescribed changes in meteorological conditions occur. There are two primary purposes of upper-air soundings: to analyze and describe current weather patterns; and to provide inputs to short- and medium-range computer-based weather forecast models. Other uses include climate studies, air pollution investigations, aviation operations, and national security applications. The radiosonde continues to be the backbone of an eclectic suite of measurement technologies (both in situ and remote measurements, ground-based and satellites) that are used to provide data for input to numerical weather forecast models.

The radiosonde is carried aloft by a balloon as part of a flight train. The balloon itself may be made of either natural rubber (latex) or synthetic rubber (neoprene). The mass of the flight train, the desired ascent rate, the type of gas used, and the maximum height of the sounding determine the size of the balloon that is used. Operational radiosonde systems typically use balloons that may weigh anywhere from 300 to 1200 g and are filled to ensure an ascent rate of 300 m min^{-1}. Hydrogen is the gas most commonly used to inflate the balloon and provide its lifting capacity, although helium and natural gas are sometimes used for special applications. The flight train consists of four components: a parachute that is used to safely bring the radiosonde back to the surface after the balloon bursts; 20–36 m of nylon line (to isolate the radiosonde s sensors from water vapor contamination by the balloon surface);

a de-reeler to let out the nylon line; and the radiosonde itself. A few countries, such as the US and Switzerland seek to recover and then re-use their radiosondes; in the US, it is estimated that about 18% are reused after extensive refurbishment.

The radiosonde comprises three major sections: a suite of sophisticated meteorological sensors; signal processing electronics; and a radio transmitter to relay the measurements back to a receiver at the radiosonde launch station (Figures 1 and 2). The frequency with which meteorological measurements are made and reported varies according to the type of radiosonde, with a full set of data measured every 1–6 s. The meteorological community has been assigned two radio frequency bands for use in transmitting meteorological data: 400–406 and 1675–1700 Mhz.

Thermodynamic sensor types vary widely among radiosondes currently in use throughout the world. Temperature sensors are of three designs: thermistors, resistance wires, and bimetallic elements. The two common humidity elements are carbon hygristors and thin-film capacitance sensors. Pressure measurements are typically made with either an aneroid cell or a piezoresistance element. There are about a dozen different radiosonde designs presently in use throughout the world. The global radiosonde network has evolved over the last half-century, incorporating technological advances in radiosonde design to meet the changing needs of the world s weather forecasting centers (Table 1). However, the changes in radiosonde design and technology have created special challenges and limitations to climatologists seeking to piece together a consistent and homogeneous multi-decadal global database to analyze and understand climate change. As a result, climate researchers have had to account for biases in the historical records due to changes in instrumentation and observation methods, many of which have poor or no documentation. In the US alone, these changes have been varied and significant. Four distinctly different humidity sensors have been in use since 1943. Temperature measurements have undergone major changes, including sensor type, size, and coating, exposure to the air stream, and corrections to account for radiation biases. At present, the US National Weather Service uses radiosondes from two different manufacturers, each having its own distinct set of pressure, temperature and humidity sensors.

Figure 1 First radiosonde prototype built in 1931 by Professor Vilho Väisälä in Ilmala, Nr Helsinki, Finland. The sonde weighed 420 g and measured 30 cm in length and 7.5 cm in diameter. It included only one sensor, a bimetallic thermometer. The signal from the sonde's radio transmitter was received up to a height of about 7 km

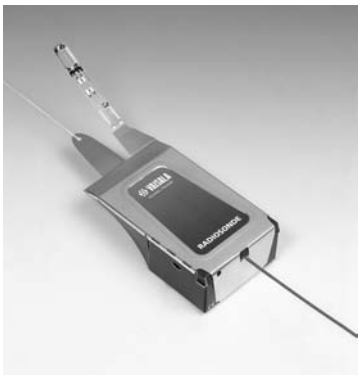

Figure 2 The Vaisala RS90 radiosonde was introduced in 1995. It weighs 290 g and measures $15 \times 9 \times 5$ cm. The arm (top right) contains the temperature sensor and dual heated thin-film humidity sensors. The pressure transducer and the navigation-signal receiver are mounted inside the housing with the battery, electronics and transmitter

Wind measurement methods vary widely as well. Winds can be measured directly, or they may be determined from the drift of the balloon. One class of wind measurement techniques tracks the balloon using any one of three methods: (1), an optical system that uses a theodolite to visually track the balloon s azimuth and elevation; (2), a radio theodolite that tracks a radio signal sent from a transmitter on the radiosonde, again to obtain azimuth and elevation information; and (3), a radar system that tracks a radar retroreflector suspended from the balloon to obtain slant range, azimuth and elevation. The first two methods require knowledge of the balloon height, which is determined from the pressure measurement. Theodolite measurements suffer from the requirement for clear conditions between the ground station and the balloon. All three of these tracking methods determine the wind from the change in the observed location of the radiosonde. Tracking methods lose accuracy as the distance to the balloon increases and its elevation angle decreases.

The second class of wind measurement techniques uses various navigation systems to determine the change in position of the radiosonde or measure the drift velocity

Table 1 Historical Milestones Leading to Development of the Modern Meteorological Radiosonde

Year	Milestone
1643	Evangelista Torricelli invents the barometer in Florence, Italy
1648	French mathematician Blaise Pascal observes the decrease of atmospheric pressure with altitude
1749	Alexander Wilson, Glasgow, Scotland, uses kites to study the variation of temperature with altitude
1783	The French Montgolfier brothers, Jacques Etienne and Joseph, invent the balloon
1783	Jacques Alexandre César Charles, Paris, France, uses a manned balloon to make first measurements of variations of pressure and temperature with altitude
1784	Englishman John Jeffries, London, and Frenchman Jean-Pierre Blanchard begin the systematic study of the atmosphere using manned balloons
1804	French physicists Louis Gay-Lussac and Jean Baptiste Biot ascend to 7 km in a balloon and discover that water vapor decreases with altitude
1822	Englishmen Sir Edward Parry and Rev. George Fisher use kites with recording thermometers to study the Arctic atmosphere
1892	Frenchmen H. Hermite and G. Besancon launch the first free-flying weather balloon with a mechanical recording system (the *meteorograph*)
1847	William Radcliff Birt is first to measure winds aloft (and temperature) with a kite flown from Kew Observatory, London
1893	Lawrence Hargrave, Sydney, Australia, invents the box kite; by the end of the decade, many major observatories are using box kites routinely to measure the atmosphere, including: Blue Hill Observatory (n. Boston), Central Physical Observatory (Moscow), Trappes (n. Paris), Kew Observatory (n. London), Lindenberg (Germany), and Ilmala (Finland)
~1900	British scientist W.H. Dines invents the mechanical meteorograph design that is widely used until 1939
1901	Richard Assmann, Germany, is first to use *extensible* rubber balloons for free-flying soundings with meteorographs
1917	Germans F. Herath and M. Robizsch use the *telemeteorograph* to transmit meteorological data from a kite using the steel kite cable as the signal cable
1920	US Weather Bureau and Army Air Corps establish a program of daily upper-air soundings using airplanes at 20 locations nationwide
1921	US Weather Bureau establishes a kite network for routine upper-air observations; remains in operation until 1933
1928	Professor P. Moltchanoff, Director of the Russian Aerological Observatory in Slutzk, publishes a paper that outlines the design of a meteorological sonde that uses a radio transmitter to send data back to recording stations
1931	Moltchanoff (Russia), Paul Duckert (Germany) and Vilho Väisälä (Finland) independently devise and fly the first radiosonde using radio oscillators that are controlled by output of temperature, humidity and pressure sensors
1974	The National Center for Atmospheric Research (Boulder, CO, USA) develops a special radiosonde called the dropsonde that is launched from research aircraft and measures winds, pressure, temperature and humidity while descending on a parachute
1976	The Vaisala Oy company (Helsinki, Finland) introduces the first computer-controlled upper-air sounding systems
1982	The US National Oceanic and Atmospheric Administration begins routine use of dropsondes for hurricane research; 1 year later, the US Air Force initiates its hurricane reconnaissance program
1995	First commercial radiosonde systems using the Global Positioning System (GPS)[a] to measure winds are introduced by the Atmospheric Instrumentation Research Company (Boulder, CO, USA) and the Vaisala Oy Company (Helsinki, Finland)

[a] GPS is a constellation of 24 orbiting satellites that provide precise measurements of time that are used to locate the position and determine the movement of surface-based and airborne objects to very high levels of accuracy.

directly. Two systems currently in use employ the LORAN-C navigation system and various VLF systems, such as the Russian ALPHA system and the US Navy s VLF system. A transponder on the balloon receives the navigation (time-of-arrival) signals and rebroadcasts them back to the ground station with the meteorological measurements. Both systems require pressure to determine the height of the balloon. These systems are being phased out as the world community ceases to use these navigation signals.

A new navigation-based windfinding technique is now coming into widespread usage. A GPS receiver inside the radiosonde very accurately measures the horizontal and vertical Doppler velocity of the radiosonde with respect to the individual GPS satellites that can be observed at any given time (typically, 4–8 satellites). Other types of GPS receivers also observe the latitude, longitude and altitude of the radiosonde. In both cases, the GPS receiver directly measures the drift velocity of the balloon, and hence, the wind. Two major advantages of the GPS-based

techniques are the high accuracy and precision of the wind measurements, together with the worldwide coverage of GPS. A current impediment is the relatively high cost of GPS technology for expendable radiosonde applications.

The airborne counterpart to the conventional radiosonde (sometimes also called an upsonde) is the dropsonde, which is ejected from research aircraft and floats downward on a special balloon-like parachute. Dropsondes are used primarily in weather research studies and for hurricane reconnaissance. Current state-of-the-art dropsonde sensors include capacitance fine-wire sensors to measure temperature, capacitance silicon pressure sensors, and GPS receivers to measure winds. Humidity is measured with a pair of thin-film capacitance sensors that are alternately heated to avoid condensation on descent from colder to warmer air. All measurements are made twice every second while the dropsonde falls at a rate of $10-25\,\mathrm{m\,s^{-1}}$. Experience has shown that dropsonde hurricane reconnaissance observations have appreciably improved the accuracy of forecasts of hurricane landfall.

Rain

Rain is liquid water precipitation made up of drops larger than 0.5 mm diameter. Precipitation with drop sizes less than 0.5 mm is referred to as drizzle. Precipitation forms when one or more processes lead to the aggregation of a large number of cloud droplets (on the order of one million) into a single drop or ice crystal. Clouds form when air is lifted, typically the result of the lifting by fronts and in cyclones, or by buoyant thermals initiating convection, resulting in expansional cooling that leads to condensation of water vapor into cloud droplets. Condensation occurs on aerosols called *cloud condensation* nuclei (microscopic particles, usually dust or salt particles from sea spray). It is very common for a cloud to be made up of liquid water droplets, even if all or a portion of the cloud is at a height where the temperature is well below freezing, because nuclei that support direct sublimation of water vapor to ice are very much rarer in natural air than condensation nuclei, and generally do not support sublimation unless the temperature is lower than $-10\,^{\circ}\mathrm{C}$. Droplets not in contact with a surface can remain liquid for temperatures down to $-40\,^{\circ}\mathrm{C}$. The typically rare ice crystal in a cloud can grow quickly at the expense of the water droplets, however, because the saturation vapor pressure over ice is lower than that over water, resulting in the liquid water droplets evaporating and supplying their water to the ice crystals. This process, called the Bergeron–Findeisen process, can create ice crystals large enough to fall as precipitation. As the ice crystal falls, cloud droplets it collides with are frozen on contact, increasing the mass of the crystal, causing it to fall faster, sweep out more cloud droplets, and grow even more quickly. Almost all mid-latitude rain forms initially through ice crystal processes in cloud regions where the temperature is below freezing, and melts as it falls into warmer air on its way toward the surface. Rain can also form when there are no ice crystals present through the collision and coalescence process. Here, cloud droplets that are slightly larger than their neighbors fall relative to them, striking some and coalescing into a larger droplet that falls faster, sweeps out more droplets, and grows even more quickly. This process is important for the formation of rain in the tropics, where clouds at temperatures above freezing throughout can produce heavy rainfall, but it also clearly contributes to rainfall in clouds whose upper portions are cold enough to initiate precipitation through ice processes as those crystals fall and melt in the lower portions of the cloud.

Remote Sensing, Terrestrial Systems

see Remote Sensing, Terrestrial Systems (**Volume 2**)

Residence Time (of an Atom, Molecule or Particle)

Residence time is the average time spent in a reservoir by an individual atom, molecule or particle. Thus, the residence time is the average length of time that a material will remain in the reservoir before it is removed or destroyed. Alternatively, the residence time is indicative of the age of the molecule or material when it leaves the reservoir.

Residence time is often used interchangeably with lifetime, particularly for gases or aerosols in the atmosphere (*see* Lifetime (of a Gas), Volume 1). Like lifetime, residence time is generally given in terms of the time to reach $1/e$ of its original value if all sources of the material into the reservoir were turned off. For chemically reactive gases or particles, lifetime tends to be used to represent the rate

of chemical reactivity. However, lifetime is also used in the more general sense. Residence time is associated with all processes that can remove the material from the reservoir including transport from one reservoir to another or chemical reactions.

If we consider a box model representation of a reservoir, then material in the reservoir can be removed either by flowing out of the reservoir or by processes destroying the material within the reservoir, such as by chemical reactions changing the nature of the material. At steady state, the total loss of the material in the reservoir through transport out of the reservoir or by destruction within the reservoir will be equal to the total sources through transport into the reservoir or production within the reservoir. The residence time is then equivalent to the total amount of the material in the reservoir divided by the total losses or total sources.

The case of carbon dioxide, CO_2 presents an interesting illustration of the difference between lifetime and residence time. For CO_2, the residence time of a particular molecule in the atmosphere is only about 4 years, because of CO_2 exchanges with the land surface and upper ocean. The lifetime of a pulse injection of CO_2, however, is roughly 100 years because the atmospheric, terrestrial, and upper ocean carbon reservoirs are nearly in balance. For CO_2 containing carbon-14 from atmospheric nuclear testing, however, the lifetime for the pulse injection in the 1960s was initially only about 4 years because the terrestrial and oceanic reservoirs were empty and so did not return carbon-14 to the atmosphere. Understanding these differences is critical to avoiding confusion about the long time-scale of the use of increasing amounts of fossil fuels.

DONALD J WUEBBLES *USA*

Revelle, Roger Randall Dougan

(1909- 1991)

Roger Revelle was one of the 20th century s most eminent, multi-faceted, productive, and influential environmental scientists. His interests, research, and achievements spanned the physical, biological, and social sciences, engineering, and the humanities. He contributed immensely to the development of modern oceanography, but also brought fresh insights to issues of population, world poverty, and hunger. At the same time, he was an inspiring and effective leader of scientific enterprises, an insightful educator, intellectual architect of a great university, and powerful supporter of international programs. He was one of the first leading figures to place the issue of global climate change on the front burner of world concern, and may be viewed as the intellectual godfather of today s international programs dealing with global environmental change.

Roger Randall Dougan Revelle was born in Seattle, Washington State, USA, on March 7, 1909 into a family of lawyers and schoolteachers. He grew up in Pasadena, California and, showing formidable intellectual powers at an early age, he was admitted to Pomona College at the age of 16. His interests first turned to geology, and after receiving his BA degree in 1929, he undertook graduate studies at the University of California, Berkeley, in 1930, where he began to study marine sedimentation as a graduate research assistant at the Scripps Institution of Oceanography (SIO) in La Jolla, CA. In 1931, he married Ellen Clark, a student at nearby Scripps College and descendant of the founder of SIO.

At Scripps, he pursued his doctoral studies on the composition and physical properties of deep-sea sediments, participating in numerous oceanographic cruises. His research focused on the nature of marine carbonates, and the buffering capacity of seawater to control carbonate solubility, research that built a strong foundation for his later work on the carbon dioxide (CO_2) issue.

In 1936, Revelle was awarded his doctorate from the University of California, and he then undertook postdoctoral studies at the Geophysical Institute in Bergen, Norway. It was during this period that he began his active involvement in international scientific affairs. Returning to California, he taught marine geology and physical oceanography at Scripps and the University of California at Los Angeles.

During World War II, Revelle served in the US Navy, conducting research on radar, sonar, and application of oceanographic research to wartime needs. After the war, he organized the scientific program connected with early atomic bomb tests, an activity that left him with a lifelong concern for the marine environment and for the need to avert nuclear war. Transferred to the Office of Naval Research, he served as head of its Geophysics Branch and left the Navy with the rank of Commander in 1948.

Returning to SIO, he led a survey in the Gulf of California to address fisheries problems. Revelle developed this into a continuing interdisciplinary program that brought together fisheries biologists and marine scientists, demonstrating the holistic approach that was the hallmark of his work. In 1951, he became director of SIO, and initiated a rapid expansion of the institution in terms of facilities, staff, and sphere of interest. Scripps s field observations

during this period played a crucial role in developing a more detailed scientific understanding of the Pacific Ocean.

Revelle s own research addressed the continuing addition of CO_2 to the atmosphere by burning of fossil fuels, and its implication for global climate. In a seminal 1957 paper, Revelle and Hans Suess termed this a great geophysical experiment. He commissioned Charles David Keeling to initiate a program of precision atmospheric CO_2 measurements on Mauna Loa, Hawaii and at the South Pole that starkly revealed the extent of human influences on the global atmosphere (*see* Keeling, Charles David, Volume 1). He later chaired a National Research Council study of the impact of energy production on climate, and contributed greatly to a subsequent broader study. At the same time, Revelle vigorously expanded SIO s work in biochemistry and microbiology, and chaired several national committees in this area, including, in 1965, chairing the subpanel that prepared the US Government s first report on CO_2-induced climate change for the President s Scientific Advisory Committee Panel on Environmental Pollution. Internationally, he played an important role in the creation of the International Council for Science (ICSU) Scientific Committee on Problems of the Environment, and the International Geosphere–Biosphere Programme (*see* IGBP (International Geosphere- Biosphere Programme), Volume 2; SCOPE (Scienti c Committee on Problems of the Environment), Volume 4). He remained deeply involved in a wide variety of United Nations (UN) and ICSU activities for nearly four decades, including the Scientific Committee on Ocean Research, serving as its first president (*see* SCOR (Scienti c Committee on Oceanic Research), Volume 1).

Expansion of the University of California system led to development of that institution s San Diego campus adjacent to SIO in La Jolla. Revelle played a central role in the intellectual development of the new university, and the recruiting of its faculty. He then moved on to Washington DC as science advisor in the Department of the Interior, back to California as University Dean of Research, and to Harvard University as Director of the Center for Population Studies. These positions led him into a diverse range of issues: pesticide damage, irrigation, global food supply, and population – issues still high on the contemporary agenda. A particular concern was the plight of the developing countries, and he was a frequent and valued visitor to India. He also chaired the National Academy of Sciences Board on Science and Technology for International Development, and advised many US and UN agencies.

In 1976, Revelle returned to San Diego to become professor of science and public policy. He kept up an active program of interdisciplinary seminars and teaching until his death in 1991. In his honor, SIO named a multidisciplinary research ship the *RV Roger Revelle*. The Revelle College of the University of California, San Diego, also memorializes his name.

Roger Revelle earned many academic and professional honors. He was elected to the US National Academy of Sciences in 1958, and received its Agassiz Medal in 1963. He was a member and fellow of numerous other learned societies. His prizes included the Order of the Sitara-Imtiaz from Pakistan, the William Bowie Medal of the American Geophysical Union, the Tyler Medal, and the National Medal of Science.

JOHN S PERRY *USA*

Richardson, Lewis Fry

(1891- 1953)

Lewis Fry Richardson is today best known for his pioneering attempt at weather prediction by numerical methods. However, during his long and productive career he made seminal contributions to a remarkable range of scientific and social problems, and stands as one of the most influential scientific figures of the 20th century.

Born of a Quaker family in Northumberland, UK, Richardson was educated at the University of Newcastle and then Cambridge University. Faithful to his pacifist values, he performed non-combatant service during World War I. While at the front, he began to address the problem of weather prediction by numerical solution of the fundamental physical equations, and actually carried out a numerical prediction of pressure change. Inadequacies in both data and numerical technique produced unrealistic results, but the giant step from witchcraft to quantitative science had been taken. Subsequently, in his famous book *Weather Prediction by Numerical Process*, he imagined how real-time predictions might be produced by a vast auditorium full of clerks orchestrated by a central director – a vision uncannily resembling the organization of parallel-processing computers of today!

Richardson s fundamental research in atmospheric fluid dynamics centered on the cascade of energy from larger scales of motion down to smaller eddies to be ultimately dissipated through viscosity, a process that he immortalized in a celebrated poem:

> Big whorls have little whorls that feed on their velocity, and little whorls have smaller whorls and so on to viscosity – in the molecular sense•••.

As a consequence, Richardson s name is attached to the non-dimensional number associated with fluid convective stability. At the same time, he saw how these eddy processes governed turbulent diffusion and limited the range of predictability. In the course of this work, he developed concepts of scaling and fractality that have had broad application to scientific and practical problems in many fields.

From 1920 onwards, he worked in academia in England and Scotland, and was elected a Fellow of the Royal Society in 1926. His interests turned increasingly to questions of war and peace, where he applied mathematical modeling techniques and statistical analysis. These studies and his database on deadly quarrels have influenced many peace researchers and continue to be a rich source of ideas. This work led to books such as *Arms and Insecurity*, and *Statistics of Deadly Quarrels*, and continues at the Richardson Institute for Peace Studies (University of Lancaster, UK).

JOHN S PERRY *USA*

Roberts, Walter Orr

(1915- 1990)

In the more than four decades of his career in scientific research and institution building, Walter Orr Roberts became internationally recognized as one who broadened the vision of meteorologists and astronomers and who deepened the understanding of science by industrialists, political leaders, and other policy makers.

Born in 1915, Roberts grew up in Massachusetts. He received his PhD in astronomy from Harvard University in 1943. His early work focused on observations of the Sun, especially solar activity and the chromosphere. This work, conducted from a mountain observing station, which he developed, led him to establish a new organization, the High Altitude Observatory (HAO). At HAO he assembled a staff of solar physicists, scientists with interests in solar–terrestrial interactions, planetary scientists, and those interested in meteorology.

This diversity of activity was unusual among astronomical observatories, but it proved appropriate for exploiting the rapid expansion of observational opportunities for measurements of the Sun, the space between the Sun and the Earth, and the Earth s atmosphere.

In 1960, Roberts became director of the newly established National Center for Atmospheric Research (NCAR) in Boulder, CO. He brought to this institution the same belief that a scientifically diverse staff was more in keeping with modern needs than a narrowly specialized one. The early recruitments to the NCAR staff included physicists, engineers, applied mathematicians, and chemists as well as meteorologists.

Roberts also pursued his interest in possible Sun–weather connections. His careful approach to this topic restored some respectability to a subject damaged by a plethora of published correlations of sunspot numbers with records ranging from typhoon frequencies to wine vintage quality. He also became prominent in the activities leading to the Global Atmospheric Research Program (GARP) (*see* GARP (Global Atmospheric Research Program), Volume 1), and he was instrumental in the design of an oversight mechanism for the program involving cooperation between the World Meteorological Organization and the non-governmental International Council of Scientific Unions. The GARP field programs – in the Caribbean, the tropical Atlantic, monsoon regions, and global – produced observations and studies that built a foundation for subsequent rapid progress in the quality of weather forecasts and in the understanding of climate and the possibility of a human-induced climate change.

His scientific work expanded to include the climate–agriculture connection, the world s food system and, indeed the world s future. As an organizer of conferences, a popular speaker, and an advisor to political and industrial leaders Roberts was a force in bringing a possible climate change to the attention of thoughtful policy makers years before the idea achieved the currency and validity that it has today. Roberts died in Boulder in 1990, having spent much of his later years participating in the communications revolution made possible by personal computers. He had earlier been a pioneer in reaching out to scientists in the Soviet Union during the uneasiest times of the Cold War, and he organized an ongoing computer conference between US and Soviet scientists discussing how a severe climate change might affect relations between these two giants.

JOHN FIROR *USA*

Rossby, Carl-Gustaf

(1898- 1957)

Carl-Gustaf Rossby was a Swedish–American meteorologist, preeminent as a theoretician, and also one of the first scientists to realize the importance of environmental influences on the global climate. His achievements were equally significant in the realms of organization and in theoretical meteorology. In both, his characteristically broad view and bold approach made spectacular achievements possible.

After a BSc at the University of Stockholm in 1919, Rossby worked for 7 years as a weather forecaster in Norway and Sweden. In 1926 he moved to the United States where he created the first airways weather service. As a professor at the Massachusetts Institute of Technology from 1928 to 1939, he established the first advanced educational program in meteorology. In 1940 he moved to the University of Chicago where he organized university training programs for thousands of American meteorologists during World War II. After the war he led an intense effort to study the general circulation, in particular the jet streams. He also reorganized and revitalized the American Meteorological Society, and established *Journal of Meteorology* (nowadays *Journal of Atmospheric Sciences*) as a leading professional journal.

During the last 10 years of his life Rossby spent an increasing amount of time in Sweden, where he established the International Institute of Meteorology at University of Stockholm, founded the geophysics journal *Tellus* and took part in the development of the first computer-produced weather forecasts. He also started an ambitious research program in atmospheric chemistry.

Rossby was associated with the Woods Hole Oceanographic Institution from its founding. In addition to membership in the National Academy of Sciences in the United States and being an honorary member of the Royal Meteorological Society, he was a foreign member of the Norwegian Academy of Science and the Royal Swedish Academy of Science.

In the 1930s, the severe drought in the United States led to government support of Rossby s studies in atmospheric motion and the general circulation of the atmosphere. During attempts to devise a 5-day forecasts system he became interested in the interactions between fluctuations in the strengths of the westerlies and the movements and developments of the large-scale anticyclones and cyclones. He saw a striking similarity between the long-period variations of the world weather patterns and the week-to-week cycle of alternating zonal and meridional flows (*see* Rossby Waves, Volume 1). He believed that climate variability on almost all time scales, from inter-annual to centennial and beyond, could be understood in terms of changes of states of the atmospheric flows.

During his last years he placed increasing emphasis on environmental aspects of the atmosphere and oceans including their chemistry. In a speech at the annual meeting of the American Meteorological Society just before he died, he outlined his vision of the future of meteorology. With computers capable of assuming much of the routine work of the forecaster, the meteorologist should be freed to direct his efforts toward more constructive applications of meteorological knowledge. This would permit meteorology to expand and broaden so that the profession would attract and utilize many highly qualified people from mathematics, physics, geophysics, chemistry, etc.

Rossby Waves

The atmospheric circulation in the extratropical troposphere is directed mainly from west to east. However, there are significant departures from this zonal flow, in the form of wave-like disturbances giving the wind northward or southward components at different longitudes. These disturbances have wavelengths of thousands of kilometers in the longitudinal direction and, relative to the Earth s surface, can be either stationary or traveling. Such disturbances affect the tracks of the wandering highs and lows that account for much of the changing surface weather patterns.

The physical basis for these wave-like features was first proposed by Rossby (1939) (*see* Rossby, Carl-Gustaf, Volume 1); as a result they are now universally referred to as *Rossby waves*. The underlying basis derives from

Kelvin s circulation theorem, related to the principle of conservation of angular momentum. Because the Earth is spherical, its local vertical component of angular velocity, with respect to the fixed stars, is a maximum at the pole, and zero on the equator. Because of this, fluid parcels displaced north or south from some reference line of latitude can lose or gain vorticity (a measure of the local angular velocity of the air) as determined in a frame co-moving with the Earth. Rossby was able to show that these induced changes in fluid vorticity would maintain a wave-like disturbance in velocity and pressure, with a westward phase speed relative to the eastward-directed flow.

The stationary Rossby waves mentioned above are forced primarily by near-surface flow over the major orographic features of the Earth s surface, and by thermal forcing from ocean–continent surface temperature contrasts. The traveling Rossby waves, on the other hand, are free-wave solutions, not tied to any specific surface forcing. Consistent with theory, lines of constant phase are always observed to retrogress to the west relative to the eastward-directed (basic-state) flow.

Modifications of Rossby s theory have been proposed. In one of the most important of these, Charney and DeVore (1979) have shown that nonlinear interactions between the east-west flow, and orographically-forced stationary Rossby waves can give rise to multiple equilibrium solutions. In one such solution, the Rossby waves have weak amplitude and the eastward flow is strong. In another solution, the Rossby waves have strong amplitude and the eastward flow is weak. These two equilibrium states correspond to two dominant types of circulation regime that occur in the extratropical atmosphere, the so-called zonal and blocked regimes, respectively. In some sense, these regimes can be considered important building blocks of the climate system, and may be important elements for understanding the impact of anthropogenic forcing on climate (Palmer, 1999).

Rossby-wave dynamics are also relevant in the tropics and in the oceans. For example, the El Niño phenomenon cannot be understood without considering the effect of westward propagating Rossby waves in the near-equatorial Pacific Ocean. In particular, according to the so-called delayed oscillator theory (e.g., Battisti and Hirst, 1989), the time it takes for equatorial oceanic Rossby and Kelvin waves to propagate across the Pacific basin, affects the lifetime of an El Niño event.

Rowland, F Sherwood

(1927-)

F Sherwood Rowland founded the Department of Chemistry of the University of California, Irvine where he serves as Bren Professor of Chemistry and of Earth System Science. In 1995, he was Nobel Laureate (with Molina (*see* Molina, Mario J, Volume 1) and Crutzen (*see* Crutzen, Paul J, Volume 1)) and has been Foreign Secretary of the US National Academy of Sciences (NAS) since 1998.

After completing his PhD in physical chemistry at the University of Chicago in 1952, Rowland s early career focused on radiochemistry and chemical kinetics. He performed and interpreted laboratory experiments designed to study reaction rates and mechanisms. He continued this kind of research well into the 1980s and established himself as a world leader through careful, accurate and well-selected experiments.

In atmospheric chemistry, Rowland has been a pioneer. He and his postdoctoral fellow, Mario Molina, discovered the role of chlorofluoromethanes and other chlorofluorocarbons (CFCs) as chlorine-atom donors in the stratosphere. They also showed in 1974 that chlorine atoms could catalyze the destruction of large amounts of ozone. This work was highly original and also exceptionally complete and careful. In a 1975 paper, they investigated many possible mechanisms that might destroy CFCs (besides ultraviolet light in the upper atmosphere), investigations that were repeated a number of times later by others, always confirming the original results (*see* Depletion of Stratospheric Ozone, Volume 1).

An early 1980s discovery (with his former student Don Blake) that atmospheric methane amounts were increasing

worldwide confirmed (less conclusive) reports by two other groups. The clear and careful experimental methods of Blake and Rowland established this fact, and many scientists worldwide are working to continue to define the upward trend and to explain its causes (propositions include emissions from rice paddies, landfills, coal mines, natural gas usage, biomass burning associated with the clearing of tropical forests, and also diminished intensity of atmospheric photochemistry that consumes methane). Atmospheric methane s alteration of the radiative energy balance of the Earth s surface is second only to carbon dioxide (CO_2), and the need to consider methane s changes has greatly complicated the study of climate change, but has also sharpened the science.

With his student, Neil Harris, he examined several long time series of ozone data from around the world and noted that decreasing amounts were being observed in middle to high latitudes in late winter and spring seasons, suggesting a chemical loss process in wintertime. Neither the empirical fact from the data or the thought of such a loss had been seen or conceived previously. Combined with a suggestion from Rowland (in Feldafing, Germany in 1984) that hydrochloric acid (HCl) and $ClNO_3$ (chlorine nitrate) might be shorter lived in the lower stratosphere than gas-phase processes alone would dictate, this work seeded the idea that heterogeneous chemical processes might cause the Antarctic ozone hole by liberating ozone-active chlorine.

The impact of Rowland s research on the fields of atmospheric chemistry and related laboratory physical chemistry is enormous. His research altered the worldwide CFC industry and led to a greatly increased awareness of environmental chemistry and human impact on the global environment by industry, government and the general public, and enabled the Montreal Protocol, a 1987 international treaty (updated in Copenhagen and London in 1990 and 1992) that launched international phase-outs of fully halogenated CFCs and related compounds.

As a communicator of science and a scientist-citizen in matters of public policy, Rowland has been powerful. He has spoken clearly and forcefully, always true to the science and its limits.

For his research and its impact on environmental preservation, Rowland has received many awards, including the Tyler Prize for the Environment, the Dana Award, and the Japan Prize, membership in the NAS and many honorary degrees. The Dana Medal recognizes that his research and his public speaking increased worldwide awareness of skin cancer and the role of excessive exposure to solar ultraviolet light. An accomplished tennis player, Rowland also played intercollegiate basketball and baseball while at Chicago, and semi-professionally in baseball. In 2000, he received the Foundation of Economic Teaching (FTE) Academic All American Hall of Fame Award for combining scientific excellence with high achievement in intercollegiate athletics.

RALPH J CICERONE *USA*

Runoff

When precipitation or meltwater from snow and ice reaches the ground surface, it is partitioned between water which moves across the surface, the *overland ow*, and that entering the soil, the *in ltration*. Initially most water may enter the soil, but the proportion will decrease with time, as infiltration capacity is approached and exceeded. Then water starts to pond on the surface and when this ponded water spills, it becomes overland flow, or quick flow, which collects in rills, gulleys and small channels. These channels may also receive water emerging from the ground; altogether water from these different sources flows into the larger channels, streams and rivers. These watercourses contain the runoff from the basin. This is the traditional Hortonian view of runoff (Horton, 1933) with its division between surface flow and subsurface flow. The subsurface flow is usually separated between the *inter ow* (that part of the infiltration, which has traveled laterally through the upper soil horizons and the base flow) and the base flow, or *groundwater ow* (that part of the runoff contributed by drainage from the aquifers in the basin). This is the flow that sustains the runoff in dry weather. Flow velocities are considered to decrease from overland flow, to interflow, to base flow, giving rise to the possibility of differences in the age of the water that may be in one increment of runoff.

There are a number of factors that govern the runoff process such as: intensity and duration of the precipitation, soil type, geology, land use, the characteristics of the surface and the stream channel network. That all parts of a basin do not react to precipitation in the same manner results from the mix of these factors and has led to the concept of the contributing area (Betson, 1964) and the further developments which have been incorporated into contemporary runoff models.

Salinity

Salinity is a general concept related to the amount of dissolved material in sea water, measured historically as grams of salt per kilogram of sea water. Seawater density depends on temperature, pressure and the amount of dissolved matter, which primarily consists of various salts. Because the salts come from continental weathering and deep-sea vents, the total amount of salt in the whole of the world s oceans varies on a time scale (order 100 000 years) that is much longer than the 1000-year time scale of ocean circulation. Therefore, the relative proportion of the constituents of sea salt is nearly constant throughout the oceans. However, the total amount of water in the ocean is not constant; it is affected by evaporation, precipitation, and runoff. The total amount of dissolved matter per kilogram of seawater therefore varies.

Historically, salinity was measured by evaporating the water and weighing the residual matter. This method was replaced by a titration method to determine the amounts of chlorine, bromine and iodine, which were then related to salinity through an empirical formula. Since the International Geophysical Year (1957), the standard method for measuring salinity uses seawater conductivity, which is related through an empirical formula to salinity. A seawater standard is required to provide high accuracy. The conductivity-based method is far more precise (0.00015) and accurate (0.001) than the previous methods. In 1978, the United Nations Educational, Scientific and Cultural Organisation (UNESCO) Joint Panel on Oceanographic Tables and Standards produced a standard algorithm for salinity based on conductivity, this was the practical salinity scale 78 (PSS-78), reported in a 1981 publication. Until that time, salinities were commonly reported in units of (parts per thousand). The UNESCO panel recommended that, henceforth, no units should be used for salinity, which is the convention followed here. Within the oceanographic community, the unit practical salinity scale (psu) came into common usage with PSS-78; psu and remain in common use. The range of salinity in the open ocean, away from continental margins, is about 31–40, with the mid-latitude oceans in the range 34–36. Lowest values occur at high latitudes where ice melt lowers the salinity, and highest values are found in strongly-evaporating regions such as the Red and Mediterranean Seas.

LYNNE D TALLEY *USA*

Salinity Patterns in the Ocean

Lynne D Talley
Scripps Institution of Oceanography, University of California, La Jolla, CA, USA

Ocean salinity varies geographically and with time. Fresh water input occurs at the sea surface due to precipitation and river in ow, reducing salinity. Salinity is increased by evaporation and also as a by-product of sea ice formation. Because freshening and salini cation occur in different places, salinity at a particular location re ects the upstream source of the water there. In subtropical latitudes, high surface evaporation creates high salinity near the sea surface. In subpolar latitudes, high precipitation creates low salinity near the sea surface. As these waters ow into the ocean interior, they create layers of high and low salinity.

At mid-depth (i.e., around 1000 to 2000 m deep), out ows from the highly evaporative Mediterranean and Red Seas create a vertical salinity maximum in the North Atlantic and Indian Oceans, respectively. Also at mid-depth in the subtropical and tropical regions, the relatively fresh, but dense, surface water from higher latitudes ows in and creates a vertical salinity minimum, most prevalent in the Southern Hemisphere and North Paci c. The North Atlantic is the most saline ocean and the North Paci c the freshest.

Salinity affects sea water density and therefore can be a controlling factor for the depth of the ocean surface mixed

layer. This depth also depends on wind speed and cooling at the sea surface. Feedbacks can occur as precipitation and evaporation are affected by the atmosphere, which in turn is affected by sea surface temperature. The atmosphere in turn is affected by sea surface temperature, which is affected by mixed layer depth.

The distribution of dissolved salts (*see* Salinity, Volume 1) in the oceans and adjacent seas varies in space and time. Salinity is changed near the sea surface by precipitation and evaporation of fresh water and by salty water produced sea ice forms and excludes salt. Geographical variations in inputs create regional differences in salinity at the sea surface. As seawater circulates down into the ocean away from the sea surface, it carries these differences along, creating large-scale salinity patterns throughout the ocean. Changes in time in the inputs at the sea surface also affect the salinity distribution. By mapping the salinity distribution and tracking changes in salinity over time, much insight is gained into both the basic ocean circulation and the processes that change the ocean circulation and temperature distribution.

Salinity is a seawater property related to the amount of matter, mainly consisting of salts, dissolved in the water (*see* Salinity, Volume 1). The original definition of salinity was in terms of grams of dissolved salts per kilogram of seawater. Salinity is now defined in terms of seawater conductivity, and is currently calibrated using a standard solution prepared at a laboratory in the UK. The quantity of dissolved salts, hence the salinity, affects seawater density, which also depends on temperature and pressure. Quantifying these dissolved constituents as the single parameter, salinity, is possible because the source of solids is weathering, which occurs on geological time scales. Ocean circulation and mixing, on the other hand, distribute the solids throughout the World Ocean on a time scale of no more than thousands of years, and so the various salt constituents are essentially well mixed. Therefore, salinity differences are created only by dilution or concentration as fresh water is added or removed, or as salty water is rejected from sea ice as it freezes. Other dissolved non-salt constituents such as carbon, calcium and silica, which are affected by biological cycles, have enough spatial variability to affect seawater density (e.g., Millero *et al.*, 1978); this small variation is not usually included in salinity and density studies.

In many ocean regions, particularly in the tropics, the subtropics and the deep ocean, temperature variations are more important than salinity in changing density. However, at higher latitudes, the presence of freshened surface waters resulting from high precipitation and/or ice melt has a strong influence on whether the water column can be cooled enough to mix vertically with other layers. Because winter surface cooling at high-latitudes determines water properties for the global ocean at depths below about 1500 m, salinity can control the occurrence of convection and its penetration depth. With a surface layer that is relatively fresh compared with the underlying water that came from another ocean region, surface waters can cool to freezing without overturning. If the high-latitude surface waters are not much freshened, as is the usual case in the northern North Atlantic, then overturn to great depth at the end of winter can occur with even modest surface cooling, leaving the surface waters well above the freezing point. Because ocean surface temperatures are part of the forcing for the atmosphere, changes in high-latitude salinity distribution can be involved in climate change.

In addition to its effect on seawater density, salinity is useful in itself as a tracer of ocean circulation and mixing. Salinity is established in the ocean s surface layer by local processes, and therefore salinity variations within the ocean depend on the surface origin of a parcel of water. Mixing between waters of different salinities occurs within the ocean, and so the original salinity changes gradually. However, mixing rates are low enough that salinity (and other chemical tracers) can provide a great deal of information on the pathways of flow.

SEA SURFACE FORCING OF SALINITY: PRECIPITATION, EVAPORATION, RUNOFF AND ICE PROCESSES

The total amount of salt in the ocean is constant on time scales of millions of years, and hence is assumed constant for studies at almost all time scales. However, the total amount of water in the oceans varies daily due to exchange at the sea surface. Rainfall, runoff from land, and ice melt all reduce salinity by increasing the amount of fresh water. Evaporation increases salinity by decreasing the amount of fresh water.

Ice formation also locally increases salinity through a process called brine rejection. As ice forms from seawater, the dissolved salts are rejected from most of the ice and collect in pockets in the ice. This briny water drips through the base of the forming ice. More brine is released during slow ice formation than if the ice forms quickly, so the strength of brine rejection depends on the local air temperature. The brine mixes with the seawater beneath the ice, raising the seawater s salinity. The net salinity increase depends on the thickness of the mixing layer below the ice. In shallow locations, such as on shallow continental shelves, salinity might increase more than over a deep bottom where mixing occurs to greater depth. Because the water below sea ice is usually very cold, the addition of salty brine may increase salinity without increasing temperature. This results in a density increase in the seawater. This denser water then sinks until it reaches a depth where surrounding waters have the same density. Because these deeper waters may have come, at least in part, from somewhere else (e.g., in the Arctic from

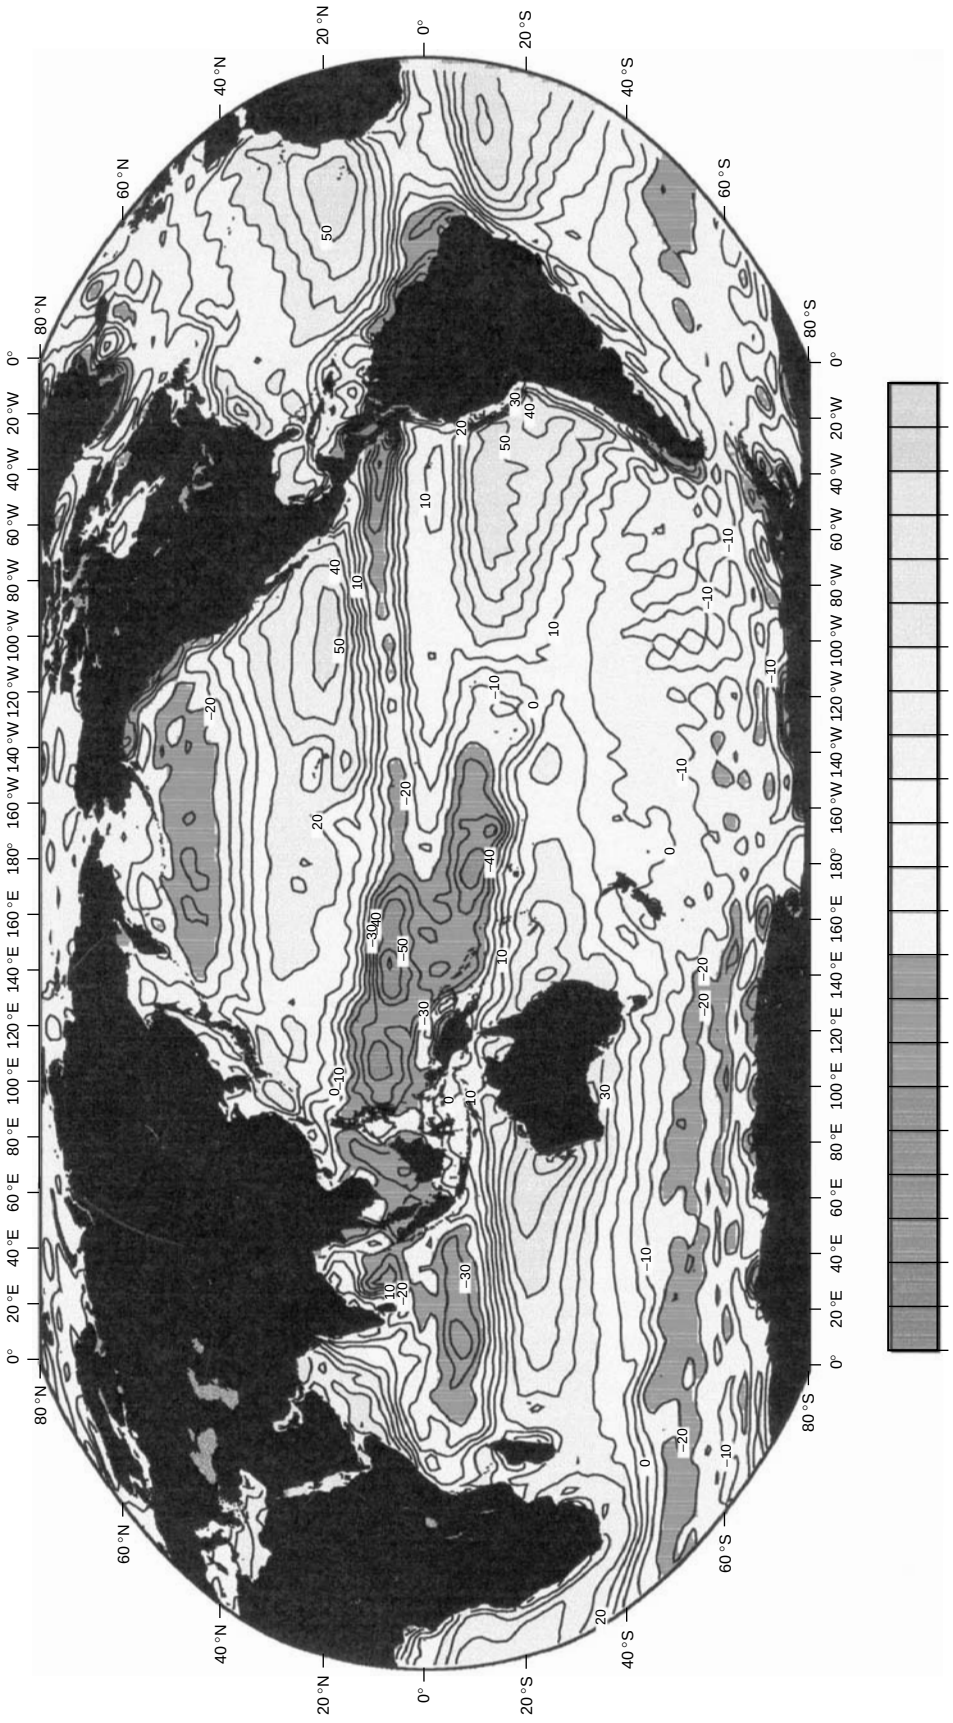

Figure 1 Evaporation minus precipitation (cm year^{-1}), annual average. The major rivers of the world are also indicated. (Reproduced using data from the National Centers for Environmental Prediction Reanalysis Project, Kalnay *et al.*, 1996)

the North Atlantic Ocean), these waters will usually not be as cold as the new ice-rejected brine. Although warmer, their density will be equal to the ice-rejected brine because they are even saltier. That is because the ice-rejected brine was formed from near-freezing surface waters that initially had much lower salinity (e.g., because they had a higher proportion of meltwater and river runoff), and therefore lower density, than the deeper waters. Although it seems paradoxical, the ice formation and brine rejection processes are thus able to create the coldest and freshest waters on a surface of constant density within the ocean.

Because sea ice has lower salinity than the original seawater from which it formed, melting of sea ice creates a fresh surface layer of low-density waters that float over the more saline waters below.

Ocean salinity patterns at the largest scales are affected primarily by the annual average of evaporation and precipitation, with additional major effects from ice melt and freezing at high-latitudes. Evaporation and precipitation, usually reported in cm year^{-1}, are primarily calculated from observations collected on a routine basis by most ships. The difference between evaporation (E) and precipitation (P) has been calculated from the complete historical data set compiled from these ship observations (Figure 1). The range of E$-$P is about -10 to 10 cm year^{-1}. There is more evaporation than precipitation in the subtropical regions between about 15° and 40 °S and N latitude, under the atmosphere s large-scale high pressure centers, with descending, dry air. At higher latitudes, there is more precipitation than evaporation, under the atmospheric low-pressure centers. In the tropics, especially at about 10 °N over the Pacific and Atlantic, surface air rises in the intertropical convergence zone (ITCZ), forming enormous cumulus clouds that produce large amounts of rain.

Runoff from land affects the coastal salinity distribution. On a global scale, runoff is most important at the major river outlets, indicated in Figure 1. The net fresh water input is not shown in Figure 1, but the effect of these major rivers is apparent in the surface salinity distribution considered next.

SURFACE SALINITY DISTRIBUTION

Salinity at the sea surface (Figure 2) resembles the evaporation$-$precipitation pattern, with some differences due to runoff, ocean currents and ice melt. The total salinity range of the open ocean is about 30$-$40 parts per thousand or (*see* Salinity, Volume 1). The international convention is that salinity has no units; its value is approximately grams salt per kilogram of sea water. Many authors continue to use the practical salinity unit (psu) rather than leaving the quantity unitless. While salinity in coastal estuaries can be much lower, it does not affect large oceanic-scale patterns. Lowest salinities occur in the Arctic and Antarctic where there is both net precipitation and seasonal ice melt. Highest salinities occur in the Red Sea and Persian Gulf, both located in the northwestern Indian Ocean, where net evaporation is high. High salinity is also found in the Mediterranean Sea. In the open ocean, high salinity occurs in the subtropical areas of net evaporation seen in Figure 1. A band of low salinity underlies the ITCZ at 10 °N.

The effect of continental runoff is apparent in lowered surface salinity near the mouths of major rivers such as the Amazon and the Congo and the numerous large rivers that empty into the Bay of Bengal, east of India, including the Ganges and Brahmaputra. Runoff from many rivers around the Gulf of Alaska in the northeastern Pacific and around the Arctic Ocean is important in the lowered salinities of high-latitude ocean regions.

VERTICAL STRUCTURE OF THE SALINITY DISTRIBUTION

Waters at the sea surface flow down into the interior. Salinities from the sea surface (Figure 2) carried with this flow into the ocean interior are helpful in identifying sources and pathways of the circulation. The two primary mechanisms for this downward flow are: (1) flow following constant density surfaces that slope gently into the ocean interior, and (2) vertical convection and brine rejection at higher latitudes.

Flow down along constant density surfaces is primarily through a process called *subduction*, occurring in subtropical regions between about 15° and 40 °S and N latitude. In this process, waters in the surface mixed layer circulate equatorward, encountering warmer, less dense waters to the south, which they are carried beneath. Surface waters are most saline in the middle of these subtropical regions. Therefore, all equatorward subtropical regions are characterized by a subsurface vertical maximum in salinity caused by subduction of more saline waters from the center of the gyre, as described later (*see* Ocean Circulation, Volume 1).

Convection occurs in many places, but reaches most deeply into the ocean at high latitudes. Convection is not so much a downdraft of water from the surface as it is a deep mixing, which brings surface water to great depth, from whence the water spreads laterally along constant density surfaces. Major deep convection areas can be identified from subsurface properties, such as the salinity distributions discussed below. In the North Atlantic and Arctic, these sites are in the Labrador Sea between Labrador and Greenland, in the Greenland Sea east of Greenland and north of Iceland, and in the Mediterranean Sea. In the North Pacific, convection in the Okhotsk and Japan Seas is significant in modifying water properties at mid-depth. In the Southern Hemisphere, convection occurs all around Antarctica at about 40° to 45 °S, which is just north of the major current

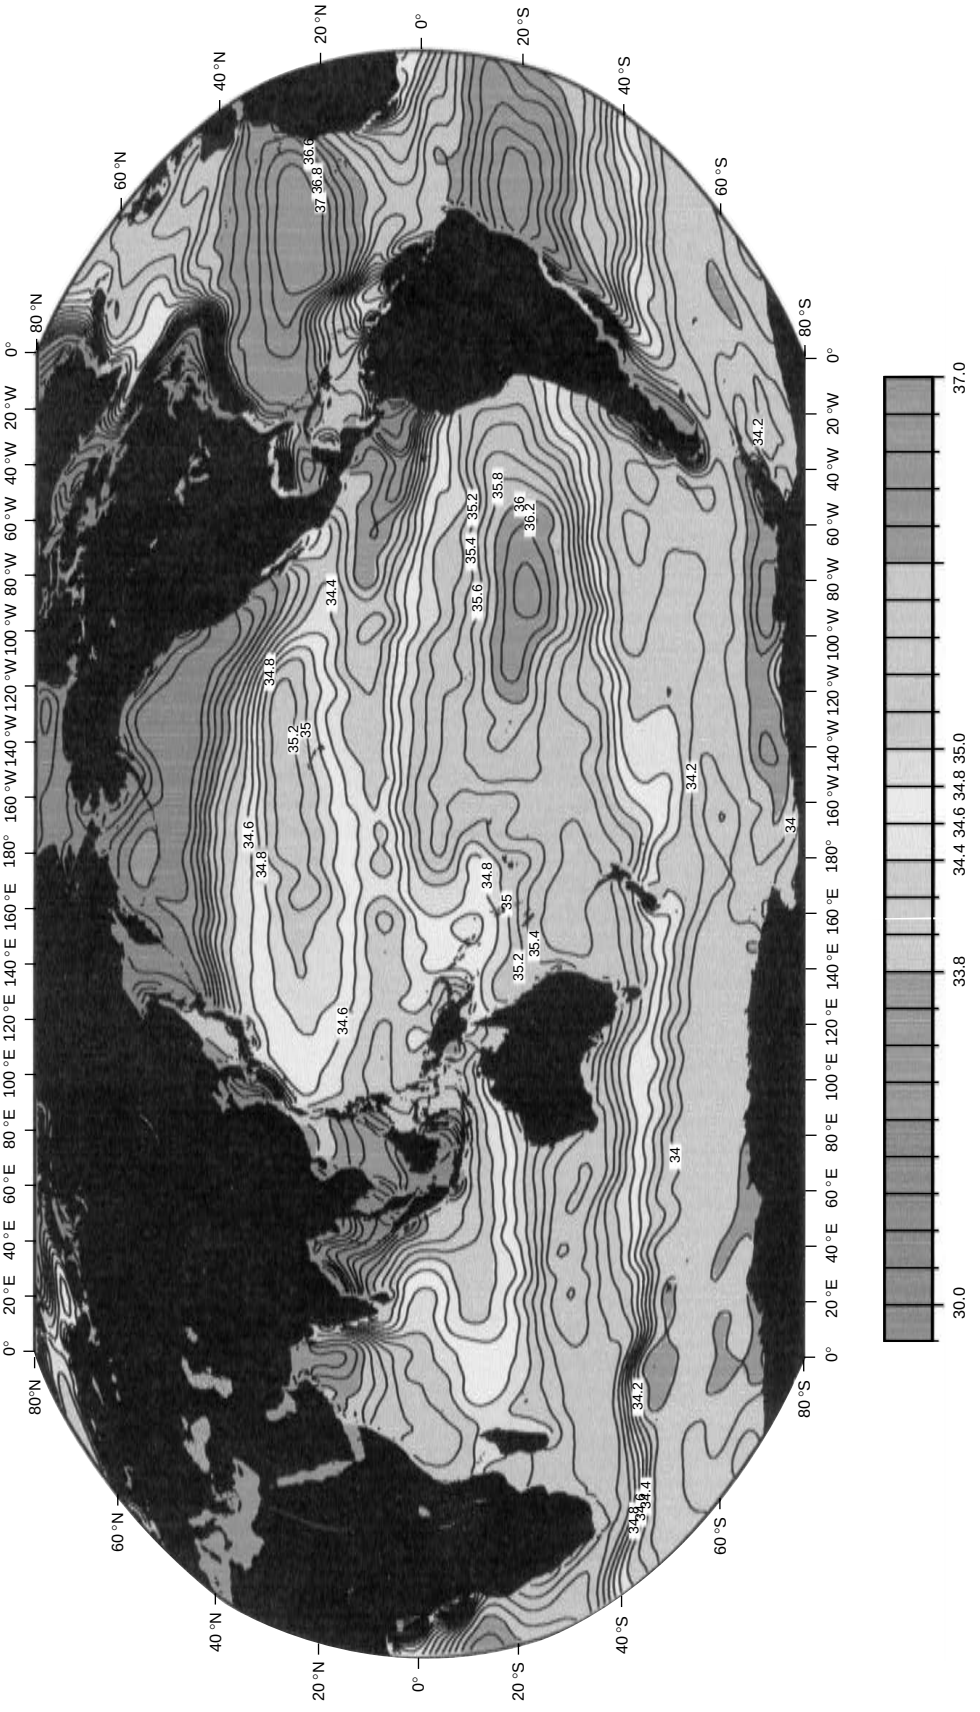

Figure 2 Surface salinity (g salt per kg of seawater), using annually averaged ship observations. (Reproduced using data from Levitus *et al.*, 1994)

called the Antarctic circumpolar current. Brine rejection is important for subsurface water properties primarily in the Antarctic (Weddell and Ross Seas and other locations around the continent), the Okhotsk Sea, and the interior of the Arctic Ocean.

The following definitions are useful for discussing the salinity distribution in the vertical: (1) *halocline* – where the salinity value changes rapidly in the vertical in comparison with changes above and below the halocline; (2) *halostad* – where salinity changes very slowly in the vertical; (3) *intermediate water* – usually referring to a minimum or maximum in salinity in the vertical which is found over a large horizontal area at mid-depth in the ocean. Equivalent terms for vertical variations in temperature and density are *thermocline*, *thermostat*, *pycnocline* and *pycnostad*.

SUBTROPICAL SALINITY STRUCTURE

In the subtropical regions of every ocean, salinity (Figures 3 and 4a) is high close to the sea surface due to strong evaporation. At the location of the highest surface salinity (Figure 2), the highest salinity in vertical profiles is at the sea surface. This high salinity water is carried downward and equatorward through subduction. Therefore, equatorward of the center of the highest surface salinity, there is a vertical maximum in salinity. This salinity maximum is at about 50 m depth, which is very shallow compared with the ocean depth. These subsurface salinity maxima are sometimes called *Subtropical Underwater* (Worthington, 1976).

At all locations in the subtropical gyres, and below the near-surface salinity maximum, salinity decreases smoothly with depth to a salinity minimum. Temperature also decreases smoothly and rapidly (Figure 4b). This layer of changing properties is called the *thermocline* (region of high temperature change in the vertical), and is also often called *central water*. Central water is the subducted water of the subtropical gyre; the colder waters come from farther north within the subtropical circulation, with little input from the subpolar region. It is clear from Figure 4(b) that the North Atlantic central waters are the most saline and the North Pacific the freshest.

Below the central waters, at depths between about 500 and 1500 m, each subtropical gyre (except in the North Atlantic) has a vertical minimum in salinity. The salinity minimum in the North Pacific is called *North Paci c intermediate water* (Reid, 1965). It arises from cold, low salinity surface waters in the subpolar region of the North Pacific, specifically in the Okhotsk Sea and near the Kuril Islands (Talley, 1991, 1993). These waters flow southward along the western boundary in the Oyashio current and enter the subtropical circulation east of Japan. The existence of the low salinity layer throughout the subtropical circulation reflects the presence of this subpolar water underlying the waters from subtropical sources.

The salinity minimum in the Southern Hemisphere is called *Antarctic intermediate water* (Reid, 1965). It comes from low salinity surface waters found just west of Chile and just east of Argentina (McCartney, 1977). Antarctic intermediate water in the Pacific Ocean originates primarily from the Chilean source. The Atlantic and Indian Ocean Antarctic intermediate waters originate from the Argentinean source. The Argentinean waters arise from Chilean surface waters, which flow eastward through the northern side of Drake Passage between South America and Antarctica. The Chilean waters are modified somewhat during their passage into the Atlantic. Therefore, the properties of the Atlantic and Indian Antarctic intermediate waters differ slightly from those of the Pacific Antarctic intermediate water.

The salinity structure in the subtropical North Atlantic is somewhat different. While there is a salinity minimum at the base of the central water, this results primarily from the northernmost subducted waters of the subtropical region, and is not the major fresh intermediate water of the North Atlantic, which dominates the subpolar region (described later). The main fresh intermediate water is displaced in the subtropical gyre by the high salinity outflow at mid-depth from the Mediterranean Sea. This outflow creates an intermediate depth salinity maximum in the vertical.

In the Indian Ocean, a dense, high salinity source in the Red Sea creates a high-salinity intermediate water in the north, similar to the Mediterranean water of the Atlantic. Because there are no northern high-latitude sources of water in the Indian Ocean, there is no fresh intermediate layer arising from the north. The fresh water at the surface in the Bay of Bengal arising from major river runoff is much too warm to sink to mid-depth. Thus, the mid-depth northern Indian Ocean is dominated by the highly saline outflow from the Red Sea.

Beneath the low salinity intermediate waters of the North Pacific and Southern Hemisphere, salinity increases towards the bottom. The higher salinity of the deep waters of the Southern Hemisphere and North Pacific results from input of saline North Atlantic waters. Beneath the saline intermediate water of the North Atlantic and tropical Indian Oceans, salinity decreases to the bottom. In the South Atlantic Ocean, low-salinity intermediate water (Antarctic intermediate water) lies above higher salinity deep waters from the North Atlantic. Beneath the high-salinity North Atlantic deep water, salinity decreases to the bottom. The lower salinity of the bottom waters in the Atlantic and Indian Oceans results from deepwater sources in the Antarctic that are of lower salinity.

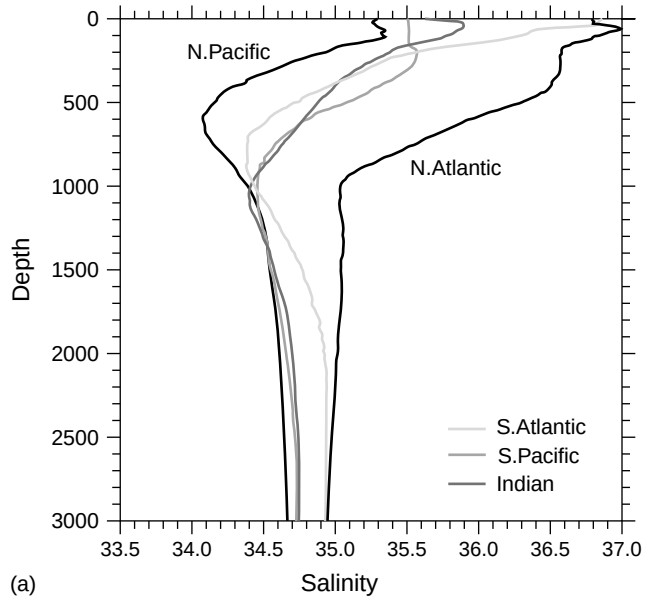

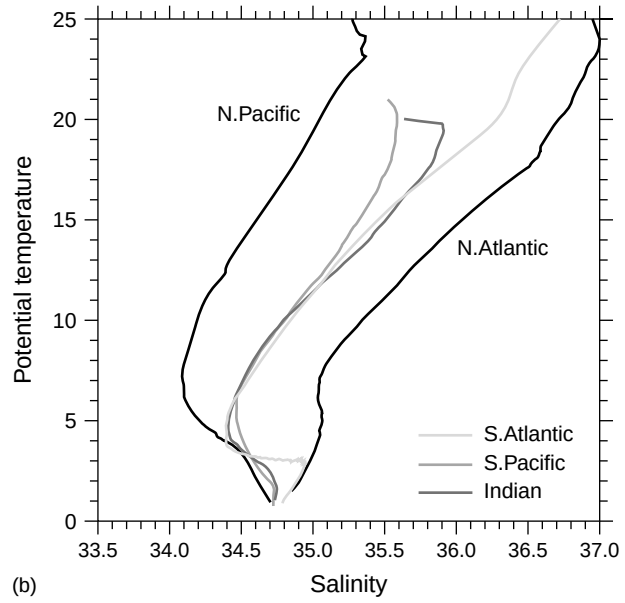

Figure 4 (a) Salinity distribution with depth from each subtropical gyre. All profiles are chosen from the centers of the subtropical circulations, at about 25 °N (Northern Hemisphere) and 30 °S (Southern Hemisphere), and from the center of the basins rather than near the boundaries. (b) Potential temperature as a function of salinity for each subtropical ocean basin

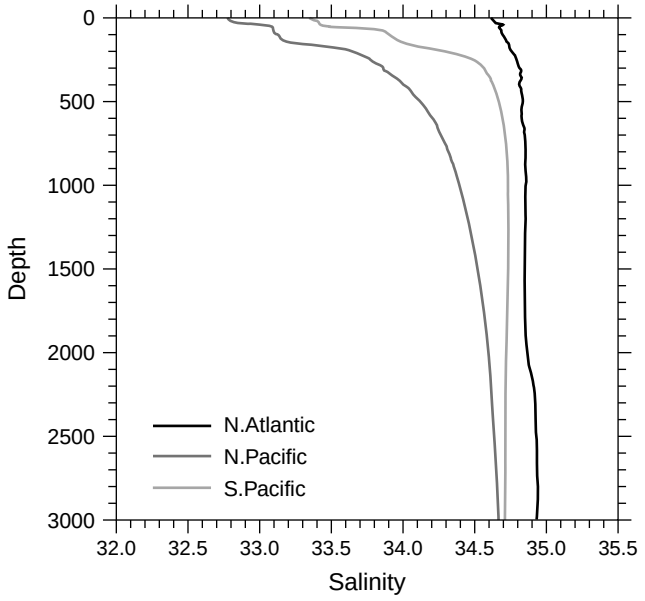

Figure 5 Salinity distribution with depth from the subpolar regions. The Northern Hemisphere profiles are from about 50 °N. The Southern Hemisphere profile is from the Pacific Ocean at about 65 °S

SUBPOLAR SALINITY STRUCTURE

In high latitude regions dominated by precipitation and ice melt, salinity is lowest at the sea surface and increases downward through a halocline (Figure 5, North and South Pacific profiles). In the North Pacific and Southern Hemisphere, and also in most of the Arctic Ocean, the halocline is very sharp, with a large change in salinity over several tens of meters. Because of the salinity structure, the surface layer can be colder than the water below the halocline. This pre-conditions the region for sea ice formation. The cooled surface waters can circulate away from their winter outcrop locations and appear as a subsurface temperature minimum between warmer water below from inflow from other regions and warmer water above from local seasonal warming.

The North Atlantic s subpolar gyre is affected by inflow of a thick layer of saline, warm surface water from the subtropical gyre. Therefore, the halocline typical of the subpolar Pacific and subpolar Southern Hemisphere is absent in most of the subpolar North Atlantic (Figure 5, North Atlantic profile). The saline flow into the central and eastern subpolar gyre is affected by precipitation, and the surface waters become gradually fresher as they circulate counterclockwise. When the surface waters enter the Labrador Sea, they are much fresher than when they first enter the subpolar region. Winter convection to about 1500 m depth in the Labrador Sea then mixes the relatively fresh water to intermediate depth. This spreads away from the Labrador Sea and forms a salinity minimum throughout the subpolar gyre, beneath the inflowing warm, saline waters. This differs from subpolar regions in the other oceans where the surface waters are strongly dominated by local fresh water sources. Therefore, most of the North Atlantic s subpolar gyre has a vertical salinity structure similar to a subtropical structure, with saline waters at the surface and an intermediate depth salinity minimum.

TROPICAL SALINITY STRUCTURE

The upper ocean salinity distribution depends on local precipitation patterns. Thus, a band of low salinity is found under the high precipitation of the ITCZ at 5–10 °N in the Pacific. This band is separated from the saline waters below it by a halocline. Excess precipitation is also found in the western Pacific at the equator, creating a halocline there as well. The eastern equatorial Pacific on the other hand is dominated by evaporation and so there is no halocline there. The Bay of Bengal in the Indian Ocean is the site of major runoff from Asia; this relatively fresh, warm water creates a shallow halocline throughout the northeast Indian Ocean. The intermediate and deepwater salinity distributions in each ocean within 15° of the equator are similar to those of the adjacent subtropical regions.

GLOBAL SCALE SALINITY PATTERNS

As indicated above, there are significant differences in salinity between oceans. Considering the total ocean basin, the North Atlantic is the most saline and the North Pacific the freshest of the major oceans. Because of significant river inflows, the surface waters of the Arctic are the freshest. The three Southern Hemisphere oceans are connected around Antarctica and hence their salinities are similar, midway between the North Atlantic and North Pacific. The main reason for the differences between the North Pacific and North Atlantic salinities is the difference in net evaporation per unit area. There is relatively more evaporation in the North Atlantic s subtropical regions than in the North Pacific s subtropics. The evaporative regions occur where there are easterly trade winds. The North Atlantic s trade winds originate over the deserts of Africa and the Middle-East. The North Pacific s trade winds originate over the much smaller continental areas of Central America and Mexico. Therefore, the North Atlantic s trade winds are drier than the North Pacific s and cause more evaporation per unit area. High salinity in the North Atlantic is present at intermediate depth because of the Mediterranean Sea. The North Atlantic exchanges water with the Mediterranean Sea through the Strait of Gibraltar. Evaporation and cooling in the Mediterranean cause the outflowing water to be much denser than the inflow. This dense outflow sinks to intermediate depth and creates the mid-depth high salinity that marks North Atlantic waters. This input of high salinity at mid-depth in the North Atlantic is one reason for the overall higher salinity of the North Atlantic compared with the North Pacific. Similarly, in the Indian Ocean, high evaporation in the Arabian region creates very saline and dense water in the Red Sea, which enters the Indian Ocean and raises the salinity at mid-depths compared with the inflowing fresher deep waters from the Antarctic.

ROLE OF SALINITY IN CLIMATE CHANGE

Salinity is a major factor in climate change because it can affect the depth of mixing at the sea surface. If for instance there is a shallow, fresh layer atop a denser, more saline layer, even large surface cooling can act only on the surface layer, creating a large temperature drop without deep convection. In the absence of a halocline, heat can be removed from a much thicker layer, which then results in a smaller temperature change. The processes that set the salinity of the waters beneath the surface layer, and hence the strength of the halocline, are complex. This salinity control of surface-layer processes in the present climate has been studied, e.g., in the tropical Pacific, as part of the El Niño and La Niña cycle. In the normal state in the northern Atlantic, up to and including the region between Greenland and Norway, surface salinities are not much lower than those of the underlying waters, permitting overturn to more than several hundred meters depth. This overturn is part of the global thermohaline circulation in which deep waters are produced from surface waters at high-latitudes, mainly through heat loss to the atmosphere. (The presence of a permanent and strong halocline in the northern North Pacific and in the Arctic Ocean prevents deep overturning of waters there.) During observed decadal climate changes in the North Atlantic, a halocline sometimes forms as a result of excessive ice melt and runoff and is associated with shutdown of deep wintertime convection. This then affects the sea surface temperature as described previously, and can then affect the atmosphere. From ocean computer modeling experiments it is hypothesized that similar controls by salinity on deep overturn have occurred on much longer climate timescales.

SCOR (Scientific Committee on Oceanic Research)

SCOR was created by the International Council for Science (ICSU) in 1957 as the first of its interdisciplinary bodies, and is charged with the promotion of international activities in oceanography. SCOR s scientific activities fall into two categories: small, short-lived working groups formed to address narrowly focused scientific topics, and longer-term, large-scale international research programs in oceanography designed to address issues of the role of the ocean in global climate change. SCOR also serves as an official scientific advisory body to the Intergovernmental Oceanographic Commission (IOC) of the United Nations Educational, Scientific and Cultural Organization (UNESCO). Lastly, SCOR administers a program of travel awards to marine scientists from developing countries. National committees for SCOR exist in many countries.

SCOR cooperates with ICSU and IOC in the development of projects such as the Global Ocean Observing System (*see* Global Ocean Observing System (GOOS), Volume 2) and the Joint Ocean Flux Study (*see* JGOFS (Joint Global Ocean Flux Study), Volume 1). The latter program has completed its worldwide sequence of field data-collection cruises, and is entering an intensive period of data assembly, analysis, modeling, interpretation and synthesis. Its objective is to develop a global picture of the oceanic carbon cycle.

Another major SCOR initiative is the Global Ocean Ecosystem Dynamics effort, which is one of the core projects of the IGBP.

Sea Ice

Douglas G Martinson
Columbia University, Palisades, NY, USA

Sea ice is ice that forms by the freezing of ocean seawater. It is distinctly different from icebergs (of Titanic fame), which are pieces of glacial ice formed by the compaction of snow that have broken off from continental ice sheets (on Greenland and Antarctica) or from alpine glaciers.

Sea ice is important to global environmental change because it resides at the interface between the ocean and the atmosphere. Global climate patterns in space, and variations in time, re ect complex interactions between the atmosphere, ocean and land surfaces (including biosphere).

When and where sea ice is present, the nature of the planet's surface is dramatically altered (from a dark liquid ocean surface to a white solid ice surface), as are the interactions between the atmosphere and ocean. These surface alterations are the primary means by which sea ice influences the environment, both in the immediate region where it is present, as well as on global scales.

Sea ice formation is dependent upon distinct atmospheric and oceanic conditions. The conditions are met predominantly in the polar seas (Figure 1), specifically in the Arctic Ocean and neighboring seas, and in the seas surrounding the Antarctic continent (Figure 2). However, despite what might appear to be some rather obvious similarities between the Arctic and Antarctic polar seas including, the presence of a sea ice cover included, there are some rather dramatic differences. Most notable is the fact that the land-locked Arctic Ocean and neighboring polar seas are blanketed by a sea ice cover that averages 3–4 m thick and covers nearly 15×10^6 km^2 (an area comparable in size to the US). About half of this ice cover is perennial (8×10^6 km^2), i.e., year round. Conversely, the Antarctic seas, unbounded to the north, are blanketed by a rather thin seasonal sea ice cover, typically less than 1 m thick and covering approximately 20×10^6 km^2. Like ice on a pond, most of the Antarctic sea ice melts away in the spring, is absent in summer (except for 4×10^6 km^2 of thicker perennial ice) and reforms the following fall and winter. The dissimilarities between Arctic and Antarctic sea ice reflect a wealth of differences in the manner by which the ocean, ice, and atmosphere interact in the two regions.

Regardless of differences, one might wonder why an expanse of relatively thin floating ice in the most remote reaches of the Earth would have any influence on climate outside of the polar regions themselves. From the broadest perspective, this influence is not unexpected when considering that climate is the consequence of the natural redistribution of excess heat in the tropics to the heat-starved polar regions. This meridional heat imbalance reflects the fact that, in the tropics, the Sun (the planet s primary source of surface heat) beats down almost directly overhead throughout the year, whereas in the polar regions, the Sun does not even rise above the horizon for much of the year. When it finally does, in the polar summer near the top of the spherical Earth, the Sun is never directly overhead. Consequently, the incoming sunlight strikes the surface at an oblique angle, reducing its heating effectiveness. The oblique angle also causes much of the solar radiation to be reflected back into space, further reducing its heating potential. The vast fields of highly reflective snow and sea ice (and glacial ice) greatly enhance this reflective loss.

This differential heating leads to a strong temperature contrast between the equator and poles. Heat always flows from warm to cold regions, and this flow, complicated by a rotating Earth and complex distribution of land and sea, drives all of the atmosphere and ocean circulation systems that form the basis of our climate. In the crudest sense, the stronger this temperature contrast, the more vigorous the atmospheric circulation and climate system. Changes in the temperature gradient from the equator to the pole may thus be expected to change the basic state or vigor of the climate system.

Such changes can be induced by changes in the tropics, the polar regions, or anywhere in between. Because of sea ice, the polar regions are particularly susceptible to change. This susceptibility stems from a variety of ocean–atmosphere feedbacks, unique to sea ice, and

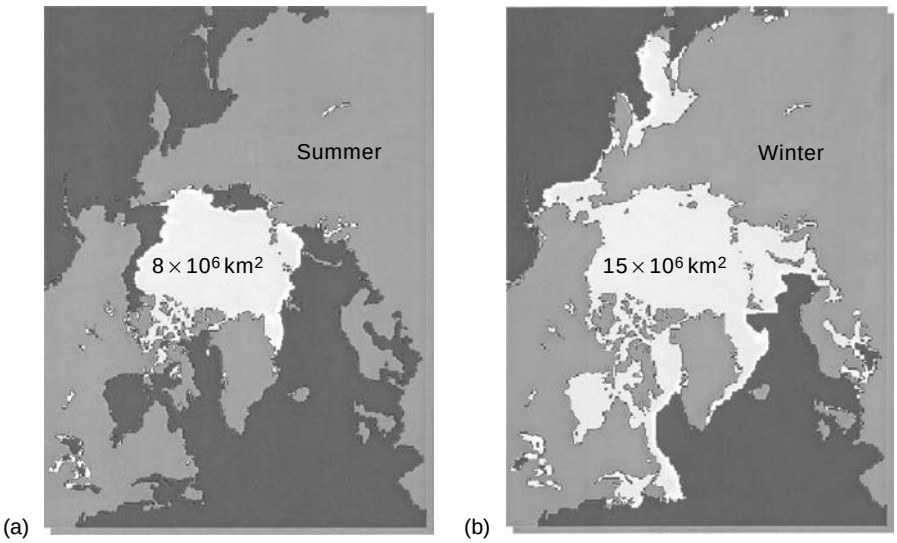

Figure 1 Summer (a) and winter (b) sea ice distribution in the Arctic polar region

Figure 2 Photograph of newly formed sea ice in the Antarctic. When ice crystals first float to the surface of the ocean, the wave motion causes them to coalesce into the characteristic shape seen here. This new ice, approximately 30 cm thick, is referred to as pancake ice (though it often looks more like lily pads, especially given the turned edges resulting from the collision of pancakes amongst themselves in the wave field). For scale, the fur seal resting on one of the larger pancakes is approximately 2 m in length. (Photo by Richard A. Iannuzzi)

capable of amplifying small sea ice changes into relatively large impacts. Of these, two dominate: (1) the ice–albedo feedback; and (2) the ice–ocean feedback. The former influences the effectiveness of solar heating, and is primarily active in summer when sunlight is present. In the polar regions, as previously noted, much of the cooling is due to the reflectance of the solar radiation from the sea ice or its snow cover. The degree of reflectance is indicated by the albedo (*see* Albedo, Volume 1). The ocean has an albedo of ~0.2 (it absorbs most of the incoming radiation), whereas fresh snow has an albedo of ~0.8 (it is a strong reflector). Thus, if the ocean is covered with ice overlain with snow, the effectiveness of surface radiation absorption (surface warming) is dramatically reduced (by 75%). This leads to a colder atmosphere (which draws heat from the warmth of the surface). Such conditions favor the formation of more ice, reflecting back more radiation, chilling the atmosphere further, causing more ice growth, etc. If the ice cover disappears, the opposite occurs, resulting in a rapid increase in local warming, increased ice loss, more warming, etc. This enhanced warming with the loss of a sea ice cover, or cooling with the addition of a sea ice cover describes the ice–albedo feedback mechanism (*see* Climate Feedbacks, Volume 1).

This self-amplifying cascade of effects, the ice–albedo feedback, is most active and effective in summer when the Sun is above the horizon, and in the Arctic because of the perennial sea ice. If the Arctic were to begin losing its perennial ice cover, exposing the ocean, with its significantly lower albedo, to summer sunlight, one might expect a self-amplifying warming to begin, driving more summer ice loss and further warming, all the while altering the equator–pole temperature gradient, and presumably climate. This feedback is inefficient in the Antarctic because most of the sea ice fields are absent in summer (and because the land-based Antarctic icecap is extremely cold and unlikely to significantly melt). However, unlike the Arctic Ocean, the Antarctic sea ice fields extend equatorward of the polar circle. Therefore, they are exposed to some (though not much) sunlight in winter, and even more in the fall and spring, thus allowing some ice-albedo influence at those times.

The ice–ocean feedback encompasses an ensemble of interactions between the ocean, ice and atmosphere. Of these, the primary one involves the insulation effect of sea ice. This is a positive feedback mechanism that complements the ice–albedo feedback by operating primarily in winter. Specifically, sea ice, floating on the ocean water, serves to isolate the frigidly cold winter atmosphere from the relatively warm ocean. That is, the water cannot get colder than the freezing point ($-2\,^{\circ}$C for seawater) or it will freeze, whereas the winter atmosphere over ice, in the absence of warming sunlight, cools to approximately -15 to $-40\,^{\circ}$C. The layer of ice lying on top of the water insulates the water just as double-glazed glass insulates a home – if the window is opened (the ice removed), the warm ocean immediately loses heat to the atmosphere and, because the ocean water contains considerably more heat than the overlying atmosphere, the latter will warm to the water temperature, e.g., from – 40 to $-2\,^{\circ}$C, about a $40\,^{\circ}$C warming! Thus, as sea ice forms, it insulates the water. This leads to a colder atmosphere favoring more ice growth (the thicker the ice and overlying snow cover, the better the insulation), and thus colder atmospheric temperatures, etc. In the warmer summer, the air and water temperatures both hover near the freezing point, so this insulating effect and positive feedback occurs primarily in winter, when the atmosphere is at its coldest and the ocean is its only source of heat.

Even small cracks in the ice (known as leads), like a window slightly open, allow a considerable amount of heat to escape. In fact, heat is lost through leads 100 times more effectively than it is lost via conduction through the thick Arctic ice cover, and 20 times more effectively than it is through the relatively thin Antarctic ice cover. In both cases, this means that even a small increase in the number and size of leads can result in a tremendous amount of atmospheric warming. More leads also decrease the area covered by the highly reflective ice, which reduces the albedo as well, further warming the system.

Leads reflect a balance between the rate at which winds and tides open them, by moving ice apart, relative to how fast new ice growth in the leads closes them. Because of

their importance, we typically classify a sea ice cover not only as perennial or seasonal, according to its persistence in time, but also by the fraction of leads within an ice cover. A 95% ice concentration, or ice cover, indicates that 95% of the area is covered by ice, while the remaining 5% represents leads, exposing the ocean directly to the atmosphere. It is difficult to sustain a 100% ice cover over broad areas because irregular winds tend to blow the ice apart in some regions, while forcing it to collide in other locations. Where it collides, it often crumbles into broken and overridden blocks, forming rough and irregular ridges. This is *ice rafting*.

In summary, both the albedo and insulation of the ice cover work to reduce the polar atmospheric temperature and thus exacerbate the equator–pole temperature contrast, and increase the vigor (and with that, the characteristics) of our climate. In addition, a multitude of secondary feedbacks, unique to the sea ice region, also operate in response to sea ice changes. For example, as sea ice forms, and leads close, the atmosphere is impeded in its ability to draw moisture from the ocean for local cloud formation. Clouds serve as warm insulating blankets by trapping heat, but they also serve as umbrellas that cool the surface by blocking sunlight. Whether a change in cloud cover leads to a net warming or cooling in polar regions is a matter of debate (there is some indication that the net influence of clouds is different in polar regions relative to their net influence in tropical regions; recent evidence suggests clouds lead to a net warming in the Arctic – that is, the blanket warming dominates over the umbrella cooling).

Other aspects of the ice–ocean feedback can influence climate by modifying the ocean s ability to transport heat. The slow but unremitting ocean circulation is part of the Earth s arsenal for moving heat from the equator to the poles, though the ocean often accomplishes this through convoluted and circuitous paths. In the Southern Hemisphere, the circulation of the deep waters accomplishes this ocean transport of heat to the polar region. In the Antarctic polar seas, ocean circulation, driven by the winds, forces the deep water to the surface where the excess heat (relative to the freezing point) is vented to the atmosphere, accomplishing the delivery of heat to this cold region. How effective this heat transfer is depends on ocean–ice interactions in both the Arctic and Antarctic polar seas.

For example, sea ice formation works like a distillery, separating the freshwater from the salt in seawater, resulting in nearly freshwater ice (though a small amount of salt is still trapped between the crystals of frozen water) and saltier seawater. The density of seawater is controlled by its saltiness in regions where the water is very cold (in warmer regions, temperature controls the density). In polar regions, the water column can be divided predominantly into two layers, a relatively cold but fresh buoyant surface layer (typically the uppermost 100–200 m) and warmer but saltier deep water (several kilometers thick). As the seawater freezes, the salt is released into the ocean, which makes the surface water saltier and thus denser. This denser water begins to sink because it is heavier than the water immediately beneath it (which is not as dense). The warmer, underlying deep water replaces the sinking water as it mixes upward to replace the sinking surface water. This delivers heat to the surface that reduces ice growth or melts existing ice (a primary reason why the Antarctic sea ice is so thin). This process is not active in the Arctic because the surface ocean layer is so fresh; even with salinization it does not grow dense enough to sink and bring warmer deep water upward, which is why Arctic ice is so thick. If enough ice forms in the Antarctic, the surface layer may become so dense that the entire upper layer mixes downward into the deep layer, destroying the ocean stratification and delivering considerable heat to the ocean surface. In fact, enough heat can be delivered in this manner to eliminate all of the overlying sea ice (forming what is called a *polynya* – an area of ice-free water surrounded by ice). This sinking water will also replenish the deep-water circulation because the sinking of dense surface waters drives that circulation.

Conversely, as sea ice is blown by the winds (generally at 2–4% of the wind speed), it drifts into regions where it eventually melts, freshening the surface ocean layer. This can influence the global deep-water circulation, which begins in the northernmost North Atlantic, where warm and salty subtropical waters, transported northward by the extension of the Gulf Stream are cooled (warming the neighboring atmosphere and helping to keep NW Europe warm). As it cools, the salty subtropical water grows denser, eventually sinking (while still warmer than the freezing point) north of Iceland and southwest of Greenland. This initiates southward flow to the Antarctic and eventually the rest of the world s oceans. If an unusual amount of sea ice from the Arctic drifts into these sinking regions and melts, the buoyant melt water prevents sinking, which inhibits, or shuts down the deep-water circulation (and its ability to deliver heat to the Antarctic). It also has the potential for altering the Atlantic surface circulation, because warm subtropical water no longer needs to flow northward to replace the water from that region that is sinking and flowing southward. Such influences have been hypothesized as being responsible for abruptly altering climate, particularly in Europe, because that region depends on the warm extension of the Gulf Stream to keep the winters moderate. However, counter arguments state that an unusual sea ice incursion is more likely a consequence of an already changing climate, not a cause. Comparable arguments suggest such sea ice incursions and their impact on the deep-water circulation can initiate an avalanche

of global feedbacks that ultimately trigger the great ice ages.

How sensitive global climate is to changes in the sea ice distribution and its growth/melt processes is still undetermined. This reflects the complexity of the processes involved and the myriad of feedbacks operating elsewhere in the climate system that may ultimately diminish or enhance the sea ice driven impacts. At present, our best estimates come from model studies. However, because of the complexities and still imperfect understanding, many of the sea ice processes and feedbacks are represented in the climate models in quite simplified ways, if at all. Consequently, a recent comprehensive international study found that the most important reason for differences among the results of global climate models was related to differences and inadequacies in their treatment of the polar regions.

However, some model studies explicitly targeting the impact of sea ice on climate have shown that sea ice fields play a major role in determining the extent of change in global climate. For example, an investigation using NASA s Goddard Institute of Space Studies climate model to simulate the climate under conditions of doubled atmospheric CO_2, found that 37% of the global warming simulated by that model was a consequence, directly and indirectly, of the modeled changes in the sea ice fields. While this estimate cannot be viewed as precise, it serves to underscore just how important the treatment of sea ice is in models, and it suggests how significant the various sea ice related feedbacks can be.

In the final decades of the 20th century, perennial sea ice appeared to have gotten thinner, and to have been slowly diminishing in areal extent, retreating in the Arctic at a rate of approximately 4% decade^{-1}. If sustained, the perennial ice cover would be eliminated in a few hundred years. However, theoretical and modeling studies suggest that, unless some other compensating changes are introduced elsewhere in the climate system, the various feedbacks will work to accelerate the rate of retreat. One recent study suggested that the perennial ice cover could be eliminated within 50 years (though it will likely always be cold enough to grow some winter sea ice). At present, it is not clear why the ice is retreating, but one detailed model study suggests that the decrease is consistent with the accelerated global warming experienced over the latter quarter of the 20th century. One model suggests that such a sustained retreat is highly unlikely to arise as a result of natural climate variability and that the melting is more consistent with anthropogenic warming. Clearly these ideas need further testing and analysis as understanding improves and improvements are made to models to better represent sea ice-related processes (progress is slow given the difficulty of studying these processes in the remote and hostile polar environment).

Finally, in addition to having the potential of playing a major role in determining climate, sea ice has another interesting characteristic that makes it valuable for climate studies. Sea ice has been identified as a sensitive indicator of climate change because global temperature changes are amplified in the polar regions: warming in the temperate zones is accompanied by even stronger warming in the polar regions. Consequently, as we seek to identify clear signals of anthropogenic warming, it has been noted that such a signal may first appear above the background noise (natural variability) in an amplified response of the polar regions. Furthermore, in the Arctic, where the ocean offers little resistance to ice growth, changes in atmospheric temperature may be reflected as changes in sea ice extent. Sea ice has the distinct advantage of being a highly visible medium, easily monitored from space via satellites. Thus, changes in sea ice may be easily observed and serve as an early warning indicator of global warming. However, while this basic concept appears to be valid, whether such warming is due to anthropogenic change or natural variability requires additional investigation, such as the modeling studies mentioned above. Besides the obvious physical influences and implications, the sea ice fields play a major role in the seasonal evolution of the unique and limited polar flora and fauna. The sea ice is thought to help establish surface ocean conditions that allow the large and impressive phytoplankton blooms to occur in spring and summer. In the Antarctic polar oceans, these blooms are exceptionally large, playing a role in the global uptake of atmospheric CO_2 and providing food for larger animal life, such as krill, penguins and whales. In the Arctic, the sea ice provides the means by which polar bears access the highest northern latitudes where they feed and live during the summer months. Without the sea ice, the bears would be limited to the continental regions surrounding the Arctic. Thus, changes in sea ice extent, and its seasonal cycle, may have profound, although unknown implications to the polar biology.

Sea Level

Michael C MacCracken
Lawrence Livermore National Laboratory, Livermore, CA, USA

Oceans currently contain about 97% of the Earth's water and cover about 70% of the Earth's surface. At the edges of oceans, shorelines have been created. The geological record provides clear evidence that there have been very large changes in both the level of the oceans and in the locations of shorelines over the history of the Earth. While the natural processes governing sea level continue to play out, human activities have introduced some new ways in which sea level, and thereby coastlines and the coastal environment, can be changed. For example, projections are that human activities are likely to cause sea level rise during the 21st century to be several times larger than the rise of about 10- 20 cm that occurred over the 20th century.

OBSERVATIONS OF SEA LEVEL

Viewed from an airplane, the different nature of the land and oceans is quite apparent. The land is very rough and rigid, with mountains reaching up to almost 9 km. From a distance, however, the ocean seems quite smooth. For several reasons, this smoothness is somewhat deceptive. First, soundings of the ocean bottom indicate that ocean depth varies about as much as the land surface, and it is just the effect of gravity on the water that is creating the apparently smooth surface. Second, while the water surface can be smooth locally, the various currents, ocean ridges, temperature variations, and gravitational effects cause the ocean height, relative to the geoid, to vary by a few tens of meters (with extremes of as much as 100 m).

Viewed from up close, the oceans are also seen to be always moving. Walking near a shoreline, the most obvious feature of the ocean is perhaps how much the height of the water is going up and down. The level rises and falls with each wave and how it strikes the shoreline, the level varies through a semidiurnal and daily cycle of tides and these tides vary in location along coastlines and estuaries. The heights of the tides also vary through the month, roughly in phase with lunar influences (*see* Tides, Oceanic, Volume 1). Ocean currents and variations in the heights of waves and tides also depend on the weather and on the nature of the location (e.g., the depth of the water and the shape of the coastline). In addition, changes in winds and sea level pressure can push the ocean down or allow it to surge upward relative to the level established by the tides (e.g., the winds and low pressure during a hurricane or typhoon can cause water levels to rise up to several meters, depending on the storm and location).

In many regions, sea level varies with what is happening in the global ocean, including whether there is an El Niño or La Niña or other such global climatic fluctuation. Historic records also document that the level of the ocean is changing relative to the level of the land. For example, islands present in historic times in the Chesapeake Bay in the eastern US are now covered with water, and the state of Louisiana is losing about 50 $km^2\,year^{-1}$ to inundation. In addition, anthropological records suggest that the Americas were populated by peoples migrating across what are now the Bering Strait and Bering Sea at a time when the oceans had receded to expose lands currently up to 100 m below sea level. Geological records provide even more dramatic evidence of there being changes in ocean locations and boundaries, with what are clearly ocean bottom sediments now located well inland and lofted to become parts of mountains. Quite clearly, the location and the level of the sea has varied quite extensively due both to climate variations and to land movements, and there is no basis for thinking that long-term changes due to these natural processes will not continue into the future.

For the purposes of considering the potential importance to society of sea level change, what is important, however, is to determine how the average sea level may change over the time scales of societal interest. Tide predictions and weather and storm forecasts focus on how sea level will fluctuate over hours to days. Satellites now provide relatively accurate estimates of the variations in mid-ocean sea level due to changes in ocean currents and temperature, allowing forecasting, for example of El Niño and La Niña events (*see* El Niño and La Niña: Causes and Global Consequences, Volume 1).

In the context of long-term environmental change, the time periods of interest are decades to centuries, even though the effects of sea level rise are likely to be most noticed during times of extreme weather (e.g., hurricanes and typhoons). In addition, to provide context for understanding whether such changes are significant and how they may affect society, gaining an understanding of changes experienced over historical times are of interest.

Until recently, virtually all high-precision sea-level measurements have been made at coastlines. Coastal measurements typically involve creating some vertical scale that is solidly anchored (e.g., initially markings on a rock or on a piling). Boxes or baffles are also constructed to reduce the variations in level caused by the waves. A time-varying history of changes is recorded and then a time-averaged value is generated. As shown in Figure 1, however, even averaging over a year does not create a smooth record. That there is general agreement in interannual departures between locations as far apart as San Diego and San Francisco, for example, is an indication that large-scale oceanic conditions are playing a role in determining these fluctuations. This suggests the need to average over much longer times (e.g., a century) to get a trend. This has been done for a number of stations around the world. What becomes evident is that the long-term changes vary with where the measurement is taken, suggesting that long-term regional-scale processes are also important to consider.

Until very recently, measurements of sea level along coastlines have been relative sea level measurements because they have not been able to determine the separate contributions due to changes in the absolute level of the ocean and changes in the level of the land. This becomes an important issue because there are a number of factors that can cause the level of the land to change. These include compaction of newly deposited materials (which is particularly important along river deltas), subsidence caused by the extraction of water or other substances from the ground, vertical shifts caused by earthquakes, and the long-term upward or downward isostatic adjustment of the land surface (*see* Isostasy, Volume 1) occurring in response to the melting of the very heavy glacial ice that covered many continental areas from roughly 20 000 to 10 000 years ago. Such changes in land elevation can introduce an important bias into observations made at particular locations (e.g., Scandinavia, northeastern North America). To derive a meaningful estimate of the absolute change in sea level, this bias needs to be accounted for, either by removing the bias (if it can be determined, e.g., by using the new global positioning satellites) or by considering only results from stations where the land is not moving vertically. When the upward and downward movement of observation stations is accounted for, the results indicate that, over the 20th century, the average sea level rose by about 10–20 cm (Church *et al.*, 2001), with perhaps a tendency toward the upper limit (Douglas, 1997).

In that coastal observations at a global set of stations go back only of order 100–150 years, historic records can be used to estimate sea level at earlier times. For example, some Roman baths were apparently built at sea level over 2000 years ago, and until recently have remained near sea level. Heights of coral and of beaches also suggest that global average sea level has been relatively constant for several thousand years, with estimates being that sea level has varied by less than about 0.3–0.5 m over the past 6000 years. These records also indicate that the long-term average rates of change of sea level have been only about 1–2 cm per century, or about one-tenth of the rate of change during the 20th century (Church *et al.*, 2001).

Quite certainly, observations indicate that the historical development of coastal cities occurred during times of relatively stable sea level, but that coastal dwellers are now facing a rising sea level.

Further back than 6000 years, large ice sheets covered much of North America and Eurasia, with maximum extent peaking during the Last Glacial Maximum about 20 000 years ago (*see* Last Glacial Maximum, Volume 1). At that time, sea level was roughly 125 m below current levels. This is equivalent to about 3% of the oceans waters being accumulated on land as glacial ice. Although there are some uncertainties due to uncertainties about the amount of subsurface waters, this about doubled the amount of water not in the oceans. At the last interglacial (the Eemian), which peaked about 125 000 years ago and was probably a bit warmer than at present, there are some indications that sea level may have been a few meters higher than at present. This suggests that warming could indeed induce some melting of either the Greenland and/or West Antarctic ice sheets.

FACTORS CAUSING SEA LEVEL CHANGE

Global sea level is affected by many factors, some obvious and some quite subtle. In analogy with a bathtub, the level of the water is affected by the shape of the tub, the density of the water in the tub (less dense water takes up more space, so levels are higher), and by the amount of water put into the tub.

Over very long time scales, the shape of the ocean basins is changing (*see* Continental Drift, Volume 1). While continents are drifting relative to each other at rates of centimeters per year, the rate of continental drift is unlikely to be changing and this factor is not contributing significantly to changes in sea level, especially the increase rate of rise during the 20th century. In addition, the relative stability of sea level over the past few thousand years suggests that these contributions to sea level change must be small. Sediments are also carried into the oceans in rivers, thereby displacing some of the water, but this process is likely to be quite small. For the distant future, the melting of methane clathrates in the ocean sediments may become a contributing factor (*see* Methane Clathrates, Volume 1). Because these substances expand when frozen (just as ice takes up more volume than water), melting would create a tendency for ocean levels to drop slightly. However, such a process would likely take many hundreds to thousands of years to occur to cause a significant change.

In addition to changes in sea level that might result from changes in the shape of the ocean basins, sea level is also dependent on the density of the water. As for other fluids, the warmer it is, the less dense it is; as a result, the warmer it is, the more volume a fixed mass of water needs to occupy. Thus, sea level depends on the temperature of the oceans, and changes in sea level can result from changes in the temperature of the oceans. Although data sets of the temperature of the oceans at depth are relatively limited, recent compilations of the observations indicate that the upper 1–2 km of the oceans are warming, and that this is contributing to sea level rise (Levitus *et al.*, 2000). Combined with model simulations, the observations suggest that this thermal expansion effect has caused a rise in sea level of roughly 3–7 cm during the 20th century.

Finally, there are quite a number of factors that can affect the amount of water that is in the oceans. Among the major factors are the amount of ice and snow on land, the amount of water in underground aquifers, the amount of water stored in permafrost, and the amount of water stored on the land in reservoirs. In considering the transformation of snow and ice to ocean waters, it is important to recognize that a significant time lag is created by the time it takes to accumulate the energy to carry out the melting. Thus, while warming of the atmosphere can warm the ice, melting takes much longer because as much energy is needed to melt the ice as it takes to warm the ice by 80 °C. This large energy requirement has the effect of essentially anchoring the temperature at the melting point for a considerable time as warming is occurring.

Based on studies reported in Church *et al.* (2001) that account for the appropriate delay times, Table 1 provides a summary of the various factors that may change the amount of water in the oceans. The table also indicates the best estimates for how changes in these terms may have affected sea level during the 20th century.

- Mountain glaciers and icecaps (excluding Antarctica and Greenland) store an amount of water equivalent to about 50 cm of sea level (*see* Global Plate Tectonics, Volume 1). Over the past 100 years, the retreat of many glaciers has been evident in mountain ranges around the world from the tropics to upper mid-latitudes. Although some mountain glaciers in high latitudes are advancing, the overall effect is estimated to have caused a rise in sea level of 2–4 cm.
- Greenland is an ice sheet that is quite old, with some drill holes finding ice as old as 200 000 years. Other geological evidence suggests the ice sheet is likely to be much older. The Greenland ice sheet holds enough water to raise sea level by about 7 m were it all to melt, a long-term possibility suggested by the near absence of large ice sheets at the same latitude on adjacent continents. There are relatively limited observations of changes in the Greenland ice sheet until quite recently, when a network of surface stations was established. Surface and satellite observations indicate that some regions are currently melting while other regions are accumulating snow (*see* Greenland Ice Sheet, Volume 1). For the 20th century, the limited

Table 1 Estimates of contributions to changes in sea level for the period 1910–1990, based on observations and on modeling studies (Church *et al.*, 2001)

Factors contributing to sea level rise	Lower bound estimate (cm)	Central value estimate (cm)	Upper bound estimate (cm)
Thermal expansion of seawater due to oceanic warming	3	5	7
Greater retreat than growth of mountain glaciers and icecaps	2	3	4
Greater melting than snow accumulation on Greenland	0	0.5	1
Accumulation of snow on Antarctica	−2	−1	0
Long-term adjustment of Greenland and Antarctica in response to end of last glacial period	0	2.5	5
Melting of some permafrost	0	0.25	0.5
Changes in the amount of water stored in reservoirs and aquifers and changes in land cover	−11	−3.5	4
Rise in sea level due to flow of sediments into the ocean via rivers	0	0.25	0.5
Sum of estimates of individual contributions to sea level rise (1910–1990)	−8	7	22
Observed rise in sea level during the 20th century (Church *et al.*, 2001)	10	15	20
Observed rise in sea level during the 20th century (Douglas, 1997)	17	18	19

observations combined with modeling studies suggest that a small melting of the Greenland ice sheet has occurred, causing a sea level rise of up to 1 cm.

- Antarctica is a very large ice sheet, holding enough water to raise sea level by roughly 60–70 m were it all to melt (the range resulting from how the long-term adjustment of the land is accounted for after melting occurs). The Antarctic ice sheet is believed to be many millions of years old and it would take a very long time to melt, especially because of its location near the South Pole where the sun angle is quite low. Although observations are quite limited, the best observational and modeling results suggest that the current climatic conditions are causing snow to accumulate over much of Antarctica, and that this accounted for the removal of about 0–2 cm of sea level equivalent from the oceans during the 20th century.
- In addition to the estimates of actual accumulation and melting over Greenland and Antarctica due to recent climatic change, geological data suggest that changes in these ice sheets are still occurring as a continuing adjustment to the warming and sea level rise that took place as the climate shifted from glacial to the interglacial conditions. The best estimates, which are constrained by the rates of crustal rebound, are that these changes could have contributed 0–5 cm to sea level rise during the 20th century, although this number is quite uncertain.
- Permafrost is observed to be melting across locations in North America and Eurasia. This has caused the release of water to rivers that in turn flow into the oceans. This is estimated to have caused up to 0.5 cm of sea level rise.
- Changes in the storage of water on land, in aquifers and in reservoirs, as well as changes in land cover, could have caused quite large changes in sea level, although estimates are still quite uncertain. The ways in which this could occur include the pumping out of groundwater, the drawdown of lakes, impoundment in and downward infiltration of water from reservoirs, infiltration through irrigation, runoff from urbanization, deforestation, and changes in evapotranspiration. Estimates in Church *et al.* (2001) suggest the net effect on sea level change could have reduced sea level by as much as 11 cm or to raised it by as much as 4 cm during the 20th century.

As summarized in Table 1, these terms would allow for a sea level change of from −8 to 22 cm. This range brackets the independently determined observations of sea level rise, which suggest a rise of 10–20 cm during the 20th century (Church *et al.*, 2001), perhaps more likely to be in the upper half of this range according to Douglas (1997). That the agreement is not better is somewhat discouraging, in that each centimeter of sea level rise is equivalent to about 4000 km^3 of water or ice, and to be missing several times that much ice or water seems quite an oversight. However, just to make clear how hard even such a large amount is to detect, when spread across Antarctica, for example, each centimeter of sea level amounts to only about 30 cm of ice, and so, over a century, even seemingly large amounts of water can become hidden from direct measurement, even though other constraints (as for example on changes in the rotation rate of the Earth) may point indirectly to what is happening.

PROJECTED CHANGES IN SEA LEVEL IN THE FUTURE

The projected rate of sea level rise for the 21st century is likely to be significantly larger than for the 20th century. Warming of the global ocean waters will become a much more important contributor to sea level rise during the 21st century. With projections that the global average temperature is likely to rise a few degrees rather than about 0.5 °C, thermal expansion is projected to contribute to an increase in sea level of roughly 10–40 cm over the 21st century, with comparable amounts during ensuing centuries even if the rate of rise in global temperatures is slowed because the deep ocean will be continuing to warm to catch up with surface warming. At the same time, there are likely to be contributions to sea level due to the warming of the land surface. This is likely to lead to the lowering of some lakes, increased pumping of some aquifers, and changes in land surface vegetation. While these factors are likely to contribute to sea level change, estimates of their potential influence remain quite uncertain.

The increased rate of warming is also projected to substantially increase the rate of melting of mountain glaciers and icecaps. Estimates are that this could lead to a loss of up to 30–50% of the mass of mountain glaciers, which would contribute to a potential rise in sea level of roughly 15–25 cm. In addition, the melting of permafrost will likely accelerate, contributing an additional small amount to sea level rise. Other changes due to factors involving storage or depletion of water in reservoirs and aquifers and due to changes in vegetation are quite uncertain.

For Greenland and Antarctica, the situations are quite complex. At least for some conditions, observations and model calculations suggest that warming of the adjacent oceans and the very cold air over the ice sheets is very likely to lead to increased snowfall, tending to pull sea level down. At the same time, the ice at the edges and at lower elevations will be subjected to warmer conditions. For Greenland, there are already indications that deterioration of the ice sheet is occurring in some regions (*see* Greenland Ice Sheet, Volume 1). For Antarctica, there is melting in the area of the Antarctic Peninsula due to regional warming, but, although some ice streams are moving in unusual ways (*see* Antarctica, Volume 1), there are no indications of warming-related losses for the East or West Antarctic ice sheets. However, there is expected to be a continuing adjustment of these ice sheets to the long-term rise in sea level and warming that occurred coming out of the Last Glacial Maximum. The net effect on sea level due to changes in these two ice sheets together is estimated here to range very roughly from −15 cm to +15 cm during the 21st century, depending on the climate change scenario, with Greenland adding to a tendency for sea level rise and Antarctica to a tendency for a sea level drop.

In their analysis of all of these factors, the Intergovernmental Panel on Climate Change (2001) used a number of model-based analyses to arrive at a best estimate that sea level would rise by from 9 to 88 cm during the period 1990–2100, with a mid-range estimate of about 48 cm. Such a rate of rise would be roughly 2–5 times higher than during the 20th century, and a rate not experienced during historical times. For those living along coastlines, converting these estimates of change in global sea level to particular locations requires adding (or subtracting) the local rate of subsidence (or uplift) of the land surface. In particular locations, these vertical adjustments can amount to as much as several tens of centimeters per century.

What might be most important, however, is that during the 21st century, warming could pass a threshold that would start a multi-century long deterioration of the Greenland and Antarctic ice sheets. For example, Church *et al.* (2001) cite studies indicating that a 3–6 °C warming of Greenland, if sustained, could lead to a few meter rise in sea level over the next 1000 years, and some projections of warming are indeed this large. Similarly, such a rise in Antarctica, if sustained, could lead to a similar size rise in sea level over many centuries. Thus, while not at all yet certain, the warming projected for the 21st century could initiate events that would lead to significant inundation of coastal regions over the very long term.

SUMMARY

After apparently showing relatively little change over the past several thousand years, sea level started to rise during the late 19th century and this upward trend continued through the 20th century. Projections indicate that the rate of rise is likely to further increase during the 21st century, posing serious threats to such low-lying areas as river deltas, barrier islands, coastal wetlands, and, in many regions, coastal cities and infrastructure.

Sea Surface Temperature

Yochanan Kushnir
Columbia University, Pailsades, NY, USA

The oceans affect climate primarily through their surface temperature. Determined through a complex interaction between the atmosphere and oceans, sea surface temperature (SST) is arguably the most important indicator of the oceans' climate. It is important not only because the oceans cover about 70% of the Earth's surface, but also because it is a rough indicator of the heat contained in the upper ocean. The difference between SST and the overlying surface air temperature is one of the factors determining the heat exchange between oceans and atmosphere in the form of evaporation, sensible heat ux, and infrared radiation. Month-to-month and year-to-year changes in SST in uence the state of the atmosphere, particularly in the tropics, where they can modulate the strength and location of deep convection, the engine that drives the global atmospheric circulation. Information on the climatological (mean) SST distribution and its temporal uctuations is essential for simulating the current climate and predicting its future evolution.

Because the ocean is continually mixed by the action of winds and gravity, a homogeneous layer of some thickness forms at its surface. This mixed-layer exhibits a vertically uniform temperature (and salinity) distribution represented by the SST (and surface salinity). The depth of the oceanic mixed layer generally ranges between 20 and 200 m (and in some locations is even deeper), depending on the season and the geographical location (Figure 1). At the ocean surface, the specific heat of water is about four times greater than that of air and its density a thousand times larger; thus the mixed layer capacity to store heat far exceeds that of the entire atmosphere (see e.g., Pexióto and Oort, 1992). This large heat capacity explains the damping effect of the upper ocean on the thermal variability of the marine atmosphere, as well as the moderate nature of coastal climates compared to those of inland regions. The heat contained in the mixed layer is available for transport by the upper ocean circulation and can affect regions far away from where the thermal properties of the water were initially shaped.

The horizontal and seasonal distribution of SST is set by a balance between net incoming solar radiation (what is left after absorption in the atmosphere and reflection from clouds, aerosols, and the ocean surface) and the net loss of heat by infrared radiation (the difference between the surface emission and the heat radiated downward from the atmosphere). Solar radiation is absorbed in the ocean s upper few tens of meters, while outgoing infrared radiation cools just the surface. Evaporation (latent heat flux) and thermal conduction (sensible heat flux) also cool the surface by moving moisture and heat from the ocean to the atmosphere (only in a very few locations, primarily during summer, does the atmosphere lose heat to the ocean). Under the action of gravity (water parcels that cool at the surface, become denser than the water below and sink down) and the mechanical mixing induced by the surface wind stress, a nearly uniform temperature distribution is established within the mixed layer (Figure 1). At its interface with the deep ocean, changes in mixed-layer depth cause the entrainment of cold water from below, imposing additional constraints on SST. Where wind-induced mixing and surface heat loss are large, as is the case over the mid-latitude and subpolar oceans during winter, the mixed layer is deep and relatively cold. In the subtropics and tropics, where winds are usually weak and solar heating is large, gravitational and mechanical mixing in the upper ocean are weak and the mixed layer is generally shallow and warm. Weak winds and strong solar heating also cause the seasonal thinning of the mixed layer during summer compared to winter (Figure 1).

In addition to these air–sea processes, oceanic heat advection in the horizontal and vertical also affects SST. Advection involves the movement of heat by the flow of water masses from warm to cold regions and *vice versa*, damping or enhancing the influence of surface fluxes, depending on the geographical location and time of year. The interactions governing SST are further complicated by the fact that surface fluxes depend not only on atmospheric condition but also on ocean heat advection, which can also occur in response to forcing by local and distant surface winds.

The mean seasonal variation of SST is shown in Figure 2, which depicts the average January and July conditions over the global ocean. Year round, SST is warmest in the tropics and coldest in the polar latitudes, a reaction to the latitudinal variation of available solar radiation between the equator

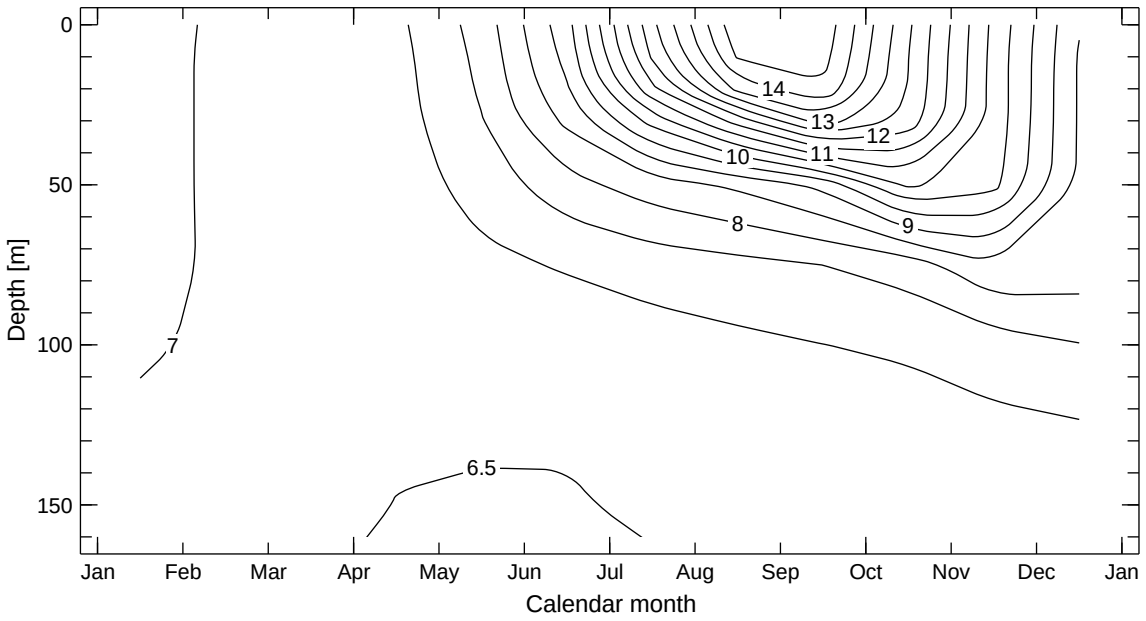

Figure 1 The annual march of upper ocean temperature in the North Pacific (175 °E–150 °W, 40 °N–50 °N) as a function of depth. Contour interval is 0.5 °C. The abscissa is the calendar month and the ordinate is depth in meters. The figure depicts the mixed layer of the ocean. Temperature is uniform from the surface to more than 150 m in March and April, but only to 20–50 m between July and November. (Data are from Levitus and Boyer, 1994)

and the poles. The large influx of solar heating over the tropical and subtropical oceans is offset mainly by the cooling effects of evaporation and ocean heat transport. On the eastern side of the tropical Pacific and Atlantic Oceans, the upward movement of deep cold-water masses in response to the pumping action of the surface winds (called *upwelling*) also causes surface cooling.

An east–west contrast in SST is also found in subtropical latitudes (i.e., between 15 and 30° north and south of the equator) where it is believed to be shaped by the oceans subtropical gyre circulation (the latter is driven by the action of the surface atmospheric winds over the entire basin). The ocean circulation transports water masses from the tropics poleward on the western side of the ocean basins and from the subpolar regions equatorward on their eastern side, thus warming the western side and cooling the eastern side. The Kuroshio (North Pacific), Gulf Stream (North Atlantic), and Brazil Current (South Atlantic) move warm tropical water poleward to warm western boundary SST. The California (North Pacific), Peru (South Atlantic), Canary (North Atlantic) and Benguela (South Atlantic) currents move subpolar water equatorward to cool eastern boundary SST. Low-level atmospheric clouds (stratocumulus) that prevail over the eastern subtropical oceans (partly because SST is colder there) enhance the cooling effects of the eastern boundary currents by sheltering the ocean surface from the full effect of solar radiation. In the eastern coastal waters, upwelling forced by off-shore winds also cools the surface. In the polar latitudes of the Northern Hemisphere oceans, the western basins are colder than the eastern ones. Here the Oyeshio (Pacific) and Labrador (Atlantic) currents bring cold, polar water south, to meet with the warm western boundary currents and create strong horizontal temperature gradients. On the eastern side of the high latitude Northern Hemisphere oceans, the eastern extensions of the western boundary currents (the North Pacific and North Atlantic Currents, respectively) are responsible for relatively warm SSTs. A different, more zonal SST distribution exists in the Southern Ocean. Unperturbed by continental boundaries but constrained by the steep, subsurface topography, the Southern Ocean responds to the strong prevailing surface winds (westerlies) to produce a strong eastward flowing Circumpolar Current that is delineated by a strong SST gradient along the latitude of 40 °S (the Roaring Forties).

The seasonal contrast in surface temperature is depicted in Figure 3, which shows the difference between the January and July averages. In the tropics the differences are small and limited to the far-eastern Pacific and Atlantic Oceans. These eastern ocean differences result from the larger rates of upwelling during boreal summer compared to winter (a direct result of surface wind circulation changes there). Outside of the tropics, local summer SST values are higher than in winter. In the mid-ocean basins, along the latitudes of about 40° north and south of the equator, the difference between January and July reaches up to 6 °C. Due to the large ocean storage capacity and horizontal heat transport, this SST range is much smaller than the corresponding range in land-surface air temperature at the same latitude.

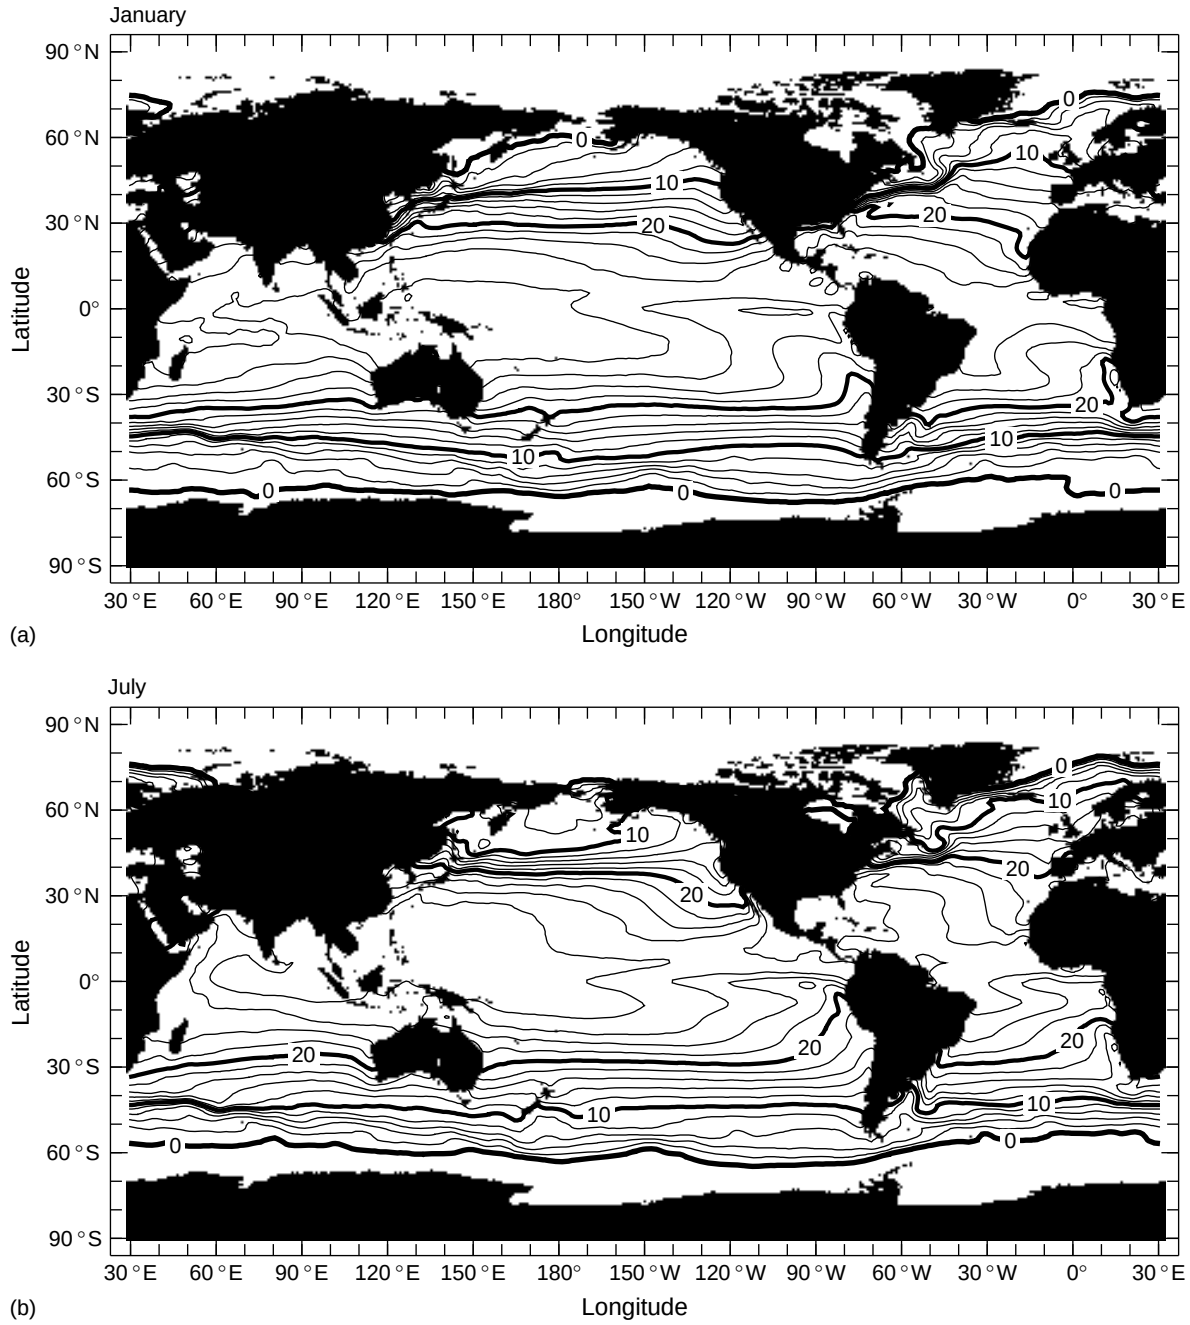

Figure 2 Mean SST for January (a) and July (b). Contour interval is 2 °C. The zero contour is heavy and so are the contours for 10 and 20 °C. (Data are from National Oceanic and Atmospheric Administration (NOAA)/National Centers for Environmental Predictions (NCEP) as described in Reynolds and Smith, 1994)

In the waters along the eastern seaboards of Asia and North America, the seasonal differences reach maximum values. This is due to a combination of low wintertime solar radiation compared to summer and the vigorous wintertime off-shore movement of cold, dry air from the continental interior, which causes ocean-to-atmosphere heat fluxes, by evaporation and conduction, to be very large. Additional discussion of the SST climatology and the associated mechanisms can be found in Peixóto and Oort (1992), and Hartmann (1994).

The departure of SST from its mean state is considered an important measure of the oceans contribution to climate variability (*see* Natural Climate Variability, Volume 1). These departures can result from the passive, local response of the ocean to atmospheric forcing or from an active involvement of ocean heat transport. The

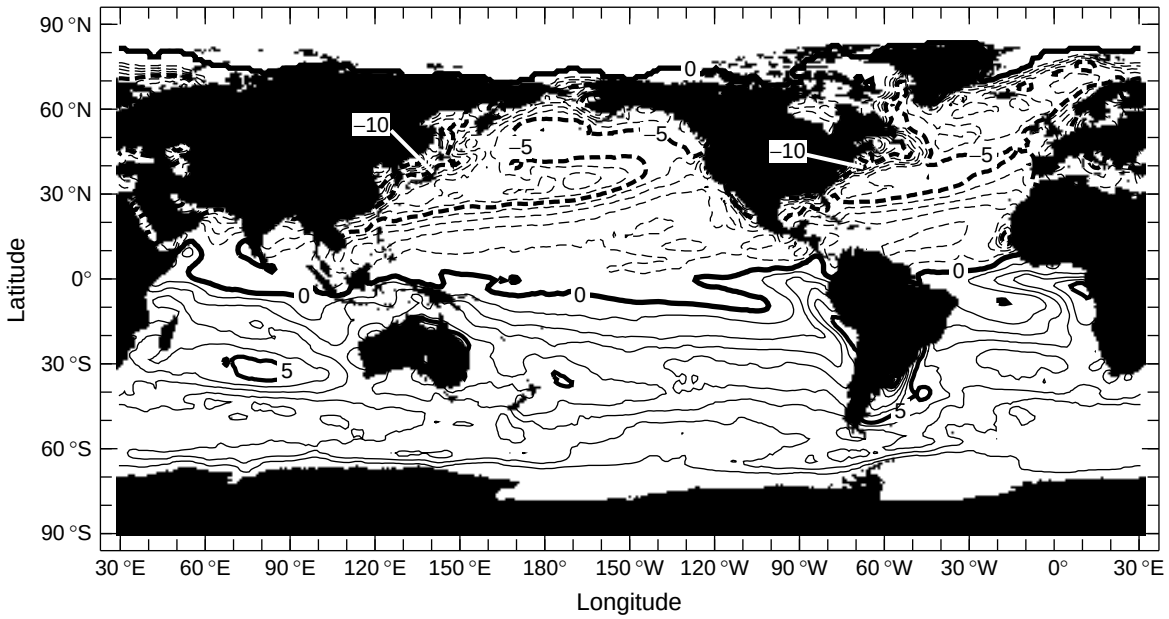

Figure 3 The difference between mean January and July SST of Figure 2. Contours are every 1 °C. Negative contours are dashed. Contours at 0 °C and at 5° intervals thereof are heavy

local interaction is most clearly observed in the extratropics during winter. To a large extent, SST variability in that region results from the slow adjustment of the oceanic mixed layer temperature to random, day-to-day fluctuations of wind, temperature and humidity in the overlying atmosphere, the latter arising from changes in wind speed and direction. The mixed layer s slow adjustment is due largely to its large heat capacity and its feedback on the atmospheric surface air temperature and absolute humidity. The time-averaged effect of fast, chaotic atmospheric fluctuations on the extratropical ocean mixed layer produces anomalies that vary much more slowly than the atmospheric forcing (see excellent review by Frankignoul, 1985 for a mathematical discussion of these processes).

The atmosphere also displays low-frequency variability in the form of large-scale, month-to-month and year-to-year variations in its circulation over the ocean basins (*see* North Atlantic Oscillation, Volume 1; Paci c- North American (PNA) Teleconnection, Volume 1). These low-frequency fluctuations organize the more random variability of weather and leave a basin scale imprint on the SST field (see Figure 4 and Frankignoul, 1985). Recent experiments with climate models show that the response of the extratropical ocean mixed layer to anomalous atmospheric forcing has a positive influence on the latter. Apparently the reaction of the ocean surface temperature to changes in surface windspeed, temperature, and humidity, reduces the thermal drag on the atmosphere. This effect enhances the amplitude and persistence of anomalies in the atmospheric circulation over the ocean (see e.g., Lau, 1997).

The effect of ocean circulation on SST and the maintenance of its anomalies is evident everywhere because the mean circulation can transport SST anomalies and change local conditions elsewhere (*see* Ocean Circulation, Volume 1). Fast responding currents forced by surface wind stress anomalies (often referred to as *Ekman currents*) can instantaneously enhance or dampen the effect of atmospheric flux forcing, depending on their direction with respect to the mean regional SST gradient. The role of the ocean circulation in climate is of particular significance in regions where it responds strongly to changes in surface winds and occurs with a long delay. Such delayed response can affect SST long after the action of the atmosphere has passed and open the way to semi-regular and possibly predictable ocean–atmosphere oscillations. Such oceanic response is involved in the El Niño–Southern Oscillation phenomenon (*see* El Niño/Southern Oscillation (ENSO), Volume 1), where the interaction between the immediate and delayed interaction between the atmosphere and ocean enables the prediction of the phenomenon. Scientists have speculated that a delayed circulation response, such as that acting in the equatorial Pacific Ocean, can also be found in the extratropical oceans where patterns of decadal climate variability are apparent (Latif and Barnett, 1994).

The debate on global climate change drew attention to a possible widespread rise in SSTs, particularly in the tropics. Such a change could be of large consequence to climate worldwide because of the implied potential for increased evaporation. An increase in evaporation must lead to an increase in globally averaged precipitation. Higher SSTs would also lead to an increase in atmospheric water vapor

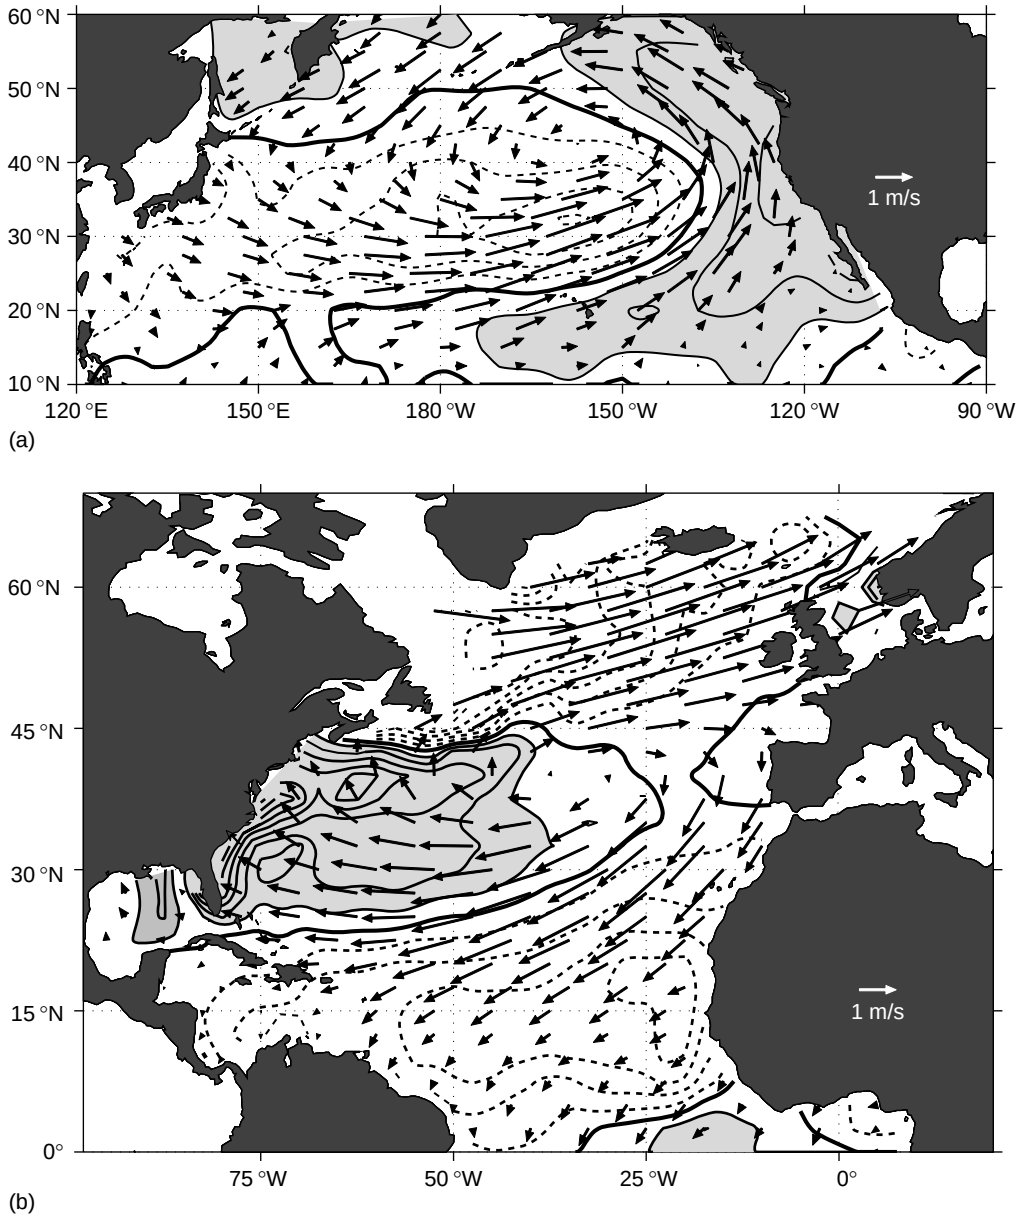

Figure 4 Surface atmospheric wind anomalies (arrows) and SST anomalies (contours) associated with typical wintertime (January–March) climate fluctuations in the North Pacific (a) and North Atlantic (b) Ocean Basins. Contours are every 0.1 °C with heavy zero contours and dashed negative ones. The agreement between the surface wind features (intensity and direction) and the regions of large SST anomalies reflects the role of atmospheric forcing in the generation and maintenance of the latter. (The data used for this figure are from the NCEP/National Center for Atmospheric Research (NCAR) Climate Data Assimilation System 1 (CDAS–1) dataset described in Kalnay *et al.*, 1996)

concentration and this enhances the ability of the atmosphere to absorb and emit infrared radiation (the so-called greenhouse effect). Other influences of higher SSTs could include an increase in the strength of tropical convection including the occurrence and strength of tropical storms (see Henderson-Sellers *et al.*, 1998). The outcome of such tropical changes could be dynamical changes in such extratropical circulation features as the location of jet streams and the seasonal low and high-pressure centers. Warming of the tropical oceans can also lead to changes in the strength and frequency of El Niño (Timmermann *et al.*, 1999) and its global teleconnections.

Because the surface of the Earth is covered mostly by ocean, estimation of the global surface temperature change with time, a primary indicator of global warming, requires knowledge of the concomitant change in SST. Routine SST measurements date back to the mid-19th century when the world merchant fleet initiated weather observations (as

a result of an international agreement). In the 1970s the world climate community began assembling comprehensive global archives of ship weather data in order to reconstruct a century long, monthly history of SST over the World Ocean. Several national meteorological centers were involved in this initiative. The compilation of marine data became available for research and applications in the late 1980s (e.g., Woodruff *et al.*, 1987; Bottomley *et al.*, 1990) and hinted that the ocean was warming. These data influenced many of the recent advancements in understanding and modeling of the climate system and its atmospheric and oceanic components.

The compilation of SST data involved formidable efforts to overcome the errors and biases in the raw data. The errors were due to multiple sources. One such source was the uneven distribution of ship observations in time and space (see e.g., Trenberth *et al.*, 1992; Parker *et al.*, 1995). Such non-uniformity affects not only the calculation of regional and global averages, but also increases the uncertainty in the local, monthly mean SST estimates. Today, satellite infrared radiation measurements are processed to derive more evenly spaced weekly estimates of SST that can be blended with ship data to overcome the latter s uneven coverage (Reynolds and Smith, 1994). The impact of uneven sampling of historical SST can be alleviated by sophisticated space-filling procedures (Kaplan *et al.*, 1998). Large biases in SST also resulted from changes in observational practices, such as the time of day when SST was measured and the type of bucket used to draw the seawater samples. Early buckets were porous and cooled off slightly because of evaporation lowering the deck temperature measurement. Later, better buckets were designed to overcome this bias. A large discontinuity in SST data was found around 1941 and attributed to a sudden shift from bucket measurements to temperature readings at the ship engine cooling water intake. This practice and probably adopted in response to wartime restrictions but was widely embraced in the post war era. Bias correction work has been essential for obtaining a self-consistent picture of worldwide SST evolution during the industrial era, one that is consistent with changes in other variables such as the change in air temperature over ocean and land (Parker *et al.*, 1995). It is important to note that SST bias correction and space-filling methodologies continue to evolve and the details of these corrections do have a limited effect on the final estimates of global SST change.

Since 1979, several estimates of the global (and hemispheric) changes in SST since the mid-19th century have been published, together with the concomitant land surface air temperature data (e.g., see summary in IPCC, 1996). The picture emerging from these global SST estimates is that there has been an overall rise in ocean surface temperature that follows most of the details found in the land record. Comparison of the two records shows a slower rise in SST compared to land surface air temperature during the years 1920–1940 as well as in the most recent two decades. These differences are likely the result of real physical processes, such as the horizontally non-uniform change in the atmospheric circulation associated with the global temperature rise (Wallace *et al.*, 1995). There also remains a large difference between the land and ocean records during the last two decades of the 19th Century that seems to be due to data problems.

The importance of the oceans in climate and climate variability is strongly connected to the ability of the oceans to affect SST and the sensitivity of the atmosphere to the resulting SST anomalies. Extensive modeling and observational studies show that in the tropics, particularly in the tropical Pacific, the ocean can be as important in generating SST anomalies as the atmosphere. Tropical SST anomalies also exert a strong impact on the local atmosphere by affecting tropical convection. This in turn produces significant changes in remote locations, including regions outside the tropics. In the extratropical ocean, SST anomalies are produced primarily by concurrent changes in atmospheric conditions. The effect of extratropical SST anomalies on the atmosphere is rather subtle, probably mainly local, and not yet fully resolved or understood.

molecular kinetic energy. Temperature change due to sensible heat transfer for this case is directly proportional to the change in enthalpy.

The temperature change of a body due to sensible heat transfer depends not only on the amount of sensible heat transferred and the associated change in volume of the body but also on the mass of the body, and chemical characteristics of the body described by its specific heat. Energy transfer by electromagnetic radiation can also change the temperature of a body. This is an important factor for environmental situations. Sometimes the colloquial terminology *radiative heat* is used when radiation is involved in the increase of internal energy (temperature) of a body. An example of this occurs when sitting near a hot stove.

Sensible heat transfer between the Earth s surface (ocean and land) and the atmosphere is an important factor in the global energy balance and temperature distribution. The upward sensible heat energy transfer is one-third as large as the latent heat transfer and accounts for 5% of the total upward energy transfer on a global and annual average basis. [Note: radiation accounts for 80% of the transfer of energy from the surface to the atmosphere.]

DAVID HOUGHTON *USA*

Sensible Heat

Sensible heat (sometimes just called heat) is the energy transferred between two material bodies by intermolecular interactions. This transfer occurs when the internal mean molecular kinetic energy (measured by temperature) is different between the two bodies. The transfer goes from the warmer to the cooler body. Sensible heat can be sensed or explicitly recognized, hence the term *sensible*. An example would be the feeling of warmth or coolness to a person when touching a substance that has a temperature higher or lower, respectively, than that of the human body. A warm feeling results when sensible heat is being transferred from the substance to the human body. In the case of sensible heat transferred from the human body, a cold feeling results.

In many environmental situations, warming and cooling associated with sensible heat transfer occur under constant-pressure conditions. In this case, the energy transferred accounts both for changes in the internal mean molecular kinetic energy (temperature) of the body and for the energy of work associated with a change in the volume of the body. This situation can be conveniently handled by the thermodynamic variable *enthalpy*, defined by adding the product of pressure and volume to the internal mean

Snow

David A Robinson
Rutgers University, Piscataway, NJ, USA

The impact of snow on humans and the environment is considerable. Snow covers approximately 30% of the Earth's land surface on a seasonal basis, with additional coverage at high elevations, over polar ice sheets and sea ice. Snow lying on the ground, or on ice in uences hydrologic, biologic, chemical, and geologic processes. Snow exerts an impact on activities as diverse as engineering, agriculture, travel, recreation, commerce and safety. In turn, the presence and state of snow are in uenced by weather, climate, topography, proximity to water bodies and humankind.

INTRODUCTION

The low heat conductivity, high thermal emissivity, low vapor pressure and high reflectance of snow differ greatly from snow-free land. The accurate forecasting of local daily temperatures, regional climatic anomalies and the location and strength of cyclonic systems relies, in part, on knowledge of the distribution and state of regional

snow cover (Walsh and Ross, 1988; Groisman *et al.*, 1994; Clark *et al.*, 1999). Model simulations of climate change show that spatial decreases in snow extent amplify global warming (Meehl and Washington, 1990).

Recent years have seen the availability of more accurate and complete information on the spatial extent and physical state of snow. This is leading to a better understanding of the variability of snowfall and snow cover on annual to decadal scales, of cryosphere–climate interactions, and of the role snow may play in regional and global climate change.

OBSERVING SNOW

Station observations are the primary means of monitoring snowfall, despite the spatial limitations of the global observing network. Data-scarce areas include high latitudes and mountainous regions. Where station density is high, these point measurements provide data of sufficient accuracy for baseline climatologic applications. There is no hemispheric snowfall product derived from station data for either daily or monthly totals.

Ground-based data on snow cover depth are also relatively sparse outside of the lower elevations of the middle latitudes. Included, are station observations made at a single point, and along less abundant, several kilometer long snow courses. Data on the amount of water in a snow pack (water equivalent) are gathered at a very few of the point sites, along snow courses, and by snow pillows that measure snow mass in some mountainous regions.

Visible and passive microwave sensors, on geostationary and polar orbiting satellites, record information used to monitor snow cover on regional to hemispheric scales. Snow cover extent is best identified on visible imagery by recognizing characteristic textured surface features and brightness. Shortcomings include the inability to detect snow cover when solar illumination is low or when skies are cloudy, and the lack of all but the most general information, on pack depth.

The recognition of snow using microwave techniques results from differences in the emissivity of snow-covered and snow-free surfaces across several different frequency ranges. Information on water equivalent can be obtained, although not of the accuracy necessary for climatologic studies. Clouds and low solar illumination are not problems when using microwave data to chart snow cover; however there are difficulties in identifying shallow or wet snow.

SNOW VARIABILITY

The considerable interannual variability of snow makes long-term data sets a necessity when investigating means, trends, low frequency events or interactions of snow with other climatic elements. The standard 30-year climatic normal used for variables such as temperature and precipitation may not be of a sufficient length for realistic cryospheric means. Unfortunately, consistent decades-long data are scarce. Satellite-derived snow maps have been available since the late 1960s. Station data exist for approximately the past century, though of decreasing abundance early on. In all cases, limitations in the collection, quality control, archiving and synthesis of snow data must be considered before applying the data in long-term climatologic investigations.

For the past several decades, weekly maps of Northern Hemisphere snow extent have been produced by US National Oceanic and Atmospheric Administration (NOAA) analysts (Robinson *et al.*, 1993). This constitutes the longest satellite-derived data set of any environmental variable. While produced in a relatively consistent manner since late 1966, original observer inexperience and lower image resolution necessitated a reanalysis of the interval prior to 1972. The earlier period is currently being reanalyzed, but until it is completed, only the time series from 1972 to the present is available for analysis. Microwave records go back to the late 1970s, but studies of time series over this period are just beginning.

According to the NOAA maps, the mean annual Northern Hemisphere snow cover extent is 25.3 million km^2, with 14.7 million km^2 over Eurasia and 10.6 million km^2 over North America (including Greenland). Snow cover was more extensive in the first half of the satellite record than in the past decade (Figure 1). Between 1972 and 1985,

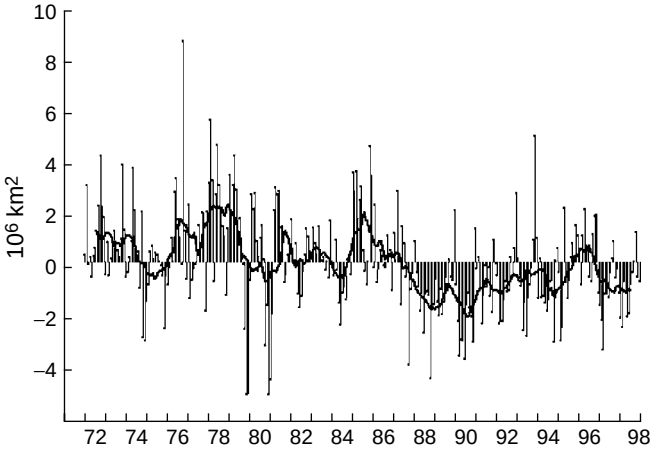

Figure 1 Anomalies of monthly snow cover extent over Northern Hemisphere lands (including Greenland) between January 1972 and December 1998. Also shown are 12-month running anomalies of hemispheric snow extent, plotted on the seventh month of a given interval. Anomalies are calculated from NOAA snow maps. Mean hemispheric snow extent is 25.3 million km^2 for the full period of record. Updates to the time series may be viewed at http://climate.rutgers.edu/snowcover

annual means of snow extent fluctuated around a mean of 25.9 million km^2. An abrupt transition occurred in 1986 and 1987, and since then the mean annual extent has been 24.2 million km^2. Monthly anomalies from the long-term mean are most often less than 3 million km^2, however on occasion they are 4 and 5 million km^2, with October 1976 having a positive anomaly of over 8 million km^2.

Recent decreases in snow extent are large during the spring and summer, while winter and fall extents show no statistically significant change. The tendency toward less late-season cover in recent years begins in February. During seven of the first 15 years of record, February snow extent exceeded the January value. This has occurred only once in the past 12 years.

Station records for portions of the Northern Hemisphere continents suggest that spring and early summer snow extents in the past decade may be at their lowest values of the century. Otherwise, seasonal extents in the latter portion of this century exceed those of earlier years. Annual and decadal fluctuations are embedded in this upward trend, and at least over portions of central North America, the variability of snow cover duration has also increased throughout the century (Frei *et al.*, 1999). The increase in snow cover duration in this region is accompanied by statistically significant increases in seasonal snowfall. In recent decades, snowfall has also been heavier to the lee of the North American Great Lakes than earlier in the century (Leathers and Ellis, 1996). These findings are in line with observations from Canada and the former Soviet Union, with all areas appearing to be part of a trend towards increased precipitation over the middle latitudes lands in the Northern Hemisphere (Brown, 2000).

CONCLUSIONS

An increasing body of evidence suggests that snow plays a critical role in the climate system and will continue to be an important climate variable to monitor when assessing climate change. However, there remain many unanswered questions regarding the variability of snow and the long-term representativeness of recent empirical studies of cryosphere–climate interactions, such as links between snow extent and monsoon strength. Additional information is needed over space and time, including better information over sea ice and ice sheets in both hemispheres. Historic station data sets of snowfall and snow cover remain to be collected and analyzed. Recent efforts to integrate visible and microwave satellite and station data must continue for past intervals and future years. Studies need to examine variations in snow water equivalent, and work begun recently to improve model simulations of snow must continue.

Should increasing levels of greenhouse gases result in warmer conditions over the coming decades, it can be expected that the coverage of snow across continental landmasses will decrease, which in turn should enhance the warming. Snow cover is likely to become established later in the fall, and melt sooner in the spring. Areas where snow cover is ephemeral throughout the winter season will see the ground covered less often. Likewise, it is possible that warming will be accompanied by an increased flux of moisture into the high latitudes, resulting in a deeper winter snow pack in some regions, though probably in a shortened snow season.

Soil Moisture

Soil moisture is a measure of the amount of water contained in a soil column (a vertical section of arbitrary areal dimension from the soil surface to the underlying bedrock). Soil moisture is described in terms of the volume of water contained compared with the entire volume of soil. It is also described with reference to the soil s water holding capacity as a ratio of the current volume of water to the maximum possible content if fully saturated. The soil column is fully saturated when water drains readily into or away from the underlying rock. In the absence of replenishing precipitation, this downward drainage to the rock will cease, leaving the voids (capillaries) in the soil still full of water.

In this state, the soil moisture is said to be equal to the *field capacity*: the water content of soil after gravitational free drainage ceases.

Evaporative removal of soil water in the absence of precipitation reduces the soil moisture to below field capacity, causing a soil moisture deficit. Even after direct evaporation from the soil ceases, plants can continue to transpire, further depleting the soil moisture. As the soil water deficit increases, plant transpiration also ceases and the soil moisture is said to have reached the *wilting point*. Although evaporative demand cannot further reduce soil moisture, the soil water content is rarely zero (i.e., oven drying could remove additional water). The environmental limits of soil moisture (or synonymously soil water) are therefore field capacity and wilting point.

Models employed for global change simulations attempt to capture soil moisture characteristics and variability within the constraints of data availability and computational power. The first global soil moisture scheme, developed by Manabe (1969), was a bucket with a maximum soil water capacity equal to an approximated world mean field capacity of 15 cm. This scheme did not, as originally formulated, include representation of the transfer of water from the soil to the atmosphere by plants (i.e., transpiration). More recent schemes attempt to parameterize soil evaporation and plant transpiration by employing multiple soil layers. For example, a two-layer soil scheme transfers water directly from soil to air from an upper thin soil layer by evaporation and also allows plants to access soil water in a deeper soil layer through transpiration. Current formulations include many other embellishments, which have tended to increase the attributes and complexity of soil moisture parameterization schemes through time.

Solar Irradiance and Climate

Judith Lean
Naval Research Laboratory, Washington, DC, USA

Earth's primary energy source is the Sun. Solar radiation heats the surface of the Earth, which emits infrared radiation that is absorbed by gases in the atmosphere. The greenhouse that results from downward reradiation of this energy further increases the surface temperature so that together the Sun and atmospheric gases permit habitability. Although relatively steady and reliable, the Sun's radiation is not, in fact, constant, and its fluctuations must be considered as possible causes of climate change that may exacerbate or mitigate anthropogenic influences.

SOLAR RADIATION

The Sun radiates energy with a spectrum, shown in Figure 1. The spectrum is similar in shape to that of a black body near 5770 K, the approximate temperature of the Sun s visible surface. Solar irradiance is the radiant power (energy per unit time) incident on unit area of the Earth s surface when it is separated from the Sun by one astronomical unit ($\mathrm{AU} = 1.49 \times 10^{13}$ cm). The total irradiance of the contemporary Sun is, on average, $1366\,\mathrm{W\,m^{-2}}$ with a measurement uncertainty of $\pm 2\,\mathrm{W\,m^{-2}}$.

Solar radiation ranges in wavelength across the entire electromagnetic spectrum, from very short wavelength X-rays, to ultraviolet, visible, infrared and very long wavelength radio waves. Solar spectral irradiance, which is the power per unit area attributable to radiation within a specified wavelength interval, varies with wavelength over five orders of magnitude, with peak values in the visible spectrum. The Sun s irradiance at wavelengths from 0.16 to 5 micron emerges from the vicinity of the Sun s surface in a layer of the solar atmosphere a few hundred kilometers thick called the photosphere.

Most of the Sun s irradiance penetrates the Earth s atmosphere to below 15 km (i.e., into the troposphere). As Figure 1 shows, the spectrum reaching the surface (0 km) comprises radiation mainly in the wavelength region from 0.3–1 micron (μm). Atmospheric gases including water and carbon dioxide control the actual penetration of infrared radiation through the troposphere to the surface. Above the troposphere, other atmospheric gases, primarily ozone, oxygen and nitrogen, absorb the ultraviolet, extreme ultraviolet and X-ray radiations that would have detrimental biological effects were this energy able to penetrate to the surface. This shorter wavelength, higher energy solar radiation provides the primary energy input to the Earth s atmosphere, where it initiates and controls the ozone layer in the stratosphere and the neutral upper atmosphere and its embedded ionosphere at higher altitudes.

SOLAR IRRADIANCE VARIABILITY

Although the Sun s total irradiance has in the past been called the solar constant, in reality the levels of total and spectral irradiance fluctuate continuously. Prominent in the space-based record of total solar irradiance, shown

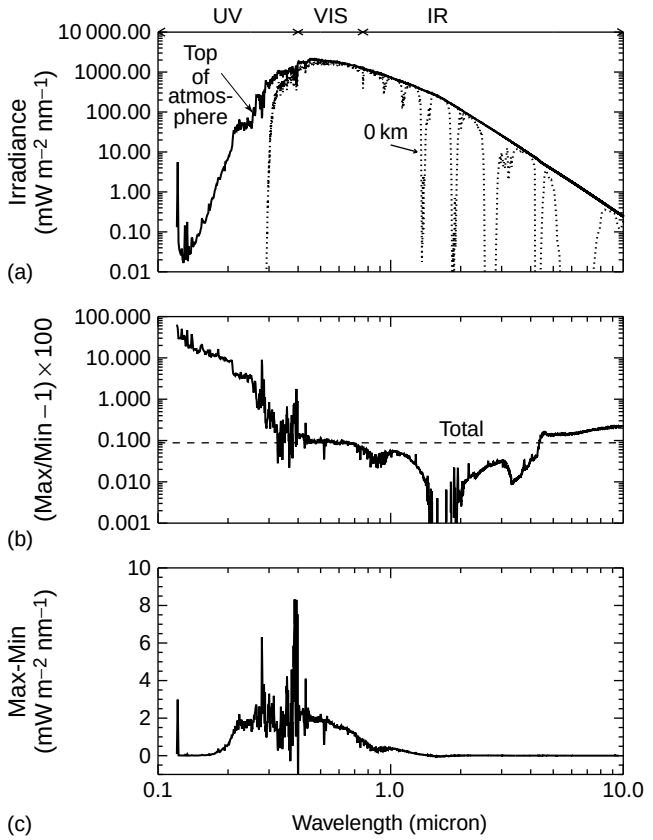

Figure 1 Shown in (a) is the spectrum of the Sun's radiation incident at the top of the Earth's atmosphere (solid line), and at the surface (0 km, dashed line). The broad spectral bands identified along the top of this figure are designated the ultraviolet (UV), visible (VIS) and infrared (IR). Shown in (b) are estimates of the percentage changes in solar spectral irradiance during a recent 11-year activity cycle. At wavelengths longer than 400 nm these estimates are speculative because very few observations exist. The dashed line indicates the percentage variation of total solar irradiance. In (c) the spectrum of irradiance changes during the solar cycle is shown in energy units (maximum minus minimum irradiances)

in Figure 2, is an 11-year cycle upon which are superimposed shorter-term variations (shown in detail in the upper left panel) associated with the Sun s rotation on its axis (approximately once every 27 days). The irradiance cycle is but one manifestation of an 11-year cycle of magnetic activity thought to be driven by a dynamo residing near the base of the Sun s convection zone. During recent maxima of this cycle (near 1980 and 1990), mean levels of total irradiance were observed to be higher by almost 0.1% (1.3 W m^{-2}) relative to levels during cycle minima (near 1986 and 1996), with dips of a few tenths percent often occurring during solar rotation. Wavelength-dependent spectral irradiance changes accompany these total irradiance fluctuations as Figure 1 shows for a recent 11-year cycle (middle and lower panels). Solar cycle increases are of order a few tenths percent at visible and near infrared wavelengths, increasing to 8% in the ultraviolet spectrum near 200 nm and factors of two and more at shorter extreme ultraviolet and longer radio wavelengths. Note that the actual radiant energy falling on the Earth varies by ±3% annually because of regular changes in the distance of the Earth from the Sun. This wavelength-independent fluctuation is a geometrical effect of the Earth s orbit around the Sun. Solar irradiance variability refers to changes intrinsic to the Sun, specified at a fixed Sun–Earth distance of 1 AU.

The primary cause of solar irradiance variability is changes in the activity of the Sun. Solar activity refers to the amount of magnetic flux present in the Sun s atmosphere. Some magnetic fields coalesce to form features that are small and dark, called sunspots, in which the upward flow of energy from the convection zone is inhibited. Sunspots are therefore cooler (by about 1000) and darker (by about 30%), than the surrounding photosphere. Magnetic fields also exist in much less compact features called faculae that are bright rather than dark. Faculae occur both widely dispersed over the solar disk and clumped in contiguous active regions. Sunspots and faculae, evident in the images in Figure 2, are both significant sources of solar irradiance variability. Records of the number of dark sunspots on the solar disk exist since about 1600 and provide the longest direct observation of solar activity. Cycles near 11 years and 27 days are prominent in the sunspot record. As Figure 2 clearly demonstrates, the 11-year cycle in total solar irradiance tracks the annual mean sunspot numbers during the solar activity cycle.

When solar activity is high (such as in 1980 and 1990, and in the left image in Figure 2), many sunspots and faculae are present in the Sun s atmosphere. These magnetic features respectively reduce and enhance solar radiation locally, by different amounts depending on wavelength. Although the local radiation enhancement in faculae (a few percent) is much less than the reduction in sunspots (∼30%), their greater dispersion over the solar surface makes them as important as sunspots in modifying the radiative output of the Sun. Solar cycle irradiance variability reflects the net effect of the these two competing influences, whose numbers and areas evolve continually. Total solar irradiance (Figure 2) is enhanced during solar maximum epochs because the increase in facular brightening during the 11-year activity cycle exceeds (by about a factor of two) the increase in sunspot darkening. Thus, total solar irradiance and sunspot numbers, which provide a generic indicator of solar activity, vary approximately in phase during the 11-year cycle. Solar rotation further modulates irradiance by presenting different populations of these magnetic features to the Earth s view, thereby producing a strong 27-day cycle, evident in Figure 2. On

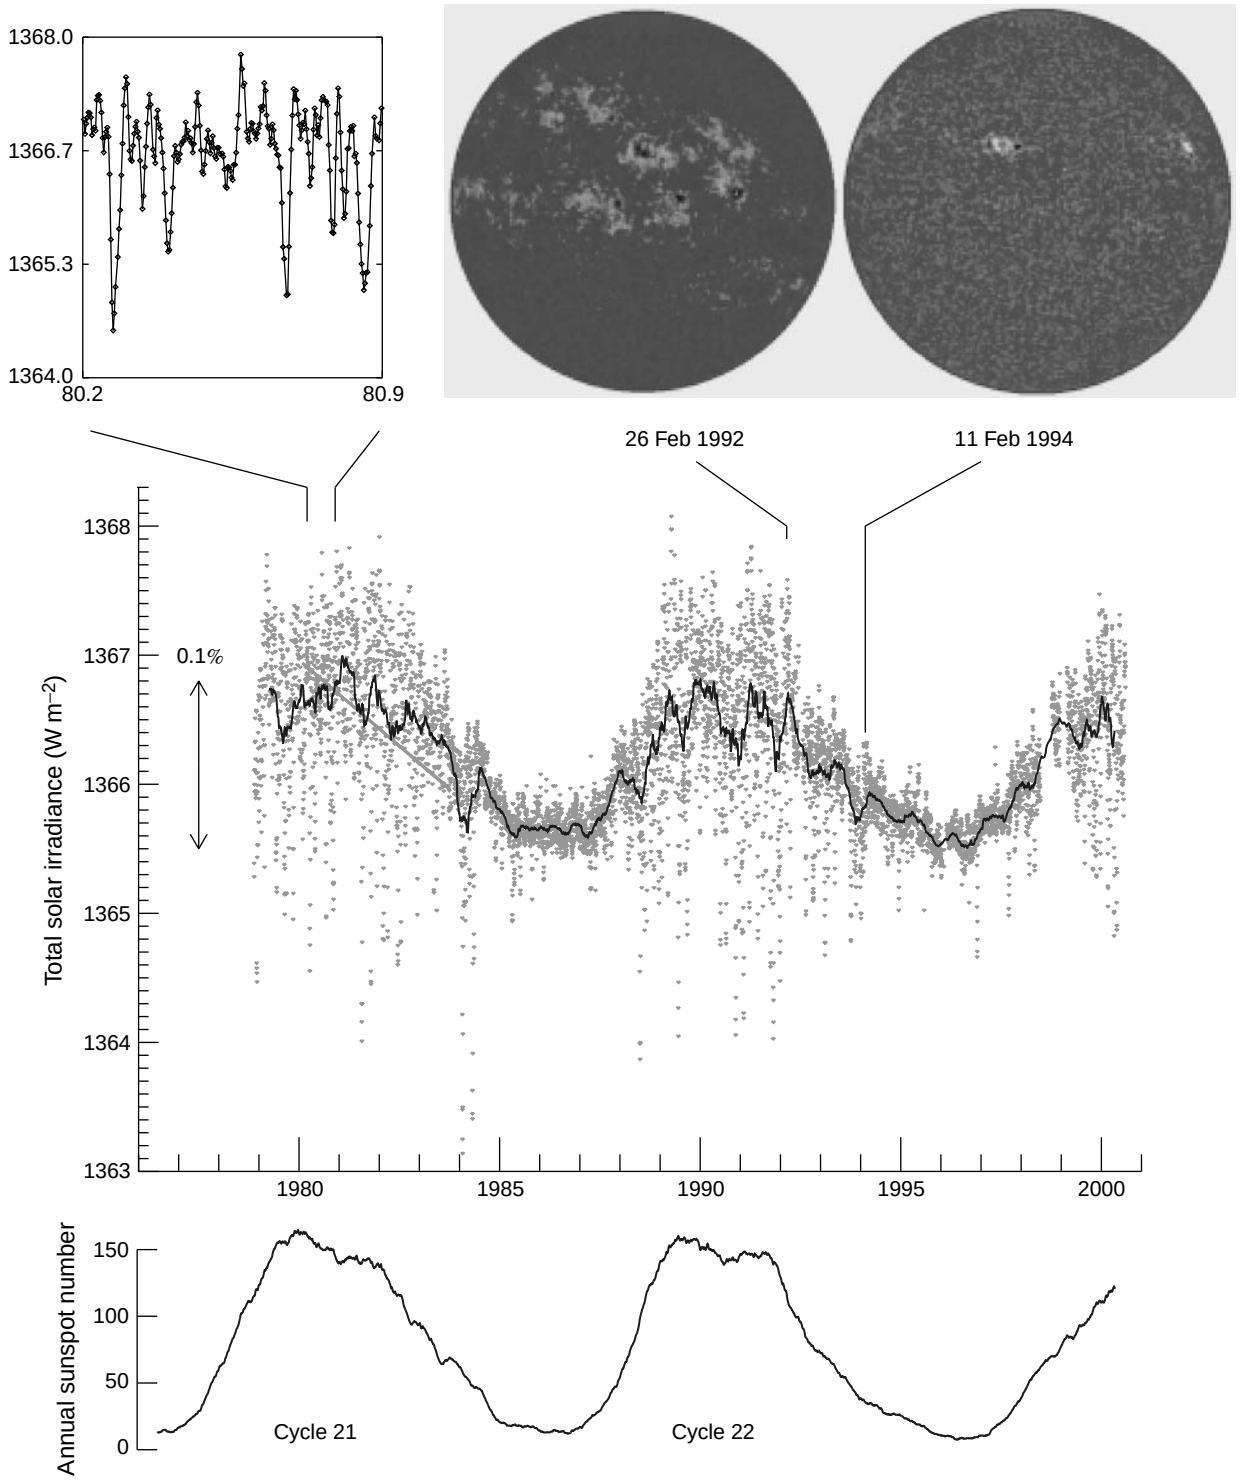

Figure 2 Daily mean values of the Sun's total irradiance since 1979 are shown in the middle panel. Fröhlich and Lean (1998) constructed this composite irradiance record from observations made by four different solar radiometers at various times throughout the epoch. A pronounced 11-year cycle with an approximate peak to peak magnitude of 0.1% is evident. The 11-year total irradiance cycle tracks the general level of solar activity, indicated by the sunspot numbers, in the lower panel. Superimposed on the 11-year cycle are larger weekly to monthly fluctuations of a few tenths percent, shown in detail in the upper left panel, that are associated with the Sun's rotation on its axis, approximately every 27 days. Solar activity and solar rotation irradiance modulation occurs in response to changes in the distribution of bright and dark magnetic features present in the solar atmosphere, as shown in the two solar images in the upper right of the figure. The images are made by the Big Bear Solar Observatory (located at Big Bear Lake, CA) in the Ca K line at 393 nm

these shorter time scales total solar irradiance and sunspot numbers often fluctuate out of phase because sunspot darkening frequently exceeds facular brightening, especially near maximum activity.

Quantitative knowledge – of the locations, brightnesses and areas – of all magnetic features in the solar atmosphere permits the construction of models of solar irradiance variability. Ground-based visible light solar images supply information about areas and locations of sunspots, from which sunspot darkening functions are calculated. Solar images made in other spectral regions, such as the images made at the Ca K Fraunhofer line (393 nm) in Figure 2, record the locations and areas of enhanced facular regions, seen in their chromospheric counterparts (called plage) and in the surrounding bright network. Solar variability models that use wavelength dependent combinations of sunspot and faculae parameterizations can account for much of the variability observed in the total irradiance and the ultraviolet spectrum (there are insufficient observations of the visible and infrared spectral regions to test the models). A model with significant contributions from both sunspot darkening and facular brightening accounts for more than 80% of the variance in the daily mean total irradiance data over nearly two decades, shown in Figure 2.

LONG-TERM IRRADIANCE TRENDS

Direct observations of solar irradiance exist only for the last 20 years, which is a very short period on climatological and solar time scales. However, selected solar, stellar, geomagnetic and geological records contain information about long-term solar activity fluctuations. From these proxy records can be inferred irradiance trends that presumably accompany fluctuating solar activity, not just during 11-year cycles but also on longer time scales as well. Solar activity proxies unanimously suggest that solar activity during the era of space-based solar irradiance observations is higher than in past centuries and that the possibility exists for past and future solar irradiance variability to exceed the range observed thus far.

Sunspots, which provide the only direct observations of historical solar activity, appear frequently during recent 11-year activity cycles, but in the past have disappeared from the Sun s disk entirely for years at a time. Such episodes of solar quiescence, typified by the Dalton, Maunder and Sporer minima from 1790–1820, 1645–1715 and 1425–1575, respectively, are apparent at semi-regular intervals in the Sun s multi-centennial past, and expected in its future. They are evident also in indirect cosmogenic proxies of historical solar activity recorded by $\Delta^{14}C$ in tree-rings and $\Delta^{10}Be$ in ice-cores, whose variations reflect changes in galactic cosmic ray fluxes due to solar activity modulation of the magnetic coupling of the Sun and the Earth (*see* Radionuclides, Cosmogenic, Volume 1). Cosmogenic isotopes exhibit long-term changes that exceed the amplitudes of their 11-year cycles, decreasing from relatively high levels in the recent past, concurrent with increasing sunspot number cycle amplitudes and geomagnetic indices since 1880. Geomagnetic activity recorded by magnetometers at the Earth s surface varies because solar activity influences the solar wind, which modulates the interaction of interplanetary and terrestrial magnetic fields. In suggesting that the Sun s present activity is relatively high compared with the historical range, the evidence from sunspots, cosmogenic isotopes and geomagnetic indices is furthermore consistent with the range of flux levels present in a collection of Sun-like stars.

Solar irradiance is expected to track solar activity on longer time scales, as it does during the 11-year cycle, because solar activity alters the magnetic features that are primary causes of irradiance variability. Solar irradiance has been reconstructed during the past from associations of sunspots and faculae with historical solar activity proxies, using assumptions about additional long-term trends consistent with the range of variability in Sun-like stars and in the cosmogenic isotope and geomagnetic records. The irradiance reconstructions shown in Figure 3 suggest long-term total irradiance changes of order 0.2–0.4%, and associated spectral irradiance changes that are also larger (by about a factor of two) than their solar cycle amplitudes. However, the possibility remains that long-term irradiance variability is confined to 11-year cycles, a scenario that Figure 3 also illustrates in the upper panel. That solar activity during the past 8000 years has ranged from low levels similar to the Maunder Minimum to high levels on a par with the present suggests that even if long-term irradiance variations exist, future levels may be comparable to or less than present values. However, projections of future solar activity are exceedingly difficult for even one 11-year solar cycle, and are essentially impossible for the long-term.

EMPIRICAL SUN–CLIMATE RELATIONSHIPS

An array of empirical relationships implicates the role of the Sun in climate change on Earth. Warmer (colder) climate epochs in the past millennium generally correspond with higher (lower) levels of solar activity, while climate parameters of many types often exhibit cycles that also occur in solar activity proxy records (near 11, 22, 88, 210 and 23 000–25 000 years). Solar variability offers a plausible explanation for significant pre-industrial climate change in the recent Holocene, and possibly also in present day processes.

Of cooler terrestrial epochs in past millennia, the Little Ice Age (1450–1850) is the most recent (*see* Little Ice Age, Volume 1). Surface temperatures then were from

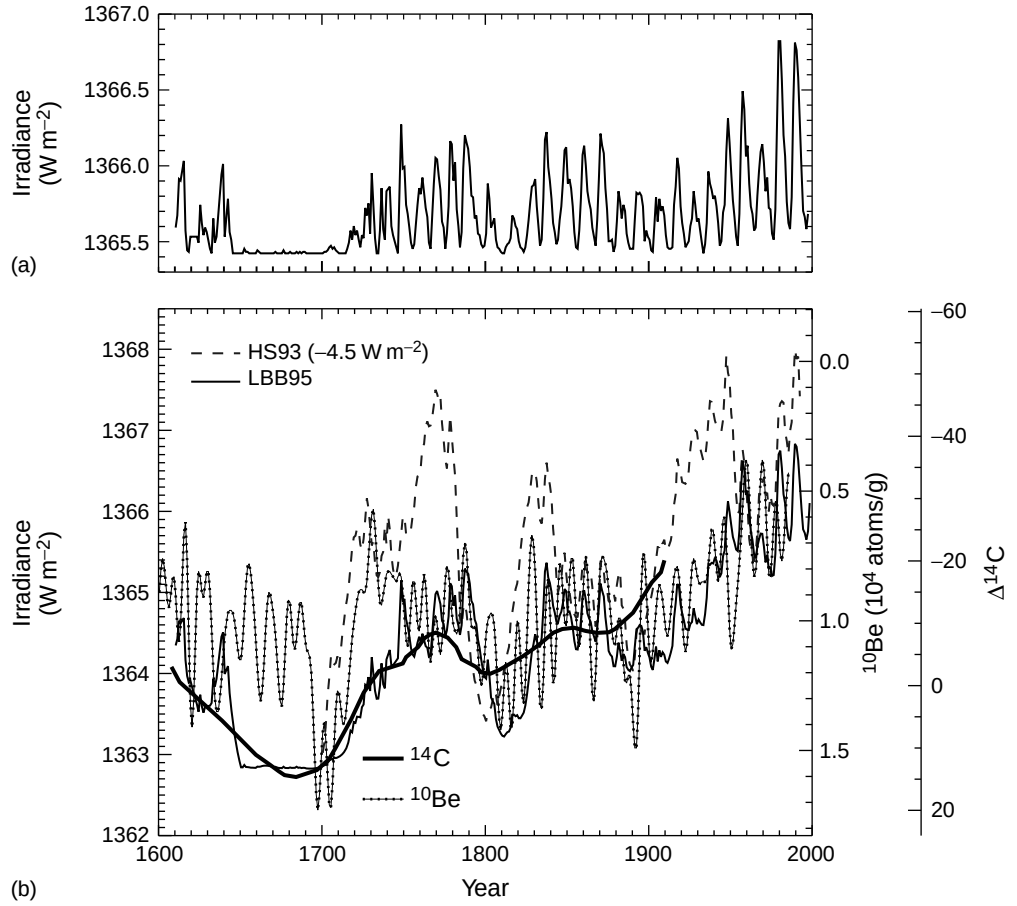

Figure 3 Reconstructions of the Sun's total irradiance, assuming in (a) that the 11-year cycle alone is the only source of long term variability, and in (b) that the 11-year cycle combines with a longer term component. In the LBB95 reconstruction of Lean *et al.* (1995), this long-term component is based on the average amplitude of each sunspot cycle, whereas in the HS93 reconstruction by Hoyt and Schatten (1993), the adopted long-term component is related to sunspot cycle length, rather than amplitude. Also shown for comparison are changes in cosmogenic isotopes (^{14}C and ^{10}Be) that are terrestrial proxies of solar activity

0.6 °C to 1 °C colder than at present (depending on geographical location) and solar activity was lower than at present because of the occurrence of the Maunder and Sporer minima. For almost 200 years, from 1600–1790, surface temperatures tracked solar activity, as the lower panel of Figure 4 shows. The apparent relation of the Little Ice Age and the Maunder Minimum is the most recent example of a general coincidence of increased $\Delta^{14}C$ production (i.e., lower solar activity) and decreased $\delta^{18}O$ (colder temperatures) which may reflect centennial climate change in response to net forcing from combinations of solar periods.

Many climate records (such as temperature, rainfall and drought) exhibit quasi cycles on decadal time scales. Large stochastic climate variability often obscures these cycles, which are not truly deterministic, nor global, nor always present. Although their physical origins remain ambiguous, the commonality of quasi-decadal climate cycles with solar activity (for example near 11, 22 and 88 years) suggests that external solar forcing plays a role. As well, some climate cycles correspond to combinations or harmonics of solar frequencies (7.8, 18, 30, 45 years), as expected for non-linear systems. Comparison of recent annual global surface temperature anomalies and annual total solar irradiance in the upper panel of Figure 4 illustrates the significant decadal variability present in both, compounded in the surface temperature record with shorter term volcanic cooling. The correspondence of higher solar activity with generally enhanced terrestrial warmth also occurs in both the tropospheric and stratospheric regions of the Earth s atmosphere during recent solar cycles. However, decadal Sun–climate correlations appear to be considerably more complicated than simple linear associations, and may involve phase locking by solar forcing of internal atmosphere–ocean variability modes that have distinct regional patterns whose temporal evolution may at times obscure the global signal.

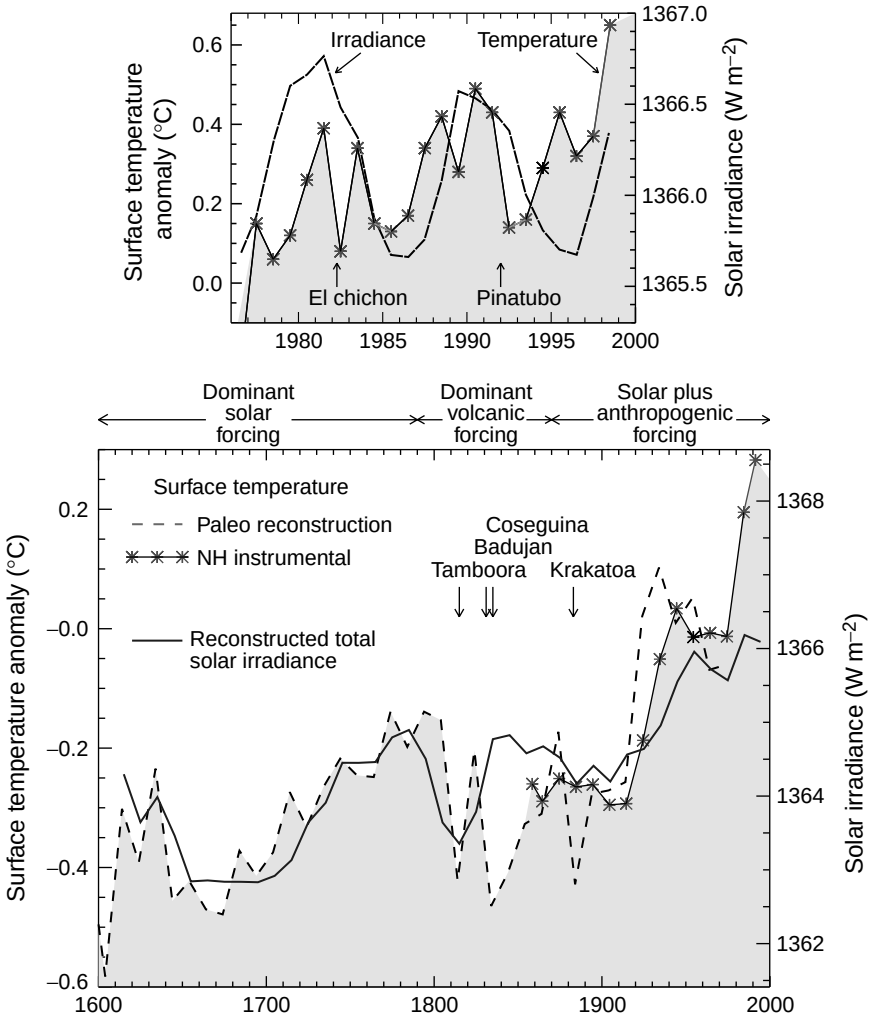

Figure 4 Comparisons are shown in the upper panel of total solar irradiance and annual mean global surface temperatures since 1976 and in the lower panel of a reconstruction of historical total solar irradiance (LBB95 from Figure 3) and surface temperatures since 1600. The symbols show actual surface temperature measurements whereas the solid dashed line is a paleoreconstruction based primarily on tree rings, by Bradley and Jones (1993). Significant volcanic events (Tamboora in 1815, Badujan in 1831, Coseguina in 1835, Krakatoa in 1883, El Chichon in 1982 and Pinatubo in 1991) are clearly evident as surface temperature depressions of a few tenths degree. Nineteenth century volcanism may have prolonged the Little Ice Age beyond that arising from low solar activity, alone

CLIMATE RESPONSE TO SOLAR FORCING

Quantifying the physical processes that facilitate solar-induced climate change is essential for validating and interpreting empirical Sun–climate relations. The balance between incoming solar radiation and outgoing terrestrial radiation determines the equilibrium surface temperature of the Earth. Climate responds to a perturbation in either of these quantities (whether by natural solar variability or anthropogenic changes in greenhouse gas concentrations) by adjusting to a new equilibrium surface temperature. The magnitude of surface temperature adjustment depends on climate sensitivity, which results from a number of feedback processes involving water vapor, sea ice/snow cover, clouds and ocean transport. Climate sensitivity is generally considered to be in the range of $0.2–1\,^{\circ}\mathrm{C}\,(\mathrm{W\ m^{-2}})^{-1}$ and likely depends on the geographical, altitudinal and historical character of the forcing.

Climate models with sensitivities that are generally consistent with paleoclimate evidence simulate global surface temperature changes of about $0.5\,^{\circ}\mathrm{C}$ since 1650, in response to plausible variations in solar irradiance (such as those shown in the lower panel of Figure 3). In the simulations, regional changes can exceed the global mean as a result of dynamical motions driven by differential heating of the land and oceans. Of the $0.5\,^{\circ}\mathrm{C}$ global surface temperature increase, 35% is thought to result from direct surface heating and 65% from feedbacks involving water

vapor (35%) which increases, cloud cover (20%) which also increases, and sea ice/snow cover (10%) which decreases. Figure 5 compares simulated solar-induced surface temperature fluctuations with actual changes determined from instrumental measurements and proxy reconstructions based on tree-rings, ice-cores and corals. Simulated changes of order 0.3 °C during the pre-industrial epoch agree well with reconstructed surface temperatures. However, the simulated 0.25 °C increase from 1900 to 1990 is notably less than the observed 0.6 °C increase. These scenarios are consistent with the empirical results in Figure 4 and suggest that solar irradiance variability contributes to climate change but is not the primary causes of the 20th century warming (*see* Climate Change, Detection and Attribution, Volume 1).

Establishing the contributions to 20th century climate change of solar variability, anthropogenic influences (by greenhouse gases, sulfate aerosols, ozone depletion and albedo changes) and other natural processes (volcanoes and unforced internal oscillations such as the El Niño Southern Oscillation, the Arctic Oscillation and the Quasi Biennial Oscillation) is a challenging task. With the exception of greenhouse gas concentrations, the forcings themselves are uncertain, as is climate sensitivity to each forcing. Also uncertain is the geographical and latitudinal extent of actual climate change. Furthermore, attribution scenarios must account simultaneously for pre-industrial surface temperature changes of about 0.3 °C and post industrial changes in excess of 0.6 °C, by different combinations of forcings. As Figures 4 and 5 illustrate, solar forcing alone permits a satisfactory explanation for the 0.3 °C warming from 1650 to 1790, when changes in greenhouse gas concentrations and aerosols, shown in the upper panel of Figure 5, were small. However, with realistic climate sensitivity, changes in solar forcing and greenhouse gas concentrations together contributed a factor of two or more warming since 1850 than is observed. An attribution scenario mutually consistent in both periods includes cooling by volcanic and sulfate aerosols in addition to warming by solar variability and greenhouse gases. During the past two decades, identification of the Sun s role in long-term climate change is more secure because direct observations of solar irradiance and surface temperature both exist (as Figure 4 shows). That solar radiation levels were approximately equal during two successive solar cycle minima (in 1986 and 1996) suggests negligible long-term solar forcing of climate during a period when measured surface temperatures nevertheless increased 0.2 °C.

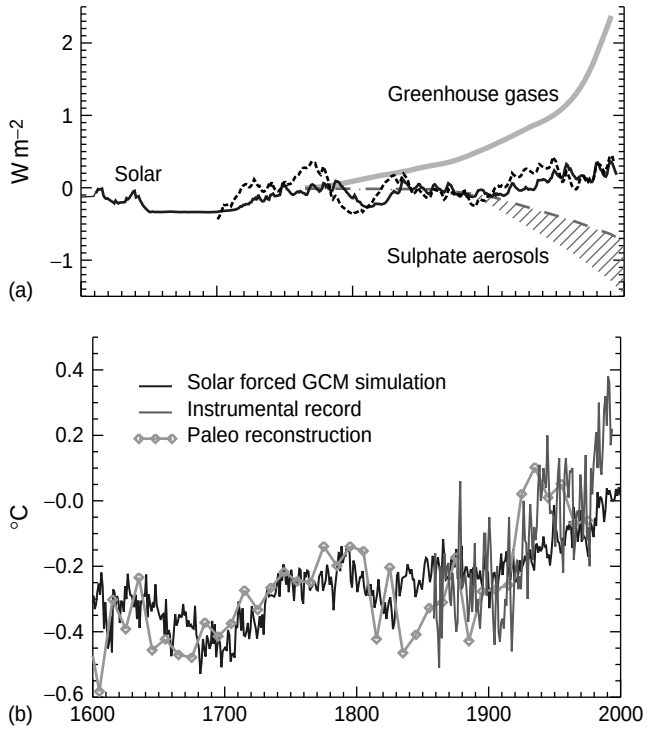

Figure 5 Climate radiative forcing by solar irradiance variability (from Figure 3) is compared in (a) with anthropogenic forcings by changes in concentrations of greenhouse gases (thick solid line) and sulfate aerosols (thick dashed line), including indirect effects (hatching). In (b) are compared annual simulations of surface temperature response to solar forcing by Rind *et al.* (1999) using the Goddard Institute for Space Studies moderate resolution general circulation model, with the annual instrumental record and with the paleoreconstruction by Bradley and Jones (1993) from Figure 4

An upper limit to the surface temperature changes to be expected from solar irradiance variability may be 0.5 °C. Both climate model simulations and empirical Sun–climate relations suggest that the Sun s variability since the Maunder Minimum has contributed about this level of surface warming. It is consistent, as well, with solar-induced climate change inferred from the correlation of $\Delta^{14}C$ (solar activity proxy) and $\delta^{18}O$ (surface temperature proxy) during the past millennium. Solar activity is presently at high levels relative to the historical record of the past 8000 years. This suggests that, were solar activity to undergo another Maunder Minimum type event over the next 200 years, surface cooling would be 0.5 °C or less, as a result; and future long-term solar forcing would either be small, or negative relative to the climate forcing by greenhouse gases, whose concentrations are projected to increase.

Of course, even when long-term solar forcing is minimal, as is apparently the case during the past few decades, decadal climate variability may accrue from prominent 11-year irradiance cycles in ways implied by empirical associations, but not presently understood or accounted for in climate models. Current climate models fail to simulate significant decadal variability in response to 11-year cyclic solar forcing in part because the feedbacks fail to reach their full equilibrium responses, which mutes surface temperature changes. An additional reason may be that the general circulation models do not adequately simulate

natural modes of atmosphere–ocean variability (such as the El Niño Southern Oscillation, the North Atlantic Oscillation and the Pacific Decadal Oscillation) which themselves exhibit decadal variability patterns that may become phase locked with the solar cycle.

Indirect solar-driven processes are expected to influence climate, in addition to direct forcing by solar irradiance variations in the visible and near-infrared spectrum. Most important of these indirect processes are variations in solar ultraviolet irradiance, which varies by an order of magnitude more than total irradiance. The ultraviolet irradiance variations alter ozone concentrations and middle atmosphere temperature, thereby facilitating radiative and dynamical coupling of the middle atmosphere with the biosphere. Changes in solar energetic particles and in galactic cosmic rays, whose penetration to the lower atmosphere depends on solar activity, are also postulated to affect climate indirectly through modification of cloud formation and other processes. Ongoing research is presently exploring such Sun–climate pathways. Improved understanding of all processes by which solar radiation interacts with the Earth is essential for better specifying the impact of solar variability on climate change. Ultimately, a more refined determination of the Sun s role in climate change requires long duration, high precision measurements from space of solar radiation over the entire spectrum, indefinitely.

Solar Variability, Long-term

Juerg Beer

Swiss Federal Institute of Environmental Science and Technology (EAWAG), Duebendorf, Switzerland

The Sun is the engine that drives the climate. It emits a total power of 3.9×10^{26} W (luminosity). At the top of the Earth's atmosphere the arriving power still amounts to 1.7×10^{17} W (irradiance or solar constant). From the environmental point of view the most important questions are: how variable is the solar irradiance and how does solar variability affect the Earth System. Today it is well known that the Sun is indeed a variable star as are many other solar type stars. It shows variability on time scales ranging from minutes to billions of years.

The power is generated in the core of the Sun by fusion of hydrogen to helium. It is then transported by radiation and for the last about 30% of its way to the surface by convection. The standard solar model reveals that, after the formation of the solar system 4.5 billion years ago, the luminosity was only 75% of its present value. Since then it has been steadily growing and will continue to do so for another 4- 5 billion years.

Variability on time scales shorter than 100 000 years is produced within the convection zone by the complex interplay between circulating plasma, magnetic elds and the differential rotation of the Sun (Lang, 1995).

DIRECT PARAMETERS OF SOLAR VARIABILITY

We can distinguish between direct and indirect data of solar variability. Direct data are continuously or regularly recorded from ground based as well as from space borne instruments. In general their quality is high, but the time interval they cover is limited to a few decades or centuries.

The main direct parameters of solar variability are listed in Table 1. All of them have a temporal resolution of at least 1 year.

Table 1 Direct parameters of long-term solar variability

Solar variability	Records since
Sunspots	~1600
Aurorae	~1700
aa-index	1843
Neutrons	1937
Solar irradiance	1978

During the last several decades the number of direct observational parameters has increased significantly (http://www.spaceweather.com/, http://umbra.nascom.nasa.gov:80/sdac.html, http://www.ngdc.noaa.gov/stp/stp.html, http://www.sunspotcycle.com/).

Historically the sunspot number is the most famous measure of solar variability. However, only after the discovery of the 11-year cycle by Schwabe in 1843 was a scientific observational program set up leading to a continuous record from about 1600 AD to the present (Figure 1). Sunspots occur on sites where magnetic flux tubes cross the solar surface. Because the strong magnetic fields hinder the upward movement of hot plasma, the local temperature is lower by some 1000 K compared to the surroundings (Hoyt and Schatten, 1997).

Aurorae are produced by solar plasma (solar wind) streaming out of coronal holes. The interaction of this solar wind with the upper part of the Earth s atmosphere leads to ionization processes, which can be seen as spectacular colored phenomena at high latitudes in both hemispheres.

The solar wind not only causes ionization in the atmosphere, it also disturbs the geomagnetic field. The aa-index is a measure for this disturbance. The earliest measurements go back to the time when the magnetometer was invented (Figure 1) (Mayaud, 1973).

The neutron flux is the result of the interaction of cosmic radiation (mainly protons and helium nuclei) with the atmosphere. The cosmic ray flux is modulated by the solar wind and the geomagnetic field. During periods of a very active Sun, the strong solar wind shields the cosmic ray flux and therefore reduces the neutron production. The first instruments monitoring the cosmic ray flux became operational in 1937.

Finally, after a long period of unsuccessful attempts to detect changes in solar irradiance (solar constant) from the Earth s surface, satellite based radiometers launched in 1978 showed a positive correlation between solar irradiance and solar activity (Lean, 1997). Although the changes observed during an 11-year Schwabe cycle are small (0.15%), they raised the fundamental question whether larger changes occur on longer time scales that could affect significantly the global climate.

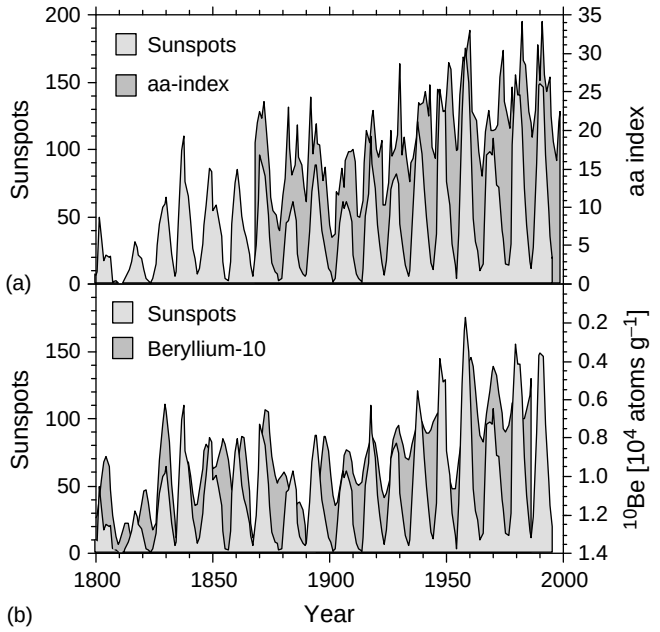

Figure 1 Comparison of two direct parameters of solar variability: (a) the aa-index with the sunspot number, and (b) the indirect parameter ^{10}Be with the sunspot number. Note that the ^{10}Be data (number of atoms per gram of ice) are plotted on an inverse scale

INDIRECT PARAMETERS OF SOLAR VARIABILITY

All parameters discussed so far are observational and therefore restricted in time. Observations in the pretelescopic era before 1600 AD are sparse and often not very reliable. Indirect parameters, however, have the potential to extend the variability record of the Sun back much further in time. The most promising tools for this purpose are cosmogenic radionuclides such as ^{10}Be and ^{14}C (*see* Radionuclides, Cosmogenic, Volume 1). They are produced in the atmosphere by the interaction of cosmic ray particles (mainly neutrons) with nitrogen and oxygen. As a result of the shielding effect of the solar wind on the cosmic rays, the production rate of these nuclides depends on the solar activity (Masarik and Beer, 1999).

In order to reconstruct the past, solar variability changes in the production rate of radionuclides must be recorded in an appropriate archive. Nature provides such archives in the form of ice sheets for ^{10}Be and tree rings for ^{14}C. Ice sheets contain the precipitation of more than 100 000 years. After its production in the atmosphere ^{10}Be becomes attached to aerosols and is removed within 1–2 years, mainly by precipitation. ^{14}C on the other hand forms CO_2 and exchanges then occur between the atmosphere, biosphere, and ocean. Tree rings therefore reflect the $^{14}C/^{12}C$ ratio at the time when they are formed. As a consequence of the ^{14}C exchange between the reservoirs, its system behavior is

different from that of ^{10}Be and has to be taken into account using a carbon cycle model.

Since radionuclide records in natural archives reflect the superposition of solar and geomagnetic effects on the production rate and changes within the system, the interpretation is not always straightforward. System effects can be separated from the production signal by comparing ^{10}Be with ^{14}C variations making use of the fact that variations in the two nuclides are very similar regarding production, but completely different regarding system effects.

LONG-TERM SOLAR VARIABILITY DERIVED FROM COSMOGENIC RADIONUCLIDES

Cosmogenic radionuclides provide long-term information on cyclic and non-cyclic solar variability. The well known 11-year Schwabe cycle was found for the first time in the ^{10}Be record of an ice core from Greenland (Beer *et al.*, 1990) (Figure 1) and extended beyond the sunspot record back to 1423. The 88-year Gleissberg and the 207-year De Vries cycle are also present in ^{10}Be ice core records (Beer *et al.*, 1994). The De Vries cycle is the most prominent solar periodicity in the radiocarbon tree ring record (Stuiver and Braziunas, 1993). Shorter cycles are dampened by the large sizes of the carbon reservoirs and are therefore very difficult to detect. Longer cycles (e.g., around 2000 years) do exist, but cannot yet be attributed unambiguously to solar variability.

Especially interesting features are periods of low solar activity such as the Maunder minimum (*see* Maunder Minimum, Volume 1), which is characterized by the almost complete absence of sunspots. The detrended Δ^{14}C record (Stuiver *et al.*, 1998) shows that several of these minimum periods occurred (Figure 2) during the last 7000 years. The fact that these periods often coincide with a change from warmer to colder climates indicates that solar forcing plays an important role in climate change (Beer *et al.*, 2000). However, the underlying mechanisms are still subject to investigation.

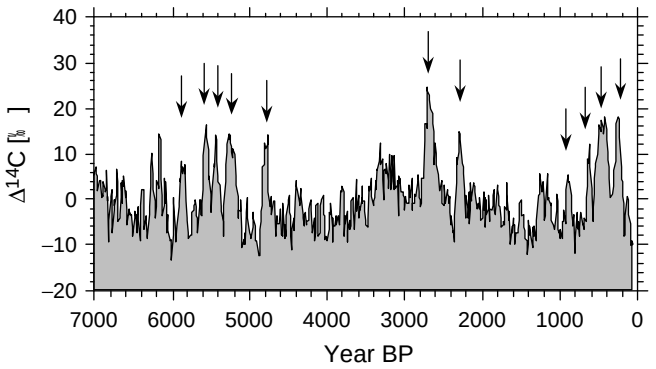

Figure 2 Δ^{14}C (deviation of the atmospheric $^{14}C/^{12}C$ ratio from a standard in permil) for the last 7000 years (BP, before 1950) after removing the long-term trend. The main periods of low solar activity are marked by arrows. The last arrow on the right hand side corresponds to the Maunder minimum (1645–1715 AD)

Southern Ocean

John A Church

Antarctic CRC and CSIRO Marine Research, Tasmania, Australia

The Southern Ocean plays a critical role in decadal and centennial climate variability and in determining the timing and regional impact of anthropogenic climate change. Its circumpolar extent allows inter-basin exchange and thus adds a global dimension to the ocean's vertical overturning

circulation that dominates ocean heat transport and storage. Over 50% of the global ocean's water mass properties are determined through interaction with the atmosphere and cryosphere in the Southern Ocean region. These waters carry their heat, freshwater, dissolved oxygen, nutrient and carbon dioxide content to lower latitudes and into the ocean interior.

Projections of 21st century climate change indicate that surface warming will be a minimum in the Southern Ocean. The Southern Ocean absorbs additional heat from the enhanced greenhouse effect that is exported to lower latitudes, resulting in sea-level rise through ocean thermal expansion. Formation and subduction of Antarctic water masses result in the Southern Ocean being the largest long-term sink for anthropogenic carbon dioxide. These water masses are transported into the ocean interior, thus preventing further exchange of carbon dioxide with the atmosphere for decades or longer.

Observations suggest that changes in the properties of water masses formed north of the Antarctic circumpolar current (ACC) and subducted into the subtropical oceans may have occurred in recent decades. These changes include a warming, a freshening, a decrease in dissolved oxygen and an increase in dissolved inorganic carbon concentrations. Some climate models also project a decrease in the meridional overturning of the Southern Ocean. However, the relevant processes are not well represented in the current generation of models and con rmation of this decrease awaits further observations and analysis.

The Southern Ocean, with an area of $7.6 \times 10^{13}\,\mathrm{m}^2$ south of $40\,^{\circ}\mathrm{S}$, is the only circumpolar ocean and forms a zonal connection between the southern parts of the Pacific, Atlantic and Indian Oceans. The major topographic features and horizontal transports are shown in Figure 1 and a schematic of the vertical overturning circulation is shown in Figure 2. The eastward flowing *Antarctic Circumpolar Current* (ACC) is constrained by choke points south of America, Australia/New Zealand and Africa. The ACC extends over the full depth of the Southern Ocean and has an estimated transport of about $134 \times 10^6\,\mathrm{m}^3\,\mathrm{s}^{-1}$ through Drake Passage and about $145 \times 10^6\,\mathrm{m}^3\,\mathrm{s}^{-1}$ south of Australia (Rintoul *et al.*, 2001). The surface layer south of the ACC is freshened by an excess of precipitation over evaporation and the melting of sea ice. This surface water is advected northward across the ACC in the surface Ekman transport (Figure 2).

On the northern side of the ACC, heat loss during winter results in surface mixed layers several hundred meters deep and the formation of sub-Antarctic mode water (SAMW). From there, SAMW s distinctive temperature/salinity characteristics, low vertical density gradient and high oxygen values can be tracked to lower latitudes as it is advected into the thermocline of the subtropical gyres of the Southern Hemisphere oceans. The coldest and densest form of SAMW, Antarctic intermediate water (AAIW), is formed in the South–East Pacific.

Several studies have shown significant changes over recent decades of SAMW and AAIW properties in the South Pacific and southern Indian Oceans (Dickson *et al.*, 2001). The changes are consistent with a warming and a freshening in the formation regions. Wong *et al.* (1999) argue that the freshening of AAIW, together with an increased salinity of water masses formed at lower latitudes, is consistent with increased precipitation at high latitudes and an intensification of the hydrological cycle as projected in climate-change simulations. Banks *et al.* (2000) see similar changes in global climate model results and argue that this climate change signal is most easily detected in the southern Indian Ocean. These same water mass formation and circulation processes are responsible for a significant uptake of anthropogenic carbon (C) and its storage in the ocean (Wallace, 2001). From analysis of model results, Cai and Whetton (2000) argue that the advection of warmed SAMW into the Pacific equatorial band is likely to result in greater warming in the eastern rather than the western Pacific Ocean during the 21st century (i.e., more El Niño-like conditions). The subduction of heat into the ocean with warmed SAMW is an important component of ocean thermal expansion and steric sea-level rise (Church *et al.*, 2001).

Relatively warm ($2\,^{\circ}\mathrm{C}$) salty water upwells south of the ACC and is transported onto the Antarctic shelf, where it loses heat to the atmosphere and ice shelves. Its density is also increased through the addition of salt rejected during sea-ice formation. The resultant dense Antarctic bottom water (AABW) cascades down the slope and flows northward into the ocean interior. The main formation site for AABW is the Weddell Sea, with lesser amounts being formed around the Antarctic coastline, particularly the Adelie Coast and the Ross Sea (Rintoul *et al.*, 2001). A number of studies (e.g., Comiso and Gordon, 1998; Jacobs and Giulivi, 1998) have documented changes in AABW and high salinity shelf water properties in the Weddell and Ross Seas, but the reasons for these changes are unclear. Farther north in the South Atlantic, observed changes in deep-water properties are attributed to variability in open-ocean convection in the Weddell Sea (Coles *et al.*, 1996; Zenk and Hogg, 1996).

Anthropogenic climate change has the potential to result in a reduction in the area of the Southern Ocean covered by sea ice from its present values of about $3 \times 10^6\,\mathrm{km}^2$ in summer and about $19 \times 10^6\,\mathrm{km}^2$ in late winter. Such a change would reduce the albedo of the Southern Ocean (a positive feedback), freshen the surface ocean and allow greater air sea exchange of heat, freshwater and carbon dioxide (CO_2). In a controversial result, de la Mare (1997)

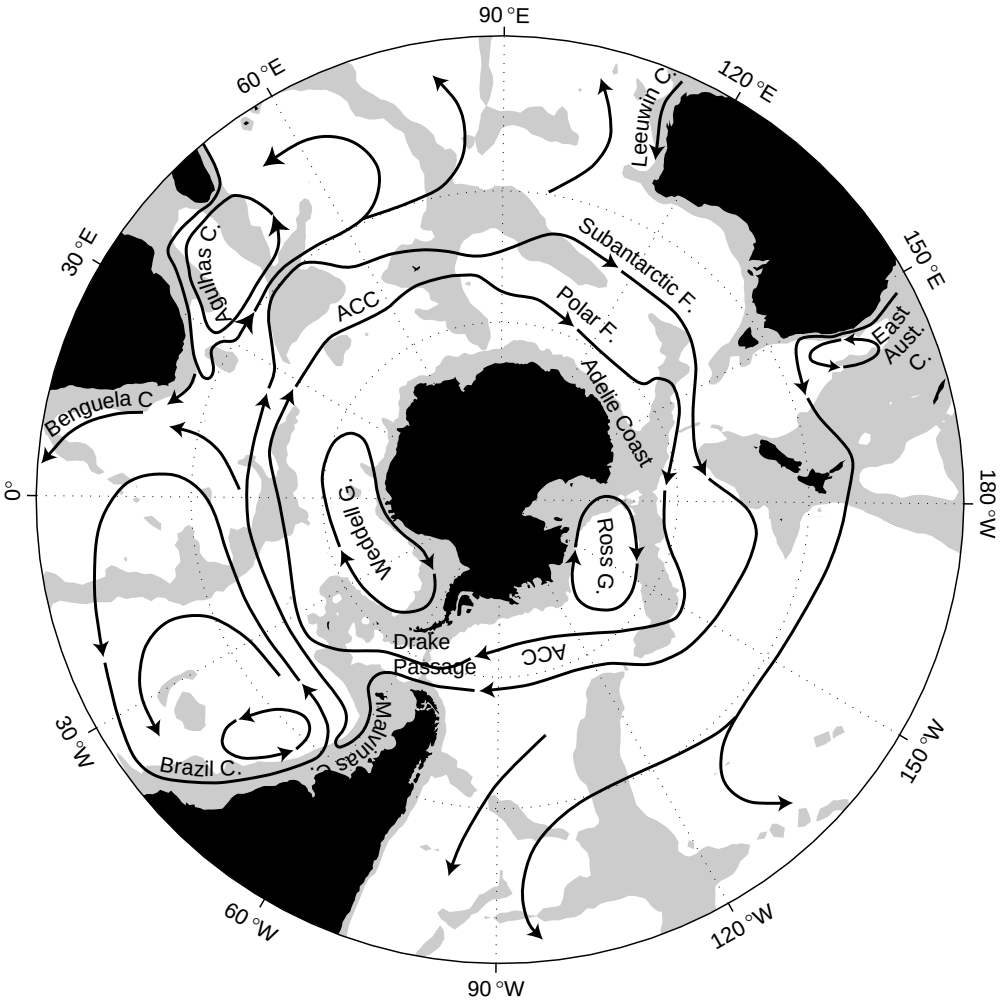

Figure 1 Schematic map of the major current systems. Depths shallower than 2500 m are shaded. The two major cores of the ACC are shown, the Subantarctic front (SAF) and the polar front (PF) (Abbreviations used are F for front, C for current and G for gyre). (Reproduced by permission from Academic Press in Rintoul *et al.*, 2001)

argues, from records of the location of whaling vessels close to the ice edge, that there was a significant retreat in the edge of the sea-ice zone during the central decades of the 20th century. While there has been a 20% decline in sea ice extent in the Amundsen and Bellingshausen Seas during the two decades from 1973 (Jacobs and Comiso, 1997), there appears to have been a slight increase in the area of the Southern Ocean covered by sea ice since modern satellite records commenced in the early 1970s (Cavalieri *et al.*, 1997).

Some recent coarse-resolution climate models project an increased stability of the Southern Ocean as a result of surface warming and freshening. This leads to a reduction in the rate of formation of AABW and a decrease of downwelling adjacent to the Antarctic coast by 20% by 2000, with a virtual shutting down of ventilation of waters below 2000 m after a further 300 years (Hirst, 1998). The slowdown in the overturning circulation, together with surface warming, may reduce the oceanic uptake of carbon dioxide (Matear and Hirst, 1999) and lead to a reduction in ocean oxygen levels, similar to observed reductions south of Australia (Matear *et al.*, 2000). Further changes to ocean uptake of carbon dioxide as a result of biological response to the changed physical conditions are uncertain but potentially important (Sarmiento and Le Quéré, 1996). The observational estimate of the rate of formation of AABW comes from ocean chlorofluorocarbon (CFC) inventories (Rintoul *et al.*, 2001). Broecker *et al.* (1998, 1999) use CFC, nutrient and $\triangle^{14}$C distributions to infer that there has been a recent reduction in the formation of Antarctic deep water. However, an analysis of these changes in the formation of deep water masses are confounded by insufficient observations, differing definitions of deep water masses and a lack of confidence that global models adequately represent the small-scale processes responsible for the formation of AABW and other deep water masses.

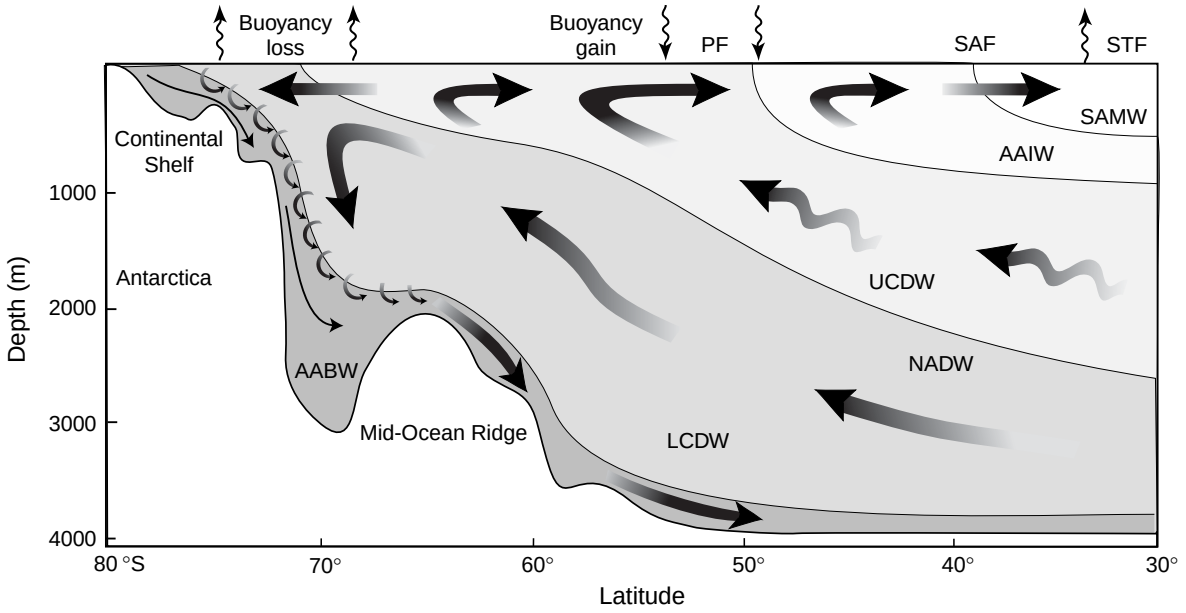

Figure 2 A schematic view of the meridional overturning circulation in the Southern Ocean. Abbreviations used are SAMW, AAIW, UCDW (upper circumpolar deep water), NADW (North Atlantic deep water), LCDW (lower circumpolar deep water), AABW, STF (subtropical front), SAF, PF. (Reproduced by permission from American Meteorological Society in Speer *et al.*, 2000)

Changes in the Southern Ocean have global as well as local significance. Increased confidence in potential changes requires ongoing observations, numerical modeling and analysis.

Southern Oscillation

The *Southern Oscillation* is a year-to-year seesaw in low latitude surface atmospheric pressure between the eastern and western hemispheres. This pressure oscillation is intimately related to the climatic conditions known as El Niño and La Niña. The British meteorologist Sir Gilbert Walker first defined the southern oscillation in the early 20th century.

One phase of the Southern Oscillation occurs when surface pressure is unusually high over the tropical Indian Ocean region and the western tropical Pacific, and unusually low east of the international date line in the southeastern tropical Pacific. During these periods, the pressure force across the Pacific basin that drives the trade winds is reduced. The trade winds therefore weaken, resulting in the abnormally high sea surface temperatures that characterize El Niño. Conversely, when the surface pressure is unusually high east of the date line and low west of the date line, the trade winds are unusually strong and cold sea surface temperatures develop in association with La Niña.

A commonly used indicator for the Southern Oscillation, the Southern Oscillation Index, is based on departures of surface atmospheric pressure from normal at Tahiti, French Polynesia and Darwin, Northern Australia. When this index is negative (low pressure at Tahiti relative to Darwin), the trade winds are weak (El Niño conditions). When the index is positive, the trade winds are strong (La Niña conditions).

Collectively, El Niño, La Niña, and the Southern Oscillation are referred to as El Niño/Southern Oscillation (ENSO). These phenomena are intimately related and arise from coupled interactions between the atmosphere and the ocean in the tropical Pacific. Shifts in tropical rainfall patterns associated with ENSO result in anomalous tropospheric heating that alters the global atmospheric circulation, producing droughts, floods, unusual storminess, heat waves and other weather extremes in many regions of the globe. The social, economic, and public health consequences of ENSO-related climate variability have motivated international efforts since the mid-1980s to better understand, monitor, and predict the evolution of the ENSO cycle (*see* El Niño/Southern Oscillation (ENSO), Volume 1).

SPARC (Stratospheric Processes and their Role in Climate)

SPARC is a research project established in 1992 by the Joint Scientific Committee of the World Climate Research Programme (WCRP) to investigate the role played by the stratosphere in the climate system. While intensive research was carried out on stratospheric ozone depletion, there were important areas that were not receiving sufficient attention, notably those concerning the role of the stratosphere in changing the climate and the feedback of climate change on the stratosphere. The mandate of SPARC was to stimulate research in those areas that require its attention.

SPARC deals with the role of stratospheric dynamical, chemical and radiative processes in the global climate of the troposphere–stratosphere system. The key scientific issues were identified by the SPARC Scientific Steering Group in 1992 as follows: the influence of the stratosphere on climate, the physics and chemistry associated with stratospheric ozone decrease, stratospheric variability and its monitoring, and changes in ultraviolet radiation.

Since 1992, SPARC s activities have been structured around the three following issues: stratospheric processes and their relation to climate, stratospheric indicators of climate change, and modeling stratospheric effects on climate. Results from SPARC s activities have been used in *Scienti c Assessment of Ozone Depletion, 1998*, trends in temperature and changes in the ozone vertical profile were assessed. The results of the water vapor assessment have been made available for the Intergovernmental Panel on Climate Change s Third Assessment Report (2001).

SPARC interacts with the other WCRP projects concerned with different aspects of the climate system, acting as the expert group on the atmosphere in the vicinity of the tropopause and above. Some of the research interests of SPARC are closely related to those of the International Global Atmospheric Chemistry project of the International Geosphere–Biosphere Programme, although with a different focus.

Storm Surge

Orrin H Pilkey[1] and David M Bush[2]
[1]*Duke University, Durham, NC, USA*
[2]*State University of West Georgia, GA, USA*

One of the deadliest aspects of hurricanes and other coastal storms is the storm surge - the local and temporary rise in water level above the normal astronomical tide. Historically, 90% of hurricane-related deaths have been attributed to the storm surge, such as the 1900 hurricane that killed at least 6000 in Galveston, TX. In the US today, storm surge is no longer such a threat because of watches and warnings, evacuation, and sheltering. Worldwide, however, storm surge is still a devastating killer. The storm surge associated with great hurricanes can range from 4 to 7 m or greater.

The US National Hurricane Center (NHC) defines storm surge as an abnormal rise in sea level accompanying a hurricane or other intense storm, and whose height is the difference between the observed level of the sea surface and the level that would have occurred in the absence of the cyclone. Storm surge is usually estimated by subtracting the normal or astronomic high tide from the observed storm tide. The NHC defines storm tide as the actual level of sea water resulting from the astronomic tide combined with the storm surge. Storm tide is poor terminology because of the confusion with astronomical tides. Another common term, and perhaps less ambiguous, is simply storm high water level.

Storm surge impacts include flooding, floating structures off of their foundations, and floating debris inland. The initial flow over and around obstructions (e.g., pilings) may cause scouring and sediment transport. The rising water also elevates waves and increases their landward incursion resulting in a wider zone of potential destructive impact. Waves combined with storm surge act to wash beach and dune sand landward forming washover deposits. Associated currents can transport sediment offshore. Saltwater flooding and spray kills or damages inland plants.

All coastal storms can cause storm surge. Hurricanes usually get most of the attention because of the potential for very high storm surge owing to their fierce winds and rapid forward movement, but they typically have only a localized impact (*see* Hurricanes, Typhoons and other Tropical Storms - Descriptive Overview, Volume 1; Hurricanes, Typhoons and other Tropical Storms - Dynamics and Intensity, Volume 1). Extratropical cyclones (winter storms, northeasters, southwesters) usually have markedly lower storm surge than hurricanes but they may affect much longer stretches of coastline.

CONTROLS ON STORM SURGE

The major components of storm surge can be considered as: (1) those relating to the storm physical characteristics; (2) those relating to the movement of the storm; and (3) those relating to the characteristics of the shoreline of impact. In addition, timing of hurricane landfall with astronomical tides can raise or lower the storm high-water level.

Storm physical characteristics include wind speed (faster means higher potential storm surge), wave height (nearshore, larger breaking waves mean more water transported shoreward thus higher storm surge), and storm size (radius of maximum winds for hurricanes, overall size for extratropical storms – the larger the storm the longer stretch of shoreline will be impacted by surge). Also important is the barometric effect, i.e., the air pressure of the storm system relative to surrounding normal atmospheric pressure. In general, a 1-mb drop in air pressure translates into about a 1-cm rise in sea level. Overall, the barometric effect is not the major contributor to storm surge. A Category five hurricane (the strongest on the Saffir–Simpson Hurricane Scale) can have a central pressure of less than 920 mb, compared to about 1013 mb for normal atmospheric pressure, that means that even for the strongest storms only about 1 m of the total storm surge can be due to atmospheric pressure differences. Also of major importance is the rotational effect of the water column created by the inward-spiraling winds. As the rotating water column beneath the hurricane moves into shallower water, the water is forced to rise upward to conserve vorticity – to keep the same volume of water rotating. That is, the water column now limited by depth must rise, further increasing the storm surge. Hurricanes are very fast moving compared to most winter storms so the duration of hurricane winds is not a major controlling factor in hurricane storm surge. Winter storms, however, may have surge levels that continue to build somewhat as the storm persists for several days.

Movement of the storm for extratropical storms means how long the storm persists to impact the coast; for hurricanes, the more important factors are how fast the storm center is approaching the coast (30 mph (48 km h^{-1}) or faster increases potential storm surge by at least one category on the Saffir–Simpson Scale) and what the angle of approach to the shoreline is (perpendicular approach means higher potential storm surge).

The shape of the shoreline of impact can be considered in profile and in plan view. In profile, storm surge is augmented by shelf width just as tidal amplitude is. On narrow shelves there is little shallow water to be impacted by the storm frictional processes. Narrow shelves such as those off the Caribbean Islands, Cape Hatteras, NC, or Miami Beach, FL, have inherently lower maximum potential surge elevations. On wide shelves, a broad expanse of shallow water can be piled up as a storm surge. Storm surges are potentially higher along the Gulf Coast and southern Atlantic Coast of the US between Cape Hatteras, NC and Cape Canaveral, FL. In plan view, a concave shoreline shape tends to funnel surge water. The 1993 storm of the century northeaster blew straight onshore in the concave Apalachee Bay area of Florida, creating storm surges of nearly 30 ft (9 m). Straight and especially convex shorelines have the opposite effect.

Under the right conditions, large estuaries can have profound storm surges. Hurricane Emily s (1993) winds blew offshore over Pamlico Sound, NC, causing maximum storm surge on the back side of Hatteras Island. Surge elevations were amplified by the concavity of the sound side shoreline of the Cape Hatteras cuspate foreland.

STORM CURRENTS

Storm surges are also responsible for bottom currents, which are set up because of the local rise in sea level creating a downwelling pressure gradient current. These types of currents are not very strong, but they can be responsible for moving great quantities of sediment away from the beach and into deeper water. Once sediment is resuspended by storm waves, only a slight current is needed to transport sediment offshore and possibly permanently out of the beach/dune system.

STORM-SURGE EBB

Storm-surge ebb is an important process where the storm surge water flows back to sea, either by the force of gravity alone or driven by offshore-blowing winds, generating an erosive ebb current. This type of current is different from downwelling pressure gradient currents because it occurs while the storm is moving out of the area or diminishing. Storm-surge ebb can cause an existing inlet to change shape, breach a spit or island creating a new inlet, scour shallow cross-island channels, transport storm debris (including houses) offshore, and cause permanent removal of sand from the beach/dune system to the deeper offshore. After Hurricane Hugo, the shoreface in front of Myrtle Beach, SC was covered with deep scour tracks, perpendicular to the shoreline, formed by the storm-surge ebb.

DEFINING THE STORM SURGE RISK IN US

A computer simulation model developed for the US National Weather Service called SLOSH (sea, lake and overland surges from hurricanes) is used in the US to predict the storm surge. The SLOSH model is essential for developing hurricane evacuation plans in exposed coastal areas. Such indundation information is available from state or local emergency management offices, the US Federal Emergency Management Agency (FEMA), the US National Weather Service, as well as local governments. Another measure of storm surge is relative to the 100-year flood. FEMA publishes maps called flood insurance rate maps (FIRMs) showing various flood zones for the entire US, in order to identify flood hazard areas (riverine as well as coastal). The highest-hazard coastal areas, according to the FIRMs, are A-zones (100-year flood zone; a statistical 1% chance of flood reaching or exceeding a predetermined area in any given year), and V-zones (portions of the 100-year flood zones subject to waves 3 ft (0.91 m) or greater). For further information on SLOSH modeling and hurricane processes, visit the US National Oceanographic and Atmospheric Administration (NOAA) web site: http://www.noaa.gov. For further information on FIRMs and related hazard management issues, visit the US FEMA web site: http://www.fema.gov.

Stratosphere

The *stratosphere* is the layer of the Earth s atmosphere from about 11 km to about 50 km in which the temperature is isothermal or increases with height. The temperature structure of the stratosphere is a result of atmospheric ozone, which absorbs ultraviolet solar radiation and warms the air. The stratospheric ozone concentrations are at a maximum near 25 km, but the temperature increases with height to about 50 km because the ozone concentrations above the ozone maximum are sufficient to effectively intercept ultraviolet solar radiation, warming these levels, and allowing less ultraviolet radiation to penetrate to the

lower levels, where it could be absorbed by the higher concentrations of ozone. The lower air densities at higher altitudes also contribute to the absorbed radiation yielding higher temperatures. The peak in temperature defines the top of the stratosphere, known as the *stratopause*, above which the temperature decreases with height in the mesosphere.

KEITH L SEITTER *USA*

Stratosphere, Chemistry

Douglas Kinnison
National Center for Atmospheric Research, Boulder, CO, USA

In this overview of stratospheric chemistry, the important chemical processes are outlined from a historical point of view, starting with the discovery of molecular oxygen and continuing with a detailed focus on the chemical processes that affect both the distribution and trend of stratospheric ozone. The increasing realization that the stratosphere is an important and interesting component of the Earth system has gone hand in hand with: our capability to monitor the stratosphere (stimulated in part by the International Geophysical Year (IGY) eld programs in the 1950s); our need to know more about the stratosphere for operational aviation reasons, e.g., the high- ying supersonic transports (SSTs) that began to emerge in the late 1960s; and our growing realization that the stratosphere was a major player in a number of global environmental issues, including the stratospheric ozone hole over Antarctica and greenhouse gas-induced climate warming.

*Air generally enters the stratosphere in the equatorial region, carrying upward chemical constituents from the troposphere to the lower stratosphere. In the troposphere vertical mixing is on the order of hours to days, while in the stratosphere, vertical mixing tends to require months to years. Chemical constituents that have a relatively long chemical lifetime in the troposphere will be transported into the stratosphere. These species (e.g., methane (CH_4), nitrous oxide (N_2O), and chloro uorocarbons (CFCs)) are typically designated as long-lived and the photochemical destruction of these species within the stratosphere produces short-lived radicals that are important in stratospheric ozone (O_3) balance (*see *Lifetime (of a Gas), Volume 1; Residence Time (of an Atom, Molecule or Particle), Volume 1; Stratosphere, Temperature and Circulation, Volume 1).*

*Stratospheric ozone absorbs both solar and infrared radiation, which impacts the thermal structure of the atmosphere. These radiative processes help to determine the circulation of the global atmosphere. O_3 is also an important greenhouse gas. The radiative balance in the mid-to-upper troposphere and lowermost stratosphere is quite sensitive to the O_3 concentration, so changes in O_3 concentration in these regions are very important. In addition, because O_3 absorbs potentially harmful solar ultraviolet radiation, any depletion of stratospheric O_3 increases the amount of solar ultraviolet radiation reaching the Earth's lower atmosphere and the surface. Increased ultraviolet radiation is known to affect many chemical and biological processes and to increase the rate of skin cancers in humans and animals (*see *Depletion of Stratospheric Ozone, Volume 1; Ultraviolet Radiation, Volume 1).*

EARLY HISTORY OF GAS-PHASE STRATOSPHERIC CHEMISTRY

The stratosphere is composed primarily of molecular nitrogen (N_2) and molecular oxygen (O_2), 78.084% and 20.946% respectively. In the stratosphere, N_2 is unreactive; however, O_2 can be appreciably photolyzed, producing atomic oxygen (O) down to levels as low as 20 km. Both Priestly and Schelle independently discovered O_2 in 1774. As discussed below, photolysis of O_2 is responsible for production of stratospheric ozone (O_3). The development of the field of stratospheric chemistry is closely tied to understanding of the chemical processes that affect stratospheric O_3 abundance.

Knowledge of the physical properties of O_3 was greatly enhanced during the 19th century. O_3 was discovered and named in 1839 by Schonbein (from the Greek word *ozein*, to smell). In 1864, Soret presumed that O_3 had a structure made up of three-oxygen atoms (O_3). Cornu (1878) observed that there was a sudden break off of the solar spectrum at wavelengths shorter than 300 nm. Hartley (1880–1881) discovered a strong absorption band between 200 nm and 320 nm. Experimental and observational work led Hartley to conclude that the absorption feature noted by Cornu was due to O_3 ultraviolet absorption in the middle atmosphere. Chappuis (1880) discovered eleven absorption bands of O_3 contained within the visible spectrum between 500 nm and 700 nm. Finally, Huggins (1890) observed ultraviolet absorption bands between 320 nm and 360 nm in the spectrum of the star Sirius and concluded that this absorption was also due to O_3. The absorption by O_3 of solar radiation in the visible has a significant influence on the dynamics of the middle atmosphere. In addition, the absorption by O_3 in the ultraviolet region is necessary for

life to exist on Earth (*see* Atmospheric Composition, Past, Volume 1; Earth System History, Volume 1; Solar Irradiance and Climate, Volume 1; Stratosphere, Temperature and Circulation, Volume 1; Ultraviolet Radiation, Volume 1).

The chemical processes that influence stratospheric O_3 abundance have been examined and updated throughout the 20th century, with most of the significant advances in theoretical understanding coming in the last three decades. In 1913, the first quantitative measurement of O_3 in the atmosphere was made by Fabry and Buisson. Dobson (1926) developed an ultraviolet spectrometer that measured the total column of O_3 routinely. Total column O_3 is the integrated O_3 measured in a vertical column from the surface to the top of the atmosphere and is often expressed in Dobson units (DU), where 1 DU is equivalent to a column of O_3 of 10^{-5} meters in height at standard temperature and pressure (STP) (1 atm pressure and 273.15 K). Because approximately 90% of atmospheric O_3 is located within the stratosphere (the other 10% is located within the troposphere), perturbations to stratospheric O_3 will significantly impact the total column O_3 abundance. In 1929, Dobson established a surface network of stations at various latitudes. The present day O_3 monitoring network still includes many of these same stations (*see* Stratosphere, Ozone Trends, Volume 1).

In 1930 Chapman proposed that photochemical processes produced O_3, specifically by the photolysis of O_2 (Equation 1), producing two oxygen atoms (*see* Photochemical Reactions, Volume 1).

$$O_2 + h\nu \longrightarrow O + O \quad (1)$$

$$\underline{O + O_2 + M \longrightarrow O_3 + M} \text{ (twice)} \quad (2)$$

$$\text{NET: } 3O_2 + h\nu \longrightarrow 2O_3$$

Subsequent photolysis of O_3 (Equation 3) was not considered a net loss, because the oxygen atom produced would rapidly react in a three-body reaction to produce O_3 again (Equation 2). The third body reactant (i.e., M) is typically either N_2 or O_2. In many reactions, this chemical constituent is necessary to remove excess energy for the stabilization of the O_3 bond. Because Equations (2) and (3) do not result in a loss of O_3, this is typically called a null cycle.

$$O_3 + h\nu \longrightarrow O + O_2 \quad (3)$$

$$\underline{O + O_2 + M \longrightarrow O_3 + M} \quad (2)$$

NET: Null Cycle

Chapman proposed two reactions that would reduce stratospheric O_3 abundances. The first reaction is between an oxygen atom and an O_3 molecule (Equation 4). This is the primary stratospheric loss reaction for O_3 in the odd-oxygen (i.e., $O + O_3$) family of chemical constituents. We use the term odd-oxygen because any oxygen atom produced reacts rapidly with an oxygen molecule (Equation 2) to form O_3, therefore, a loss of oxygen atom is essentially a loss of O_3 in the stratosphere. A schematic of the Chapman mechanism is shown in Figure 1. In the scientific literature, the expressions, odd-oxygen loss and O_3 loss are used interchangeably. In this article we will use O_3 loss .

$$O + O_3 \longrightarrow 2O_2 \quad (4)$$

$$O + O + M \longrightarrow O_2 + M \quad (5)$$

Laboratory measurements indicated that Chapman s reaction (Equation 5) was too slow to impact O_3 abundance in the stratosphere, although this reaction becomes more important above the stratopause, within the mesosphere.

In 1936, Wulf and Deming were the first to calculate the O_3 profile using a photochemical model. They incorporated the Chapman mechanism into their photochemical model and used a solar intensity that corresponded to a black body temperature of 6000 K, typical of solar output. Using measured photochemical rate constants for that period, they were able to calculate a vertical O_3 profile. Three years earlier, Gotz (1934) developed the Umkehr method to measure the O_3 vertical profile. This method used spectra taken from scattered radiation from the overhead sky through sunrise and sunset. The results of the Umkehr method showed O_3 to have a vertical profile that peaked approximately between 22–25 km in the Northern Hemisphere, mid-latitudes. Considering the uncertainties in the photochemical rate constants and solar irradiance for that period, the calculated versus observed O_3 vertical profiles were in good agreement. However, in the 1950s, U–2 rockets were used for the first time to directly measure the solar intensities throughout visible and ultraviolet wavelengths. It was found that the solar intensity could not be represented by a blackbody temperature profile of 6000 K. Correcting with this discrepancy and making additional changes in

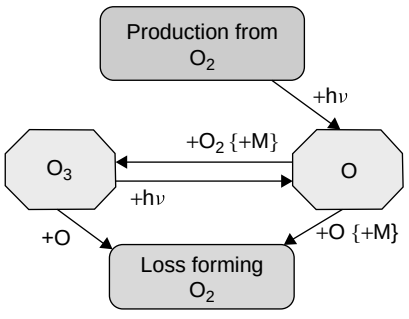

Figure 1 Schematic diagram of the principal reactions making up the Chapman mechanism. The rounded rectangular boxes represent production and loss processes of odd-oxygen species. The octagonal boxes represent the O_3 and O odd-oxygen radicals. The arrows show the possible reaction pathways

photochemical rate constants, model-derived vertical profiles of O_3 were found to be more than the observed values.

During the 1960s, scientific research was focused on finding additional chemical processes that would bring theory into alignment with measurements. McGrath and Norrish (1960) experimentally showed that the hydroxyl radical could be produced through reactions of water (H_2O) vapor with electronically excited singlet atomic oxygen or $O(^1D)$. The initiation step for this process occurs when O_3 is photolyzed at wavelengths less than 310 nm, forming $O(^1D)$ and O_2 (Equation 6). The subsequent $O(^1D)$ reaction with H_2O produces two hydroxyl (OH) radicals (Equation 7).

$$O_3 + h\nu(\lambda < 310\,\text{nm}) \longrightarrow O(^1D) + O_2 \quad (6)$$

$$O(^1D) + H_2O \longrightarrow 2OH \quad (7)$$

The OH radical is then available to react with O_3, producing the hydroperoxyl (HO_2) radical and O_2 (Equation 8). Because the concentration of OH is several orders of magnitude less than O_3, Equation (8) will have negligible effects on O_3 abundance. However, the HO_2 radical produced by Equation (8) can react with another O_3 to reproduce the OH radical. This chain process will continue thousands of times before it is interrupted, and it is therefore termed a catalytic cycle. The net effect of Equations (8) and (9) is the loss of two O_3 molecules, forming three O_2 molecules. This catalytic cycle is important in the lower stratosphere.

$$OH + O_3 \longrightarrow HO_2 + O_2 \quad (8)$$

$$\underline{HO_2 + O_3 \longrightarrow OH + 2O_2} \quad (9)$$

$$\text{NET: } 2O_3 \longrightarrow 3O_2$$

Figure 2 shows the schematic of the hydrogen oxide (HO_x) family. As in Figure 1, the octagons represent species that interconvert rapidly with each other (i.e., H, OH, and HO_2). Species highlighted within rectangles are considered temporary reservoir species. For the simple schematic shown in Figure 2, H_2O_2 would be a temporary reservoir species. A reservoir species by definition is a species that removes the active radicals from the O_3 destruction cycle(s).

In 1966, Hunt modeled the atmosphere using photochemical reactions that corresponded to the Chapman mechanism plus the water reactions. He found that, by adjusting the values for the rate constants of reactions (8) and (9), a calculated vertical O_3 profile could be derived that matched the observed profile. However, when more accurate values for the rate constants in the above mechanism became available, the theoretical value of both the O_3 profile and total column O_3 still exceeded observational data.

In 1968, Murcray and colleagues measured the concentration of nitric acid (HNO_3) in the stratosphere to be in the parts per billion by volume (ppbv) range. Expanding

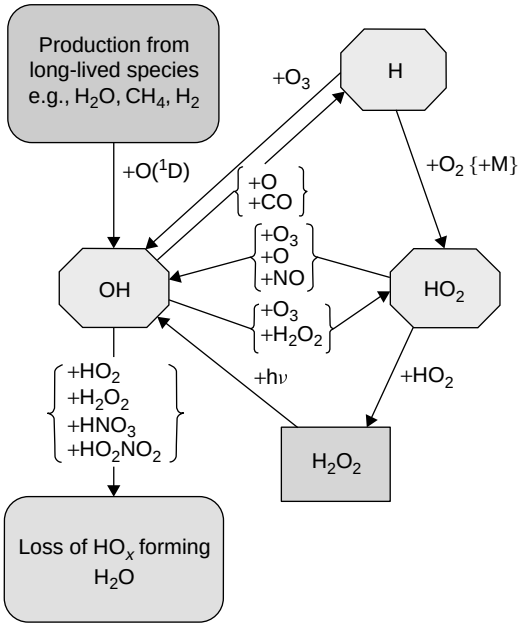

Figure 2 Principal reactions for the HO_x chemical family. The rounded rectangular boxes represent production and loss processes of odd-hydrogen species. The octagonal boxes represent HO_x radicals that have a short atmospheric lifetime (i.e., >1 day for H, OH, and HO_2). The species highlighted within the rectangular box is considered a temporary reservoir species (i.e., H_2O_2)

on this, Crutzen (1970) reasoned that the observed HNO_3 concentration implied enough nitric oxide (NO) and nitrogen dioxide (NO_2) to support a catalytic cycle that would reduce O_3 in a manner similar to the hydrogen oxide catalytic cycle (*see* Crutzen, Paul J, Volume 1).

$$NO + O_3 \longrightarrow NO_2 + O_2 \quad (10)$$

$$\underline{NO_2 + O \longrightarrow NO + O_2} \quad (11)$$

$$\text{NET: } O + O_3 \longrightarrow 2O_2$$

In 1971, Crutzen and Nicolet independently proposed the primary source of stratospheric nitrogen oxides (i.e., $NO_x = NO + NO_2$) to be reaction of nitrous oxide (N_2O) with $O(^1D)$:

$$N_2O + O(^1D) \longrightarrow 2NO \quad (12)$$

See Figure 3 for a schematic of the NO_x family of reactions. N_2O is primarily produced and subsequently released from the surface by bacterial nitrification and denitrification in soils and aquatic systems. N_2O is not appreciably destroyed in the troposphere, but is removed in the stratosphere by both photolysis and by the above-mentioned reaction with $O(^1D)$. The NO_x production in the stratosphere is a prime example of how, through modification to the biospheric nitrogen cycle, life on Earth controls natural levels of stratospheric O_3.

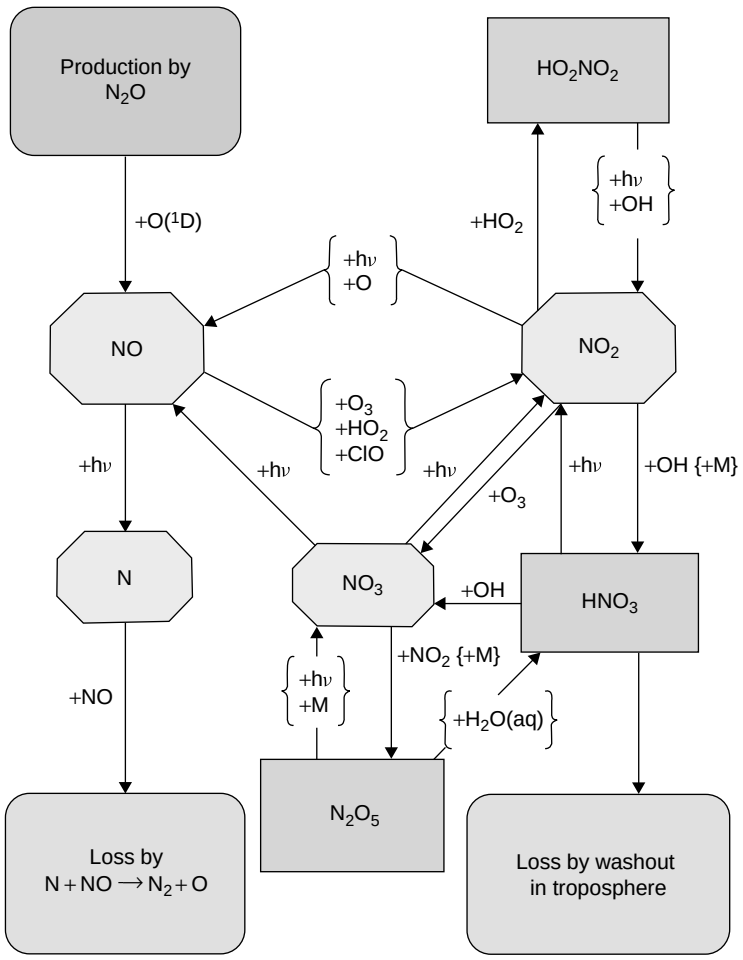

Figure 3 Principal reactions for the NO_x chemical family. The rounded rectangular boxes represent production and loss processes of odd-nitrogen species. Species contained within octagonal boxes represent NO_x radicals with short atmospheric lifetimes (i.e., N, NO, NO_2, and NO_3). Species highlighted within rectangular boxes are considered temporary reservoir species (i.e., N_2O_5, HO_2NO_2, and HNO_3)

An additional source of NO_x in the stratosphere is believed to be from galactic cosmic ray (GCR) production of NO. These processes occur through secondary electrons ejected by heavy cosmic particles. This production process is not insignificant, especially in the polar regions, where N_2O oxidation is slow. NO_x could also be produced in the lower stratosphere by a fleet of SSTs. Johnston (1971) clarified the role that a proposed fleet of SSTs would have on stratospheric NO_x and subsequent changes in O_3. NO_x is formed from the breakdown of molecular nitrogen from the high combustion temperatures contained within the jet engines. NO_x increases in the lower stratosphere from a fleet of proposed SSTs could increase ambient NO_x by approximately 50%. To investigate this potential environmental issue, the US Department of Transportation created the Climatic Impact Assessment Program (CIAP). This program was responsible for not only increasing understanding of SST impacts on stratospheric O_3, but also, potentially more important, for sponsored research that greatly increased understanding of physical, dynamical, and chemical processes related to stratospheric O_3.

NO_x is eventually removed in the upper stratosphere and lower mesosphere by reaction of atomic nitrogen (N) with NO, forming chemically inert molecular nitrogen (N_2).

$$NO + N \longrightarrow N_2 + O \tag{13}$$

NO_x can also be removed by the formation of HNO_3 (Equation 14). Because HNO_3 does not readily regenerate NO_x, it is considered a temporary reservoir species for NO_x. In addition, HNO_3 is water-soluble and any HNO_3 transported into the troposphere can be precipitated out of the atmosphere (*see* Nitrogen Cycle, Volume 2). Therefore, Equation (14) effectively short-circuits the NO_x catalytic cycle (Equations 10 and 11).

$$NO_2 + OH + M \longrightarrow HNO_3 + M \tag{14}$$

Shortly after the importance of NO_x was proposed by Crutzen and Johnston, an additional catalytic cycle based on chlorine oxides (ClO_x) (i.e., $ClO_x = Cl + ClO$) was also proposed. Stolarski and Cicerone (1974) realized that chlorine, if in high enough concentrations, could be important in controlling stratospheric O_3 abundance. They proposed a catalytic cycle similar to the NO_x cycle proposed by Crutzen.

$$Cl + O_3 \longrightarrow ClO + O_2 \quad (15)$$

$$\underline{ClO + O \longrightarrow Cl + O_2} \quad (16)$$

$$\text{NET: } O + O_3 \longrightarrow 2O_2$$

The source of ClO_x radicals in the stratosphere was identified by Molina and Rowland (1974) (*see* Molina, Mario J, Volume 1; Rowland, F Sherwood, Volume 1). See Figure 4 for a schematic of the ClO_x family of reactions. They suggested that CFCs were insoluble and relatively unreactive in the lower atmosphere and could be transported into the stratosphere (*see* Chloro uorocarbons (CFCs), Volume 1; Halocarbons, Volume 1). It is known that CFCs and other long-lived molecules that are heavier than air can rise up into the upper atmosphere based on prevailing winds and atmospheric mixing processes. This large-scale upward motion in the tropics and downward motion toward the poles is known as the Hadley circulation (*see* Hadley Circulation, Volume 1). This air motion that mixes molecules to greater altitudes is faster than gravitational settling. Once in the stratosphere, CFCs are photodissociated, releasing ClO_x radicals. This source of ClO_x was of particular importance because CFCs are primarily of anthropogenic origin (human-related). This pointed to the need to investigate the potential impacts that anthropogenic emissions of CFCs may have on future stratospheric O_3 abundance (*see* Depletion of Stratospheric Ozone, Volume 1; Stratosphere, Ozone Trends, Volume 1).

ClO_x is removed from the atmosphere primarily by the formation of hydrochloric acid (HCl). HCl, like HNO_3, is water-soluble and will be removed in the troposphere.

$$Cl + CH_4 \longrightarrow HCl + CH_3 \quad (17)$$

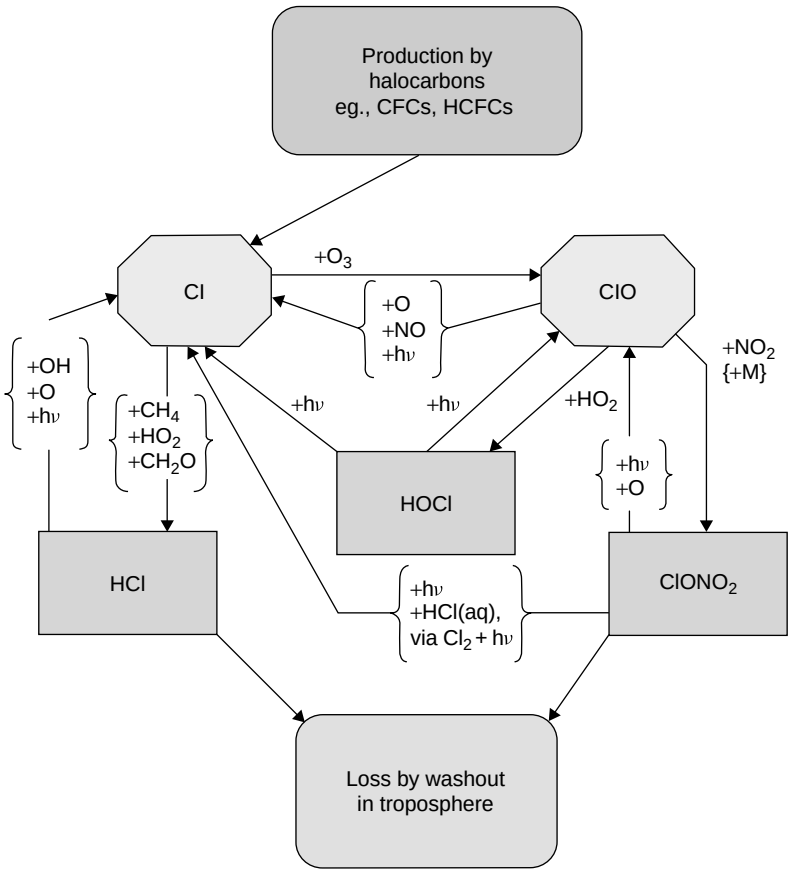

Figure 4 Principal reactions for the ClO_x chemical family. The rounded rectangular boxes represent production and loss processes of odd-chlorine species. Species contained within octagonal boxes represent ClO_x radicals with short atmospheric lifetimes (i.e., Cl and ClO). Species highlighted within rectangular boxes are considered temporary reservoir species (i.e., HOCl, $ClONO_2$, and HCl)

In addition, Wofsy *et al.* (1975) proposed that bromine oxide (BrO_x) (i.e., $BrO_x = Br + BrO$) radicals, like ClO_x, would be an effective catalytic O_3 reducing agent in the stratosphere.

$$Br + O_3 \longrightarrow BrO + O_2 \quad (18)$$

$$\underline{BrO + O \longrightarrow Br + O_2} \quad (19)$$

$$\text{NET: } O + O_3 \longrightarrow 2O_2$$

The source of BrO_x radicals is from halons and bromocarbons (*see* Halocarbons, Volume 1). The present day concentration of BrO_x (<20 pptv) is considerably less than ClO_x (~3.5 ppbv), however, per molecule, the reactivity of BrO_x is considerably greater, being up to 45 times more effective than ClO_x in global O_3 destruction. The analogous BrO_x reaction to the ClO_x (Equation 17) does not occur; however, other reactions do occur that convert active BrO_x to HBr, $BrONO_2$, and HOBr. These species are all water-soluble and will be removed in the troposphere.

Figure 5 shows a comparison of a model-derived O_3 distribution using only the Chapman mechanism relative to a mechanism that also includes all the important gas-phase species contained within the HO_x, NO_x, ClO_x, and BrO_x chemical families. Including all the above-mentioned gas-phase processes (reference atmosphere in Figure 5) yields a model-calculated vertical O_3 profile significantly less than the Chapman only mechanism. The reference atmosphere in Figure 5 is consistent with the mid-latitude observed distribution of O_3 typical of 1960 conditions (i.e., prior to significant loading of CFCs).

The work of Crutzen (1970) and Rowland and Molina (1974) was cited in award of the 1995 Nobel Prize in Chemistry. Additional reading on the history and theory of gas-phase chemical processes that affect stratospheric O_3 abundance can be found in Wayne (1985); Brasseur and Solomon (1986), Johnston (1992); Brasseur *et al.* (1999); and Finlayson-Pitts and Pitts (2000).

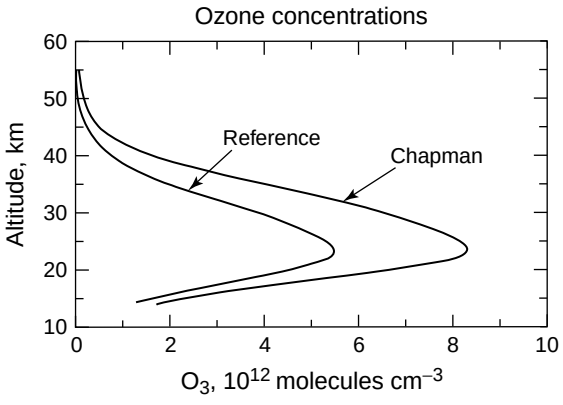

Figure 5 Model-calculated ozone vertical profile for both a Chapman mechanism and a reference atmosphere including a complete O_x, NO_x, HO_x, and ClO_x mechanism. The reference atmosphere is representative mid-latitude 1960 conditions. (Reproduced with permission from Kinnison *et al.*, 1988, copyright by the American Geophysical Union)

AEROSOL INFLUENCES ON STRATOSPHERIC CHEMISTRY

The basic understanding of gas-phase (also defined as homogeneous) chemical processes was essentially complete by the beginning of the 1980s. There certainly were needs for refinements in laboratory kinetics, in the development and evaluation of multi-dimensional models, and comprehensive multi-platform measurements (e.g., *in situ* aircraft, and remote satellite measurements) of the above mentioned chemical species. However, this confidence in our basic understanding of stratospheric chemistry was short-lived and changed dramatically after the release of a 1985 paper by Farman and colleagues in the journal *Nature*.

Farman *et al.* (1985) reported a dramatic decrease in the total column O_3 abundance in the austral spring over Antarctica (*see* Depletion of Stratospheric Ozone, Volume 1; Stratosphere, Ozone Trends, Volume 1). This decrease in total column O_3 was unprecedented and pointed to the need for the atmospheric science community to understand the physical, chemical, or dynamical process (or combination thereof) that was responsible for this unprecedented O_3 loss.

It quickly became apparent that known gas-phase chemical processes could not explain this dramatic change in O_3, which had been occurring since the mid-to-late 1970s. Farman *et al.* (1985) had suggested that anthropogenic changes in chlorine might be responsible for the observed O_3 change. However, the reactions that control O_3 loss in the ClO_x catalytic cycle (Equations 15 and 16) were not important at high latitudes in the 15–25 km altitude range where this O_3 depletion was believed to occur. These reactions were more important at 35–45 km. Gas-phase chemical processes might be responsible for total column O_3 depletion of 5%, but certainly not the observed 50% depletion.

Solomon *et al.* (1986) suggested heterogeneous chemical processes were the explanation; specifically, that reactions of gas-phase constituents on stratospheric particles (or aerosols) were necessary to explain this rapid O_3 loss. It was well known that ice particles or mother-of-pearl clouds were common during the cold (<190 K) Antarctic winter/spring. Solomon *et al.* (1986) specifically proposed that the reaction of HCl and $ClONO_2$ on polar stratospheric clouds (PSCs) would convert the temporary chlorine reservoir species (i.e., HCl and $ClONO_2$) into active ClO_x radicals, capable of destroying O_3 (*see* Aerosols, Polar Stratospheric Cloud, Volume 1; Aerosols, Stratosphere,

Volume 1; Depletion of Stratospheric Ozone, Volume 1):

$$HCl(ads) + ClONO_2(g) \longrightarrow Cl_2(g) + HNO_3(ads) \quad (20)$$

In Equation (20), HCl is adsorbed (ads) on the surface of the particle and $ClONO_2$ is in the gas-phase. When a collision occurs between $ClONO_2$ and the HCl adsorbed on the surface of the particle, molecular chlorine (Cl_2) is formed and released into the gas-phase. HNO_3 remains adsorbed on the surface of the particle. This process occurs throughout the winter period under polar night conditions. When sunlight returns in the spring, Cl_2 is photolyzed and the active chlorine is released to destroy O_3. However, as mentioned above, under these conditions, the ClO_x catalytic cycle (Equations 15 and 16) is not efficient, therefore a new catalytic cycle was proposed by Molina and Molina (1987).

$$Cl_2 + h\nu \longrightarrow 2Cl \quad (21)$$

$$Cl + O_3 \longrightarrow ClO + O_2 \text{ (twice)} \quad (22)$$

$$ClO + ClO + M \longrightarrow Cl_2O_2 + M \quad (23)$$

$$Cl_2O_2 + h\nu \longrightarrow Cl + ClOO \quad (24)$$

$$\underline{ClOO + M \longrightarrow Cl + O_2 + M} \quad (25)$$

$$\text{NET: } 2O_3 \longrightarrow 3O_2$$

This set of reactions (Equations 22–25) regenerates atomic chlorine and therefore is catalytic. A similar catalytic cycle has been proposed with BrO_x species. The heterogeneous ClO_x activation process is represented in Figure 4 (see HCl (aq), via $Cl_2 + h\nu$).

One very important consequence of heterogeneous reactions like Equation (20) is that the HNO_3 remaining on the particle will eventually settle with the particle and the stratosphere will become denitrified. Denitrification (i.e., loss of $NO_y = NO_x + HNO_3$) will tend to promote O_3 depletion by keeping the NO_x abundance low. If NO_x is low, the ClO_x and BrO_x radicals responsible for O_3 depletion cannot readily reform the temporary reservoir species $ClONO_2$ and $BrONO_2$, therefore extending the O_3 loss from catalytic cycles like Equation (22) through Equation (25).

$$ClO + NO_2 + M \longrightarrow ClONO_2 + M \quad (26)$$

$$BrO + NO_2 + M \longrightarrow BrONO_2 + M \quad (27)$$

There are additional heterogeneous reaction pathways similar to Equation (20) that deplete reservoir species (e.g., $ClONO_2$, $BrONO_2$, HOBr, HOCl, and HCl) and activate both ClO_x and BrO_x radicals. These reactions can occur not only on PSCs composed of water-ice aerosols, but also on PSCs that are composed of solid nitric acid and liquid sulfuric acid aerosols (*see* Aerosols, Polar Stratospheric Cloud, Volume 1; Depletion of Stratospheric Ozone, Volume 1; Aerosols, Stratosphere, Volume 1).

Shortly after the discovery of the Antarctic O_3 hole, Hofmann and Solomon (1989) proposed that heterogeneous chemical processes occur not only at high-latitudes during polar winter/spring, but also at mid-latitudes in the lower stratosphere throughout the year. These heterogeneous processes typically occur on liquid sulfate aerosols (*see* Aerosols, Stratosphere, Volume 1).

Sulfate aerosols are formed in the stratosphere primarily from oxidation of carbonyl sulfide (COS). At temperatures above approximately 200 K, sulfate aerosols are composed of a binary mixture of sulfuric acid (H_2SO_4) and H_2O. As the temperature decreases, uptake of HNO_3 occurs, forming a ternary solution of H_2SO_4, HNO_3, and H_2O. One of the most important heterogeneous reactions on the surface of liquid sulfate aerosols (at mid-latitudes) is the reaction of dinitrogen pentoxide (N_2O_5) with H_2O. As shown in Figure 3, N_2O_5 is a temporary reservoir species for NO_x and is formed from the three-body reaction of NO_2 and nitrogen trioxide (NO_3).

$$NO_2 + NO_3 + M \longrightarrow N_2O_5 + M \quad (28)$$

$$N_2O_5 + H_2O \text{ (aq)} \longrightarrow 2HNO_3 \quad (29)$$

Equation (29) will convert N_2O_5, a temporary NO_x reservoir, into HNO_3, effectively reducing the importance of the NO_x catalytic cycle on O_3 loss (Equations 10 and 11). Since the HO_x, NO_x, ClO_x, and BrO_x O_3 loss processes are tightly coupled, reducing the importance of the NO_x catalytic cycle increases the importance of the other O_3 depleting catalytic cycles. In fact, increased mid-latitude O_3 depletion is exacerbated following large volcanic eruptions (e.g., the recent eruptions of El Chichon and Mt. Pinatubo) that introduce sulfur dioxide (SO_2) gas into the stratosphere. The SO_2 is oxidized to form liquid sulfate aerosol, increasing the surface area density and therefore, increasing the rate of O_3 depletion by heterogeneous reactions (*see* Depletion of Stratospheric Ozone, Volume 1; Volcanic Eruptions, Volume 1; Volcanic Eruption, El Chichón, Volume 1; Volcanic Eruption, Mt. Pinatubo, Volume 1).

Additional reading on the history and theory of heterogeneous chemical processes that affect stratospheric O_3 abundance can be found in World Meteorological Organization (WMO) (1999); Brasseur *et al.* (1999); Solomon (1999); and Finlayson-Pitts and Pitts (2000).

PROSPECTS FOR THE 21st CENTURY

Future stratospheric research will be conducted within the context of the Earth system and its response to natural and anthropogenic-induced changes. The physical, dynamical, and chemical couplings between the different regions of the atmosphere (i.e., troposphere, stratosphere, mesosphere, and thermosphere), the ocean, and the biosphere need to be better understood in order to assess the impact

of natural and anthropogenic influences on stratospheric chemistry and climate in the 21st century (*see* Earth System Processes, Volume 1).

New observational platforms (e.g., satellite-based instruments) will be developed and launched to study global change. These satellite-based measurements will be compared with ground-based and *in situ* measurements from balloons and aircraft. These data will be used to evaluate Earth system models (ESMs) that attempt to represent the above-mentioned components of the Earth s system. In turn, these ESMs will be used to assess the impacts of future anthropogenic emissions on atmospheric composition of not only stratospheric O_3, but also the climate impacts that changes in stratospheric O_3 may induce.

One of the most important environmental issues to address in the 21st century will be the future change in the stratospheric O_3 layer. Will the magnitude of the Antarctic O_3 hole depletion increase? Will the temporal and spatial area of the observed O_3 depletion increase? Will a similar decrease in O_3 occur in the Arctic? When (if ever) will stratospheric O_3 return to natural abundances? How will the increase in greenhouse gas abundances influence stratospheric chemistry and climate? These questions are currently at the forefront of scientific research related to the stratosphere (*see* Arctic Climate, Volume 1; Depletion of Stratospheric Ozone, Volume 1).

Since the days of Priestly, Schelle, and Schonbein, there have been great advances in our understanding of stratospheric chemistry and the role that the stratosphere plays in global chemistry and climate. As in the past, there most likely will be many surprises in store for researchers in the 21st century.

Stratosphere, Ozone Trends

Rumen D Bojkov

World Meteorological Organization, Geneva, Switzerland

Results from more than 40 years of continuous observations, laboratory experiments, and modeling studies have led to a scienti c consensus regarding the fragile state of the stratospheric ozone layer. Starting in the 1970s, a stratospheric ozone decrease has been observed, and it is continuing at variable rates. In general, the decrease is twice as strong in the winter and spring (>5% per decade decrease) as during the summer and autumn. The ozone decrease is most extensive over the Antarctic, especially during September to November (>20% per decade decrease). Over the Northern Hemisphere mid- and polar latitudes, the ozone decline is also quite pronounced, especially during the cold winter- spring seasons of the 1990s. Only the equatorial belt (20°S- 20°N) is experiencing no signi cant changes. Although tropospheric ozone has increased, especially over the Northern Hemisphere mid-latitudes, this increase cannot compensate for the large decline in stratospheric ozone and the resulting increase in ultraviolet (UV) radiation at the surface.

Theoretical, experimental, and observational studies all con rm that the multi-decade stratospheric ozone depletion is related to increased human-induced emissions of chlorine- and bromine-containing compounds such as chloro uorocarbons (CFCs) and halocarbons. Low ozone values observed over short time periods are also in uenced

by atmospheric circulation processes. In addition to their effect on UV-radiation, the ozone changes contribute to radiative forcing of the climate comparable to other minor greenhouse gases. With the very cold lower stratospheric temperatures that are characteristic of springtime in both the Arctic and Antarctic, the ampli ed losses of ozone in polar and mid-latitudes are likely to persist until the overall stratospheric chlorine loading decreases to below ~3 parts per billion by volume (ppbv). A recovery of the global ozone layer to its pre 1970s conditions is not expected to occur until after ~2050, when the chlorine loading is expected to fall below 2 ppbv. This will only occur if all countries strictly adhere to the Montreal Protocol requirements for phasing out ozone-depleting compounds.

INTRODUCTION

A German physicist (C F Schonbein) discovered ozone when observing electrical discharges at the University of Basel in 1839, but it was not until after 1850 that it was determined to be a natural atmospheric constituent. The word *ozone* comes from the Greek word meaning smell, a reference to ozone s distinctively pungent odor when present in large concentrations. Surface ozone measurements were made at hundreds of places during the second half of 19th century. However, total column ozone measurements were initiated only at the end of 1920s using a few Dobson spectrophotometers. Only starting in the 1960s has their number exceeded 100.

Ozone (O_3) is a form of the element oxygen (O) that has three atoms in each molecule instead of the two atoms making up normal oxygen molecules (O_2). In the atmosphere, most ozone is formed in the tropical middle stratosphere by the action of solar radiation on oxygen molecules in a process called photolysis. In this process, O_2 molecules are broken down to yield atomic oxygen, which in turn combines with molecular oxygen to produce ozone. Ozone is then transported at stratospheric levels from the tropics to higher latitudes and then downward to the lower stratosphere. In the lower stratosphere, the ozone lifetime is ~1 year. Ozone is destroyed naturally through a series of catalytic cycles involving reactive nitrogen (NO_y), chlorine, bromine and hydrogen species (HO_x) (*see* Stratosphere, Chemistry, Volume 1; Stratosphere, Temperature and Circulation, Volume 1).

The stratosphere (extending ~10–50 km above the Earth s surface) contains ~90% of all the ozone in the atmosphere. The ozone molecules are concentrated mainly between altitudes of 15–35 km. Looking up through the atmosphere, the ozone column has its maximum partial pressure in the lower stratosphere at a level of 19–23 km above the surface. The balance between photolytic production, transport, and chemical destruction determines the abundance of ozone at any particular stratospheric location. This balance is also strongly seasonally dependent, having a maximum in the middle and polar latitudes in the winter-spring and a minimum in the autumn.

Ninety-nine per cent of the air we breathe is nitrogen (78%) and oxygen (21%). This ratio has not changed for millions of years. On average, trace components such as water vapor, carbon dioxide, methane, nitrous oxide, ozone and inert gases (e.g., argon, helium, neon) make up less than 1% of the volume of air. Although concentrations vary widely throughout the atmosphere, on average, only three of every 10 million molecules of air are ozone molecules.

Total ozone is a measure of the amount of ozone contained in a vertical column of air reaching from the surface up through the whole atmosphere. Total ozone is expressed in units of pressure (milli-atmosphere centimeters, or matm-cm), being the depth the ozone layer would be at standard pressure and temperature. If all the ozone in the atmosphere were moved toward the Earth s surface to calculate the total ozone, it would, averaged around the world, assume a thickness of about 3 mm (300 matm-cm). Except when the ozone hole is present (see herein), the lowest monthly mean values of total ozone typically occur over the equatorial belt (~220 matm-cm) and the amount increases toward the poles. The maximum monthly mean value that is observed reaches ~480 matm-cm in the Northern Hemisphere. These variations in total ozone at any particular place are mainly determined by the interplay between large-scale atmospheric dynamics and atmospheric chemistry.

Although only present at exceedingly low concentrations, ozone molecules play a vital role in the life of our planet. Of most importance, the stratospheric ozone layer normally absorbs virtually all of the highly energetic solar UV radiation (i.e., radiation having wavelengths below about 320 nm that can cause sunburn and skin cancer), thereby providing an important shield that protects humans and all other animals and plants. Ozone also largely determines the thermal structure of the stratosphere (10–50 km) where temperature increases with height, and, by absorbing infrared radiation, ozone serves to enhance the Earth s greenhouse effect.

Since the early 1970s, ozone, as an atmospheric trace gas, has gone from being of interest only to a small group of scientists to an issue of global prominence. This leap occurred because it was determined that the normal concentration of atmospheric ozone is under attack from chemicals released by human activities (*see* Depletion of Stratospheric Ozone, Volume 1). The Nobel Prize in Chemistry for 1995 was given to three ozone researchers for their contributions in working out the chemical destruction mechanisms (*see* Crutzen, Paul J, Volume 1; Molina, Mario J, Volume 1; Rowland, F Sherwood, Volume 1).

The ozone decline that these scientists projected was detected from data collected by the World Meteorological Organization s (WMO) Global Ozone Observing System,

which has operated more than 150 stations around the world since the mid-1950s. In the last 20 years, ozone depletion has also been detected from a few specialized satellites. In the mid-1980s, evidence of ozone destruction also became evident as a result of identification of the dramatic ozone decline in the Antarctic spring, popularly labeled the ozone hole.

That these downward trends in total ozone were due to human factors has also been established. Because stratospheric ozone is primarily created by UV radiation, the Sun s output affects the rate at which it is produced. Indeed, the Sun s energy release in the UV part of the spectrum varies significantly over the well-known 11-year sunspot cycle (*see* Solar Variability, Long-term, Volume 1; Sunspots, Volume 1). Observations over several solar cycles since the 1950s show that total global ozone levels decrease by 1–2% from the maximum to the minimum of a typical solar cycle. The long-term ozone decline observed during the last two decades, however, has been much greater than this, making clear that this decline cannot be due to changes in solar activity.

Based on more than 25 years of research by scientists from around the world, including laboratory studies, field measurements and theoretical investigations, a strong link has been clearly established between human-made compounds and these ozone losses. Even as the Sun s energy produces new ozone in the upper stratosphere, natural compounds containing oxygen, nitrogen, hydrogen and chlorine or bromine continuously destroy ozone molecules. Such chemicals were all present in the stratosphere in small amounts long before humans began altering the composition of the atmosphere. Nitrogen compounds come from soils and the oceans, hydrogen comes mainly from atmospheric water vapor and some chlorine comes from the oceans in the form of methyl chloride and methyl bromide. However, human activities have significantly upset the delicate balance of production and destruction. By releasing relatively large amounts of chlorine- and bromine-containing chemicals (e.g., *see* Chloro uorocarbons (CFCs), Volume 1; Halocarbons, Volume 1) into the atmosphere, societal activities have enhanced the destruction of ozone, leading to lower ozone concentrations in the stratosphere.

It was on the basis of this information, summarized and evaluated in a series of WMO Ozone Assessment Reports (see references), that countries agreed to the first environmental Convention for the Protection of the Ozone Layer (Vienna, 1985) and its Montreal Protocol (1987) (*see* Ozone Layer: Vienna Convention and the Montreal Protocol, Volume 4). Their implementation represents an environmental success story. The countries took action to halt and then reverse an emerging problem. Results of these treaties provide a model for further international action against global threats to the environment. The action to defend the ozone layer will rank as one of the great international achievements of the 20th century. There are still some uncertainties regarding the future of the ozone layer. For example, its recovery in the next 50–60 years depends on the ability of nations to comply with international agreements and curb emissions of substances containing chlorine and bromine that deplete stratospheric ozone.

The opposite process is occurring in the troposphere, which is the lower part of the atmosphere extending up to 10–14 km. Here, mainly as a result of combustion processes, the local concentrations of ozone in the Northern Hemisphere mid-latitudes have nearly tripled in the last 100 years (*see* Troposphere, Ozone Chemistry, Volume 1). This tropospheric ozone increase, however, cannot compensate for the effects of the decline in stratospheric ozone on UV radiation, although the changes could influence the radiative balance of the surface-atmosphere system.

OBSERVED CHANGES IN THE GLOBAL OZONE

The ozone concentration varies over many time and space scales. A major component of the global ozone variation is its annual cycle. Total ozone in the polar and mid-latitudes reaches its annual maximum in the winter–spring and minimum in the autumn months. In the pre-1976 period, the annual peak to trough differences were ∼180 and ∼145 matm-cm in the polar and mid-latitude regions, respectively. Since about 1985, these peak to trough differences have decreased by 15–20%, due mainly to the decline of total ozone during the period of the ozone annual maximum.

In addition to the annual cycle, the natural variability of atmospheric ozone is evident over a broad spectrum of time scales, from day to day and month to month, to interannual and interdecadal. Atmospheric circulation, chemistry and radiative processes all play important roles in this ozone variability. For example, the amplitude of synoptic-scale (i.e., weather-driven) variations can be ∼30% of the monthly mean over polar and mid-latitudes. This compares to the peak to peak amplitude of the annual cycle at particular latitudes ranging from less than 6% in the equatorial and tropical belts to ∼30% at sub-polar latitudes.

At longer time scales, a number of factors contribute to the variability. For example, the quasi-biennial oscillation (QBO) (*see* Quasi- Biennial Oscillation (QBO), Volume 1) contributes to interannual variability. The amplitude of the QBO-induced variation ranges from 3 to 7–8%, depending on latitude. Variations in solar activity over the 11-year sunspot cycle are observed to range between 1 and 2%. Large volcanic eruptions reaching the stratosphere also can cause temporary reductions in the average ozone loading of from 2% at low latitudes up to 4–5% over high latitudes in winter.

In addition to the natural variations, the comprehensive international ozone assessment reports sponsored by the WMO, which are based on extensive sets of papers analyzing ground station observations and satellite radiances, all note that total ozone has been decreasing significantly in mid- and polar latitude regions over the last 20–25 years. Only in the equatorial belt (20 °S to 20 °N) are the trends not statistically significant.

Based on ground-based and satellite observations, Figure 1 shows the estimated annual cycle of average monthly means for two different periods. The years 1964 to 1976 are taken as the base period. During these years, the concentrations of anthropogenic compounds that led to the destruction of ozone were quite low and no systematic ozone trends were noticed. The later period of 1986–1999, however, was the time of maximum emission of CFCs and halocarbons. The annual cycle for the base period has two maxima, corresponding to the time of the Northern Hemisphere spring ozone increase in March–April and to the maximum reached in September–October in most of the Southern Hemisphere. The overall average total ozone for the globe was ∼307 matm-cm, with more in the Northern Hemisphere than in the Southern Hemisphere by ∼4%.

Data for the last 14 years show very significant ozone destruction. The depletion is concentrated during the austral spring and during the winter–spring period in northern latitudes. These changes have substantially altered the amount of ozone and the shape of the annual cycle. In the 1986–1999 period, the average global ozone amount declined to ∼296 matm-cm. The secondary maximum in September–November has disappeared due to the drastic ozone decline over Antarctica during these months.

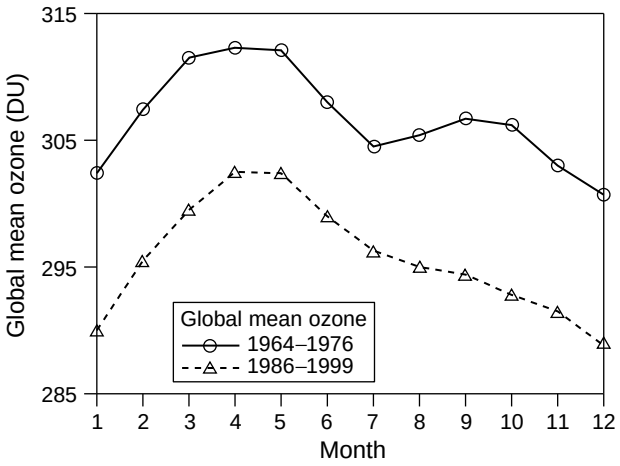

Figure 1 Monthly global average ozone values (in Dobson units, DU) for two periods show substantial overall decline during the latter years. (Updated from Bojkov, WMO, 1999)

Although there has been relatively little change over equatorial regions, the overall ozone decline for the rest of the globe between these two periods was greater than 3.5%.

Figure 2 shows total ozone mapping spectrometer (TOMS) instrument satellite data indicating the change in total ozone for 60 °N–60 °S, adjusted for seasonal, QBO and solar influences. The linear trend prior to May 1991 is −2.3% per decade. The strong, nearly linear, decrease in total ozone throughout the early 1990s is followed by a sudden decrease in 1992–1993, possibly related to effects of the Mt Pinatubo eruption (*see* Volcanic Eruption, Mt.

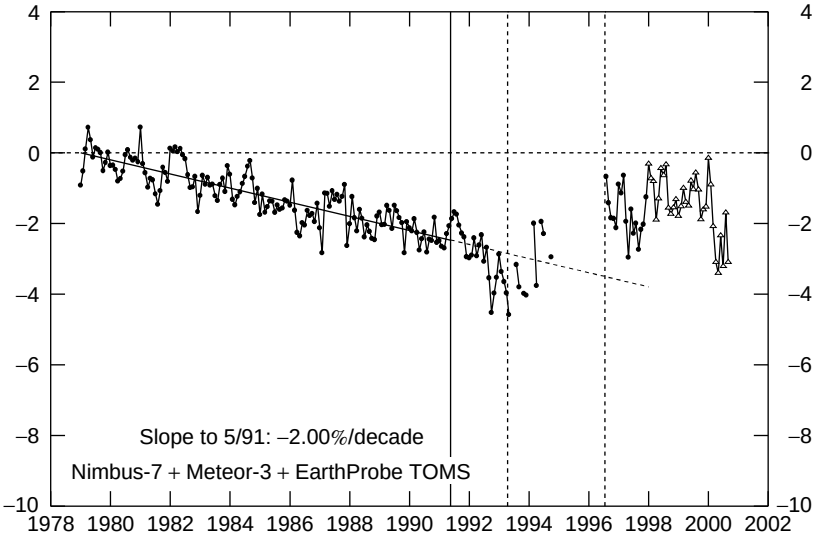

Figure 2 Deviations in total ozone, area weighted over 60 °S–60 °N adjusted for seasonal, QBO and solar effects. Straight line is the least squares fit. (*Source:* WMO Assessment-98, updated to 30 September 2000 by L Bishop)

Pinatubo, Volume 1). Thereafter, the trend is no longer a linear extension from the previous period, but is leveling off. However, this apparent leveling off may be an artifact because reliable ground station data indicate that the preliminary data from the TOMS instrument on the Earth Probe satellite that are available since September 1996 are showing ~1–1.5% higher values than the ground station data. Some unusually warm Arctic winters also contributed to the appearance of higher ozone in 1998 and 1999. In addition, it is also possible that the long-term influence of changes in solar radiation is not represented well enough in the statistical model, and so this may account for some of the leveling off. It should be noted that this reduction of the downward trend should not be interpreted as a recovery of the ozone layer.

In both hemispheres, the negative ozone trends are stronger during the winter–spring seasons than during the summer–autumn seasons. The calculated annual average trend for the period 1979–2000 (in % decade^{-1}) for the latitude band 35–65 °N is roughly constant at ~−2.4% decade^{-1}. In the southern latitudes, there is a significant difference between the trends in the bands 35–50 °S and 50–65 °S, with values of ~−1.7 and −4.1% decade^{-1}, respectively. If one considers also the stronger ozone decline in the polar regions, the ozone amount outside the tropics is estimated to be 6–8% less than it was about 25 years ago.

Observations, experiments and model simulations confirm that chlorine- and bromine-activated heterogeneous reactions in the stratosphere are responsible for the main part of the observed ozone destruction. However, parts of the low ozone and its fluctuations are related to variations in the atmospheric circulation wave activity. During the past two decades, ozone has been varying in unison with the fluctuations in the lower stratospheric temperatures. Much of the interannual and seasonal variations in both ozone and temperature are related to the specifics of the atmospheric circulation, and were present before the anthropogenic influence started to dominate the ozone decline. In particular, changes in the upwelling planetary wave activity from the troposphere that enters the stratosphere have the effect of modulating the diabatic circulation and thus the ozone transport. These effects are considered to play an important role in the persistence of the Arctic vortex, in determining springtime stratospheric temperatures in polar regions, and in interannual ozone variations.

The chemical processes leading to ozone depletion can be summarized in terms of a relatively few chemical reactions (*see* Depletion of Stratospheric Ozone, Volume 1). The depletion of ozone in the polar lower stratosphere is due to a sequence of chemical reactions that starts with the conversion of halogen-containing (chlorine and bromine) gases with long lifetimes into less stable reservoir forms. The reservoirs of chlorine are hydrochloric acid (HCl) and chlorine nitrate ($ClONO_2$). Dinitrogen pentoxide (N_2O_5) and nitric acid (HNO_3) are reservoirs of nitrogen oxides. The Cl-containing reservoirs are then broken down by reactions involving polar stratospheric clouds (PSCs) to release high concentrations of reactive chlorine and chlorine monoxide radicals (Cl and ClO). These in turn contribute to catalytic cycles that can destroy ozone very rapidly in the presence of sunlight.

Laboratory experiments suggest that the most important reactions are:

$$HCl + ClONO_2 \longrightarrow HNO_3 + Cl_2 \quad (1)$$

$$ClONO_2 + H_2O \longrightarrow HNO_3 + HOCl \quad (2)$$

$$HCl + HOCl \longrightarrow H_2O + Cl_2 \quad (3)$$

$$N_2O_5 + H_2O \longrightarrow 2HNO_3 \quad (4)$$

Particles that support heterogeneous reactions exist throughout the lower stratosphere (e.g., sulfate aerosol particles, sulfur dioxide). The reactions involving chlorine species are temperature dependent and become much more efficient on liquid PSCs in the cold (<−78 °C) polar lower stratosphere. Furthermore, at mid-latitudes aerosol reactions can also perturb the chemistry, especially when large amounts of aerosol are inserted by a large volcanic eruption.

Following the heterogeneous production of active chlorine, sunlight can drive the following catalytic cycles in the polar region:

(I) $ClO + ClO + M \longrightarrow Cl_2O_2 + M$

$Cl_2O_2 + h\nu \longrightarrow Cl + ClO_2$

$ClO_2 + M \longrightarrow Cl + O_2 + M$

$2 \times (Cl + O_3 \longrightarrow ClO + O_2)$

net: $2O_3 \longrightarrow 3O_2$

(II) $ClO + BrO \longrightarrow Br + Cl + O_2$

$Cl + O_3 \longrightarrow ClO + O_2$

$Br + O_3 \longrightarrow BrO + O_2$

net: $2O_3 \longrightarrow 3O_2$

The dimer of the ClO radical (Cl_2O_2) involved in cycle I is thermally unstable, and the cycle is most effective at low temperatures. It is thought to be responsible for most of the ozone loss in Antarctica, with a large contribution from cycle II involving reactive bromine. In the warmer Arctic, a larger proportion of the loss may be driven by cycle II. In the mid-latitude lower stratosphere, the coupled ClO + BrO (Cycle II) and $BrO + HO_2$ cycles are responsible for increased halogen-induced chemical depletion.

The roles of these reactions are coupled to the climatic conditions in each hemisphere. The next two sections cover the effects in the Northern and the Southern Hemisphere. Although much attention is devoted to the ozone hole in the Southern Hemisphere, the changes in the Northern Hemisphere may well emerge as most important for society in the 21st century, so that is covered here first (see Box 1).

OZONE DECLINE IN THE NORTHERN HEMISPHERE

In the mid-latitudes in general, the natural day to day variations of ozone amounts are seldom greater than 10% of the mean. The changes vary from day to day and are regionally distributed as a function of meteorological conditions. The variations increase toward the polar latitudes. Therefore, one indication of ozone decline would be if the surface area covered with deviations of greater than -10% from the pre-1976 mean (i.e., areas experiencing $>10\%$ depletion) is increasing.

Figure 3 shows the fraction of the entire surface poleward from $35\,^{\circ}$N with contours greater than $+10\%$ and -10% ozone deviations occurring during the winter–spring period. It is clear that the area of the negative deviations has grown from $\sim$15% in the beginning of 1980s to $>$45% in the last 11 years, an increase of a factor of three. The highest fractions of $>70\%$ correspond to major ozone declines in 1993 and 1995. Over the same period, the fraction of the area covered by positive deviations of greater than $+10\%$ has declined from $\sim$15% to $\sim$5%.

Figure 4 shows the total ozone data from a dozen European and North American stations having long-term observations, smoothed to generate a 12-month running mean. The underlying decline from the 1970s to the early 1990s is modulated by large, sawtooth-like variations over time scales of every two to two and a half years that are related to the QBO (*see* Quasi- Biennial Oscillation (QBO), Volume 1). The QBO oscillations are best expressed in the periodic easterly to westerly changes of stratospheric winds in the equatorial belt. The QBO modulates the diabatic circulation, which is accompanied by a similar modulation

Box 1 State of the Ozone Layer – 2000

- The total abundance of ozone-depleting compounds in the troposphere peaked in about 1994 at about 3.7 parts per billion by volume and is now starting to decline slowly, indicating that the measures formulated by the Montreal Protocol are having an effect. Total bromine, however, is still increasing. The combined abundance of chlorine and bromine in the stratosphere peaked around the year 2000 and is expected to remain high for the next decade or two.
- The observed total column ozone losses for Northern Hemisphere mid-latitudes from the mid-1970s to 1998–1999 are close to 7% in winter–spring and $\sim$3% in summer–autumn. Year-round losses in the Southern Hemisphere mid-latitudes are less than 5%. The strongest rate of decline in stratospheric ozone at mid-latitudes has been during 1985–1995. Some of the higher ozone values observed in the northern latitudes in 1998 and 1999 winter–spring periods were related to an intensified transport of sub-tropical air that had a low ozone concentration. However, in the spring of 2000, the ozone chemical destruction in the European sector of Arctic and adjacent middle latitudes reached nearly 60% at 18 km altitude. There are no statistically significant trends in total ozone in the equatorial region ($20\,^{\circ}$S to $20\,^{\circ}$N).
- In the Arctic, late winter-spring ozone values were unusually low in seven out of the last 11 years (since 1990). The seven years were unusually cold and this led to protracted stratospheric winters with minimum Arctic vortex temperatures near the threshold for large chlorine activation. Ozone has declined during some spring months by 25–30% below the pre-1976 average. For short-periods, declines of 200 matm-cm (a decrease of 45%) were registered. Continued presence of an elevated stratospheric halogen abundance over the next decade or two in conditions of low stratospheric temperatures would imply the Arctic's continuing vulnerability to very large ozone losses.
- Above Northern Hemisphere mid-latitudes, the downward trend is largest near 40 km and 15 km ($>$7% per decade) and is smallest at 30 km (2% per decade). The bulk of the column ozone decline is between the tropopause and $\sim$24 km.
- The springtime Antarctic ozone hole continues unabated. Although the extent of ozone depletion was strongest in 1998, the depletion has, during the last 3–4 years, remained generally similar to depletions in the early 1990s, with monthly total ozone in September and October continuing to be 40–55% below the pre-ozone hole values. The austral spring of 2000 did show an early (in late August–early September) record ozone decline. However, due to an early polar vortex breakdown (in the beginning of November), the seasonal deficiency was not the strongest.
- Field studies show that anthropogenic emissions of ozone precursors (nitrogen oxides, carbon monoxide and hydrocarbons) lead to large-scale production of ozone in the troposphere. Through long-range transport, these emissions influence the ozone concentration in large regions of the troposphere in both hemispheres. Trends in tropospheric ozone since 1970 in the Northern Hemisphere show large regional differences, with increases over Europe and Japan, decreases over Canada, and only small changes over the US. In the Southern Hemisphere, small increases have now been observed in surface ozone.

Box 1 (*continued*)

- The inverse dependence between the decline of overhead amount of ozone by 1% causing about similar increase of surface UV radiation, has been further quantified, but this ratio is strongly dependent on the presence of clouds, particles and surface reflectivity.
- Stratospheric ozone losses have caused a cooling of the global lower stratosphere and contributed to a negative radiative forcing to the climate system. Much of the observed downward trend in lower stratospheric temperatures (more than 0.6 °C per decade from 1979–1999) is attributed to the ozone loss in the lower stratosphere. The stratospheric ozone losses since 1980 may have offset about 30% of the positive forcing caused by increases in the well-mixed greenhouse gases (i.e., carbon dioxide, methane, nitrous oxide and the halocarbons) over the same time period.
- The increase of ozone in the troposphere since preindustrial times is estimated to have augmented the average radiative forcing by $+0.35\,W\,m^{-2}$, which is thought to have contributed 10–20% of the warming attributed to the increase in radiative forcing of long-lived greenhouse gases during the same period.
- The most vulnerable period for ozone depletion will be the next decade or two. Evidence for the recovery of the ozone layer lies still further off. Because of the slow rate at which natural processes remove these compounds from the stratosphere, the drop in total chlorine and bromine abundances in the stratosphere in the 21st century will be much slower than the rate of increase observed in past decades. Thus, because of natural ozone variability and changing atmospheric conditions, unambiguous detection of the recovery of the ozone layer may not be possible for perhaps another 20 years.
- The issues of ozone depletion and climate change are interconnected. Changes in ozone affect the Earth's climate, and changes in climate and meteorological conditions affect the ozone layer. This is the case because the ozone depletion and climate change phenomena share a number of common physical and chemical processes. Stratospheric cooling caused by increased concentrations of greenhouse gases could prolong the period for ozone recovery well beyond the middle of this century.

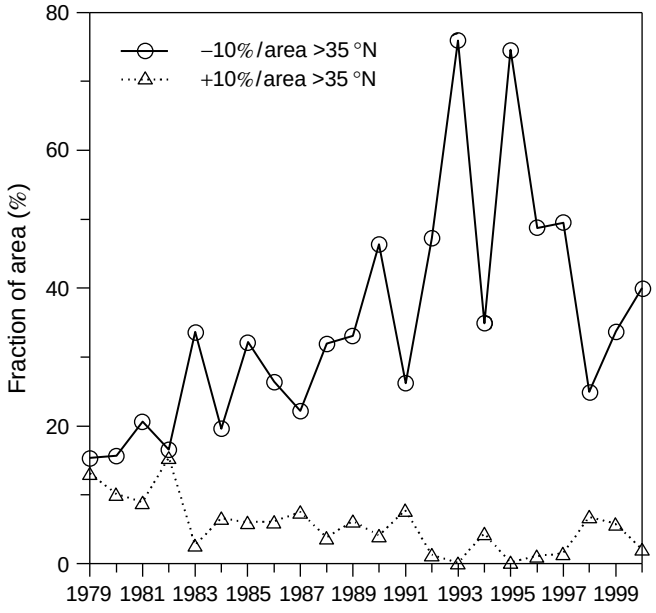

Figure 3 The fraction of the −10 and +10% contours surface area from the entire hemisphere poleward of 35 °N, during 1 January–15 April of each year since 1979 (updated from Bojkov, WMO, 1999)

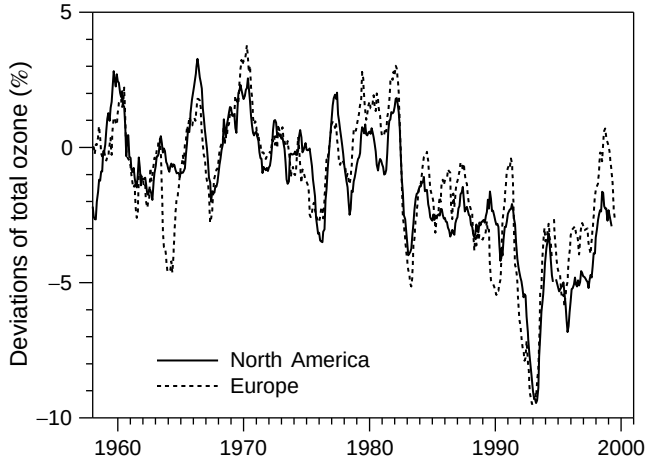

Figure 4 The deviations (in % from the pre-1976 average) of the total ozone measured at the European and North American stations (40–64 °N) with long-term observations, smoothed by a 12-month running mean. A substantial decline of the ozone column starting in the 1970s and major fluctuations during the years are obvious

of the ozone transport poleward. The QBO-induced changes in the planetary waves cause the appearance of a more disturbed and warmer polar vortex that exhibits higher ozone during the easterly phase of the equatorial winds than during the time of westerly phase. These ozone variations in middle and polar latitudes can be 3–7%. Detailed analyses of the long-term ozone records also show a solar signal of up to 2% per solar cycle. Slightly higher ozone values have been detected at the time of the solar spot maximums (about 1958, 1969, 1980, 1991 and 2000).

The behavior of the ozone deviations since the deep decline in the early 1990s has been somewhat different. Although there continues to be winter–spring ozone

destruction, the 12-month smoothed mean ozone values have been variable around a fairly constant level. There is even an indication of an increase in 1998 and 1999 followed by a substantial decrease in early 2000 (not shown on the plot).

In addition to the significant ozone decline in the last few decades, of particular interest is the variability of the ozone amount from year to year, and appearances of periods with major ozone deficiencies (sometimes >25%) that last for number of weeks over the Northern Hemisphere mid- and polar latitudes. Figure 5 shows the evolution of the total ozone area-averaged departures from the pre-1976 averages occurring during December–January–February–March (winter–spring season) over North America, Europe and Siberia during 1975–2000. Negative deviations exceeding two standard deviations for the seasonal mean have occurred in seven of the last 11 years. The major deviations in 1983 and 1992–1993 are after major volcanic eruptions (El-Chichón in 1982 and Mt Pinatubo in 1991), each of which introduced aerosols into the stratosphere that facilitated chemical destruction. However, the atmospheric circulation during the westerly phase of QBO also contributed to the low ozone levels in these winter–spring periods. QBO was also a contributing factor to the low ozone values in 1995.

Differences in the strength of the ozone departures also exist between the three continental-scale regions of the Northern Hemisphere. These relate mainly to the position and state of the Arctic stratospheric vortex. Its position is influenced by the planetary wave structures, which also modulate the circulation and resulting upwelling of air from the troposphere. In most of the springs with major negative deviations, the Arctic vortex was very strong and the lower stratospheric temperatures fell below −76 °C. Such low temperatures generate PSCs and facilitate ozone destructive reactions. From late February through early March 1996, there is evidence from UARS-HALOE satellite measurements, for example, that cold chemically preconditioned air, known to have excess ClO content, moved over the sunlit latitudes where some of the highest ozone destruction (>100 matm-cm) has been detected.

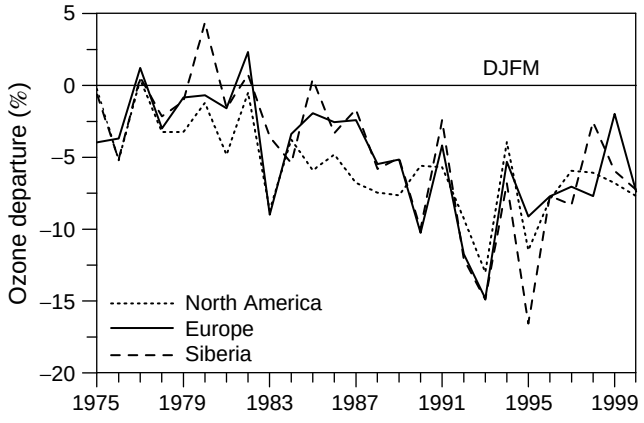

Figure 5 Total ozone departures (% from the pre-1976 average) from Dec–Jan–Feb–Mar over North America, Europe and Siberia in the 45–65 °N belt during 1975–2000. Two standard deviations of the seasonal mean is ∼6%. (Updated from 4–20 of the WMO Ozone Assessment-98)

During most of the winter–springs of the 1990s, the vortex was tilted from the central Arctic toward Siberia, frequently reaching upper middle latitudes where the solar exposure was significant enough to trigger ozone destruction even over adjacent areas. This is the main reason that the four-month averaged deviations over Siberia exceed those over the other regions. For a large number of days in 1995 and 1997, the negative ozone deviations there reached 35–40%. The regional deviations during 1990, 1995 and 1997, which exceeded 10% for the entire 4-month season, as shown in Figure 5, suggest that the presence of volcanic aerosols (as in 1992 and 1993) is not the only reason for the appearance of record low ozone values. Recent studies have demonstrated that the appearance of low ozone values, particularly over the Northern Hemisphere mid-latitudes, is related to the variability of wave activity affecting the stratosphere, changes in diabatic circulation, and transport of ozone-poor air from the sub-tropical latitudes.

The spatial distribution of the mean February–March 1990–2000 total ozone departures (in % from the pre-1976 averages) over the Northern polar and middle latitudes shows that the strongest deviations (i.e., those exceeding 15–20% for the last 12-year period) were observed over the Arctic. However, the strongest deviations were tilted (displaced) toward Siberia and deviations exceeding 10% extended toward northern and central Europe. This shape is mostly due to the location of the polar vortex.

In the Arctic vortex and adjacent areas, ozone loss reached about 100 matm-cm below the pre-1976 averages of 420–450 matm-cm. During the 1990s, extremes lasting a week or so exceeding 200 matm-cm also occurred. International campaigns conducted in the 1990s (AASE, EASOE, SESAME, THESEO, etc.) have estimated cumulative chemical ozone destruction of between 100 and 140 matm-cm during each Arctic winter–spring since 1989, except in 1998 and 1999. In the vortex in the lower stratosphere, ozone mixing ratios as low as ∼1 ppmv were observed in 1995, 1996, 1997 and 2000. In the same seasons, the concentrations of ozone depleting substances were similar to those in the Antarctic spring and, consequently, daily ozone-loss rates of ∼40 ppbv have been observed for short periods of time. The ozone loss at 18 km even reached 60% during the spring of 2000.

During the last 10–15 years, record low ozone values of less than 240 matm-cm were observed for a few days over very large regions in the October–February period. Such major negative ozone deviations are related not only to the

increased chlorine loading in the stratosphere, but also to the unusually low winter–spring temperatures facilitating ozone destruction. The atmospheric circulation causing the injection of subtropical low-ozone content tropospheric air into the lower stratosphere of the middle and polar latitudes also played a role in causing the extremely low ozone values during these short periods. Appearance of such episodes over the European–North Atlantic region has shown some increase occurred during the 1990s. Their occurrence could contribute noticeably to the observed ozone deficiency in mid-latitude ozone levels. However, to clearly distinguish between the relative role of the chemical loss and the atmospheric transport processes has proven to be extremely difficult.

To characterize the ozone changes quantitatively and to be able to objectively compare year to year and region to region variations, it is useful to introduce the concept of ozone mass deficiency (O_3MD). In order to calculate the O_3MD, the deviations from the pre-1976 zonal averages are first determined daily from homogenized satellite data using a $3^\circ \times 5^\circ$ grid. If the deviations are found to be greater than -10% (assumed scale of natural fluctuations $\sim$2 standard deviations of the typical latitudinal mean) and knowing its value in matm-cm, it is a simple matter to determine the respective ozone mass (in megatons, Mt). The daily O_3MD are subsequently integrated over time and/or space to arrive at an estimate of the overall mass deficiency for a given period and/or region.

As already indicated herein, there is a remarkable correlation between the changes in lower stratospheric temperature and in total ozone. Figure 6 shows the O_3MD amounts integrated for the 59 days of February–March period for the northern polar region (60–90 °N) together with the deviations from the pre-1978 average of the 50 hPa temperatures for the last two decades. The integrated O_3MD for February–March is capturing more than 70% of the entire winter–spring ozone deficiency. As can be estimated from Figure 6, the integrated deficiency over the polar region has increased from an average of less than 500 Mt for the early and mid-1980s to greater than 2000 Mt in 1996 and 1997. The increasing strength of the negative deviations of the stratospheric temperatures during the 1990s is also obvious. The interruption of the temperature decline and appearance of a warming in 1998 and 1999 is the main cause of the observed reduction of the strength of the O_3MD. In February–March of 1999, the ozone deficiency was, quite surprisingly, back to its normal pre-1976 level. However, with circulation changes causing a cooler stratosphere and a stronger polar vortex in the spring of 2000, the O_3MD substantially increased to $\sim$1500 Mt.

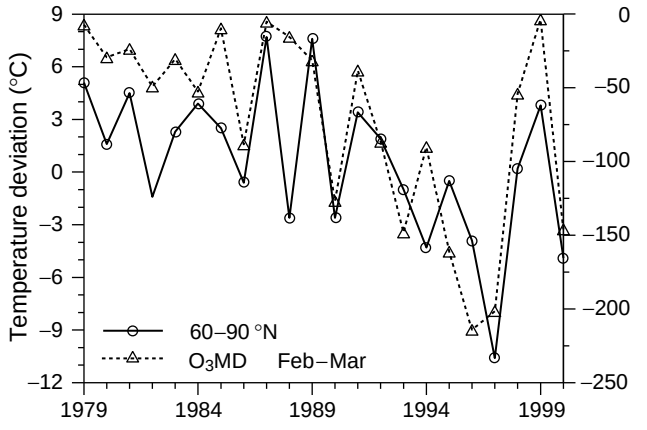

Figure 6 The Feb–Mar 50 hPa temperature deviations from the pre-1978 averages in the polar region (60–90 °N) – continuous line, and integrated for the same months and region O_3MD [Mt] (dashes with triangles) for the period 1979–2000

The O_3MD poleward of 35 °N, integrated for the first 105 days of each year, has increased from $\sim$2800 Mt in the early 1980s to an average of $\sim$7400 Mt in the last 11 years. It should be recalled that the O_3MD in the northern spring times of 1993 and 1995 exceeded 12 000 Mt. This quantity is comparable with the average O_3MD for the last 10 austral springs. Figure 7 shows the distribution of the O_3MD of February–March in three main zones: within the vortex, in the southern part of the middle latitudes (35–45 °N), and in their northern part (45–65 °N). It is clear that the northern belt is contributing in absolute value the largest portion of the O_3MD poleward of 35 °N. The strength of the deficiency in this belt has increased similarly to the intensification seen in the vortex, whereas over the more southern part of the middle latitudes the increase of the O_3MD is marginal. This part of the middle latitudes is also more frequently influenced by tropospheric transport from the sub-tropical belt.

Table 1 indicates the relative (normalized by area) contribution of the different latitudinal belts during the past 11 years. The area poleward of 35 °N is taken as unity, and then the O_3MD values over the three belts, and separately for within the vortex, are considered. The most interesting result is that the contribution to the entire O_3MD poleward of 35 °N, on a per unit basis of the vortex area, is more than four times greater than the contribution of the southern middle latitudes and twice as much as that of the band from 45–65 °N.

With this overview of the total ozone changes in the northern latitudes, it is interesting to examine where the observed ozone has declined in the vertical plane. Figure 8 shows the vertical variation of ozone trends (% per year) for 40–52 °N over the period 1979–1996 calculated from three different measuring systems. A variety of data sets are shown: ground-based data are Dobson/Umkehr measurements (triangles and vertical bars are averages for below 20 km and above 37 km); SAGE I/II satellite sunrise and sunset observations (diamonds); and BUV/2 satellite observations (circles), which are known with less confidence

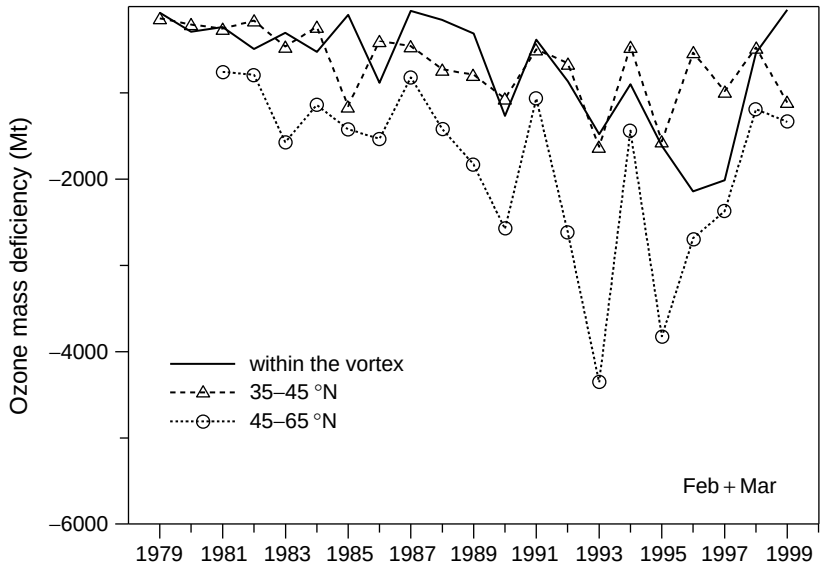

Figure 7 The O_3MD from the pre-1976 averages integrated for 1 Feb–31 Mar within the Arctic vortex and within the −10% deviation contours in the 35–40 °N and 45–65 °N belts during 1979–1999

Table 1 The top row gives the area of selected latitudinal belts as a fraction of the entire area poleward from 35 °N[a]

	Latitudinal domain				
Parameter	North of 35 °N	35–45 °N	45–65 °N	65–90 °N	Northern Hemisphere polar vortex
Area in %	100	33	45	22	variable
O_3MD for 1990–2000 (Mt)	4700	860	2310	1530	1160
O_3MD north of 35 °N (%)	100	18	49	33	25
Relative contribution to change in O_3MD north of 35 °N	1.0	0.5	1.1	1.5	>2.0

[a] The second and third rows give the O_3MD [in Mt] integrated for 105 days (1 January–15 April) within the −10% deviation contours in the specified belts, averaged for 1990–2000, and as % contribution to the entire O_3MD north of 35 °N. The bottom row gives the contribution of a 1% area of each belt (and of the vortex) to the overall O_3MD >35 °N, thereby indicating the relative contribution to the change by latitudinal band.

due to potential drift problems with this satellite. There is good agreement between the independent Umkehr and SAGE I/II measurements. All three systems show a general decline, with statistically significant peak values of −5 to −8% decade^{-1} at 40–45 km and the smallest decline at about 30 km. Balloon ozone-soundings also indicate that there is second maximum of ozone depletion of about −7% decade^{-1} in the lower stratosphere at about 15 km.

STRATOSPHERIC OZONE CHANGES OVER ANTARCTICA

Since the early 1980s, the total ozone over the southern polar region has exhibited significant declines. Each year, starting in the sunlit periphery of the Antarctic in August, but mainly from September through November, there has been a sharp ozone reduction, reaching ~40–50% in the 1990s as compared to its pre-1976 values. A number of field measurement campaigns and analysis programs have confirmed that chlorine-activated heterogeneous reactions in the stratosphere are responsible for the observed ozone destruction. The stratospheric temperature and enriched aerosol content (especially soon after volcanic eruptions reaching the stratosphere, like Mt Pinatubo in 1991) have been identified as key controls over the processes at the current burden of chlorine loading. They determine the extent of the depletion and, together with the dynamics, the overall surface and length of time the ozone hole persists.

Ozone loss is especially strong over the Antarctic because the winter circumpolar vortex prevents extensive air exchange with mid-latitudes. This produces very low stratospheric temperatures (below −80 °C) lasting for months,

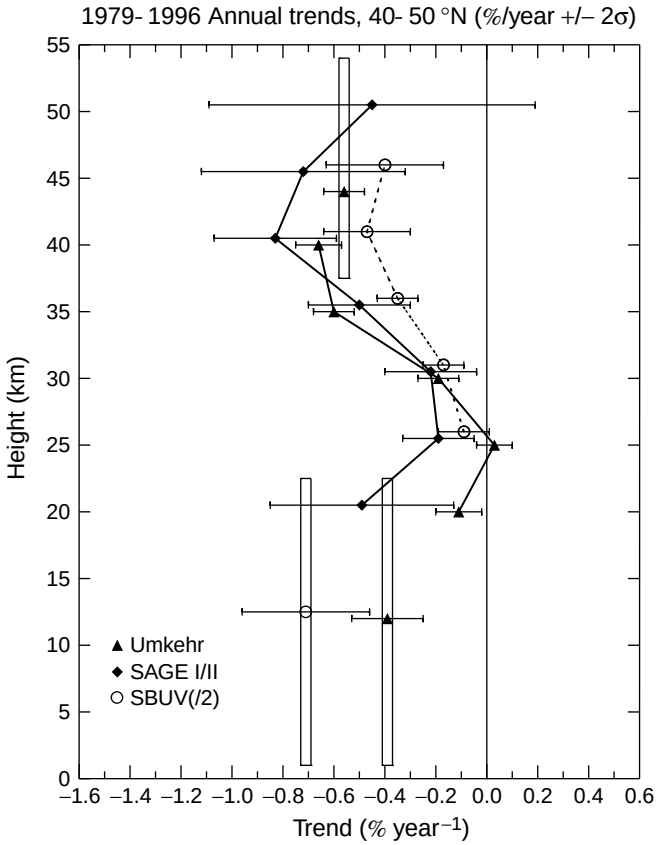

Figure 8 Ozone trends (% year^{-1}) at different altitudes deduced from three independent systems for the 40–52 °N belt over the 1979–1996 period. Horizontal bars show two standard deviations. (*Source:* Figures 4–32 from WMO Ozone Assessment-98)

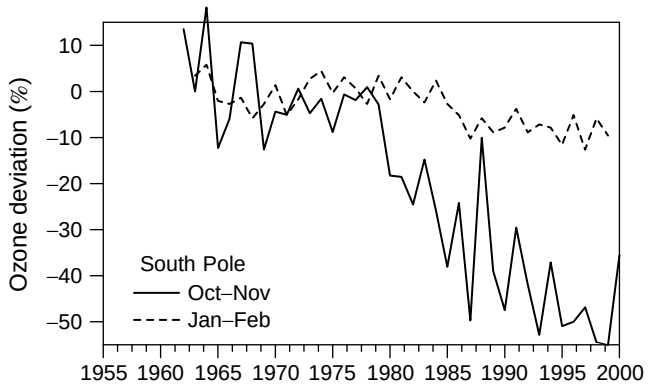

Figure 9 Ozone deviations from pre-1976 averages for Oct–Nov (solid) and Jan–Feb (dashed) over the South Pole (NOAA station) show rapid decline since the early 1980s, mainly during the late spring months

which favor the generation of PSCs of ice particles. Normally, chlorine and bromine are locked into stable reservoir compounds (such as $ClONO_2$, $BrONO_2$ and HCl). The ice particles attract water vapor and absorb nitrogen compounds, then fall to lower levels of the atmosphere, thereby dehydrating and denitrifying the air in the stratosphere. With the return of the sunlight in the early spring, these reservoir compounds are converted to active chlorine and bromine species on the surfaces of the PSC ice particles and/or on stratospheric sulfate aerosol. The released substances can split ozone molecules with amazing efficiency.

The drastic ozone decline over Antarctica was very strong during the 1990s and continues unabated. Figure 9 shows the deviations from the pre-1976 averages of the ozone values during two late spring and two summer months at the National Oceanic and Atmospheric Administration Amundsen-Scott station at the South Pole. In addition to typical interannual variability related to the specifics of the atmospheric circulation, the data show a drastic decline in October–November ozone levels, dropping 45–55% during most of the 1990s. During the summer months, the decline is about 9%. Over Antarctica the negative total ozone trends since 1979, in percent per decade, were for December–March, ~5%, for September–November ~22%, and ~9% for the annual average. By comparison, the negative trend of the annual averages in the 35–50 °S belt is only ~2% and in the 50–65 °S belt is ~4.3% per decade.

Observational and modeling studies indicate that the total ozone loss can be primarily ascribed to the depletion in the lower stratosphere. Syowa ozonesonde data from 69 °S provide information stretching back to 1968 and show that ozone depletion of ~90% occurred in the 12–20 km layer for a few consecutive weeks in September–October during the 1990s. Similar changes are observed over the Neumayer (70 °S) and South Pole stations. Springtime ozone depletion has been especially severe since 1992, reaching near complete ozone loss in the ~14–20 km layer from the end of September through mid-October. Such ozone losses in the 12–20 km layer are in agreement with modeling studies for the observed increase in stratospheric halogen concentrations from ~2.4–3.4 ppbv.

The decline of lower stratospheric ozone usually begins in early August on the sunlit edges of the vortex. The highest partial pressure, ~17 mPa before August, drops to lower than 1 mPa in the second half of September and early October. Temporal cross sections from the Neumayer and Syowa ozone soundings show a weakening of the polar vortex in November. Then, as a result of transport from the middle latitudes, ozone concentrations begin to increase, first above 25 km and then slowly propagate downward.

The ozone loss is the main reason for the temperature decline in the Antarctic lower stratosphere. In the 70–90 °S belt during September–October–November–December of the last 10 years, the temperature has dropped by about 2, 10, 12 and 5 °C, respectively, during these months. Lowering of the temperatures prolongs the persistence of the

strong stratospheric vortex. It is observed that the springtime stratospheric warming and the related vortex breakdown have been delayed by about a month during the last 10–15 years. Further stratospheric temperature declines, due to increasing emissions of greenhouse gases in the atmosphere, would facilitate even further ozone depletion, especially in the Arctic region, as shown in recent modeling studies.

Related to the ozone decline, a major change appears in the annual course of the total ozone over Antarctica. Comparing the average September–October–November values in 1985–1999 with the pre-1976 period, the total ozone was severely reduced: at Halley (76 °S) by 37–49%, at Syowa (69 °S) by 30–38% and at Faraday-Vernadsky (65 °S) by 25–31%. In December, the decline is 17–24%. As a result, the natural annual ozone maximum has been reduced by close to 30% and its occurrence shifted from November to December. The severe Antarctic decline has also affected the global ozone content by practically eliminating its secondary maximum, previously found in September–October as shown in Figure 1.

Ozone hole values (<220 matm-cm), representing a reduction of more than 30% from the pre-1976 averages, have covered an area not greater than 3–4 million km^2 at the time of ozone hole maximum during the early 1980s. This sunlit area regularly exceeded 10–13 million km^2 in the second half of the 1980s. In 1998 for the first time, the ozone hole covered an area greater than 25 million km^2 and persisted for more than 20 consecutive days. In September 2000, the ozone hole spread over such a large area for seven days. A weakening of the polar vortex in the beginning of November 2000 prevented repetition of characteristics similar to the previous two record setting seasons. In the springs of 1998 and 1999, ozone hole values prevailed for about 100 days over an area greater than 10 million km^2. This area is as big as Europe from the Gulf of Biscay to the Ural Mountains. The number of days with areas of 15 and 20 million km^2 also increased, which is indicative of strengthening of the ozone depletion in the 1990s (see Table 2). In the process of polar vortex rotation and expansion toward the lower latitudes, the very low ozone hole values were measured for a few days over the southern tip of South America (~56 °S) during each of the last 10 years.

The basic characteristics of the ozone hole each year since 1979 are shown in Figure 10. The maximum extent of the ozone hole area, which for the first time exceeded 10 million km^2 sunlit area in the mid-1980s, exceeded 22 million km^2 each year since 1990. The lowest ozone values within the ozone hole have usually occurred at the end of September and/or early October. The daily-minimum total ozone values have fallen from ~200 matm-cm in the early 1980s to ~150 matm-cm in the mid-1980s and down to values a few units less than 100 matm-cm in most of the 1990s. The date of disappearance of the ozone hole values

Table 2 Number of days when the ozone hole area (total ozone <220 matm-cm) covered a sunlit area surface greater than 10, 15, 20 and 25 [km^2 × 10^6] in the last eight years

2000	75	54	41	7

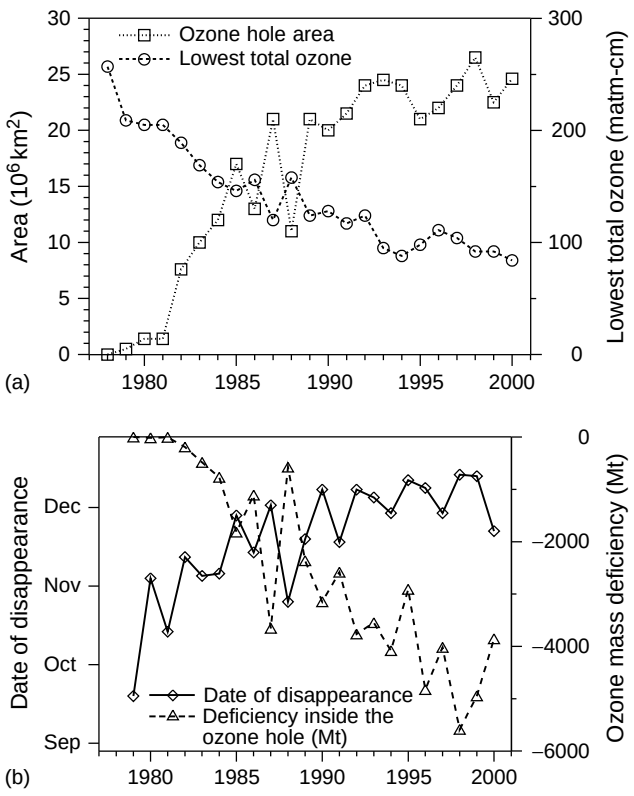

Figure 10 Evolution of basic characteristics of the ozone hole since 1979. (a) (□) maximum sunlit day-area covered by <220 matm-cm in [millions of km^2]; (○) lowest total ozone measured each year. (b) O_3MD [in Mt] as difference from pre-1976 averages integrated for 1 Sep–15 Dec (△); and date of disappearance of values less than 220 matm-cm (◇) [updated from Bojkov, WMO, 1999]

(<220 matm-cm) has been delayed from mid-October and early November in the first half of the 1980s, toward early December for most of the last 10 years. The date of disappearance is very closely related to the breakdown of the polar stratospheric vortex each spring.

Another important characteristic of ozone decline plotted on Figure 10 is O_3MD. This characteristic over different latitudinal belts or for different seasons is directly comparable on a molecule per molecule basis, independent of the different background levels. The O_3MD is calculated as deviations from pre-1976 zonal averages on a daily base using satellite observations homogenized over $3^\circ \times 5^\circ$ grid. If the deviations were found to be greater than -10% ($\sim$2 standard deviations for most locations), and knowing its value in matm-cm, it is a simple matter to determine the respective ozone mass. The O_3MD over the sunlit area poleward of 60 °S, integrated for the 1 September–15 December period of each year, shows a continuous increase within the ozone hole area since early 1980. The average O_3MD for the last six austral springs (September–October–November for 1995–2000) was $\sim$6400 Mt. In the first six years (1979–1984) this amount was only $\sim$2100 Mt.

Table 3 provides numerical expressions for the changes in area with deviations stronger than -10% (from the pre-1976 averages) in September–October–November and the corresponding integrated O_3MD for three time-periods. The average O_3MD for the last three springs (1998–2000) was close to six times stronger than for the years of initial ozone hole appearance (1979–1981). This measure is now 15% stronger than the previously record-setting 1992–1994 season! The increase of the O_3MD between the three periods is strongest in November followed by September, indicating expansion of the time with ozone destructive processes. Looking at the summary line of Table 3, it is clear that between the two end periods, the area with anomalies greater than -10% increased by almost a factor of 2.5. The O_3MD increased five times to 1992–1994 and nearly six times to 1998–2000, demonstrating an intensification of the ozone depletion per unit area in the later periods.

Table 3 Area (10^6 km^2) with deviations greater than -10% poleward of 60 °S (left entry), and O_3MD (in Mt) over these sunlit areas integrated for each of September, October, November (right entry, in italics) for three different time-periods

	Area and O_3MD for three different periods		
Month	1979–1981	1992–1994	1998–2000
September	330/*360*	670/*1770*	800/*2300*
October	370/*470*	740/*2010*	800/*2320*
November	230/*270*	700/*1720*	680/*1820*
Average	930/*1100*	2110/*5500*	2280/*6440*

Figure 11 compares the values of O_3MD over the southern polar region with values over the southern middle latitudes. In the 61-day period (1 September through 31 October) the integrated values of O_3MD over the middle latitudes show great variability but have grown by very little since the mid-1980s. Contrary to this stability, in the polar region, as already discussed, the O_3MD has continued to increase even during the late 1990s.

It is also important to provide perspective on events in the Northern Hemisphere. Over the mid-latitudes (35–55°) the O_3MD in the two hemispheres was about equal in the early 1980s, but in 1993–1998 the deficiencies over the Northern Hemisphere mid-latitudes have been significantly greater ($\sim$30%). This fact is also supported by the smaller negative trends calculated for the Southern Hemisphere mid-latitudes mentioned earlier. The stronger decline over the Northern Hemisphere mid-latitudes could be related to the sequence of colder springs for most of the 1990s and more extensive meridional exchange of chemically disturbed air from the Arctic vortex to the sunlit middle latitudes. The latter is in contrast to a predominantly zonal circulation over the Southern Hemisphere mid-latitudes and the nearly completely isolated Antarctic vortex, but this is not completely understood and requires further study.

The O_3MD ratio is generally opposite over the two polar regions (>60°). At the beginning of the rapid ozone decline in the early 1980s, Antarctic O_3MD was double that of the Northern Hemisphere polar region. Even for the last six years, it remains more than one-third greater than for the Arctic. If the O_3MD is taken relative to the actual surface area of the -10% deviation contours during the respective spring period in both hemispheres, the total ozone over the last six years is $\sim$120 matm-cm less over the

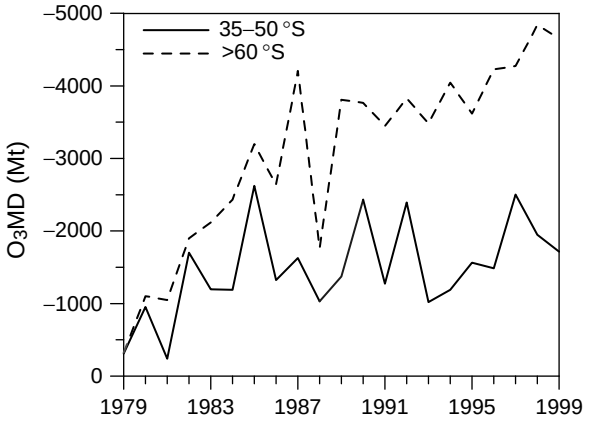

Figure 11 Ozone-mass deficiency (O_3MD) from pre-1976 averages, inside the -10% deviations contours, integrated for 61 days (1 Sep–31 Oct) in Mt for Southern Hemisphere polar region (dashes) and middle latitudes (continuous line) in the period 1979–1999. the data show a major O_3MD increase only over the polar region [updated from Bojkov, WMO, 1999]

Antarctica and ~80 matm-cm less over the Arctic. It should be remembered that the pre-1976 winter–spring averages over Antarctica were ~300–320 matm-cm, and over the Northern Hemisphere polar region, ~420–450 matm-cm. Therefore, the actual total column ozone thickness in the northern polar region is still, on average, well above the conventional ozone hole values of <220 matm-cm.

RADIATIVE EFFECTS OF OZONE CHANGES

Both ozone and halocarbons are greenhouse gases. Much like carbon dioxide (CO_2), they intercept and re-radiate the Earth s outgoing infrared radiation, thereby helping to warm the lower atmosphere. However, neither ozone nor its changes is uniformly distributed. As a result, ozone s radiative forcing is more complicated than those of the other principal greenhouse gases that have a long life span, and are therefore well mixed throughout the global atmosphere. To characterize a potential for climatic effects, radiative forcing (in units of $W\,m^{-2}$) is frequently used. It estimates the net solar and thermal infrared radiance at the tropopause level. These estimates are much less dependent on uncertainties concerning the combined interactive role of clouds, aerosols or oceans than for predicting surface climate change. A positive value signifies increased energy retention, producing a warming influence; a negative value implies greater energy loss, producing a cooling influence. In general, ozone increases in the troposphere, especially near the tropopause, induce warming, whereas ozone decreases in the stratosphere induce cooling. The observed temperature decline (0.6–0.8 °C per decade) in the 12–20 km layer over the middle latitudes during the past 25 years seems to be consistent with expected radiative impacts of a stratospheric ozone decrease. In the Antarctic in October–November, the decline is much stronger (10–12 °C).

An accurate assessment of the radiative effect of ozone changes is limited by the lack of detailed information on the variation in vertical distribution of ozone with latitude and longitude. However, recent calculations support earlier conclusions that stratospheric ozone depletion in recent decades has resulted in a negative radiative forcing of about $-0.2\,W\,m^{-2}$ (causing a cooling effect on the climate). Thus, stratospheric ozone change has offset, by about 30%, the positive greenhouse forcing due to increases in all other gases in the same period.

The Northern Hemisphere mid-latitude increase of tropospheric ozone since pre-industrial times is estimated to be $0.35\,W\,m^{-2}$, which has enhanced the total greenhouse forcing by as much as 15–20%. The net global mean radiative forcing arising from ozone changes is likely to have been positive since pre-industrial conditions, contributing about 15% of all the greenhouse gas-caused increase of radiative forcing in that period. Such changes could have an impact on the radiative balance of the Earth-atmosphere system and the thermal structure of the atmosphere; this could cause as yet unpredictable changes to atmospheric circulation patterns.

FUTURE OF THE OZONE LAYER

The results of nearly three decades of research focused on the ozone issue have provided a progressively better understanding of the interaction of human activities and the chemistry and physics of the global atmosphere. New policy-relevant insights of the roles of trace atmospheric constituents have been conveyed to decision-makers in governments and industry through the WMO/United Nations Environment Programme coordinated ozone assessment process (see references).

Large reductions in the production and atmospheric release of ozone-depleting substances (O_3-DS) have been achieved by international regulations. Without the Montreal Protocol and assuming a (conservative) 3% annual growth rate in production, O_3-DS would have led to an equivalent chlorine loading of around 17 ppbv in 2050 and massive ozone depletion (50–70% of pre-1976 levels). Furthermore, the impacts would have continued to grow in the years beyond 2050. This is schematically shown in Figure 12. The original Montreal Protocol (1987) would have reduced

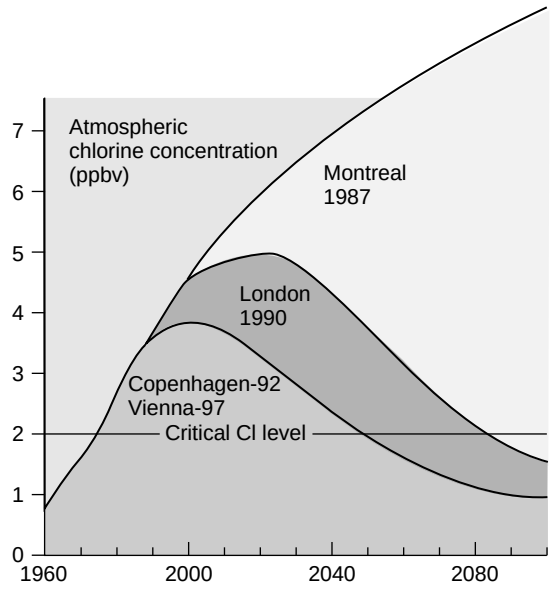

Figure 12 Schematic presentation of measured chlorine-equivalent concentrations in the stratosphere and projections according to various Montreal Protocol requirements for reductions and/or phase out of CFCs, halocarbons, and other O_3-DS. The ozone hole appeared when chlorine equivalent concentrations reached ~2 ppbv, and severe ozone destruction became predominant during polar springtimes when levels approached ~3 ppbv. (*Source:* Bojkov, WMO, 1995)

the O_3-DS concentration to ~9 ppbv. The London amendments (1990) are expected to lead to a reduction to about 4.6 ppbv, and the amendments and adjustments of Copenhagen (1992), Vienna (1995) and Montreal (1997) have further reduced the projected level to about 2.0 ppbv around the year 2050 (approximating the 1980 abundance, when the ozone hole first appeared).

Following the ozone losses of the 1980s and 1990s, recovery, in the sense of there being a negligible impact of chlorine compounds, is unlikely to occur before ~2050, when chlorine levels are expected to have been reduced considerably (<2 ppbv). At that time, the Antarctic ozone hole is projected to become as small as in the early 1980s or even disappear entirely. By that time, however, the recovery will be to a different atmosphere, in the sense that increases in greenhouse gases will have cooled the stratosphere, resulting in a reduction in homogeneous ozone loss, while increases in N_2O may have increased tropospheric NO_x to counteract this effect. Changes in H_2O will likely have complicated effects due to both its radiative and chemical impacts. Thus, due to changes in temperature, transport, water vapor and nitrogen species, the ozone vertical distribution is likely to be different in the year 2050 from that during the period before substantial ozone depletion was observed. Based on past emissions of O_3-DS and a projection of the maximum allowances of emissions under the Montreal Protocol, maximum ozone depletion is estimated by 2- and 3-dimensional modeling studies to occur within the next two decades, which will be the most vulnerable period for ozone depletion.

However, identification of, and the evidence for, the recovery of the ozone layer lie still further off. Global ozone will start to recover slowly within coming decades towards its pre-1980 level once the stratospheric abundances of ozone-depleting (halogen) gases decrease below ~3 ppbv. Because of the slow rate at which natural processes remove these compounds from the stratosphere, the reduction of total chlorine and bromine abundances in the stratosphere will be much slower than the rate of increase observed in past decades.

The main drivers of ozone change, however, could be natural and anthropogenic processes unrelated to chlorine and bromine compounds, but to which the ozone layer is sensitive because of the elevated abundances of O_3-DS. For example, the increases in N_2O and aerosol amounts will delay recovery of ozone while increases in CH_4 will have the opposite effect. Increases in NO_x emissions by supersonic aircraft in the mid-stratosphere will lead to ozone losses by gas phase destruction. Increases in aerosols provide sites for heterogeneous chemistry leading to ozone loss in the presence of halogen compounds. In contrast, increases in CH_4 lead to increased production of HCl and a reduction in the amount of active chlorine-catalyzed ozone loss. Furthermore, extreme perturbations (e.g., natural events, such as volcanic aerosols reaching the stratosphere, and/or extreme cold temperatures) could increase the loss from ozone-depleting chemicals. Arctic ozone depletion could be increased by cold polar stratospheric temperatures ($<-76\,^{\circ}$C), which, in turn, could be linked to increase of greenhouse gases or to natural temperature fluctuations.

The effect of increasing fleets of sub- and super-sonic aircraft with flight altitudes of 9–13 and 17–20 km, respectively, is sometimes listed as a factor in increasing of the tropospheric ozone and of delaying of the ozone recovery respectively (IPCC, 1999). The principal emissions of these aircraft are CO_2, CH_4, NO_x, SO_2, H_2O and particles. Their effects are highly dependent on the altitude of injection due to the changing chemical and dynamical regimes in the lower stratosphere. The available modeling results summarized below have considerable uncertainty.

Subsonic emissions result in a significant increase in the concentrations of NO_x (factor of about two increase at 12 km) and a decrease in the lifetime of CH_4 as a result of increases in tropospheric OH concentration. In all models, ozone is projected to increase, but the impact is restricted to the most frequent flight corridors over northern mid- and high-latitudes. For the latitude band 30–60 °N, the estimated maximum average tropospheric ozone increase at cruise altitudes (above background with no aircraft) is 6% for the 1992 level of emissions and 13% for 2050 emissions. The response is nearly linear, with changes in NO_x emission. The effects on the column of ozone are an increase by 0.4% in 1992, and by 1.2% in 2050.

The assessment of the impact of a projected fleet of up to 1000 super-sonic aircraft for the year 2015 atmosphere is a slightly negative (−0.4%) column ozone change, reflecting a negative change of 40–60 ppbv at 30 km and a positive change of 15 ppbv at 20 km.

There will also be effects from increasing water vapor and sulfur emissions in the stratosphere. The response to sulfur emissions depends on how much of the fuel sulfur is converted to sulfate particles in the aircraft exhaust plume, with larger ozone loss from larger conversion to aerosols. The overall impact on ozone of this probably unrealistically large projected fleet of supersonic aircraft is small compared to perturbations due to halogens.

Because there is less variability in the ozone loss, the detection of the onset of ozone recovery from halogen-induced depletion should be possible earlier in the Antarctic than in the Arctic or globally. In particular, reduction of the rates of ozone destruction in the 12–20 km layer during the Antarctic spring would be an early indicator of the beginning of the ozone recovery. However, this would not be expected before the chlorine

loading declines to less than 3 ppbv, which requires a decade or two according to current Montreal Protocol requirements.

Despite the uncertainties regarding the modeling simulations, some delay in Arctic ozone recovery is likely because of the impact of climate change on lowering the stratospheric temperature. Climate-induced changes are projected to lead to increased production of PSCs in the lower stratosphere and to enhanced heterogeneous reactions. Results from 3-dimensional models project the same or greater ozone depletion in the Arctic in 2015 as was observed around 1995, despite the assumed reduction in chlorine loading of between 3 and 16%.

Because the issues of ozone depletion and climate change are interconnected, so too are the Montreal and Kyoto Protocols. That the ozone depletion and climate change phenomena share a number of common physical and chemical processes means that changes in ozone concentrations will affect the Earth s climate and changes in climate and meteorological conditions will affect the ozone layer. Decisions taken – or not taken – under one Protocol, therefore, impact the aims of the other. For example, decisions made under the Kyoto Protocol with respect to CH_4, N_2O and CO_2 will affect the rate of recovery of ozone, while decisions regarding controlling hydrofluorocarbons (used as substitutes for some CFCs) may affect decisions regarding the ability to phase out O_3-DS.

Although the Montreal Protocol is reducing O_3-DS, springtime depletion of ozone in the Antarctic continues unabated at the same levels as observed in the early 1990s and large depletions of ozone have been observed since 1990 in the Arctic in most years characterized by unusually cold and protracted winters. The total stratospheric loading of O_3-DS did reach its maximum at about year 2000; however, it will stay at rather high levels (>3 ppbv) for many years. Therefore, the ozone layer is at present, and will, during the coming decade, be in its most vulnerable state.

Stratosphere, Temperature and Circulation

Karin Labitzke

Meteorologisches Institut der FU-Berlin, Germany

In the Arctic summer, the temperatures are higher than in winter at both the tropopause and the stratopause, but this is not so above 58 km, where the mesosphere is extremely cold in summer and where Noctilucent clouds can form. The Arctic troposphere is cold in winter, and the stratosphere too, but the tropopause is not well marked since the temperature often continues to fall into the lower stratosphere, though at a slower rate than in the troposphere. On the lee side of mountains, especially in Scandinavia, Mother-of-Pearl clouds may form where the temperature is below $-80\,^{\circ}C$; nowadays such clouds are called Polar Stratospheric clouds.

MEAN CONDITIONS IN THE STRATOSPHERE

Global Temperatures

Figure 1 shows the average vertical profile of temperature in three instances; the temperature can be appreciably higher or lower on individual days. The dashed curve is for the equator, where the tropopause is cold and lies at high elevation. The two other curves depict conditions in the Arctic, the solid line in summer and the dotted line in winter. The distribution of ozone with height in February at about $50\,^{\circ}N$ is shown in the inset at the lower right-hand side of the figure; the units are in nanobar (nb), a measure of the partial pressure of ozone (Labitzke and van Loon, 1999).

The vertical temperature profile is shown in another manner in Figure 2, which is a latitude versus height section where the temperature averaged around latitude circles (the zonal mean) in January is shown from pole to pole (Barnett and Corney, 1985). Certain associations are more easily seen in such a presentation: for instance, the tropopause lies at different elevations in different latitudes; in the tropics and subtropics it is found between 15 and 18 km, whereas it is as low as 7 to 9 km in middle and high latitudes.

The stratopause lies, on average, at a height of almost 50 km, at a pressure of about 1 hPa. Only above the winter pole (Arctic, left in Figure 2) is the stratopause on average markedly higher. The temperature in the stratopause region ranges from $-18\,^{\circ}C$ above the winter pole to $+12\,^{\circ}C$ above the summer pole (Antarctica, right in Figure 2). These are all average conditions. The deviations from the mean can be appreciable for individual situations; for instance, during a major warming in the northern stratosphere in winter, when

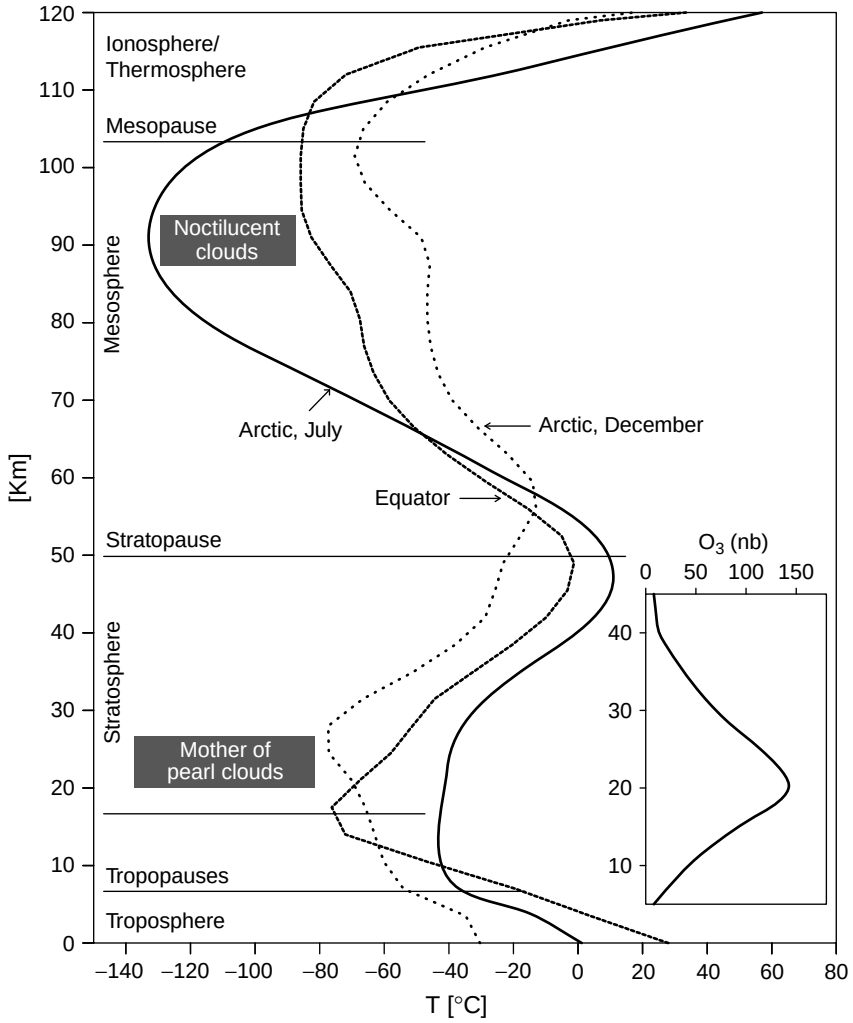

Figure 1 The layers of the atmosphere (Labitzke and van Loon, 1999)

the stratopause lowers and temperatures as high as $+49\,^{\circ}C$ have been measured at 40 km, by meteorological rockets and lidar (Scherhag, 1952; Labitzke, 1972; von Zahn *et al.*, 1998). More details on this curious phenomenon are contained in the last subsection in this article.

There are other important facts about the winter pole that must be mentioned: the temperature at high latitudes does not rise immediately above the tropopause, as it does elsewhere; in these latitudes it falls further with height to a level near 25 hPa (about 25 km) but more slowly than in the troposphere (compare Figure 1). The temperatures in the winter stratosphere over Antarctica are substantially lower than those above the Arctic in winter, (see Figure 3).

Global Meridional Circulation

Differences in temperature are always associated with pressure differences, which the atmosphere tries to even out by moving air from high to low pressure. Due to the deflection of air motion caused by the rotation of the Earth (the so-called Coriolis force, *see* Coriolis Effect, Volume 1), the air does not move directly from high to low pressure around the center of low pressure. The attempt of the atmosphere to eliminate the temperature and height differences is thus responsible for the strong west and east winds which encircle the globe.

If one averages over a longer time interval, it turns out that there is also a north–south gradient in the troposphere. This gradient is responsible for the south–north circulation cells in the vertical plane that meteorologists call meridional cells. Hadley (1735) described the general features of these cells by means of numerous observations from sailing ships: warm moist air rises in the tropics, expands and cools as the pressure decreases upward. The moisture condenses to form high reaching clouds that sometimes build upwards to the tropopause in what is known as the Intertropical Convergence Zone (ITCZ), where the trade

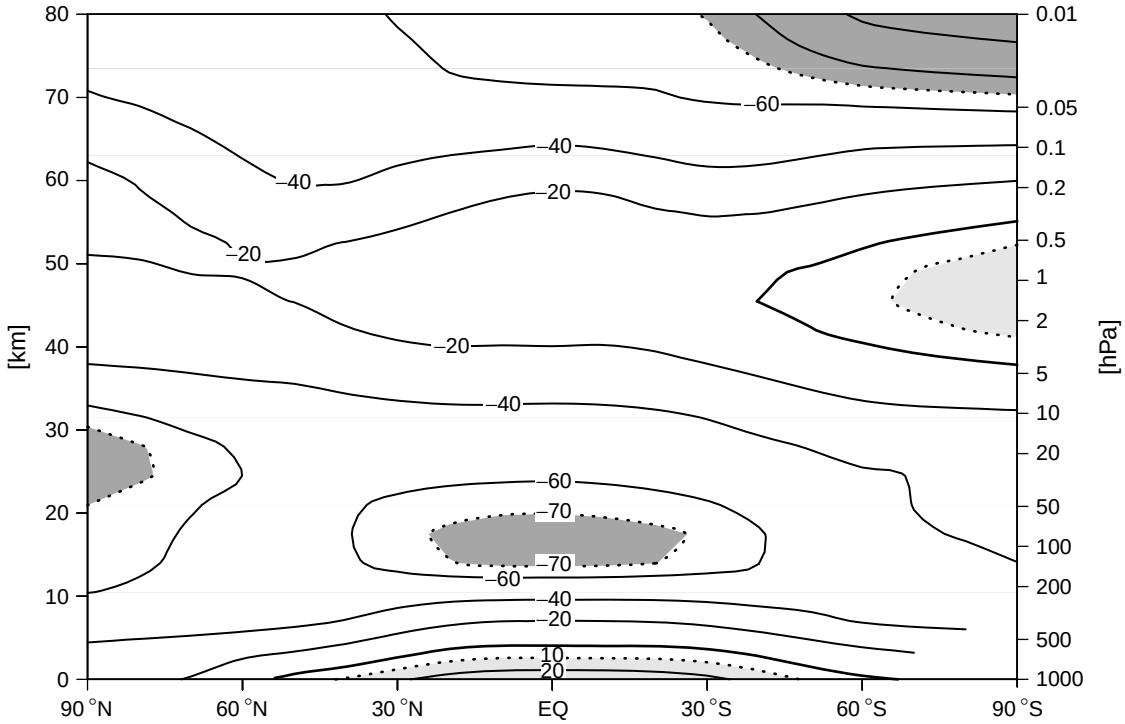

Figure 2 The mean distribution of zonally averaged temperature (°C) with height in January – winter in the Northern and summer in the Southern Hemisphere. The ordinate is in km on the left and in pressure (hPa) on the right (Barnett and Corney, 1985)

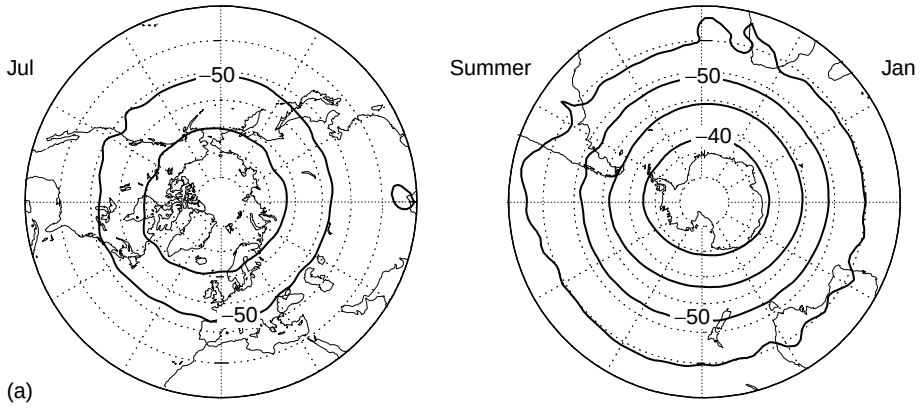

Figure 3 Monthly mean maps of the 30-hPa temperatures (°C); (a) summer, (b) winter, (c) spring over both hemispheres. Interval between isotherms is 5 °C. Data: NCEP/NCAR reanalyses (Kalnay *et al.*, 1996), 1968–1997; (d) monthly mean maps of total ozone (Dobson Units, interval 30 units) March, Northern Hemisphere (left), and September, Southern Hemisphere (right); mean total ozone based on Total Ozone Mapping Spectrometer data from National Aeronautics and Space Administration, period: 1979–1992. Polar stereographic projection, outer limit is 20 °latitude. (Adapted from Labitzke and van Loon, 1999)

winds of the two hemispheres clash. The ITCZ moves with the Sun and brings the rainy season to the various tropical regions. In the upper troposphere the air moves towards the poles in the meridional cell but it sinks in the subtropical high pressure areas, is compressed, and dries out; this is where deserts such as the Sahara and the Kalahari form. North of the subtropical highs in the troposphere are the familiar, mainly eastward-moving high and low pressure weather systems (*see* Atmospheric Motions, Volume 1).

Dobson (1930) realized through his early observations of ozone that there had to be a meridional circulation in the stratosphere as well, in order to bring the ozone created

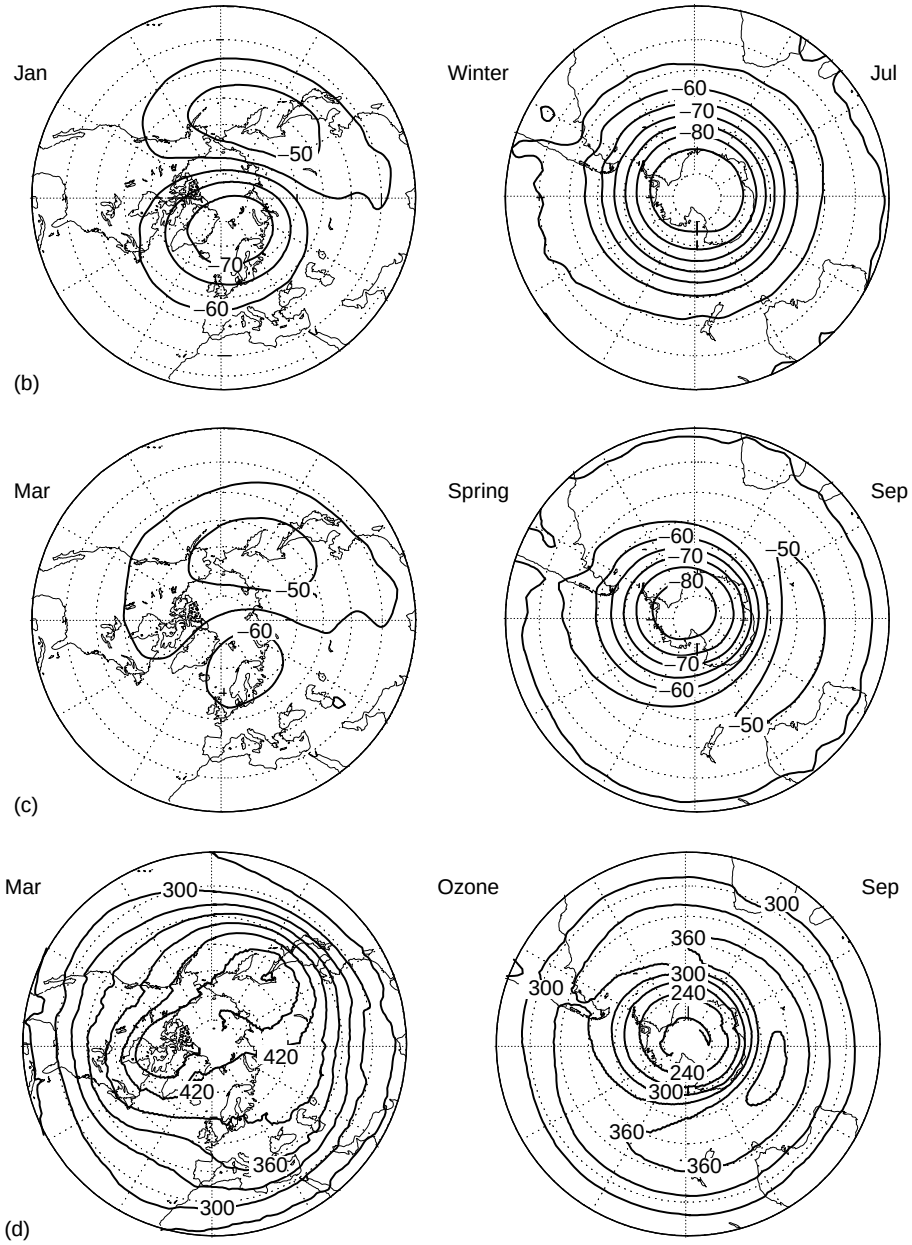

Figure 3 (*Continued*)

in the tropical stratosphere to higher latitudes. Today we know that the meridional circulation in the stratosphere (the Brewer-Dobson Circulation) is responsible for the transport of long-lived trace elements, for instance the chlorofluorocarbons (CFCs). These trace gases manage to enter the tropical stratosphere and from there to reach the polar regions in winter. It is in this way that trace gases produced in the Northern Hemisphere, like the CFCs, reach Antarctica where they destroy the ozone in spring (*see* Depletion of Stratospheric Ozone, Volume 1; Ozone Hole, Volume 1.).

The air that rises in the tropics is entrained into a large, poleward directed circulation through middle to high latitudes, where it sinks in winter; and the compression causes the sinking air to warm. This explains why the arctic mesosphere is warmer in winter than in summer (Figure 1).

The meridional cells are mainly driven by gravity waves of different scales that, under certain conditions, propagate from the troposphere to the stratosphere and mesosphere, deposit their momentum there and influence the zonal and meridional circulations.

Monthly Mean Temperature Maps

Extreme Seasons

The maps in Figure 3 show the temperature distribution at the 30-hPa level averaged over 30 years. The maps are shown for summer, winter and spring, for both hemispheres, and the 30-hPa level was chosen because this is the highest level for which reliable data are available for both hemispheres for a time span of about 30 years. Also, this is a level in the middle stratosphere where the most important features of the stratospheric temperatures are obvious and where the hemispheres can be suitably compared.

The temperatures during summer are shown in Figure 3(a). The high temperatures measured during this time of year are due to absorption, by ozone, of ultraviolet radiation coming from the Sun, and as there is little influence on the stratosphere from below, the distribution of temperature is very symmetric, parallel to the latitude circles. The temperatures are very similar over both hemispheres, but the air over Antarctica is somewhat warmer. This is due to the fact that the Earth is in perihelion (closest to the Sun) during the southern summer and thus receives more insolation; the south polar stratosphere, therefore, can absorb more short-wave radiation than the Arctic during the northern summer when the Earth is in aphelion (farthest from the Sun).

The transition from summer to fall is similar over both hemispheres (not shown). With the approach of winter, the picture changes (Figure 3b): although the sinking of air over the polar regions continues through the winter, in the stratosphere this warming is more than offset by the radiational cooling in the polar night. Over both polar regions, we find temperature minima during this part of the year that are surrounded by belts of higher temperatures. However, there are important differences between the polar regions: (1) the Antarctic polar region is much colder, and at the South Pole the mean temperature for July (midwinter) is close to $-90\,^{\circ}$C, which is $15\,^{\circ}$C lower than the mean over the Arctic; (2) the pronounced asymmetry of the northern stratosphere is not present in the southern winter stratosphere.

The reason is that the tropospheric winter jet stream in the western North Pacific is stronger than that in the western South Pacific and that, therefore, the sinking of the air in the stratosphere on the poleward side of the jet is more intense in the North Pacific. This leads to the warming over the Aleutian–Kamchatka region (Figure 3b, left) and to the build up of the so-called Aleutian high, which is the mark of large planetary waves that transport heat into the polar region, and help to ameliorate the cooling caused by the outgoing radiation. The Antarctic stratosphere does not have the same possibilities to retard or offset the cooling, and it therefore cools continuously during the polar night.

Spring

The transition from the winter (cyclonic) to the summer (anticyclonic) circulation in the stratosphere (final warming) takes place about two months earlier in the Arctic than in the Antarctic. The late interseasonal transition in the Antarctic – after the Sun has returned to the polar region – produces the meteorological conditions that are necessary for the formation of the ozone hole over the Antarctic in spring (*see* Ozone Hole, Volume 1). A comparison of the temperature (Figure 3c) and ozone (Figure 3d) distribution on the two hemispheres in spring (March and September) shows the marked differences between the polar regions: in September the temperature is still extremely low over the Antarctic when the Sun returns and enables the ozone-destroying chemistry to take place, and we find very low values of total ozone over Antarctica. In contrast, the mean temperature above the Arctic in March is high and planetary waves, which are themselves responsible for the higher temperatures, have also transported much ozone into the polar region.

There are, of course, also very late transitions (final warmings) in the Arctic, and in such a year, ozone is destroyed over the Arctic as well, but the total ozone values remain significantly higher than observed over Antarctica.

Interannual Variability

The standard deviations (scatter about the mean) of the monthly mean 30-hPa temperatures averaged along latitude circles in Figure 4 serve as measure of the interannual variability. This variability is small in the tropics and on the summer hemisphere, but increases with latitude and season. It is largest in the Arctic in winter, and then much larger than in the Antarctic winter. The larger arctic variability is related to larger wave activity there, and to the frequent occurrence of warmings during the northern winters, (see Figure 5).

During winter, the wave activity is large in southern middle latitudes as far south as $60\,^{\circ}$S, and the influence of the waves becomes noticeable in the Antarctic polar region after August. When the final warmings take place in the Antarctic spring (see previous), the interannual variability increases there, and it is then larger than in the corresponding months on the Northern Hemisphere.

Variability During the Arctic Winters

The monthly mean 30-hPa temperature at the North Pole in January–February ranges from below $-80\,^{\circ}$C to $-54\,^{\circ}$C, so we are dealing with a frequent change between warm and cold winters (Figure 5). The variability is the largest observed globally at this pressure level, (compare Figure 4). This variability is due to the occurrence or non-occurrence of stratospheric warmings. The World Meteorological Organization recognized the importance of these stratospheric

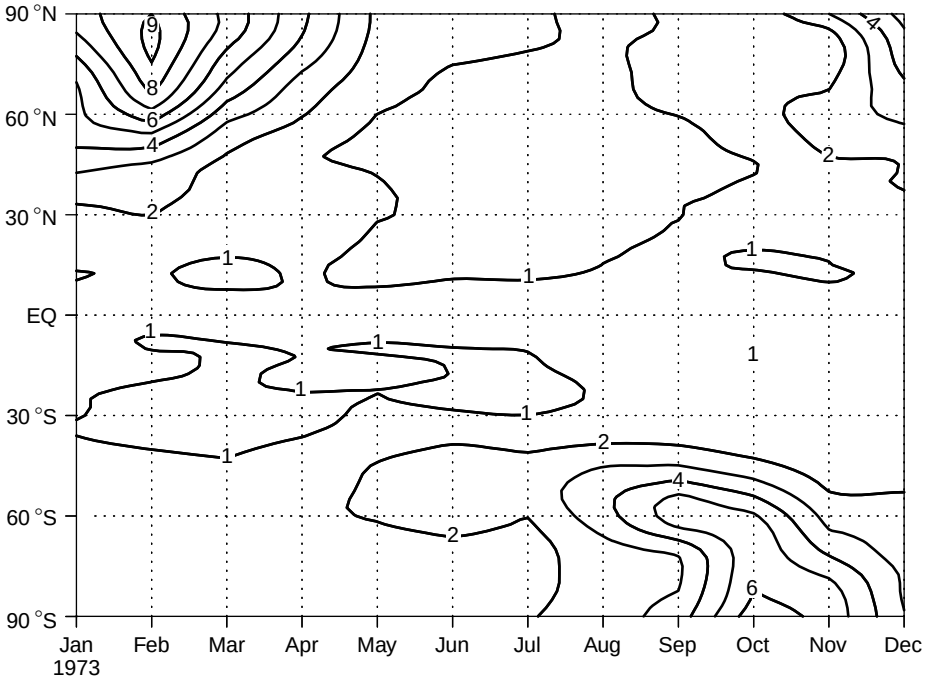

Figure 4 The global distribution of standard deviations (°C) of the 30-hPa monthly mean temperatures for the period 1973–1995, based on NCEP/NCAR reanalyses (Labitzke and van Loon, 1999, Figure 2.11)

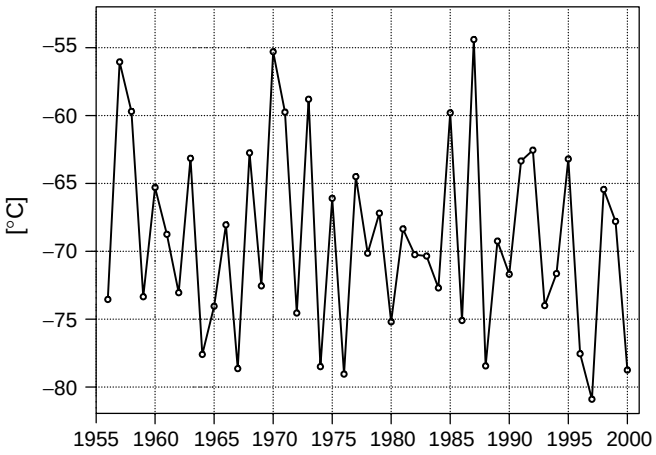

Figure 5 Time series of the 30-hPa temperature (°C) at the North Pole in January–February, 1956–2000; data: Meteorological Institute, Free University Berlin (Labitzke and van Loon, 1999, Figure 3.1, updated)

phenomena, and in 1964 asked a few meteorological institutes to issue sudden warming advisories regularly during winter, the so-called stratalerts. This alerting system is still ongoing. Four different types of warmings are considered:

- *Major midwinter warmings* occur mostly in January–February. In addition to warming of the north polar region and reversal of the temperature gradient, they are also associated with a breakdown of the polar westerly vortex, which is replaced by a high. That is, the definition of a major midwinter warming requires not only the warming but also a total change of circulation. The definition of a breakdown of the polar vortex is that the usual westerlies in the Arctic at 10 hPa are replaced by easterlies, so that the center of the vortex moves south of 60–65 °N. The vortex is either displaced entirely or split into two. This type of warming has not been observed in the Antarctic.
- *Minor warmings* can indeed be intense and sometimes also reverse the temperature gradient, but they do not result in a reversal of the circulation at the 10-hPa level. They are found in the Antarctic as well.
- *Canadian warmings* often happen in early winter. They take place when the Aleutian stratospheric high intensifies and moves poleward. The Canadian warmings can reverse the temperature gradient and sometimes briefly change the wind direction over the polar cap, but they do not, however, lead to a breakdown of the cyclonic polar vortex.
- *Final warmings* mark the transition from the cold cyclonic vortex in winter to the warm high centered on the pole in summer. Their intensity varies by a considerable amount, and they can be divided into major and minor final warmings. The time when the final warmings take place – when the westerlies of winter are replaced by the easterlies of summer – also varies a good deal, so they are further

divided into early and late final warmings. Naturally, there are also final warmings on the Southern Hemisphere.

What causes this high variability in the arctic stratosphere, or what makes a winter extremely warm or cold? We can still supply only a preliminary answer to this question, because one can only guess at the interaction between the various forcings from outside the stratosphere, and at the role played by the random variability inherent in the internal dynamics of the troposphere and stratosphere.

Meteorologists agree that planetary-scale waves, under given conditions, propagate from the troposphere into the stratosphere, and also that the explanation of why these waves are enhanced in the stratosphere must be sought in the troposphere. It is also evident, at least for the Northern Hemisphere, that much of the difference among stratospheric circulations in different winters is associated with the known oscillations in the atmosphere such as:

- The Southern Oscillation, an irregular oscillation in the tropical-subtropical sea level pressure and in the sea surface temperature of the tropical Pacific Ocean. Its period lies between two and eight years, on average four years (*see* Southern Oscillation, Volume 1).
- The Quasi-Biennial Oscillation, an oscillation in the equatorial stratospheric winds with a period between 19 and 36 months, the mean period being about 28 months (*see* Quasi- Biennial Oscillation (QBO), Volume 1).
- The North Atlantic Oscillation, a seesaw in atmospheric pressure between the subtropical high, centered in the mean near the Azores, and the Icelandic low whose center is in the Greenland–Iceland region. It has a periodicity on the order of 27 to 28 months (Hurrel and van Loon, 1997) (*see* North Atlantic Oscillation, Volume 1).

But there are other forcings from outside the stratosphere such as:

- the 11-year sunspot cycle, (*see* Solar Irradiance and Climate, Volume 1); and
- such volcanic eruptions that are violent enough for their emission to enter the stratosphere.

Even with the knowledge of these influences, it is not yet possible to forecast if a winter is going to be colder or warmer than normal in the north polar regions (i.e., if the polar vortex is going to be strong or weak), because we cannot determine how large a part the individual forcing will play – nor can we foretell the future state of the forcing, or if a volcano will erupt. Quite apart from that, the internal dynamics of the atmosphere can randomly, without any outside forcing, move the stratosphere from one state to another. The models still do not provide satisfactory longer-range forecasts of these complex associations.

But it has become more important than ever to understand the cause(s) of the large variability, because one might, for instance, then be able to explain why, so far, there has been no ozone deficit in the arctic stratosphere comparable to that above Antarctica in spring. Understanding why a winter turns out to be warm or cold in the stratosphere would also help us to understand the interaction between the troposphere and stratosphere (Labitzke and van Loon, 1999).

Sub-grid Processes

In nature, physical quantities such as temperature, pressure, atmospheric humidity, and the concentration of gases or nutrients in the ocean, vary continuously in three dimensions. Nature can thus be thought of as consisting of an infinite number of infinitely closely spaced points. However, in a computer model, only a finite number of points is possible, because the computer memory capacity is finite, and only a finite number of calculations can be performed. In three-dimensional models, the points are arranged in a three-dimensional grid. The spacing between the grid points is called the *spatial resolution*. Processes that occur at spatial scales smaller than the spatial resolution, and which therefore cannot be explicitly represented in models, are referred to as *sub-grid scale processes*. In recent three-dimensional, global-scale atmospheric models, the typical spatial resolution is about 200 km in the horizontal, with the atmosphere divided into 10–20 layers of uneven thickness in the vertical. Examples of sub-grid scale processes in these models include: updrafts and downdrafts associated with convective clouds (100 m spatial scale), convective clouds themselves (1 km spatial scale) and convective cloud systems (10 km spatial scale), microphysical processes within clouds of all types (at a scale of microns), turbulence in and above the surface layer of the atmosphere (meters to 1 km in scale). The exchange of heat, moisture, and momentum between a land surface and the atmosphere involves surface irregularities that occur below the model resolution, so the processes governing these exchanges occur at the sub-grid scale. In ocean models, important sub-grid scale processes include diffusive mixing by a variety of physical processes, and convective overturning. Finally, climate models are marched through time by computing rates of change at a given time and extrapolating these to the next point in time. The length of extrapolation is called the *time step*, and can be thought of as the grid resolution in the time dimension. Many important processes (particularly involving clouds) are sub-grid in the time dimension, as well as in the spatial dimensions.

Sunspots

Judith Lean
Naval Research Laboratory, Washington, DC, USA

Sunspots are small dark features on the Sun's disk. Observed with telescopes since the 17th century, they were recognized in the 1850s to exhibit an 11-year cycle. The number of sunspots present on the solar disk viewed from Earth is the longest, directly observed record of solar variability, and the only such record prior to the 20th century. Space-based observations of the Sun made in the past few decades con rm the signi cance of the sunspot record as a generic indicator of solar activity that relates to a wide variety of solar and terrestrial phenomena. However, in most cases these relations are neither simple nor linear.

Sunspots are compact clusters of magnetic fields in the Sun s atmosphere. Seen as small dark features in the image in Figure 1, sunspots are regions where magnetic fields erupt into the solar atmosphere from below the visible solar surface, after being twisted and stretched by the Sun s rotation on its axis (once approximately every 27 days). Sunspots appear darker than the surrounding solar atmosphere because they are cooler by about

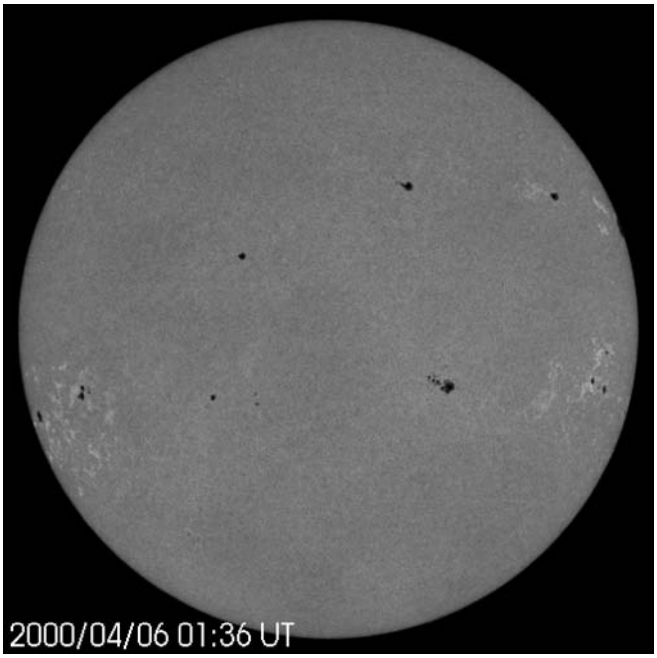

Figure 1 Shown is an image of the Sun recorded in visible radiation by the Michelson Doppler Imager on the Solar and Heliospheric Observatory on the 6th April 2000, during a period of high solar activity in cycle 23, with many sunspots present. Bright faculae are evident surrounding sunspots near the east and west limbs of the disk

1000 K. They are cooler because their magnetic fields form compact structures, as Figure 2 shows, that inhibit the upward flow of energy from the solar interior. Sunspots appear typically at mid heliocentric latitudes during the beginning of an 11-year cycle, and move to lower latitudes as the cycle progresses. Because they rotate with the Sun s atmosphere, sunspots appear to move in a band across the face of the Sun viewed from the Earth. They grow to a typical size of 50 million km^2, evolving and eventually decaying over time scales of weeks. Bright regions called *faculae*, in which magnetic fields are more dispersed and energy flow enhanced, usually accompany sunspots. Faculae are also evident in Figure 1 near the limb of the Sun s disk where their brightness relative to the background radiation is higher than at disk center.

When regular telescopic observations of sunspots commenced in the 17th century, solar activity was at lower levels and sunspots less frequent than today, as the record of sunspot numbers in the top panel of Figure 3 shows. Sunspots occur often, and with larger areas when solar activity is high. Solar activity refers in general terms to the amount of magnetic flux present in the Sun s atmosphere, not just in sunspots but also in other features, such as faculae. The nominal 11-year cycle of magnetic activity is asymmetric, having a rise time of <5 years and a decay time of >6 years. The middle and lower panels of Figure 3 show that the amplitude of this cycle varies by two orders of magnitude while the phase ranges from 8 to 15 years. Solar cycles with lower amplitudes tend to last longer, but the amplitude (Figure 3c) and length (Figure 3d) of solar cycles are only loosely related (correlation coefficient of 0.34). This suggests the behavior of a non-linear oscillator but the true origin of solar activity and the sunspot cycle is still uncertain. Also evident in the sunspot numbers are longer periods, near 90 years, called the *Gleisberg* cycle, and near 200 years.

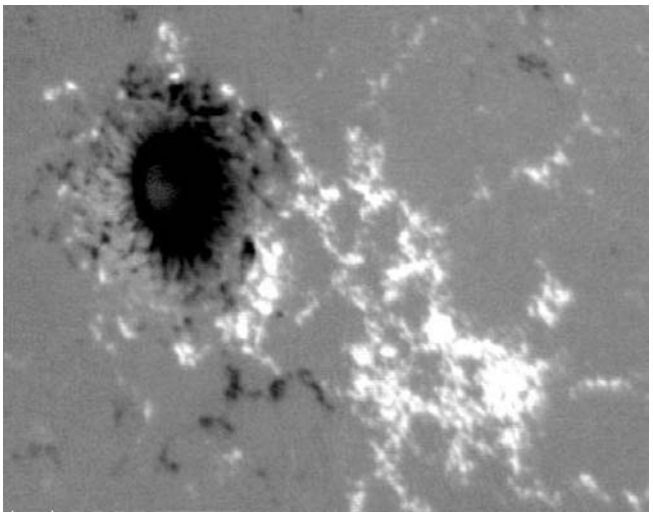

Figure 2 Shown is an image of a sunspot and surrounding magnetic features in NOAA region 7912 on the 25th October 1995 recorded by the Big Bear Solar Observatory. Bright and dark regions signify magnetic fields of different polarity

Even though the Sun s 11-year cycle of magnetic activity is often termed the sunspot cycle, sunspots are only one manifestation of numerous solar processes that vary in response to solar activity. When sunspot numbers are high, such as near maxima of 11-year cycles (1980, 1990 and 2000), bright features (faculae, plages and hot coronal loops) are also larger and more frequent. The overall amount of radiation from the Sun (irradiance) increases, eruptive events such as flares and coronal mass ejections occur more often, and the Sun emits into space a greater flux of energetic particles. Enhanced plasma flow from the solar corona modifies the solar wind and interplanetary magnetic field, which increases the complexity and strength of the magnetic coupling between the Sun and the Earth. This inhibits the penetration of galactic cosmic rays into the Earth s atmosphere, and the levels of cosmogenic isotopes such as ^{14}C and ^{10}Be (in tree rings and ice cores, respectively) are reduced correspondingly (*see* Radionuclides, Cosmogenic, Volume 1). Many solar and terrestrial phenomena have temporal variations that correlate with sunspot numbers and with each other as a result of their common connection, albeit by different physical processes, to solar magnetism.

Because of its duration and apparent homogeneity, the sunspot record is often used in the search for Sun–climate relations as a proxy for the geophysically relevant solar energy outputs, even though the actual physical relationships are complex. Sunspots are direct sources of irradiance variability because their presence in the Sun s atmosphere depletes radiation locally and reduces irradiance at Earth. But the bright faculae that accompany sunspots enhance irradiance so that the observed irradiance variability actually reflects the competing effects of two sources, each of which correlates with the sunspot number. Reconstructions of historical solar irradiance adopt either the cycle amplitude (Figure 3c) or cycle length (Figure 3d) to represent an assumed long-term component that is present in terrestrial geomagnetic and cosmogenic proxies of solar activity in addition to the 11-year cycle. Although times of many sunspots at the Sun s surface signify the presence of hot coronal loops in the outer solar atmosphere and enhanced plasma and particle emissions that also couple with the Earth, the physical associations of sunspots with geomagnetic indices and cosmogenic isotopes is complicated, and remains to be quantitatively specified. The record of sunspots is therefore a generic indicator of solar variability during the past four centuries. An important, unresolved issue for climate change is the question of long-term variability of the Sun s irradiance: Are sunspots

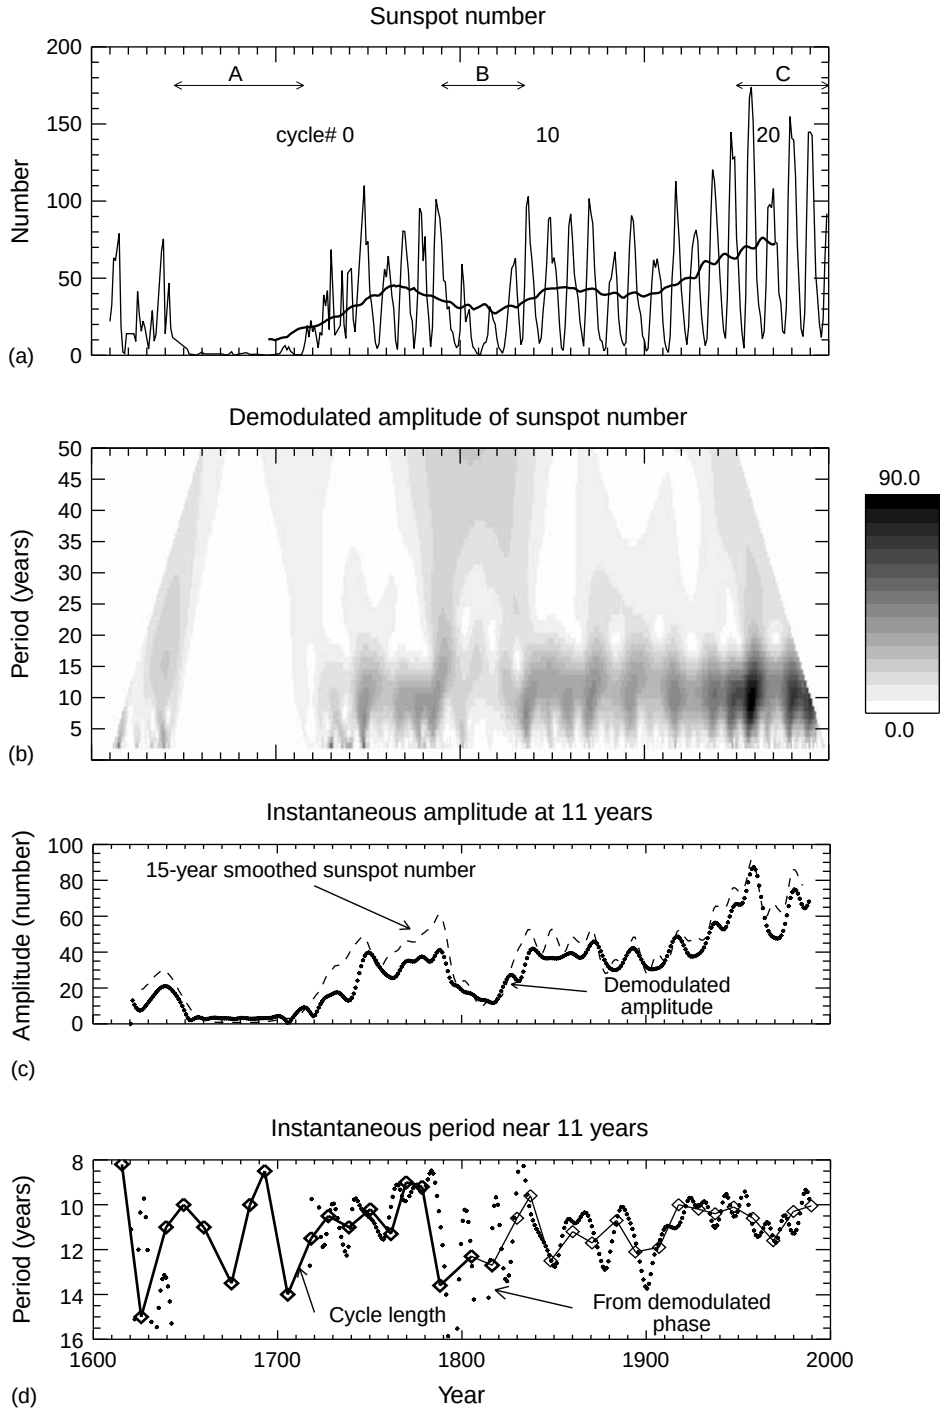

Figure 3 Shown in (a) is the 400 year record of sunspot numbers. The numbering of 11-year cycles commenced in 1750, with cycle 0. The letters A, B and C designate specific epochs called, respectively, the Maunder Minimum (*see* **Maunder Minimum**, Volume 1), Dalton Minimum and Modern Maximum. Space-based observations of the Sun exist only during the Modern Maximum. Shown in (b) are the amplitudes of periods less than 50 years present in the sunspot number record. Most prominent is the nominal 11-year cycle. Variations in its amplitude and length are shown in (c) and (d)

directly indicative of irradiance changes or are longer-term components, such as those evident in terrestrial proxies, also present?

Suomi, Verner Edward

(1915- 1995)

Verner Edward Suomi was a US scientist and educator. Universally recognized as the father of satellite meteorology, Suomi s legacy to humanity is a dramatically improved understanding of the weather, the atmosphere, and the Earth obtained from sensors in space.

His early instruments flew around the Earth, he designed space probes to study Venus and Jupiter, and he invented the camera that produced the first satellite images of the Earth and its weather now seen daily throughout the world. He was eulogized as a giant of modern science. His inventions were simple and elegant, and their consequences are ubiquitous. Suomi opened the way to a global view from space that reshaped the Earth sciences in the latter decades of the 20th century.

Born in Eveleth, MN, Suomi received a BSc degree in 1938 from the Winona State Teachers College and taught high school until 1941, when he began to study and teach meteorology in a wartime program. He joined the faculty of the University of Wisconsin-Madison in 1948 and received his doctorate from the University of Chicago in 1953. He remained on the University of Wisconsin faculty for his entire career and founded the Space Science and Engineering Center there, directing it until his retirement in 1988.

Suomi s career was shaped by his early attempts to measure the fluxes of radiation involved in the Earth s energy balance. For his PhD thesis, he developed a radiometer to measure radiative fluxes in a cornfield and was led to think about the energy balance of the planet. He created an ingeniously simple flat plate radiometer that was first flown in space in 1959. Combining his observations from space with similar observations from weather balloons, he established the critical role of clouds in the planetary energy balance and stimulated the integration of satellite observations in meteorological practice and research.

His most renowned invention was the 1963 spin-scan camera that typified Suomi s genius for penetrating simplicity. The then new communications satellites, in orbits that remain stationary over a point on the equator, were spin-stabilized. Suomi developed an electronic telescope to scan adjacent sections of the Earth from the rapidly spinning satellite. A picture of the whole disc was obtained by lining up the images of the sections. Later versions of the instrument included color images and then the capability to measure vertical profiles of temperature and water vapor in the atmosphere below.

Recognizing that advancing computer capabilities provided the opportunity to obtain even greater value from his satellite observations, Suomi led efforts to develop interactive data analysis systems that could provide replays of weather events and combine data fields for detailed analysis. These systems proved valuable as the Global Atmospheric Research Programme (GARP), conceived by Suomi and other distinguished scientists, led to worldwide observation initiatives. At the time of his death, he was exploring the uses of the new global positioning system as the basis for new satellite observations of the atmosphere.

Suomi was a tireless advocate of the benefits of science and served on a wide variety of scientific and policy bodies. He was a member of the US National Academy of Engineering and similar academies and honorary bodies of the US and other nations. Awards, honors, and prizes from around the world recognized his creativity and contributions.

Verner Suomi was an unusual individual in many ways. He was patient with other people, but always impatient for progress. His unbounded energy and enthusiasm were contagious. But most of all, he combined a deep physical intuition and understanding with the insight and ingenuity that led to powerful instruments. He described his work as dabbling around in the wonders of creation, and through his bold and sweeping grasp of life and science, he helped the people of the world touch the wonders that he loved.

Sverdrup, Harald Ulrik

(1888- 1957)

Harald Ulrik Sverdrup, a Norwegian by birth, was the pre-eminent oceanographer of the first half of the 20th century. Sverdrup s two grandfathers were churchmen. His paternal grandfather had five sons, all of whom became churchmen, and three daughters who married churchmen. But Sverdrup did not follow the family tradition. After a brief stint in astronomy, Sverdrup accepted one of the renowned Carnegie assistantships to Professor V Bjerknes, under whose guidance he wrote the doctoral dissertation *Der Nordatlantische Passat* in Leipzig during World War I (on a starvation diet, as he later reported). Here, Sverdrup s style of mathematics as a tool for quantitative description rather than for deductive reasoning is representative of all his later work. This was also the style of his famous colleague and friend C-G Rossby.

At the age of 29, Sverdrup took charge of the scientific work (with additional duties as navigator and cook) aboard the *Maud* on Amundsen s North Polar expedition. The goal to duplicate Nansen s drift of the *Fram* across the North Pole was never realized. The expedition was planned to last for 3 years, but winter after winter the *Maud* was frozen fast, and she did not return for 7 years. Sverdrup made good use of the time, taking measurements of the physical properties of sea water and sea ice, of marine geologic features, aurora borealis, gravity, magnetism, atmospheric electricity, and even of the animal and bird life on the drift ice. At one time, he left the ship to spend 8 months as the lone white man with the nomadic Chukchi tribe of north-eastern Siberia, an experience he later described in a delightful book, *Reindeer Hair in your Soup* (now published in English). The most significant of the *Maud* papers was *Dynamics of Tides on the North Siberian Shelf*, which was completed on board ship (oceanographers will appreciate this feat).

Upon his return, Sverdrup succeeded V Bjerknes in the Chair of Meteorology in Bergen and became Research Professor at the Michelsen Institute. In 1936 he accepted the Directorship of the Scripps Institution of Oceanography in La Jolla, CA, for a 3-year period. The war intervened, and Sverdrup did not permanently return to Norway for 12 years. During his tenure, Scripps grew from a land-locked marine station to a general oceanographic institute with an active seagoing program. He personally made significant scientific contributions to the war effort.

In the postwar years, Sverdrup devoted much effort to writing (with Johnson and Fleming) *The Oceans, their Physics, Chemistry and Marine Biology*. This is the last comprehensive work covering all aspects of oceanography in a single volume. The book reflects Sverdrup s broad exposure during his 7 years in the Arctic.

Sverdrup s final accomplishment while in America is now broadly known as Sverdrup dynamics. This mathematical representation of the ocean circulation relates northward mass transport $\rho \int v\,\mathrm{d}z$ to $\beta\ \mathrm{curl}\,\tau$, where τ is the wind-stress on the sea surface, and $\beta = \mathrm{d}f/\mathrm{d}y$ is the northward derivative of the Coriolis parameter f. This simple torque relation avoids the equatorial singularity of the traditional force equation, a singularity that had plagued oceanographers for generations. As is typical of his work, the origin of Sverdrup dynamics came from analysis of data and not from deductive analysis.

In 1948, at the age of 65, Sverdrup returned to Norway. He had greatly admired Nansen s decision to totally drop all scientific activity at this time of life. He did likewise. Sverdrup took charge of a Norwegian project for improving fishing in India. He also chaired a committee for re-organizing the Norwegian educational system. In August 1957, Sverdrup died from heart failure in Oslo, 2 days after the death of his good friend Carl-Gustav Rossby in Stockholm, also from heart failure. The death of the two giants drew to a close the era of explorer–scientist from the countries of the large Coriolis parameter.

Temperature

Temperature is a measure of the magnitude of mean molecular kinetic energy in a physical substance. This energy, called *internal energy*, is defined by the motions of the individual molecules relative to the motion of the center of mass of the physical body. The temperature difference between adjacent physical bodies determines the direction of transfer of this internal energy between the bodies by intermolecular interactions (sensible heat transfer). The transfer is from the body with the higher temperature to that with the lower temperature. No such transfer occurs if the temperatures are the same. Temperature may be measured by a number of physical properties of material substances. Examples include the pressure of a gas in a fixed volume container, the volume of a gas or liquid under constant pressure conditions (such as the standard mercury thermometer), the resistance of an electrical conductor, and the electromotive force (voltage) produced by temperature differences in an electric circuit with two different conductors. The magnitude of temperature is represented by several linear scales, the most common of which are the Kelvin (K), Celsius (C), and Fahrenheit (F) scales. The Kelvin scale is an absolute scale in that magnitudes are proportional to internal energy so that a temperature of 0 K represents a reference condition of no internal energy, i.e., the coldest temperature possible. In these scales and at standard atmospheric sea-level pressure, the freezing point for pure water is 273.15 K, 0 °C and 32 °F, respectively, and the boiling point for pure water is 373.15 K, 100 °C, and 212 °F, respectively.

Thermohaline Circulation

Thermohaline circulation is the part of the ocean circulation that is driven by differences in heating/cooling and evaporation/precipitation/salinity forcing, as opposed to the part of the circulation driven by winds or tides (*see* Ocean Circulation, Volume 1; Salinity Patterns in the Ocean, Volume 1). The upper ocean thermohaline circulation is difficult to detect because of the strength of the wind-driven circulation there. However, thermohaline forcing (i.e., density differences caused by salinity and temperature differences) dominates the deep ocean circulation, below about 2000 m, which is the depth of the large-scale, wind-driven gyres. In contrast to the wind-driven circulation, the thermohaline circulation is of global scale. The abyssal (deep ocean) thermohaline circulation is driven by deep convection caused by large air–sea heat exchange in winter in isolated high-latitude locations. Such convection is very localized, in patches of about 1 km horizontal extent. Convection in these regions reaches 1500–2000 m depth but rarely to the ocean bottom. The abyssal circulation is also driven by rejection of saline brine during the formation of sea ice in narrowly defined regions – the briny waters increase the density of the underlying seawater. Deep water formation sites include the Greenland, Weddell and Ross Seas whose convection fills the abyssal oceans below about 2000 m and the Labrador and Okhotsk Seas, which fill intermediate depths below about 1000 m. Upwelling of these dense waters is considered to occur throughout the world s oceans and is a major cause for the large-scale, but weak, abyssal currents. The convective source regions and ocean basins are connected through deep western boundary currents (DWBCs). DWBC velocities can reach $0.1\,m\,s^{-1}$, while interior ocean velocities due to the thermohaline circulation are usually less than $0.01\,m\,s^{-1}$. In contrast, speeds of the wind-driven currents of the upper 2000 m of the ocean are about 10 times faster, reaching $1\,m\,s^{-1}$ in boundary currents and about $0.1\,m\,s^{-1}$ in mid-ocean.

LYNNE D TALLEY *USA*

Tidal Waves

see Tsunamis, Causes and Consequences (**Volume 1**)

Tides, Atmospheric

Atmospheric tides are regular but generally small oscillations of the pressure at the Earth s surface, and also in the wind, caused principally by the Sun but to a smaller extent by the moon. The solar-generated tides follow the Sun through all meridians with nearly constant amplitude in a given latitude and nearly constant time delay. Hence, at a given place on the Earth s surface, the period of oscillation is 24 h or a submultiple thereof. Daily changes of the wind in the stratosphere and above are observed with amplitude of many kilometers per hour, but, near the surface, tides can be easily detected in barometric records only in the tropics, where they have a dominant period of 12 h. Here, typical amplitudes of order 1 millibar (mb) (100 Pascals (Pa)) are observed with maximum pressure at about 10:00 and 22:00 h and minima at about 4:00 and 16:00 h, local solar time. The amplitude falls off with increasing latitude, and in any case it is swamped by random noise due to weather at mid to high latitudes. The atmospheric tide is basically caused by the daily cycle of thermal expansion in the upper atmosphere. The reason for its twice-daily manifestation at the surface remained a mystery until about 1967 when it was shown theoretically to be due to the near-inability of the atmosphere to transmit waves of long period from the stratosphere to the surface. However, a small oscillation of period 24 h at the surface does exist in addition to the predominantly 12-h variation.

The smaller atmospheric tidal oscillation due to the moon has a dominant period of 12.5 h and amplitudes of order 0.1 mb (10 Pa). This lunar tide is driven similarly to the oceanic tide, by variations in the minute tilt of gravity from the vertical caused by the moon s orbit, but it is also affected by direct interaction with the oceanic tide itself.

DAVID CARTWRIGHT *UK*

Tides, Oceanic

David Cartwright
Petersfield, Hampshire, UK

Any regular oscillation of large horizontal scale in the sea that is related to the motion of the Moon and the Sun is known as a tide. Oscillations in the horizontal are strictly called tidal streams or tidal currents, and the closely related vertical oscillations of the surface are called tidal elevations, but the word tide is commonly used to denote both types of motion.

The lunar (and solar) components of the oceanic tides are caused by the out of balance stresses at the Earth s surface between the gravitational pull of the Moon (Sun) and the centrifugal acceleration of the orbit. These stresses tilt the directions of the vertical, towards the Moon (Sun) on the near hemisphere and away from the Moon (Sun) in the opposite hemisphere, as illustrated in Figure 1. Tilting the vertical causes currents, which in turn are modified by the Coriolis effect of the Earth s rotation (*see* Coriolis Effect, Volume 1), by the shape of the continents, and by variations in the ocean s bottom topography. The currents cause tidal elevation to change in order to preserve continuity of mass. As the Earth turns relative to the pattern of stresses, tides result.

The principal spectral component of the tide at most places has a period of half a lunar day, that is 12 h 25 min; this component is known as M_2. Next in importance is the principal solar component with period exactly 12 h; this is known as S_2. These are examples of the semidiurnal tides. The ratio of amplitudes S_2/M_2 varies, but a typical value is 0.4. M_2 and S_2 reinforce each other about every 15 days to produce the *spring tides* of larger vertical range. These higher tides come a day or two after full and new Moons, the delay being due to friction. *Neap tides* are the correspondingly weak tidal ranges occurring when M_2 and S_2 are in anti-phase at the quarter phases of the Moon. Other factors that intermittently produce larger tides are the phases of the Moon and the passage of the equinoxes in March and September.

Diurnal components of the tide, with periods close to a lunar day and a solar day (known as O_1 and K_1), also exist. These components are almost negligible in some seas and oceans, but predominate in others. The diurnal tides are largest when the Moon and Sun have a high declination (i.e., angular distance from the equator), usually near the solstices in December and June. Spectral analysis of tides also reveals many other periodic components related to the motion of the Moon and Sun, generally called harmonic tidal constituents. Predictive tide tables are computed by summing many such harmonic constituents.

Contrary to a popular misconception, tidal elevation is not in general greatest when the Moon has greatest elevation in the sky, but may lag by any fraction of a period, according to oceanic position. The ocean basins resonate with natural periods comparable with the tidal periods. As a result, the amplitude also varies with position from zero at certain nodal positions (known as *amphidromes*) to as much as 5 m in some coastal seas. Accurate global maps showing contours of phase lag and amplitude are now available from high-precision satellite altimetry for all the main harmonic constituents. A global map for the principal lunar tide M_2 is shown in Figure 2.

In shallow seas exposed to the ocean, the tidal tilt of the vertical is less important than the slopes resulting from wave transmission of the local oceanic tides across the shelf boundary. Here the current speed is greatly magnified by transmission from deep to shallow water, and the rate of

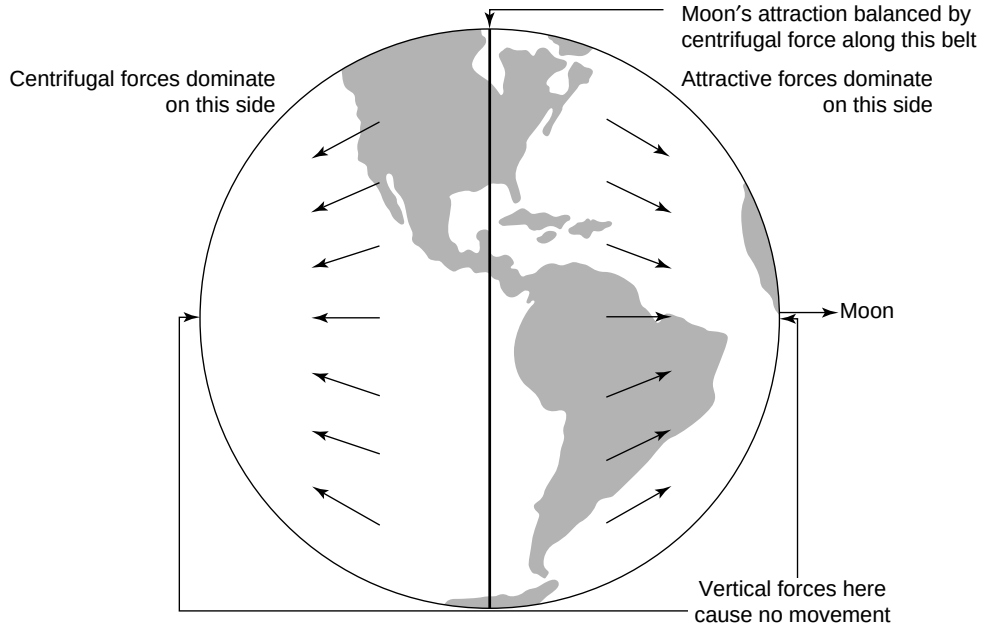

Figure 1 The pattern of the horizontal stresses that generate the tides, with the Moon in the direction shown. The effective tilting of the vertical is greatest, of order 10^{-7}, at 45° and 135° from nadir, and is zero at nadir and at 90°. When the orbit coincides with the equatorial plane, as shown, there are two equal tides per day. In general the Moon may be up to 28.5° above or below the equator, creating an asymmetry that then results in diurnal tides also being generated

energy transmission (being proportional to the square root of the depth) is reduced, with consequent magnification of the vertical amplitude. Small-scale coastal irregularities also produce local alterations. The net result is that maps of shallow coastal seas tend to have larger amplitudes and much closer spacing of contours, typically one-tenth of that of oceanic tidal maps. A little of the detailed structure may be seen in the more geographically constrained areas shown in Figure 2, particularly in the seas surrounding Britain and in the shelf seas east of Argentina and east of Asia.

Another characteristic of tides in shallow seas is that the wave form is distorted from that of a quasi-sinusoid, most commonly rising more rapidly and falling more slowly. An extreme example of this phenomenon is a *tidal bore*, familiar in some river estuaries. These distortions are due to the rise of vertical amplitude in relation to local depth, and to friction on the sea bed being stronger at low than at high tide. The distortion manifests itself spectrally in compound harmonics of the main tidal frequencies, known as *overtides*. In some coastal regions, particularly in parts of the English Channel, the overtides actually produce double high tides or double low tides, or a *stand* in level lasting a few hours.

The largest tidal ranges in the world, 12.9 m during spring tides, occur at the head of the Bay of Fundy, Nova Scotia. The large range is due to the shallow depth and dimensions of this bay together with the outlying continental shelf; in combination, these factors cause the bay to resonate to wave motions with period about 12.5 h. Similar local resonances with somewhat less tidal range are known in other shelf-sea locations.

The net effect of friction in the world s shallow seas and certain internal processes in the deep ocean is to apply a steady torque opposing the rotation of the Earth (*see* Atmospheric Angular Momentum and Earth Rotation, Volume 1). The torque lengthens the day by about 2.3 ms and causes the Moon to recede from the Earth by 3.8 m every century. These forces represent a dissipation of energy at the rate of 3.5 million MW. By contrast, the largest power station built to harness tidal power, which is located on the estuary of the river Rance in Brittany, generates less than 250 MW. A proliferation of such *clean* tidal power stations would therefore hardly harness one thousandth of the power dissipated by natural processes and would have a negligible effect in lengthening the day.

The oceanic tides are a fairly robust physical system. Little change in current strength, vertical amplitude or timing is likely to result from the expected trends in global warming or various large-scale engineering projects (*see* Tidal Power Development, Volume 3). For example, studies of secular changes at tide-gage stations that have existed for over a century in exposed locations have

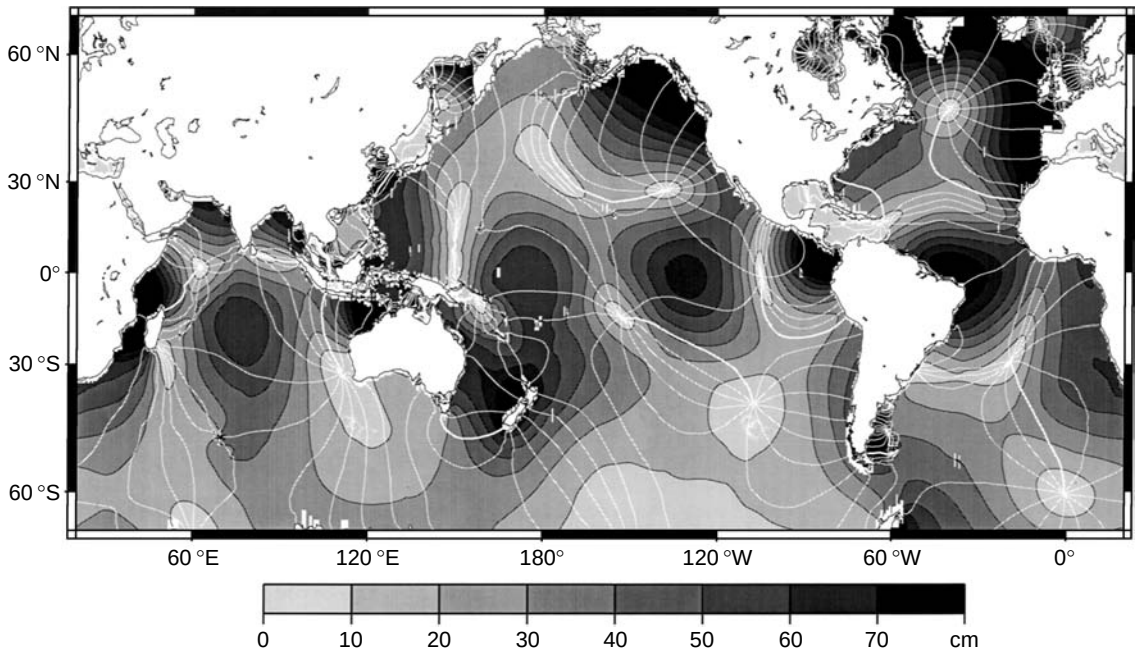

Figure 2 The principal lunar tide M_2 in the deep ocean shows a complex geographic pattern. White lines indicate the phase lag after lunar transit at Greenwich in 12 steps of 30°, each step being equivalent to 1.035 h. Phase lag is zero along the thicker white lines. Amplitude in centimeters according to shading, with black indicating the largest amplitude, pale-gray the least. The amplitude is zero at the nodal points (amphidromes) about which the phase lines radiate. (Figure by courtesy of Richard D. Ray, NASA)

shown changes of only a few centimeters and a few minutes in timing. The largest changes have been observed where a shallow river estuary such as the Thames has been intensively dredged, resulting in the tide arriving at London about 1 h earlier than in medieval times, but with little change in amplitude. A rise in mean sea level by 1 m or so is negligible compared with oceanic depths in its effect on global tidal dynamics. Of far greater consequence is the expected rise in mean sea level itself and its potential for flooding low-lying coastal terrain (*see* Intertidal Zones, Volume 2; Sea Level, Volume 1).

TOGA (Tropical Ocean Global Atmosphere)

The TOGA Program was a 10 year (1985–1995) international program of the World Climate Research Programme with formal objectives:

1. to gain a description of the tropical oceans and the global atmosphere as a time-dependent system, in order to determine the extent to which this system is predictable on time scales of months to years, and to understand the mechanisms and processes underlying that predictability;
2. to study the feasibility of modeling the coupled ocean–atmosphere system for the purpose of predicting its variations on time scales of months to years;
3. to provide scientific background for designing an observing and data transmission system for operational prediction if this capability is demonstrated by the coupled ocean–atmosphere system.

Because of resource limitations, the TOGA Program was conducted primarily in and over the Pacific Ocean and was dedicated to the elucidation of the El Niño/Southern Oscillation phenomenon. The TOGA Program met its third objective by not only designing an observing system, but by deploying a unique system of 70 moorings (the Tropical Atmosphere Ocean, TAO array) deployed along the entire tropical Pacific within 8° of the equator and reporting its observations daily and making the observations available to all (http://www.pmel.noaa.gov/toga-tao/realtime.html).

The first two objectives were aided by this system: predictability was demonstrated by using the data from this system and actually making skillful predictions of sea surface temperature in the tropical Pacific, showing the effects of these predictions on aspects of mid-latitude climate, and showing that the predictions of both tropical and mid-latitude climatic affects had societal value.

Even though TOGA ended in 1995, it has left a number of legacies: the TAO array; the initiation of climate prediction activities on seasonal to interannual times scales in many institutions throughout the world; and the creation of an institute designed to make and apply the predictions to societal benefit, especially in the developing world, the International Research Institute for Climate Prediction (http://iri.ldeo.columbia.edu/). A set of review papers covering the results of the entire international TOGA program was published as a special volume (see Anderson *et al.*, 1998). The US TOGA Program as seen in the context of the International TOGA Program was published in the National Research Council (1996).

Tornadoes

Howard B Bluestein
University of Oklahoma, Norman, OK, USA

Tornadoes are rapidly rotating columns of air that are in contact with the ground. They are observed underneath convective storms or underneath convective clouds that are quickly developing into storms but have not yet produced precipitation at the ground. Some tropical cyclones spawn tornadoes when they make landfall. Tornadoes are often, but not always, visible as a condensation funnel underneath cloud base. Some tornadoes are visible only as a rotating column of debris, while others may be hidden behind a curtain of precipitation. A tornado over water is called a waterspout.

Wind speeds at the ground in tornadoes range from around $18\,\mathrm{m\,s^{-1}}$ (40 mph) to as high as $140\,\mathrm{m\,s^{-1}}$ (312 mph) in the most violent case. The intensity of tornadoes is often rated on the Fujita (F) scale, which is based

on the nature of the damage inflicted and ranges from 0 to 5. The correspondence between F-scale rating and wind is as follows: F0 ($18-32\,m\,s^{-1}$), F1 ($33-49\,m\,s^{-1}$), F2 ($50-69\,m\,s^{-1}$), F3 ($70-92\,m\,s^{-1}$), F4 ($93-116\,m\,s^{-1}$), F5 ($117-142\,m\,s^{-1}$). The last can remove well-built houses from their foundations. The highest theoretically possible wind speed depends on both the vertical profile of temperature and moisture (which determine the potential buoyancy) and the wind field; thus, the so-called thermodynamic speed limit can be exceeded, owing to rapid accelerations of air parcels near the ground. The intensity of tornadoes is inversely related to their frequency of occurrence, since it is relatively unlikely that all the conditions necessary for the most intense ones occur.

In the Northern Hemisphere (in the Southern Hemisphere) the winds in most tornadoes rotate in a counterclockwise (clockwise) manner; in some, however, the air rotates in the opposite direction. Ranging in diameter from around 100 m to 1.5 km, some tornadoes are so shallow that they barely extend up to cloud base, while others can extend for 10 km or more, throughout the depth of their parent storm. They can last from a few seconds up to one hour or longer. Most are on the order of hundreds of meters across and last for around tens of minutes. Some convective storms produce a series of tornadoes, which altogether can produce a damage track a 100 km or longer.

Tornadoes move along with their parent storms, but may also rotate around a larger-scale vortex embedded within the storms, or may be displaced laterally by evaporatively cooled gusts of relatively dense air near the ground. Some tornadoes contain smaller-scale vortices, which may be very intense, rotating around a common axis; these multiple satellite vortices are likely responsible for the sometimes-observed spotty nature of tornado damage. Results from laboratory model experiments and computer simulations suggest that whether a tornado has multiple vortices or not depends upon the ratio of the amount of circulation about the tornado vortex to the amount of convergence into the vortex, the *swirl ratio*.

Studies of laboratory models and computer simulations indicate that in single-cell tornadoes, air converges into the vortex near the ground and rises at its center; compensating sinking air is found outside the tornado. In two-cell tornadoes, air that converges into the vortex near the ground rises before it reaches the center; sinking motion is found at the center. Two-celled tornadoes tend to occur when the swirl ratio is relatively high. There is both theoretical and observational evidence that the horizontal wind field in a tornado behaves like a rotating solid body (which has constant vorticity) surrounded by a fluid having no vorticity.

Observed over much of the world, both at low elevations and over mountainous terrain at high elevations, tornadoes are most frequent over a portion of the central US sometimes referred to as Tornado Alley, where a north–south oriented mountain range to the west and a warm body of water to the south, often create favorable conditions for storms that can spawn tornadoes. Although tornadoes can occur at any time of the day or night, or in any season, they are found most frequently in the late afternoon and early evening during the spring.

Most significant tornadoes are spawned in convective storms called *supercells*. Unlike ordinary thunderstorm cells, each of which lasts for less than one hour, supercells last for much longer periods of time, owing to a cyclonically-rotating column of air, the mesocyclone, which is several kilometers wide, and contains air ascending as rapidly as $50\,m\,s^{-1}$ (110 mph) or more. Supercells tend to move to the right (left) of the tracks of ordinary thunderstorms in the Northern (Southern) Hemisphere and often produce large hail.

Supercells can form when there is relatively strong vertical wind shear, i.e., when the wind speed and/or direction at low levels is much different from the wind speed and/or direction at mid- and upper-levels in the troposphere. Since underneath the jet stream there is often strong vertical wind shear, supercells tend to be found during those seasons when the jet stream is near. Since a buoyant updraft is also required, supercells are found when there is relatively warm, moist air near the ground and much cooler air aloft.

Tornadoes in supercells tend to be found near the edge of rain and/or hail, where air is descending, but attached to a lowered cloud base called a wall cloud, in which air is ascending. The tornado is often adjacent to the region where the largest hail reaches the ground. Tornadoes are produced in fewer than half and possibly in fewer than a quarter of all supercells for reasons which are not completely understood. It is also not known what role the mesocyclone has in producing tornadoes. Some tornadoes in supercells form first aloft and build downward; others appear in an air column simultaneously. The detection of rotation in a mesocyclone or developing tornado by a Doppler radar is often used as a basis for the issuance of a tornado warning, often as much as 20–30 minutes in advance. Although there has been much speculation that tornadoes may be related to electrical activity in thunderstorms, it appears that electrical effects are not responsible for their formation (Figure 1).

Other tornadoes can also occur in ordinary convective storms. Unlike supercell tornadoes, which are associated with mesocyclones, tornadoes in ordinary convective storms acquire their rotation from the boundaries along which their parent storms form.

Most tornado damage occurs as a result of wind stress, which varies as the square of the wind speed, while other damage occurs when objects become airborne debris and

Figure 1 Photo of a Tornado taken on 5th of June, 1999, southwest of Bassett, NE. (Copyright Howard B Bluestein)

then make impact. Although the pressure inside a tornado can be as much as 10% less than that of its environment, most damage to buildings is not caused by rapid pressure changes. The safest place to be when a tornado strikes is underground. If it is not possible to get to an underground shelter, one should go to an interior closet or bathroom and protect one s head from flying debris.

It is very difficult to determine whether or not the frequency of occurrence of tornadoes or their geographic locations has changed on decadal time scales, even in the US where they are most frequently observed. Reports of tornadoes are heavily weighted by population density, and have been affected by the recent public awareness of weaker tornadoes, which were not reported as often in earlier years. Estimates of tornado intensity using the F scale are not very reliable when the nature of structures damaged by the tornado is not well known; furthermore, many tornadoes strike unpopulated areas where little if any damage can be found.

Estimating future trends in tornado frequency and intensity requires knowledge of why some convective storms produce tornadoes, while others do not. One could estimate the likelihood that the frequency of occurrence of supercells would change from a predicted change in the vertical wind-shear profile and potential buoyancy. The former depends on the nature of the general wind circulation and the latter depends on the vertical distribution of temperature and moisture; both the former and latter might be sensitive to global climate change.

Trade Winds

The surface winds over most of the tropics are from the east and directed towards the equator. These are the (easterly) *trade winds*. The trade winds are much steadier in both speed and direction than the surface winds at higher latitudes. The mechanism maintaining the trades is understood as a consequence of the existence of the Hadley Circulation (*see* Hadley Circulation, Volume 1), which operates as a heat engine to transfer heat away from the warmer low latitudes to the cooler high latitudes. Because of momentum conservation, the rotation of the Earth causes the trade winds to blow from east to west.

Transient Response

In climate change research, the term *transient response* is used to indicate the time-dependent character of how a system (typically a numerical model) responds to a perturbation. Because it is sometimes difficult to specify the time-dependent changes in forcings or other boundary conditions, initial studies often are designed to determine the response to a sustained perturbation of some arbitrary size (e.g., doubling the atmospheric carbon dioxide (CO_2) concentration). Such a response indicates the equilibrium response of the system (*see* Equilibrium Response, Volume 1). However, because the forcing factors are likely to be changing at the same time other factors are changing (e.g., the CO_2 concentration is slowly increasing at

the same time solar radiation is varying) and because time lags are varied and complex, conditions are rarely the same long enough for a system to reach new steady state conditions. Thus, the system is always trying to catch up to the changes in forcings that are taking place, and even if the forcing stabilizes at some new value, there will be continuing change as the system tries to equilibrate to the new conditions.

For example, to determine how the climate is likely to respond to changes in atmospheric composition, a rough sense is provided by determining, using a numerical model, the sensitivity of the climate to a steady state doubling of the CO_2 concentration (*see* Climate Sensitivity, Volume 1). However, although some have used such results to try to interpolate how the climate might respond to a gradually increasing CO_2 concentration, this introduces quite a number of problems because feedback processes involving such processes as ice and snow cover and their albedos exhibit nonlinearities and thresholds and because the time for new equilibrium conditions to develop can be very long. For this reason, it has proven essential to attempt to represent the time-dependent nature of the forcings and to simulate the time-dependent (or transient) response.

In simulating the global climate, model simulations are being carried out that involve, for example, specifying the time-varying composition of the atmosphere and then calculating the time-dependent response of the climate system. Early model experiments of this type were based on simplified approximations to changes in atmospheric composition (e.g., the CO_2 concentration increasing at a compound rate of 1% per year). More recently, model experiments have involved simulation of the response to reconstructions of the historic rates of change in atmospheric concentration and scenarios of how the composition may change in the future.

Although such attempts to simulate the observed history of the climate would seem to be just the type of information needed, there are several challenges. A key one is in initializing such simulations. In that the climate has always been changing, and has been changing particularly rapidly over the past century due to human activities, determining how best to start the experiment can have important influences on the results. For example, if the problem is started based on observations of current conditions, a way has to be found to initialize the changing state of all of the various systems (including particularly the ocean and land vegetation). If the problem is started back in time a couple of hundred years, so prior to human influences, there are far fewer observations of key variables with which to verify and initialize the model experiment even though the approximation of near steady state may be more appropriate, allowing the model itself to develop the initial conditions. In addition, starting back in time and running up to the present requires information on the time histories of the various factors that influenced the climate over this period. And further, because the climate is a chaotic system (*see* Chaos and Predictability, Volume 1), an ensemble of simulations needs to be conducted to ensure a statistically satisfactory representation of how the model climate is responding.

Although sometimes difficult to conduct and plagued by limitations in observations to use to drive and test the models, such transient experiments are vital to developing an understanding of how rapidly or slowly the interacting set of climate processes and feedbacks will respond. Although complicated by the natural variability of the system, studies are now underway to compare the results of model simulations of the time-dependent changes in the global climate over the past 100 years with observations of these changes (*see* Climate Change, Detection and Attribution, Volume 1). It is these studies that led the Intergovernmental Panel on Climate Change (IPCC) to conclude that the balance of evidence suggests that there is a discernible human influence on global climate (IPCC, 1996). More recently, studies are focusing on the temporal and spatial patterns of the transient response of the climate to human-induced activities.

TRMM (Tropical Rainfall Measuring Mission)

TRMM is the first space mission dedicated to measuring tropical rainfall through microwave and infrared sensors; a key instrument is the first weather radar in space.

Measuring tropical rainfall and its variability is crucial to understanding and predicting global climate change. By use

of a low-altitude orbit of 350 km (217 miles), TRMM will increase knowledge of how rainfall releases heat energy to drive the atmospheric circulation. TRMM s orbit ranges between 35 °N and 35 °S so that it flies over each surface position at a different local time, permitting determination of how rain varies over the 24-h day.

TRMM is a joint project between the United States and Japan. The National Space and Development Agency of Japan provided the precipitation radar and the H-II rocket launch on November 27th, 1997 for a 3-year mission. TRMM completed 3 years of a very successful mission in November 2000, with enough fuel remaining to continue taking data for 2–4 additional years. NASA s Goddard Space Flight Center provided the observatory, three instruments, the Science Data Processing System, and operation of the TRMM satellite via the Tracking and Data Relay Satellite System. TRMM s primary instruments are a multi-channel passive microwave instrument, the rain radar, and a visible and an infrared radiometer. In addition, TRMM flies a Lightning Imaging Sensor (from Marshall Space Flight Center) and a Clouds and Earth Radiant Energy Sensor (from Langley Research Center).

TRMM runs a continuous validation program using data from four primary sites with calibrated surface radars, rain gauges, and data networks. Four intensive field programs with instrumented aircraft underflights took place over both land and ocean in 1998/1999. Some of the TRMM products involve the use of data from other civilian satellites, such as those in geosynchronous orbit, and from military satellites that fly multi-channel passive microwave instruments in polar orbits.

More information on TRMM and access to its data may be obtained from http://trmm.gsfc.nasa.gov.

Tropopause

The *tropopause* is the boundary separating the troposphere (below) from the stratosphere (above) at a height of around 11 km in midlatitudes. The tropopause is highest in equatorial regions (order 17 km) and lowest over the poles (order 8 km). It is typically defined as the height at which the temperature structure changes from decreasing with height below the tropopause, to being nearly isothermal with height above it. As the bottom boundary of the stable isothermal layer making up the lower regions of the stratosphere, the tropopause represents a barrier to vertical motion that impedes exchange of air between the troposphere and stratosphere. The barrier is not impenetrable, however, and some mixing of stratospheric and tropospheric air occurs when vigorous updrafts penetrate the tropopause or when stratospheric air is drawn downward near upper level fronts.

See also: Stratosphere, Volume 1; Troposphere, Volume 1.

KEITH L SEITTER *USA*

Troposphere

The *troposphere* is the layer of the Earth s atmosphere from the surface to about 11 km in mid-latitudes, in which the temperature normally decreases with height. On clear calm nights, however, the air near the ground cools, causing a rise in temperature in the lowest 100 m or so (called a *radiation inversion*). It is in this layer that most of the phenomena described as weather occur. The troposphere s temperature structure is a result of the vertical mixing that is prevalent in this layer. Convection, both on local and global scales, leads to the troposphere often being vertically well mixed, and the expansional cooling associated with upward motion as well as the compressional warming associated with downward motion leads to an average decrease in temperature with height of about 6.5 °C km^{-1}. The troposphere is capped by

a stable isothermal layer, the bottom of which is referred to as the *tropopause*. This stable layer impedes further vertical motion so that circulations producing clouds and precipitation are confined to the troposphere.

KEITH L SEITTER *USA*

Troposphere, Ozone Chemistry

Cynthia S Atherton
Lawrence Livermore National Laboratory, Livermore, CA, USA

Tropospheric ozone refers to ozone (O_3, a tri-atomic form of oxygen) present in the lowest layer of the atmosphere. The troposphere extends from the surface up to 10- 16 km. Because tropospheric ozone can come close to the surface, it damages materials, plants, and is a respiratory irritant. Ozone can also act as a greenhouse gas. Tropospheric ozone arises from two main sources - in situ *chemical production and transport from the stratosphere. The relative importance of these two processes is still debated.*

Few long-term records of ozone concentrations exist. Tropospheric ozone levels have increased substantially since pre-industrial times (~1850). Current models predict that tropospheric ozone may increase signi cantly between now and 2050. These increases affect not only the chemical cycle of the atmosphere, but also the amount of radiation that reaches the surface of the Earth.

Ozone (O_3) is a key atmospheric gas. Ozone in the stratosphere is beneficial because it absorbs incoming ultra-violet (UV) radiation from the Sun. Stratospheric ozone depletion, e.g., the Antarctic ozone hole, therefore, is potentially harmful because it increases human and environmental exposure to UV radiation. In the troposphere, however, a high ozone episode damages materials, vegetation, and is a respiratory irritant. Tropospheric ozone is both chemically produced *in situ* and transported down from the stratosphere, where concentrations are much higher. Within the troposphere, ozone forms when carbon monoxide (CO), methane (CH_4), and non-methane hydrocarbons (NMHCs) react in the presence of nitrogen oxides ($NO_x = NO + NO_2$) and sunlight (Crutzen, 1973). Both natural (biogenic) and human-induced (anthropogenic) processes emit these precursors. Sources include fossil fuel combustion, biomass burning, lightning and emissions from plants and soils. Transport from the stratosphere (Danielsen, 1968) occurs in extratropical latitudes, mainly due to tropopause folding events and the decay of cut-off low-pressure weather systems.

MEASUREMENTS SINCE PRE-INDUSTRIAL TIMES

Ozone concentrations appear to have increased since pre-industrial times (~1850). During the late 1800s, ozone was measured using the Schonbein method on several continents. Unfortunately, the method was susceptible to interferences, and ozone was measured for long times at only a few locations. Data, however, have been reanalyzed for Paris, Moncalieri (Italy), South America, Pic Du Midi (southwestern France), Zagreb (Yugoslavia), and other locations (see, e.g., Volz and Kley, 1988; Anfossi *et al.*, 1991; Sandroni *et al.*, 1992; Marenco *et al.*, 1994). While the results are somewhat qualitative, they suggest that in the late 19th century, annual average surface ozone concentrations may have been as low as roughly 10 parts per billion volume (ppbv). Current measurements in similar locations, as shown in Figure 1, indicate surface ozone concentrations may have increased by a factor of 2–5, corresponding to a rate of 1.6% year^{-1} for the past 100 years (Marenco *et al.*, 1994; Staehelin *et al.*, 1994).

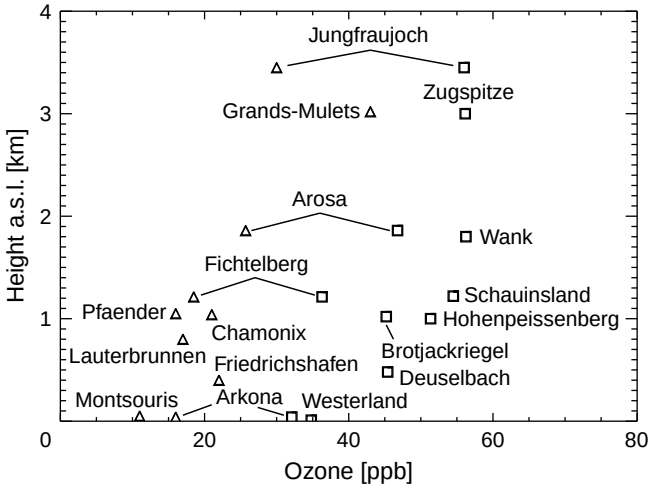

Figure 1 Measurements of surface ozone concentrations from different locations in Europe performed before the end of the 1950s (△) and in recent years (1990–1991; □) during August and September, as a function of altitude. (Reprinted from *Atmospheric Environment*, Staehelin *et al.*, 1994, with permission from Elsevier Science)

CURRENT CLIMATOLOGIES AND RECENT TRENDS (20TH CENTURY)

Climatologies of tropospheric ozone have been published using surface, ozonesonde, and satellite measurements (Fortuin and Kelder, 1998; Logan, 1999). Concentrations vary with season, location, local meteorology, and other factors (WMO, 1998). Multi-decadal records of tropospheric ozone exist for only a handful of sites that are not influenced by local sources. At a small number of locations, vertical distributions are measured by ozonesondes, which are lightweight electrochemical cells carried on balloons to roughly 30 km. These measurements are most uncertain in the troposphere. Their geographic distribution is limited, and instrument calibrations, sampling frequency, changes in methods, etc., affect results.

Tropospheric column ozone (the amount of ozone in a column from the Earth s surface to the tropopause) has recently been measured directly by satellites (Munro *et al.*, 1998). It is also derived as the difference (residual) between satellite measurements of total column and stratospheric column ozone. This residual indicates high ozone levels in the Northern Hemisphere in the summer and plumes in the South Atlantic Ocean that arise from biomass burning (Fishman *et al.*, 1991).

Tropospheric ozone trend studies of the past 30–35 years use data from a small number of ozonesondes and surface sites. In specific regions, tropospheric ozone may increase if precursor emissions increase, or decrease if stratospheric ozone decreases. At high latitudes (e.g., over northern Canada, Alaska, the South Pole), near-surface and free tropospheric ozone appear to be decreasing, perhaps due to decreasing stratospheric ozone concentrations (Oltmans *et al.*, 1998; Tarasick *et al.*, 1995). The largest decrease is over the South Pole, with a trend of $-0{\bullet}70 \pm 0{\bullet}20\%\,\text{year}^{-1}$. Ozonesondes at five Canadians sites showed negative trends for 1981–1993 of -1.0 to -2.2%, depending on height in the troposphere.

In the northern mid-latitudes, two eastern United States (US) sites show only slight increases in tropospheric ozone since 1970 (Oltmans *et al.*, 1998). Over much of the US, surface ozone did not show an appreciable trend during 1980–1995, and showed decreasing trends primarily near New York City, Los Angeles, and Chicago (Logan, 1994; Fiore *et al.*, 1998).

In Arosa, a high elevation station in Switzerland, it appears that surface ozone concentrations have increased by a factor of 2.2 since the 1950s (Staehelin *et al.*, 1994). Although European ozone concentrations increased rapidly through the mid-1980s, there appears to have been no change or little decrease since then (Logan, 1994; Oltmans *et al.*, 1998). Increases in ozone over the mid-latitudes of Japan are largest in the lower troposphere; however, they have slowed in the last decade (Oltmans *et al.*, 1998).

Less data are available for the tropics and subtropics. The tropics generally have not experienced significant changes in tropospheric ozone (Oltmans *et al.*, 1998; WMO, 1998). Sites located at 34°S and 41°S may show very slight increases in ozone (Oltmans *et al.*, 1998).

MODELING RESULTS – PAST ATMOSPHERES

Global, three-dimensional atmospheric models have simulated both pre-industrial and present day atmospheres. They show ozone increases of 10–40 ppbv (a factor of 2–4 higher) since pre-industrial times. The largest increases tend to be in the Northern Hemisphere during summer. Although the largest percentage ozone increase occurs near the Earth s surface, the largest change in total ozone mass occurs in the upper troposphere. The tropospheric ozone burden (the total mass of ozone in the troposphere) appears to have increased by 40–70% since pre-industrial times.

Increases in tropospheric ozone lead to increases in the absorption of both longwave and shortwave radiation in the troposphere. The change in the net radiative flux at the tropopause (the top of the troposphere) is called *radiative forcing* (*see* Radiative Forcing, Volume 1). Changes in ozone near the tropopause are much more efficient at increasing radiative forcing than changes near the surface, by as much as a factor of 10 (Lacis *et al.*, 1990). Increases in tropospheric ozone since pre-industrial times may have increased global annual radiative forcing by $0.2–0.5\,\text{W}\,\text{m}^{-2}$. Regional and seasonal variations may range from 0.1 to $1.0\,\text{W}\,\text{m}^{-2}$. For comparison, the increase in carbon dioxide (CO_2) since pre-industrial times is predicted to have increased radiative forcing by $1.6\,\text{W}\,\text{m}^{-2}$ (IPCC, 1995).

MODELING PREDICTIONS – OZONE IN FUTURE SCENARIOS

Ozone is expected to increase as emissions of biogenic and anthropogenic O_3 precursors increase. For example, as temperature increases, emissions of isoprene (a hydrocarbon emitted by plants) soil NO_x, and lightning NO_x are expected to increase. Increased lightning NO_x may increase ozone, but soil NO_x and isoprene have not yet been studied globally.

Several models have predicted changes in ozone and radiative forcing due to increases in anthropogenic emissions between 1990 and 2050. Brasseur *et al.* (1998) project the largest relative change in zonal average O_3 concentrations will be ~30% (4 ppbv) near the surface in the tropics. The largest absolute change in zonal average O_3 concentrations is projected to be 35 ppbv (~25%) near 300 mb in the northern mid- and high-latitudes. Ozone in the boundary layer is predicted to increase by 10–20 ppbv (~50%)

over Asia, Central America, South Africa and Brazil. This would lead to a global average increase in radiative forcing due to O_3 of 0.41 W m^{-2} (Brasseur *et al.*, 1998), compared to projections in similar studies of 0.28 W m^{-2} (van Dorland *et al.*, 1997) and 0.21 W m^{-2} (Stevenson *et al.*, 1998). The models predict a higher increase in radiative forcing in the Northern Hemisphere compared to the Southern Hemisphere.

Tropospheric Temperature

John R Christy

University of Alabama in Huntsville, Huntsville, AL, USA

Tropospheric temperature measurements, which are extensive enough to begin to address issues of global variability and change, have been reported since 1958 from balloons, and 1979 from satellites. Temperature variability is greater in the deep troposphere than observed at the surface, as can been seen in responses to transient climate events such as El Niño/Southern Oscillation (ENSO) events and volcanoes. Analyses of temperature trends in the troposphere from both balloons and satellites show a warming of approximately 0.10 °C decade^{-1} since 1958 and about 0.04 °C decade^{-1} since 1979. The rate since 1979 is about one-third the rate of temperature increase observed at the surface. In particular, the tropical latitudes show trend-differences of about 0.15 °C decade^{-1}, with the surface warming faster. Whether the period since 1979 is truly representative of the longer-term climate responses of the surface and atmosphere to in uences such as increasing greenhouse gas and aerosol

concentrations is made more dif cult to assess because of the relatively short length of time examined here.

INTRODUCTION

Research concerning climate variation and change is generally focused on the surface climate because this is where we as humans live and produce what is necessary for our survival. However, surface climate is dependent upon the behavior of the atmosphere as a whole. Above the Earth s surface is a deep layer of fairly well-mixed air called the troposphere (from Greek $\tau\rho o\pi\eta$, or turning) in which the familiar processes of weather occur. This layer stretches from the surface to altitudes of 16–17 km in the tropics, but only to about 8 km near the poles. In terms of mass, the troposphere represents over 80% of the global atmosphere. Above the troposphere lies the thin and stable stratosphere.

With the advent of aviation, and particularly the needs of aviators in World War II, knowledge of the behavior of the troposphere became vital. To measure such quantities as temperature and winds aloft, balloons were released from the surface carrying instrument packages which would transmit measurements by radio to a ground station as the balloon ascended (*see* Radiosondes, Volume 1). This radio-based system provided information necessary to reconstruct an atmospheric sounding (i.e., vertical profile), and so the balloon/instrument package was and is known as a radiosonde. Radiosonde releases were concentrated along airways in the 1940s and 1950s and so could not give a picture of, for example, the global variation of tropospheric temperature to answer scientific questions. The emphasis on global measurements during the International Geophysical Year of 1957–1958 brought several new stations into the mix so that attempts could begin to assess global temperature variations and trends, though vast oceanic regions were (and are) still unobserved.

In the 1970s, satellites were first used to create vertical profiles of atmospheric temperature as well. However, the satellite technique of temperature reconstruction, in most cases, is not a straightforward method. Unlike radiosondes, which report temperature at many discrete levels, satellite radiometers receive emissions from deep layers of the atmosphere, often several kilometers thick. Most weather forecasting and aviation problems require data at discrete levels, so estimating the true vertical profile of temperature at many levels using the broad satellite-measured layer values was and is a difficult challenge. However, it is relatively easy to produce from radiosonde data what would be sensed by the satellites. It is this type of comparison that will be examined below.

Most of the activity we call weather, such as clouds and storms, occurs within the troposphere, so that surface conditions are significantly determined by what happens in this deep layer. The connection between the surface and the troposphere, though, varies considerably around the globe. Over mid-latitude continents, for example, solar heating of the surface generates rising convective currents of air that produce substantial mixing throughout the troposphere. In these regions, the surface and tropospheric temperature tend to vary in unison, though the effect dominates during the daytime.

Over the polar ice caps, there are low-level temperature inversions due to radiation effects. In the tropics and subtropics, it is the anticyclonic subsidence inversion that is at play, which is associated with the trade-wind inversion. In such regions, the surface temperature is relatively cool and there is little mixing of surface air with the deep layer above so that a clear connection between the surface and tropospheric temperatures is not evident. Thus, the temperatures of the surface and troposphere represent the temperatures of different physical layers.

The combustion of carbon-based fuels for energy and transportation increased rapidly in the 20th century, resulting in increased atmospheric concentrations of carbon dioxide (CO_2), a greenhouse gas. In general, results from global climate models indicate that the surface and troposphere should warm as a consequence of increased CO_2 (and other greenhouse gases such as methane.) However, other emissions due to human activity, such as sulfur compounds or carbon soot, create aerosols which are thought to inhibit or enhance the flux of radiative energy to the surface, and so cause relative regional cooling or warming. When the estimated effects of all of these emissions are incorporated into climate models, the troposphere, particularly in the tropics, is predicted to warm at a more rapid rate than the average surface temperature. At the same time, other types of natural variations, such as EI Niño events and volcanic eruptions, and of human-induced changes, such as ozone depletion and land cover change, can also cause different temperature responses in the troposphere and at the surface. Thus, precise knowledge of the global surface and tropospheric temperature is needed to check against such modeled simulations and help provide clarity on the potential evolution of greenhouse-induced global climate changes.

The following sections describe the key methods used to determine tropospheric temperatures, as well as the major uncertainties associated with each. As will be shown, the remarkable correspondence between the temperatures measured by balloons and satellites independently give confidence that the long term variations they measure are substantially correct. One consistent result, that since 1979 the troposphere has warmed little while the surface has warmed considerably, is a curious finding which presents a challenge for climate researchers to explain at the dawn of the 21st century. Beginning with balloon data in 1958, the overall 40+ year tropospheric trend is very close to that of

the surface, indicating the period of the last two decades of the 20th century may be unusual.

DATA

There are three sources of tropospheric temperature data examined here. Radiosonde data are thought of as *in situ* data because the instrument carried aloft comes into direct contact with the air being measured. Satellites are remote measurements as they sense the intensity of radiation emitted by the atmosphere to space. And finally, reanalysis may be described as an intelligent combination of observations, both *in situ* and remote, with the added influence of mathematical relationships that approximate the physical laws of nature.

Radiosondes

Radiosondes (i.e., weather balloons) provide the longest record of upper air data and thus have been studied for clues as to the long-term variations of atmospheric temperature. However, changes in radiosonde instrumentation and data processing over the years have resulted in discontinuities in these temperature records (Gaffen, 1994; Parker *et al.*, 1997; Gaffen *et al.*, 2000a). Efforts to generate adjustments to account for these effects are a continuing area of research. One method uses models of the thermodynamics of radiosonde instruments to quantify the effect of varying radiation corrections applied in the processing of the raw data (Luers and Eskridge, 1998), but has yet to be applied on a daily basis to a global data set. A second method relies on statistical tests to identify change-points – sudden temperature shifts not likely to be natural (e.g., instrumental changes.) The global trend of a radiosonde dataset depends on how these inconsistencies are defined, which stations are utilized and the method of areal averaging (Santer *et al.*, 1999; Gaffen *et al.*, 2000a).

Since 1979, the temperatures from the microwave sounding unit (MSU) data have been available as a potential reference. In a third method, Parker *et al.* (1997) used the stratospheric MSU temperatures to adjust monthly radiosonde reports for stations in Australia and New Zealand at times when changes were reported in instrumentation or operational procedures. Some individual stratospheric corrections were as much as 3 K. The main disadvantage of Parker *et al.* s technique is that the raw MSU record has time-varying biases that must first be estimated and eliminated (Christy *et al.*, 2000).

For the analysis of trends, long station data records with minimal missing data are most desirable. The records for the 180 stations in the combined Global Climate Observing System Baseline Global Upper-Air Network, and the data sets that have been used in the earliest Intergovernmental Panel on Climate Change (IPCC, 1990, 1992) compiled by Angell (1988) do not generally meet this standard. In the CLIMAT dataset, a subset of about 400 radiosonde stations that report monthly statistics for tropospheric levels (850–100 hPa), only 74 stations reported enough data to produce monthly means for 85% of the overall period. Extending into the lower stratosphere (up to 30 hPa), only 22 stations meet this requirement. These deficiencies require using either relatively small networks of stations with adequate data or larger networks with lower quality, which may add uncertainty to resulting trend estimates.

The construction methodology of the various global balloon data sets is substantively different. Sterin (1997) from the Russian Research Institute for Hydrometeorological Information (RIHMI) use data from over 800 stations reported over the global telecommunication system and compiled into a special dataset known as the comprehensive aerological reference data set. The data were objectively interpolated to unobserved regions to produce global coverage. Parker *et al.* (1997) from the Hadley Center, United Kingdom Meteorological Office (HadRT) introduced a series of gridded datasets based on CLIMAT reports (HadRT2.0, ~400 radiosonde sites) containing only grids with *in situ*, unadjusted observations. Building upon HadRT2.0, derivative HadRT datasets progressively include more complete maps and adjusted values by infilling with statistical techniques and/or applying adjustments to the original data. Because the tropospheric temperatures from these datasets are relatively low in altitude, data availability is generally high and discontinuities are small (Parker *et al.*, 1997). Angell (1988) reports average volume-based temperature measurements of 63 stations with long data records.

Satellites

Unlike the discrete levels at which radiosondes measure temperatures, satellite instruments used to date observe the intensity of radiation from deep atmospheric layers. The MSU instrument detects emissions from atmospheric oxygen near the 60 GHz absorption line, the intensity of which is proportional to temperature. These satellites orbit the planet 14 times per day and measure emissions for over 30 000 systematically spaced locations every 24 h. About 98% of the Earth is observed over any 4-day period. Two temperature products made widely available are the low-mid troposphere (T2LT, surface to about 8 km) and the lower stratosphere (15–23 km, Christy *et al.*, 1998, 2000).

The MSU data have undergone three revisions since they first appeared in 1990, due to discoveries as the data were examined through time (Spencer and Christy, 1990). Mo (1995) reported that for one of the longest lived satellites (National Oceanic and Atmospheric Administration [NOAA] – 12, 1991–1998) the laboratory-tested,

non-linear calibration coefficients required corrections. In addition, Wentz and Schabel (1998) discovered that the loss of altitude during solar activity (when increased drag of the atmosphere causes orbit decay) induces gradual, spurious cooling in T2LT. Christy *et al.* (2000) found that instrument responses often differ between the laboratory assessments and on-orbit performance, and require additional corrections. Also, further adjustments to the MSU temperatures were made by explicitly recalculating temperature biases due to diurnal effects caused by east–west drift of the orbital path of the spacecraft.

Reanalyses

The methodology of reanalysis is to use historical data, along with a global computer model s data-ingestion scheme, to create a set of atmospheric data maps of weather parameters at many levels (Kalnay *et al.*, 1996). Within the ingestion scheme, potentially errant data are amended or excluded on the basis of comparisons with neighbors and/or expected conditions. However, small, time-dependent biases, of magnitudes potentially important for determining long-term warming or cooling, are virtually impossible to detect in a typical depiction of weather fields. Furthermore, in areas with few *in situ* data, the reanalyses may be affected by inadequate model physics or biased satellite data (different from products described above). Values of tropospheric temperature from the National Centers for Environmental Predication (NCEP) reanalysis are included for comparison purposes here, though it should be noted that discontinuities might exist in these data (Santer *et al.*, 1999).

RESULTS

Figure 1 shows tropospheric temperature variations since 1958 using representative datasets from those described above. Actual trend values ($^{\circ}$C decade^{-1}) since 1958 and 1979 are shown in Table 1. Consistent in the time series is the relative shift to warmer temperatures in the troposphere between 1975 and 1978 followed by large variations due to ENSO events, particularly in 1998, and volcanic events (Agung, 1963, El Chichón, 1982 and Mt Pinatubo, 1991). Christy and McNider (1994) and Michaels and Knappenberger (2000) show that over 60% of the variance in the global time series is due to these two recurring natural fluctuations with the atmospheric response lagging the event (i.e., ENSO or volcano) by a few months. In general, a sea surface temperature fluctuation during ENSO is communicated to the atmosphere through sensible and latent heat wherein a response factor of about 1.3 is measured (i.e., a rise in tropical sea water temperatures of 0.10 $^{\circ}$C translates to a rise in tropospheric temperatures of 0.13 $^{\circ}$C). Thus, the variance of the tropospheric temperature time series is greater than that of surface temperatures.

For the longer period (1958–2000), the tropospheric datasets in Table 1 indicate positive trends near $+0.10\,^{\circ}$C decade^{-1}. Since 1979, however, the tropospheric trends are less, around $+0.04\,^{\circ}$C decade^{-1}. This latter period represents an unusual result because the surface temperature trend during this period is calculated to be $+0.13$ to $+0.18\,^{\circ}$C decade^{-1} from various estimates, and is highlighted as evidence of human induced climate change (e.g., Santer *et al.*, 2000). (While all of the datasets described above are being used to detect small changes from year to

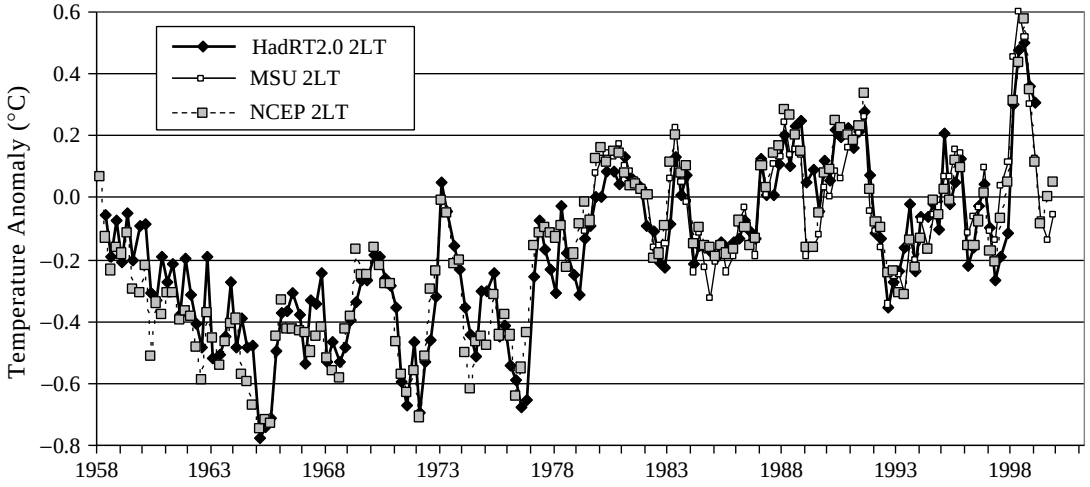

Figure 1 Seasonal global tropospheric temperature anomalies 1958–1999. HadRT2.0 is a compilation of radiosonde DATA, British Crown Copyright 2000 and was provided by Dr S J Brown, Hadley Centre, Meteorological Office, UK (Parker *et al.*, 1997). MSU 2LT represents satellite tropospheric temperatures as described in Christy *et al.* (2000). NCEP is the National Centers for Environmental Prediction (US) reanalysis (Kalnay *et al.*, 1996) converted to satellite temperatures by Dr M Stendel, Danish Meteorological Service

Table 1 Trends of annual anomalies of the following surface and tropospheric datasets computed by restricted maximum likelihood[a]

	Global		Tropics	
	1958–2000	1979–2000	1958–2000	1979–2000
Surface	+0.10	+0.16	+0.08	+0.10
Troposphere				
MSU	–	+0.04	–	−0.06
HadRT2.0	+0.11	+0.03	+0.13	−0.08
NCEP	+0.13	+0.01	+0.08	−0.07
RIHMI	+0.04	+0.00	+0.07	−0.06
Angell	+0.08	−0.02	+0.08	−0.05

[a] The surface data are comprised of land–air temperatures from the Climate Research Unit, University of East Anglia and the ocean near-surface temperatures from the Hadley Center, UK Met Office (Jones *et al.*, 1999; Folland *et al.*, 1995). MSU represents the MSU lower tropospheric values (Christy *et al.*, 2000), HadRT2.0: unadjusted radiosonde-simulated MSU temperatures (Parker *et al.*, 1997), NCEP, National (US) Centers for Environmental Prediction reanalysis-simulated MSU temperatures (Stendel *et al.*, 2000), RIHMI, 850–300 hPa radiosonde temperatures (Sterin, 1997) and Angell: 850–300 hPa thickness temperature (Angell, 1988).

year and decade to decade, it must be noted that none of the systems was specifically designed for this purpose.)

The major data uncertainties have been noted for the balloon, satellite and reanalysis temperatures. Because the balloon and satellite systems independently measure the temperature of the troposphere and have such remarkable agreement, it is highly likely that the actual slow variation (trend) of the troposphere since 1979 is fairly well characterized (Table 1 and NRC, 2000). The result implies that the bulk of the atmosphere s mass has shown little warming since 1979, and that the difference is significant (Christy *et al.*, 2001).

To further investigate this unusual phenomenon in which the surface temperatures apparently have warmed more rapidly than the tropospheric temperatures, Gaffen *et al.* (2000b) examined trends in tropical freezing elevation and lapse rate using radiosondes. They found that the mean elevation of freezing temperatures increased about 150 m between 1960 and 1980, indicating tropospheric warming. Since 1980, however, there has been a slight decrease (though not significant) in freezing height, consistent with a negative tropospheric temperature trend for this more recent period.

The lapse rate is simply the change in temperature versus altitude, which in the tropics (where the main difference in surface and tropospheric trends is found) is a slope of approximately $-6.5\,^{\circ}\mathrm{C\,km^{-1}}$. If the surface and satellite data shown here are both generally correct, then the lapse rate should reveal a tendency toward increasingly cooler values during the more recent period, as the upper air temperatures warmed less than lower level temperatures. One distinct advantage of utilizing this quantity is the elimination of radiosonde biases that come about when stations change methods or instrumentation because, here, the quantity measured is the relative difference in temperature at two levels, not the absolute temperature itself. Their results, also confirmed by Brown *et al.* (2000), indicate that since 1979 there has been a decrease of the tropical lapse rate (i.e., becoming even more negative). This provides further evidence that surface and tropospheric temperatures may respond with slightly different magnitudes of change to the sum of forces acting upon them.

Though there is less confidence in the balloon data prior to the mid-1970s, both Gaffen *et al.* and Brown *et al.* note that tropical lapse rates became more positive during the period 1958–1979, suggesting that in the two most recent decades, a reversal of the trend found in the earlier period has occurred. Upon examination of the entire time series since 1958, one notes that the surface and tropospheric trends are not significantly different.

Error estimates for the trends in temperature since 1979 are generally between ± 0.05 and $\pm 0.10\,^{\circ}\mathrm{C\,decade^{-1}}$ (Christy *et al.*, 2000). This is an estimate of measurement error of the systems themselves. In other words, this error-estimate answers the question – to what precision do we know the trend of the tropospheric temperature since 1958 or 1979?

There is another equally important question regarding the estimation of trends. To what extent is the specific period since 1979 representative of global temperature variations in general? This question leads to an examination of the statistical properties of the time series (Santer *et al.*, 1999). It is possible, for example, that since 1979, the Earth has experienced an especially anomalous period characterized by two large volcanic eruptions (El Chichón and Mt Pinatubo) as well as several substantial ENSO events. These types of events have considerable impact on the global temperature, which in turn has considerable impact on the calculation of the trend, given the relatively short climate period being studied (Christy *et al.*, 2000). In addition, the

surface and troposphere tend to respond in slightly different ways to these short-term climate fluctuations (i.e., the factor of 1.3, for example). As such, the period since 1979 might not be representative of a longer period. It is, therefore, also possible that this particular period is relatively unrepresentative of the manner in which the surface and troposphere might respond to slow increases in greenhouse gases.

Tsunamis, Causes and Consequences

Charles L Mader

Mader Consulting Co, Honolulu, HI, USA

Tsunamis occur at irregular intervals on the order of years. A tsunami is an event that results in the sea level rising

by tens of meters with widespread destruction to shoreline habitations and facilities. Few natural phenomena have popular conceptions that are more incorrect than those associated with tsunamis, including their common misnomer - tidal waves. Only recently have scienti c studies revealed that tsunami waves are primarily manifestations of the Earth's crustal readjustments caused by internal radioactive heating. Historically, an average of 10 large and 100 minor tsunamis per century occur in the Paci c. Thirteen large events have occurred during the last 250 years in the Atlantic and about 50 in the Indian Ocean and eastern Mediterranean Sea.

Tsunamis involve major, but temporary, changes in sea level that are caused most often by natural geological processes. For example, tsunamis have resulted from volcanic eruptions such as that of Krakatoa in 1883. That explosion was equivalent to 500 megatons of trinitrotoluene (TNT). It produced waves that drowned an estimated 36 000 people in the East Indies.

Earthquakes can also cause tsunamis. The tsunami waves caused by earthquakes have killed more people than the land movement itself. Over 55 000 lives have been claimed by tsunamis since 1900.

The ocean oors are composed of slowly moving crustal plates that plunge under the continental plates, creating deep ocean trenches and mountain ranges around the periphery of the ocean basins. The elastic strain at the plate edges is discontinuously relieved in the form of earthquakes. Vertical strains occur where the plates meet head on (Peru, Chile and the Aleutian Islands Arc) resulting in uplift or depression of large regions of the sea oor that results in a corresponding sea displacement, which causes the tsunami wave.

For example, the earthquake of March 28, 1964 in Alaska involved a dislocation of 2 m over 250 000 km^2 (three times the size of Florida). The resulting mound of water fanned out over the Paci c, creating its greatest damage at Crescent City, CA.

In the deep ocean a tsunami wave has a height of about 1 m and a wavelength of 100 to 500 km. Its period varies from a few minutes to 30 minutes. Tsunamis move at the speed of a jet airplane and, upon arriving at a seashore, the wavelength and speed decrease while the height increases greatly.

The severity of local wave effects at any place remote from the source of a large tsunami depends in a complicated way upon the source orientation, the ocean oor topography, and the local topography. One region of a shore may have a large amount of destruction while none occurs a few kilometers away; the reverse could occur for a tsunami from a different source. This directional dependence makes the issuing of accurate tsunami warnings and the evaluation of the tsunami hazard for any particular shoreline location very dif cult.

Advances in numerical modeling of ocean wave generation, propagation and interaction with real shoreline topography permit evaluation of the tsunami hazard resulting from historical tsunamis and from possible future tsunamis. Numerical modeling of tsunamis is being used by the West Coast- Alaskan Tsunami Warning Center to provide emergency managers along the Paci c coasts of Alaska, British Columbia, Washington, Oregon and California a reasonable range of expected wave heights during a tsunami warning for tsunamis generated in the northwest Paci c Ocean. This major improvement in tsunami warning is described in Whitmore and Sokolowski (1996).

EARTHQUAKE GENERATED TSUNAMIS

The Hilo, Hawaii Example

Hilo, Hawaii has received some of the most extensive damage from tsunami waves of any city in the US.

The tsunami of April 1, 1946 was caused by an earthquake of 7.5 magnitude off the Aleutian Islands. The source was located about 100 km SW of Scotch Cap, Unimak Island where the tsunami destroyed a lighthouse and radio towers located more than 30 m above sea level. The tsunami arrived at Hilo about five hours later with a large withdrawal of the ocean followed by several waves that flooded large regions of downtown Hilo. Losses included 173 lives with much property damage.

The tsunami of March 28, 1964 was caused by an earthquake of 8.4 magnitude in Alaska near Prince William Sound. Upon arrival at Hilo and other Hawaiian sites, the resulting tsunami was considerably smaller than the tsunami of April 1, 1946, even though the earthquake source was much larger.

The SWAN code for modeling shallow water waves has been developed over the last 30 years to numerically model tsunami waves (Mader, 1988). Flooding is described using the Mader flooding technique (Mader, 1990). The numerical model accurately simulated the actual flooding levels for the April 1, 1946 and March 28, 1964 tsunamis. The 7.5 magnitude 1946 tsunami flooding of Hilo was much greater than the 8.5 magnitude 1964 tsunami because of the directionality of the tsunami from its source.

The largest tsunami wave ever observed at Hilo, Hawaii occurred during the tsunami of May 23, 1960. The tsunami was caused by an earthquake of 8.5 magnitude occurring near Peru, Chile. The source of the tsunami was a sea floor displacement over an area 150 km wide and 800 km long, aligned along the N–S Chile coastline. The tsunami wave arrived 14 hours later at Hilo, Hawaii with the third wave being the largest and most destructive tsunami wave in Hilo s history. The waves arrived from the southeast at the Hawaiian islands. The calculated tsunami wave profile was

a 0.25 m, 3000 second half wave followed by a 0.5 m high, 2500 second wave and then by a 0.5 m 1500 third wave.

The tsunami wave interacted with the Hawaiian Islands and refracted such that the wave arrived from the east on the Hilo side of the Island of Hawaii. The calculated tsunami wave arriving outside Hilo Bay had an initial amplitude of 0.5 m and a period of 3000 second for 1500 s, followed by a 1.5 m, 1500 second wave and then by a 2.0 m 1500 second wave.

The calculated flooding levels agreed with those that occurred on May 23, 1960. The calculated third wave was the largest and steepest, in agreement with the observations. The technical details of the Hilo tsunami modeling are described in Mader and Curtis (1991).

The amount of information generated by such a series of calculations is very large. Following the complicated wave generation, propagation, interaction and flooding with single snapshot graphs of wave contours or picture plots is difficult. The wave patterns and their histories can be better understood by the generation of computer movies. A collection of over 50 tsunami computer movies is available from the author or The Tsunami Society, PO Box 37970, Honolulu, HI 96817 for tsunamis generated by earthquakes, landslides, and asteroids, showing their propagation and inundation of coastlines around the world.

Landslide Tsunamis

On July 7, 1998, a magnitude 7.1 earthquake occurred off the northern coast of Papua, New Guinea. The earthquake was observed at the Pacific Tsunami Warning Center, but because the earthquake was below the 7.2 threshold for significant earthquake-generated tsunamis, no warning was issued. Yet within fifteen minutes of the main shock, waves up to 15 m high caught the coastal inhabitants unawares. The tsunami killed more than 2200 villagers, including more than 230 children.

Apparently while the earthquake was too small to generate a significant tsunami wave, it did trigger a submarine landslide offshore that caused a large amplitude, short period tsunami wave over a relatively short (30 km) stretch of the coastline.

Tsunamis have also been generated by underwater landslides without an earthquake trigger. Because the landslides often occur when there is an extremely low tide, it appears that the pore pressure inside the slide mass can serve as a landslide trigger. So the very dangerous situation exists that tsunamis may be generated without any warning by an earthquake. The landslides often occur in regions with large river delta deposits. Such was the case in the Papua, New Guinea tsunami caused by an earthquake-triggered landslide and in the 1994 Skagway tsunami triggered only by a very low tide. Landslide generated tsunamis without an earthquake trigger such as the 1994 Skagway tsunami can occur along any coastal region without any warning to the residents of the coast.

The Skagway Tsunami

On November 3, 1994, at about 19:10 h, a tsunami wave with a period of about 3 minutes and maximum height of 8–9 m occurred in the Taiya Inlet at Skagway, Alaska. The event occurred at the time of a low tide of 1.2 m below lower low-level. The tidal range at Skagway is about 8 m. The wave was observed traveling along the Pacific and Arctic Railway and Navigation Company (PARN) dock from the South or deep end of Taiya Inlet.

The sea floor elevations before and after the event indicate that a considerable area of the sea floor was lower for about 1500 m down the inlet and then much of the sea floor was higher farther down the inlet as described by Campbell and Nottingham (1999). The Skagway River had been at its highest level in history the previous month and had deposited large amounts of sediment at the head of the landslide. The sea floor elevation changes had a volume of 15–18 million m^3.

The National Oceanic and Atmospheric Administration (NOAA) tide gauge was situated midway along the ore dock on the west side of the harbor. The tsunami recorded by this gauge on November 3, 1994, had a period of approximately three minutes, a maximum recorded amplitude of about 1 m and lasted for about 30 minutes. The Skagway tide gauge was a damped nitrogen bubbler analog gauge that gives a non-linear response at short periods. Thus, the recorded wave heights are considerably smaller than those of the actual tsunami. To determine the tsunami wave heights, Nottingham (1997) determined the water tower-generated tide gauge trace that would duplicate the tsunami tide gauge record. The tsunami wave had an initial amplitude of 3.6 m and period of 60 s followed by 3 waves with amplitudes of 1.8–2.7 m and period of 180 s. The Skagway landslide generated tsunami is the best documented and most extensively studied landslide tsunami.

The generation and propagation of the tsunami wave of November 3, 1994, in the Taiya Inlet was modeled using the SWAN code by Mader (1997) and by Kowalik (1997) using his shallow water code. The landslide model studied was that described by Campbell (1999) from the change in the sea floor topography that occurred before and after the tsunami. The Campbell model consists of three slide regions separated by ridges.

The material from the three slides moved down into the deep part of the inlet occupying an area with a volume of 16 million m^3.

The tide gauge duration and profile was best reproduced by the two-minute duration slide (about 28 m s^{-1}). The observed and calculated 30-minute duration of the tide gauge record is a result of the resonance for three-minute

waves in the harbor where the tide gauge is located. The waves decayed outside the harbor after 10 minutes. The Skagway landslide-generated tsunami is now a classic example of a tsunami generated without an earthquake trigger. Such tsunamis present the greatest hazard to the largest number of coastal dwellers because they strike with no warning.

Mega-tsunamis

Mega-tsunamis are defined as waves of over 100 m height in the deep ocean. The primary sources of mega-tsunamis are asteroid impacts with the ocean, volcanic explosions, and landslides. A mega-tsunami did occur in 1958 in Lituya Bay, Alaska.

Lituya Bay – a 520 m High Tsunami

Lituya Bay, Alaska is on the northeast shore of the Gulf of Alaska. It is an ice-scoured tidal inlet with a maximum depth of 220 m and a narrow entrance with a depth of only 10 m. It is a T-shaped bay, 11 km long and up to 3 km wide. The two arms at the head of the bay, Gilbert and Crillon Inlets, are part of a trench along the Fairweather Fault. On July 8th, 1958, a 7.5 magnitude earthquake occurred along the Fairweather fault with an epicenter near Lituya Bay.

A mega-tsunami wave was generated that washed out trees to a maximum altitude of 520 m at the entrance of Gilbert Inlet. A photograph of the region is shown in Figure 1. Much of the rest of the shoreline of the Bay was denuded by the tsunami from 30–200 m altitude.

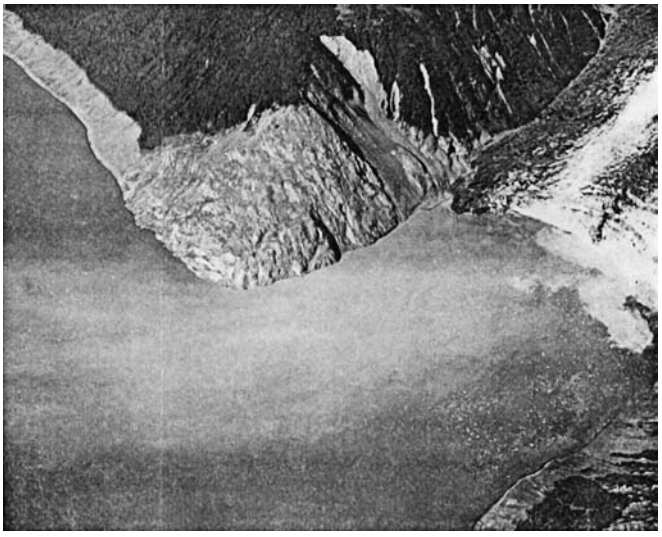

Figure 1 Photograph of where a mega-tsunami reached 520 m on the spur ridge going into Gilbert Inlet of Lituya Bay, Alaska on July 9, 1958. The camera is looking northwest at the head of the bay

During the last 150 years, five giant waves have occurred in Lituya. The previous event occurred on October 27, 1936, which washed out trees to a maximum altitude of 150 m and was not associated with an earthquake.

Miller (1960) recorded all that was known in 1960 about the giant waves in Lituya Bay.

The July 9th, 1958, earthquake occurred at about 22:15 h, which was still daylight at Lituya Bay. The weather was clear and the tide was ebbing at about plus 1.5 m. Bill and Vivian Swanson were on their boat anchored in Anchorage Cove near the western side of the entrance of Lituya Bay. Their astounding observations are recorded in Miller (1960) and were as follows:

> With the first jolt, I tumbled out of the bunk and looked toward the head of the bay where all the noise was coming from. The mountains were shaking something awful, with slide of rock and snow, but what I noticed mostly was the glacier, the north glacier, the one they call Lituya Glacier.
>
> I know you can t ordinarily see that glacier from where I was anchored. People shake their heads when I tell them I saw it that night. I can t help it if they don t believe me. I know the glacier is hidden by the point when you re in Anchorage Cove, but I know what I saw that night, too.
>
> The glacier had risen in the air and moved forward so it was in sight. It must have risen several hundred feet. I don t mean it was just hanging in the air. It seems to be solid, but it was jumping and shaking like crazy. Big chunks of ice were falling off the face of it and down into the water. That was six miles away and they still looked like big chunks. They came off the glacier like a big load of rocks spilling out of a dump truck. That went on for a little while – it s hard to tell just how long – and then suddenly the glacier dropped back out of sight and there was a big wall of water going over the point. The wave started for us right after that and I was too busy to tell what else was happening up there.

A 15 m high wave rushed out of the head of the bay toward Swanson s anchored boat. The boat shot upward on the crest of the wave and over the tops of standing spruce trees on the entrance spit of Lituya Bay. Swanson looked down on the trees growing on the spit and said he was more than 25 m above their tops. The wave crest broke just outside the spit and the boat hit bottom and foundered some distance from the shore. Swanson saw water pouring over the spit, carrying logs and other debris. The Swansons escaped in their skiff to be picked up by another fishing boat two hours later.

The front of Lituya Glacier, on July 10th, was a nearly straight, vertical wall almost normal to the trend of the valley. Comparisons with photographs of the glacier, taken July 7th, indicate that 400 m of ice had been sheared off the glacier front.

The partially subglacial lake west of the sharp bend in Lituya glacier was 30 m lower than it was two days before the earthquake.

After the earthquake there was a fresh scar on the northeast wall of Gilbert Inlet, marking the recent position of a large mass of rock that had plunged down the steep

slope into the water. The next day after the earthquake and tsunami, loose rock debris on the fresh scar was still moving at some places, and small masses of rock still were falling from the rock cliffs near the head of the scar. The volume of the rockfall was approximately 30 million m^3. The Swanson observations and numerical modeling studies by Mader (1999) indicate that a lot more than a simple landslide occurred. The Swanson observations suggest a water wave lifted the front of the glacier up and moved it out from its initial position and generated the 520 m high wave run-up.

George Pararas-Caryannis (1999) suggested that the wave was formed by a landslide impact similar to an asteroid impact, making a cavity in the inlet ocean to the depth of the inlet floor (120 m) near the landslide. The water in the inlet with the width of the landslide and between the landslide and the 520 m high run-up is sufficient to cover the run-up region to 100 m height. This high water layer is sufficient to form a wave that will reproduce the observed flooding of the bay beyond the inlet. Fritz *et al.* (2001) have shown with a physical model how the Lituya Bay landslide impact resulted in the observed movement of the water and glacier.

The Tlingit natives believe that a powerful spirit, Kah Lituya, lives in deep ocean caverns near the entrance to the bay. He resents being disturbed and rises up to shake the mountains and wash away intruders with giant waves.

Asteroid Tsunamis

Tsunami waves generated by earthquakes have typically had a maximum deep ocean amplitude of 10 m and periods of 500–2000 s. Tsunami waves with amplitudes of approximately 100 m are referred to as mega-tsunamis and may be generated by landslides, volcanic explosions, or by an asteroid impact with the ocean (*see* Asteroids and Comets, Effects on Earth, Volume 1). Landslide and small asteroid (less than 1 km in diameter) mega-tsunamis have short periods and thus the tsunami wave amplitude is not maintained as the wave travels from the source, as described in Crawford and Mader (1998). Large asteroid-generated tsunami waves have long periods and waves with large amplitudes that can propagate across an ocean basin.

The July 1994 Shoemaker-Levy-9 asteroid impact with Jupiter is typical of the type of event being investigated. To generate a 100 m high, 2000 second period tsunami that can traverse an ocean basin, an approximately 150 km wide cavity in the ocean to the ocean floor is required. Possible Jupiter asteroid parameters which could generate such a cavity are diameters of 5 km, densities of 5 g cm^{-1}, and velocities of 20 km s^{-1}. The proposed Jupiter asteroid characteristics vary at least by a factor of two in diameter and density, with velocities between 10 and 30 km s^{-1}. To create a mega-tsunami, the location of the asteroid impact would need to be in the deep ocean (at least 3000 m deep). A large, high-density asteroid could be located almost anywhere in a deep ocean basin; while a smaller, lower density asteroid would need to be located nearer the region of interest.

A tsunami wave with a 100 m height and period of 2000 s generated west of the Hawaiian island chain and its interaction with the islands has been modeled by Mader (1996). The asteroid tsunami wave would result in inundation of much of the Hawaiian Islands to between 150 and 300 m. Simulations have been done for all the ocean basins and detailed inundation studies have been performed for all the US, European, and Japanese coastal areas using the technique described by Mader (1998). These results indicate that all coastal regions below 300 m in elevation are at risk from tsunamis generated by Shoemaker-Levy-9 type asteroids.

Asteroid impacts are one of the few natural disasters that can be averted by technical means, as described by Solem (1999). The most cost-effective and only currently available means of deflection is a nuclear explosive. Asteroids more than 3 km in diameter can be most efficiently deflected with a surface burst; asteroids as small as half a kilometer can be effectively deflected with a stand-off device; and smaller asteroids are best pulverized.

The risk of being killed as a result of an asteroid impact is twice the risk of being killed in an airplane crash, as discussed by Solem (1999). Steele (1995) states that the comet impacts on Jupiter similar to the one that occurred in July 1994 were observed in 1883, 1928, 1939 and 1948, suggesting an occurrence rate of about five collision events per century. Jupiter is likely to be struck about 1000 times as often as the Earth which implies that the Earth would be hit, on the average, every 20 000 years by an asteroid that could generate a tsunami that was a hazard through the entire Atlantic or Pacific basin. However when large asteroids next impact the planet, tsunamis will probably be the least of the problems for life on our Earth.

Tunguska Phenomenon

Sergey Yazev
Astronomical Observatory of Irkutsk State University, Irkutsk, Russia

The ight of a giant bolide observed early in the morning of 30 June 1908 ended in a powerful explosion in the basin of the Podkamennaya Tunguska river (East Siberia, Russia). The explosion yield is estimated to have been between 10- 15 and 40 megatons TNT. The event was followed by a number of consequences: seismoshock, global airwave, local jump of geomagnetic eld strength, highly scattered light in the atmosphere, extensive elds of luminescent clouds, anomalously bright airglow events, etc. Investigations of the Tunguska Event made by Russian scientists are brie y described. There exist over a hundred hypotheses of differing scienti c credibility to explain the Tunguska catastrophe. The basic theory accepted by most researchers postulates explosive evaporation, at 5- 6 km altitude, of the ice nucleus of a small comet about 60 m in diameter and with a mass from 100 000 to a million tons.

Early in the morning of 30 June 1908, a giant bolide was sighted from an area of 10^5–10^6 km^2 in Siberia (Russia s eastern part), along a path as long as 800 km. Numerous eye-witnesses described it as an incandescent sphere, a barrel-shaped body, a luminous sheaf, a log, or a blackness with flame-colored tails. Its brightness was estimated in terms of from like the Sun to not bright, could be looked at. The fireball in its passage left behind it a luminous smoky trail and made a variety of sounds (a hissing whistle, peals of thunder, and a roar resembling gun volleys). According to the data available before 1964, the travel direction was almost exactly from south to north. A more recent analysis showed that in the closing stage of the flight, the trajectory projection was directed from east to west (azimuth 90–95°). The inclination of the atmospheric trajectory is estimated, by most researchers, at 10–20°, although angles of 30–45° too have been reported.

The flight ended in an explosion in the basin of the Podkamennaya Tunguska river (indigenous name Katonga). The explosion yield is estimated to have been 10–15 (commonly accepted estimate) to 40 megatons TNT. A column of material shot up to a height of 20 km. The sound from the explosion could be heard for 1200 km. The shock wave felled the forest in the area of over 2000 km^2. Within up to 15 km of the explosion epicenter, surface layers of trees were scorched, and a devastating forest fire broke out. Seismographs recorded a shock in Irkutsk (800 km from the epicenter), Tashkent, Tbilisi, and Jena. The airwave passed twice round the globe (recorded in, for example, Copenhagen, Zagreb, Washington, Potsdam, London, Jakarta, etc.).

The Irkutsk magnetic observatory recorded a jump of geomagnetic field strength. The night of July 1st was unusually light at more than 150 locations in Siberia, Central Asia, the European part of Russia, and Western Europe. A highly scattered light in the atmosphere and extensive fields of luminescent clouds were observed. During the summer of 1908 (from June 21), anomalously bright airglow events were witnessed.

The first expedition (1927) to the site of meteoritic fall was organized by Leonid Kulik (who died in German captivity in 1942). He discovered a giant area of fallen trees, and a dead standing forest devoid of twigs and branches, with a large marsh in the middle. A search for the meteoritic remains made by Kulik s subsequent five expeditions was unsuccessful. Eye witness inquiries and analyses of the expeditions results were published in the 1940s in Russia by Eugene Krinov.

Later expeditions (1958–1962) were led by K Florensky. No meteorite craters were discovered, and those existing in the area were found to be of thermokarst origin. Metallic microinclusions in the soil were similar to those in the area of Moscow, as well as in Antarctica and were of extraterrestrial origin (cosmic dust), but were not associated with the Tunguska event. It was concluded that the explosion occurred at a height of 10–12 km. During a subsequent period of many years, a comprehensive volunteer expedition under the direction of N Vasiliev worked in the area. They used novel techniques for identifying extraterrestrial dust, and theoretical analyses of the explosion and ballistic wave and of the physics of the Tunguska explosion. An increased content of a radioactive isotope, cesium-137, was detected in layers formed after 1908. It was found that the soils within 30 km around the explosion center underwent a reversal of magnetization. During the summer of 1999, a Russian–Italian expedition also studied the area using remote sensing aircraft-based methods. Bottom set beds of Chako Lake in the vicinity of the epicenter were studied with a catamaran-based sonar. In spite of a plethora of false reports (in 1994, for example), no debris of the hypothetical meteorite has ever been found.

At the same time in Antarctica, for example, deposits from 1908 were found to contain great amounts of iridium of cosmic origin, supposedly scattered in the atmosphere during the Tunguska event.

There exist over a hundred hypotheses for explaining the Tunguska catastrophe. Among the most exotic conjectures are, the explosion of an extraterrestrial spacecraft, the collision of the Earth with a micro-black hole or a meteorite made up of antimatter, and detonation of a giant swarm of gnats. Some recognition was accorded the theory of destruction of a solar plasmoid, as well as the theory of interaction of tectonic (the explosion occurred near an ancient paleovolcanic chimney) and atmospheric electromagnetic processes. The basic theory accepted by most researchers, however, postulates explosive evaporation, at 5–6 km altitude, of the ice nucleus of a small comet (about 60 m in diameter and with a mass from 100 000 to a million tons, the former estimate being preferable), probably with inclusions typical of cometary nuclei. This explanation would account for the absence of any persisting fragments of the Tunguska body and the anomalous phenomena in the atmosphere induced by the injection of cometary dust and aerosols. Explaining the changes in the atmospheric flight of the Tunguska bolide is troublesome, and the problem is dramatized by a drastic diversity of eyewitness accounts (mostly from inexpert people questioned long after the event). A central hypothesis is that the body underwent fragmentation during its atmospheric flight.

U

UARS (Upper Atmosphere Research Satellite)

The UARS was launched by the National Aeronautics and Space Administration (NASA) on the Space Shuttle Discovery on September 12th, 1991 and is still providing useful data as of early 2000. The UARS was deployed from Discovery at an orbital altitude of 585 km and an inclination of 57°.

Ten instruments are contained on the UARS, which is about 10 m long and weighs 6804 kg. The mission goals of UARS were to study the physical processes acting within and upon the stratosphere, mesosphere, and lower thermosphere. Four instruments (Cryogen Limb Array Etalon Spectrometer (CLAES), Improved Stratospheric and Mesospheric Sounder (ISAMS), Microwave Limb Sounder (MLS) and Halogen Occultation Experiment (HALOE)) provide temperature profiles and concentrations of ozone, methane, water vapor and other key trace species such as chlorofluorocarbons, hydrogen chloride and chlorine monoxide.

Two instruments (High Resolution Doppler Imager (HRDI) and the Wind Imaging Interferometer (WINDII)) map the upper atmosphere wind fields that shape the global distributions of chemical species. Four instruments (Active Cavity Radiometer Irradiance Monitor (ACRIM), Particle Environment Monitor (PEM), Solar/Stellar Irradiance Comparison Experiment (SOLSTICE) and Solar Ultraviolet Spectral Irradiance Monitor (SUSIM)) monitor energy inputs from the Sun, which strongly influences both chemistry and dynamics. Since its launch, UARS data sets have contributed to many important scientific findings. For example, UARS measurements were used to confirm the role of chlorofluorocarbons in ozone depletion, clarify the chemical processes that cause the Antarctic ozone hole, demonstrate the dominance of human-made chlorofluorocarbons in the chlorine and fluorine amounts in the stratosphere, derive the movement and mixing of air in the stratosphere and mesosphere both globally and seasonally, and quantify the solar ultraviolet spectral irradiances over both maximum and minimum levels of solar activity. Eight of the original 10 instruments continue to take measurements (as of March 2000).

Ultraviolet Radiation

E C Weatherhead and Amy Stevermer
University of Colorado, Boulder, CO, USA

Ultraviolet (UV) radiation is only a small portion of the radiation we receive from the Sun, but it has a large impact on biological activity. UV radiation has become a topic of increasing concern because of depletion of stratospheric ozone, observed since the 1970s.

Since the discovery of the Antarctic ozone hole and depletion of ozone at mid-latitudes, a number of scienti c efforts have been launched to monitor UV radiation. The interest in UV radiation arises for a number of reasons, including the following:

1. *detecting changes in the amount of radiation reaching the Earth;*
2. *increasing public awareness of potentially harmful exposures to UV radiation through daily reports carried on television weather channels and in newspapers;*
3. *assessing UV's biological effects;*
4. *establishing a basic UV radiation climatology.*

PHYSICAL DEFINITION

UV radiation is defined as all radiation between 100 and 400 nm. Although there are other sources of UV radiation,

such as welding arcs and some lamps, most UV radiation reaches the biosphere from the Sun. The UV portion is less than 10% of the total energy output from the Sun. Most of the UV radiation is then absorbed or scattered back to space by the Earth s atmosphere, resulting in very little UV radiation reaching the Earth s surface.

All radiation from the Sun travels in the form of electromagnetic waves. Wavelengths just shorter than those of light at the violet end of the visible spectrum are referred to as UV radiation.

UV radiation can be divided into three basic categories:

- UV-A (320–400 nm), containing most of the energy in the UV spectrum and most likely to reach the biosphere; weakly affected by ozone;
- UV-B (280–320 nm), some of which reaches the biosphere; strongly affected by ozone;
- UV-C (100–280 nm), little of which reaches the biosphere; primarily scattered and absorbed by atmospheric oxygen, nitrogen and ozone.

Some scientists consider 315 nm to be a more appropriate dividing point between UV-A and UV-B radiation categories; an absolute division between UV-A and UV-B has not yet been established.

UV LEVELS

The amount of UV radiation reaching the surface is measured at over 100 sites around the world, primarily in North America and Europe. Surface UV can be measured by ground-based instruments, such as a spectrophotometer, or estimated by satellite instruments, such as the Total Ozone Mapping Spectrometer (TOMS). Ground-based instruments are best at measuring the UV reaching the surface at a particular location, but require accurate calibrations and standardization to ensure accurate observations. Satellite instruments provide global coverage but the observations must be corrected for clouds and other atmospheric variables.

The ongoing measurements from both the surface and satellites show how a number of factors, including ozone, clouds, and ground cover, can affect UV levels. Generally, as stratospheric ozone amounts decrease, more UV radiation is able to penetrate to the surface. The relationship between ozone and surface level UV radiation is shown in Figure 1 for several locations around the world. In addition to ozone concentration, other important factors governing UV levels are sun angle and cloud amount. Differences in sun angle can strongly affect the amount of UV radiation received directly. Frederick and Snell (1990) found that clouds can reduce the amount of UV reaching the ground by as much as 90% on a given day.

UV levels can also be affected by surface reflectivity, altitude, and pollutant concentrations, including both aerosols and trace gases. Studies of the effects of these variables are important for several reasons. Understanding the processes affecting UV radiation allows estimation of UV levels at times and in places where measurements are not available. The improved understanding also helps scientists estimate how a changing environment will affect UV levels and vice versa.

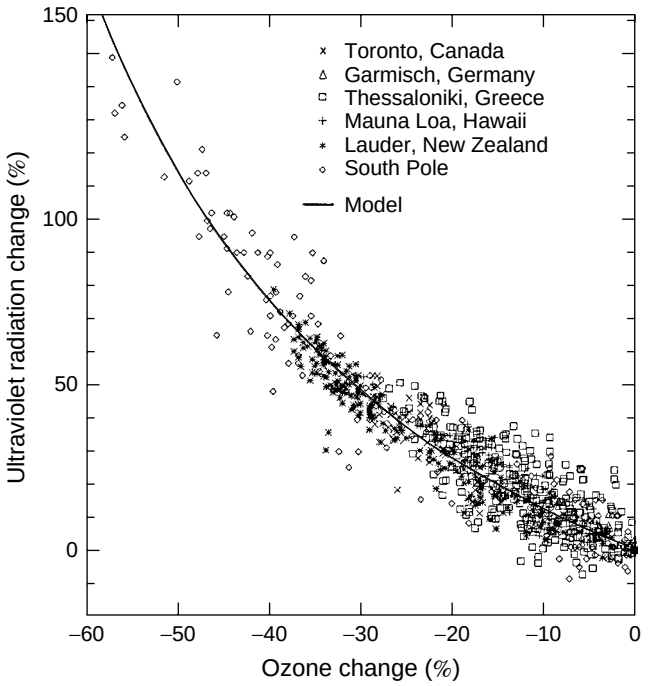

Figure 1 Increase in biologically effective UV radiation as a function of the decrease in ozone amount in the overlying atmosphere. (From the World Meteorological Organization Scientific Assessment of Ozone Depletion, 1998)

UV EFFECTS

UV radiation has a variety of effects on plants, animals, and materials in the biosphere, most of them detrimental. UV radiation is known to affect materials, particularly plastics and polymers with easily broken bonds. UV radiation provides the energy to drive both stratospheric and tropospheric chemistry (*see* Stratosphere, Chemistry, Volume 1; Troposphere, Ozone Chemistry, Volume 1). In the troposphere, UV radiation contributes to ozone formation. Unlike stratospheric ozone, ozone in the troposphere is a pollutant that can damage plants, human health, and natural materials.

The impacts of UV radiation on biological systems have been extensively studied. These effects range from human health impacts to impacts on single cell organisms. These effects tend to arise because each UV photon has more energy than most other photons encountered in nature. As shown in Figure 2, the biological response to UV radiation

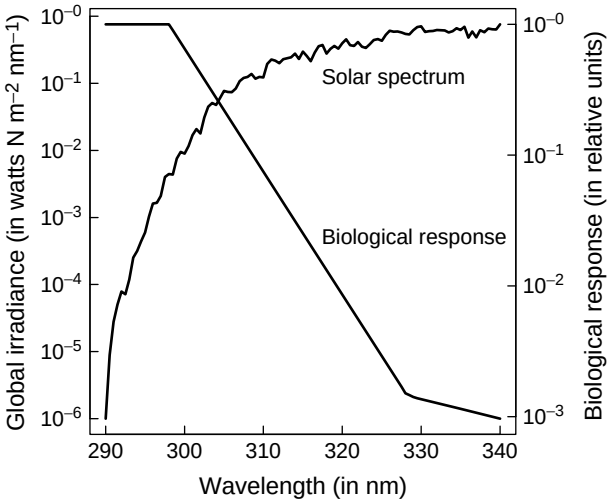

Figure 2 Biological response to UV radiation as a function of wavelength. Shorter wavelength UV radiation is the most important in causing biological damage. (Reproduced from Weatherhead and Webb, 1997)

is most significant at shorter wavelengths. Additionally, UV radiation, particularly UV-B radiation, is able to efficiently break DNA bonds. While UV radiation, particularly UV-A, can assist in repairing DNA damage, the primary effect of UV radiation appears to be damaging to both DNA and individual cells.

The effects of UV radiation on individual species and ecosystems have been studied both in the laboratory and in field experiments. UV radiation is known to have primarily deleterious effects on individual species, including phytoplankton, zooplankton, amphibians, terrestrial plants and fish. However, the effects of UV radiation on ecosystems can be unexpected or confounding. Studies by Bjorn *et al.* (see AMAP, 1998) have shown that the growth rates of some shrubs can be reduced or increased by additional UV radiation, depending on available water supplies. Other studies have shown that UV radiation can change ecosystems by favoring UV-resistant species. The effects can be strong and measurable, but are not always intuitive or obvious.

The most well-known effects of UV radiation on people include sunburn and snow blindness (photo-keratitis). UV radiation has also been linked to skin cancer, immune suppression, and cataract formation as well as to a number of other dermatological and ocular problems. These effects have been observed in controlled laboratory experiments and derived from epidemiological studies. These studies help to explain, for instance, the differences in skin cancer incidence by latitude and altitude. Skin cancer risks are often a function of lifestyle, increasing for those who pursue leisure activities outdoors. Persons who allow themselves considerable exposure to the Sun are at a higher risk, regardless of skin type. Intermittent but extreme bouts of sun exposure, such as those an indoor worker might receive when relaxing outdoors on days off work, have been linked to melanoma, a rare but life-threatening form of skin cancer.

RECENT CHANGES

Decreases in stratospheric ozone over the past three decades have been well documented and their causes are now fairly well understood (*see* Stratosphere, Ozone Trends, Volume 1). Figure 3 shows how the observed ozone decreases depend on latitude, with depletion being greatest in the mid-latitudes and at the poles. While we know from daily data that decreases in ozone amount lead to increases in UV radiation, long-term records of UV radiation are more difficult to interpret. Scotto *et al.* (1988) found that UV data from 1974 to 1985 indicated a decrease in UV radiation when an increase was expected. Weatherhead *et al.* (1997) later re-examined the long-term records and showed that the trends were inconclusive. Blumthaler and Ambach (1990) found an increase of almost 1% per year in spring alpine UV data. Using three years of data, Kerr and McElroy (1993) found an increase in UV radiation that agreed with the decrease in ozone observed during the same time period.

A question remains about UV levels in centuries past. No consistent UV monitoring existed before the 20th century, so there is no basis for a definitive answer. However, current understanding of the effects of UV allows some insights when examining biological records. While current estimates are very rough, it is likely that UV radiation was not much different during the past millennium than it was prior to the 1970s, when anthropogenic ozone depletion began.

Future UV levels are likely to be dictated by both anthropogenic factors and natural variations. Human activities are likely to affect the concentrations of ozone depleting

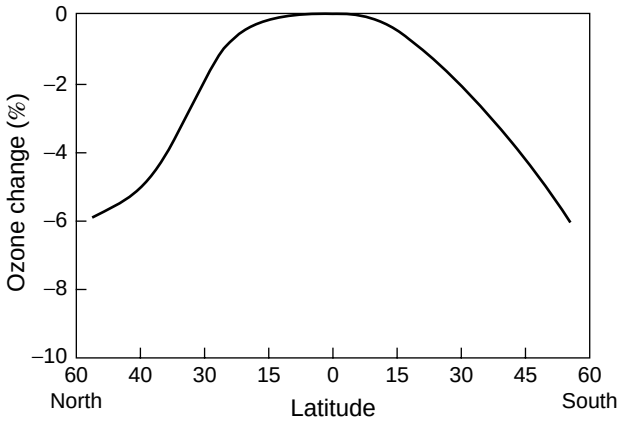

Figure 3 Schematic diagram of the latitudinal distribution of ozone depletion: 1979–1997. (Reproduced from the World Meteorological Organization Scientific Assessment of Ozone Depletion, 1998)

substances and to contribute to climate change in ways that are likely to lead to long-term changes in UV levels. The slow recovery predicted for the ozone layer and the uncertainty associated with enforcing international agreements to control emissions of ozone depleting substances are likely to mean that UV levels will be elevated above natural levels for many decades to come.

Whether elevated UV levels are a critical environmental threat or only one of the many changes affecting the environment is an important question. The answer depends on the total impact of UV to the environment, but our current understanding of the full impact of elevated UV levels does not allow a clear answer to this question.

Volcanic Eruption, El Chichón

On March 29th, April 3rd and April 4th, 1982, the El Chichón volcano in Southern Mexico erupted, injecting about 7 million metric tonnes of sulfur dioxide (SO_2) and 20 million metric tonnes total of particulate material into the stratosphere. The cloud of volcanic gases and particles traveled westward, circling the Earth in three weeks. The April 4th eruption was the largest of the three, and its cloud went right over Hawaii a couple days after the eruption, allowing detailed observations from instruments at the Mauna Loa Observatory. The cloud quickly developed into a band extending from the Equator to 30 °N for more than six months, and then gradually spread even more widely. This was one of the largest volcanic eruptions of the 20th century, only exceeded in stratospheric input by the 1991 Mt. Pinatubo eruption. The eruption took place without warning, and killed many people in towns near the volcano. El Chichón had never erupted before in historic times.

The eruption took place just as the largest El Niño of the century so far was beginning. (In fact the volcanic cloud in the stratosphere fooled the satellite sensors which monitor ocean temperatures into thinking ocean temperatures were normal, whereas they had warmed substantially. Thus, scientists were not aware of the El Niño until months after it had started (*see* El Niño, Volume 1). A dense network of buoys in the tropical Pacific now prevents that from happening.) Because of the simultaneous eruption and appearance of warm ocean temperatures, several scientists suggested that the El Chichón eruption caused the El Niño. But climate model simulations and detailed studies of past eruptions and El Niños have shown that there is no plausible mechanism connecting these two events, and in fact their timing was a coincidence.

Because of the simultaneous eruption and El Niño, the climatic system felt the impacts of both, and it was difficult to separate their effects on temperature. Normally a large eruption like this would cool the global climate, especially in the summer, but during the first year after the El Chichón eruption, no large cooling was observed, as the El Niño produced large compensating warming. Studies of these effects using climate models have improved understanding of the climate system and increased confidence in projections of global warming from anthropogenic greenhouse gases, which are made with the same models.

The climatic effects also included winter warming of Northern Hemisphere continents in 1982–1983, with the temperature over North America, Europe, and Siberia much higher than normal. During the same winter, it was colder than normal over Alaska, Greenland, the Middle East, and China. The volcanic aerosols in the stratosphere produced heating, which changed the atmospheric wind patterns, to one we now call the positive phase of the Arctic Oscillation (*see* Arctic Oscillation, Volume 1).

ALAN ROBOCK *USA*

Volcanic Eruption, Krakatau

Krakatau (Krakatoa) is one of a linear series of Javan–Sumatran volcanoes that mark a destructive margin, where the Indo–Australian plate is subducted under the Asian plate. Krakatau was once one large island, which was destroyed in eruptions (possibly in the 6th century,

and possibly of global climatic significance), to leave three fragments (Panjang, Sertung, and Rakata Islands) of the original volcanic walls, in a broken ring. Renewed activity rebuilt one island back into the centre of the caldera. Following eruptions in 1680, it was dormant until May, 1883. The three peaks of this island, Perboewatan, Danan and Rakata, each activated as the cycle of building and destruction reached its peak. The sequence ended catastrophically on August 27th 1883, with an output of 18 km^3 of ejecta. The surrounding region, for a radius of 80 km, experienced 57 h of darkness. Some 36 000 people in the coastal lowlands of the Sunda Straits were killed by tsunami, giant waves up to 40 m in height. These were generated by the emptying of the magma chamber, which led to the outer walls failing, and two-thirds of the main island being displaced in a repeat of the pre-historic caldera collapse. The marine pressure waves were detected as far away as the English Channel, and the air waves from the eruption made four journeys around the globe to Krakatau s antipodes in Colombia. The violence ended abruptly leaving a greatly reshaped archipelago. In places, extensive new land surfaces had been created, and on the persisting areas of land, an average of 60–80 m of pyroclastic ashes had been emplaced. These completely barren landscapes were soon colonized by plants and animals, and succession led to forest closure by 1930. The (temporary) climatic impacts were global in extent as volcanic ash and gases were injected 40 km into the stratosphere, also producing unusual visual effects (e.g., broad opalescent corona (Bishop s ring) around the Sun and spectacular sunsets around the Northern Hemisphere). Comparative studies show that eruptions of the magnitude of the 1883 Krakatau eruption can decrease global temperatures by about 0.2–0.4° on an annual average for 1–2 years following the eruption. After 1883, Krakatau remained dormant until 1927, when renewed activity in the center of the caldera led to the formation (in 1930) of a new island, Anak Krakatau, now approximately 2 km in diameter and over 280 m in height.

ROBERT WHITTAKER *UK*

Volcanic Eruption, Mt. Pinatubo

On June 15, 1991, the Mt. Pinatubo volcano, on Luzon Island in the Philippines, erupted, injecting about 20 million metric tonnes of SO_2 into the stratosphere. The cloud of volcanic gases and particles traveled westward, circling the Earth in 3 weeks. Although it started at 15 °N latitude, by the time it had circled the Earth once, the cloud straddled the Equator, extending from about 15 °S to 15 °N. This was the largest volcanic eruption of the 20th century.

The eruption was fairly well forecast by a team of Filipino and American geologists. Many lives were saved by these warnings, but a typhoon hit the area during and soon after the eruption. The thick layers of volcanic dust on the roofs of some of the shelters were soaked by the intense rain and collapsed, killing hundreds. The US Clark Air Force base at Angeles City, only 10 km from the eruption, was destroyed and never reopened.

The climatic effects included global cooling of about 0.3 °C for about 2 years. The cooling was particularly strong over Northern Hemisphere continents in the summer of 1992, with cooling more than 3 °C in the northern US and southern Canada. The cooling was temporary and 1998 was the warmest year in the past 1000 years. This cooling was predicted by climate models, which are also used for predicting global warming from anthropogenic greenhouse gases, thus giving strength to the global warming predictions.

Due to the heating of the lower tropical stratosphere by the volcanic aerosols, the enhanced temperature gradient produced a changed atmospheric wind pattern in the troposphere which had large impacts on winter temperatures. In the winter of 1991–1992, the temperature over North America, Europe, and Siberia was much higher than normal, and over Alaska, Greenland, the Middle East, and China it was colder than normal. In fact, it was so cold that winter that it snowed in Jerusalem, a very unusual occurrence.

ALAN ROBOCK *USA*

Volcanic Eruption, Tambora

Alan Robock
Rutgers University, New Brunswick, NJ, USA

The Tambora volcano (8.25 °S, 118.00 °E) on the island of Sumbawa in Indonesia, erupted on April 10th, 1815, sending a massive cloud of aerosols into the stratosphere. This was the largest eruption of the past 500 years.

In the summer of 1816, Lord Byron and his friends Mary and Percy Bysshe Shelley spent their vacation on the shores of Lake Geneva in Switzerland. Rather than the normally delightful weather they expected, " it proved a wet, ungenial

summer, and incessant rain often con ned us for days to the house." (Shelley, 1818, p. xxii). In fact it was so gloomy that they held a writing contest to see who could come up with the best ghost story, the most appropriate expression of their common dismal feelings. Mary won, and the famous novel Frankenstein was born. The book both begins and ends with the monster trudging across a bleak ice-covered wasteland.

Byron was also inspired that summer and wrote *Darkness*, the beginning of which is reproduced below:

I had a dream, which was not all a dream.
The bright sun was extinguish d, and the stars
Did wander darkling in the eternal space,
Rayless, and pathless, and the icy earth
Swung blind and blackening in the moonless air;
Morn came and went – and came, and brought no day,
And men forgot their passions in the dread
Of this their desolation; and all hearts
Were chill d into a selfish prayer for light:
And they did live by watchfires – and the thrones,
The palaces of crowned kings – the huts,
The habitations of all things which dwell,
Were burnt for beacons; cities were consumed,
And men were gather d round their blazing homes
To look once more into each other s face; •••

The summer in New England that year also had extreme weather. There was snow every month of the year, and the poor harvests started a mass migration from the US East Coast across the Appalachian Mountains to the Midwest. For these reasons, 1816 has come to be known as the year without a summer. Although the cool summer of 1816 was not universally felt around the globe, large regions, including North America, Europe, Argentina, India, and China experienced record anomalies. Even portions of South Africa experienced cool and wet conditions in the growing season, but Southern Hemisphere climate would not be expected to change much in response to Tambora, due to the overwhelming oceanic influence.

The extensive records of the Hudson s Bay Company prove extremely useful in this regard for determining Canada s climatic record of this period. The effects of the 1816 summer on agricultural productivity of New England did not have much to do with the average temperature, which was low but not abnormally so, but with a series of killing frosts that reduced the growing season. This, along with a severe drought, reduced agricultural output to record low levels. In Europe, by contrast, there were record low temperatures accompanied by above average rainfall and cloudiness, the combination of which slowed the growth of crops and produced fungus and molds. Thus, food production was negatively affected in both regions, but by different mechanisms, pointing out the complex relationship between climate and human impacts.

The Tambora eruption killed more than 90 000 people in the immediate vicinity, 35% of the people on Sumbawa (48 000 in two years; 10 000 immediately and 38 000 from hunger and disease) and 44 000 on Lombok 160 km to the east. A more indirect effect of the Tambora eruption has also been suggested. Because of the bad weather, a typhus epidemic broke out in Ireland, spread to England and Scotland, and killed 65 000 people. Bad harvests in India may have contributed to a cholera epidemic, which spread to Asia and Europe producing the great cholera pandemic of the century.

In addition to historical records, proxy records such as those from tree rings allow us to explore the hemispheric temperature record. While global cooling followed the eruption, climate had already begun to cool before 1815. Ice core records from Greenland and Antarctica preserve sulfuric acid layers from volcanic eruptions, and while all records at both poles show a Tambora layer, they also all show a layer from an eruption almost as large in 1808 or 1809, still unidentified. Thus, the climate was probably already cooling from a previous large eruption and several smaller ones also observed between the two large ones. If Tambora had erupted in a warmer climate, the effects would have been less harsh. While this is true in an absolute sense, in a relative sense they would have been larger and more easily attributable to the volcano.

Volcanic Eruptions

Alan Robock
Rutgers University, New Brunswick, NJ, USA

Volcanic eruptions can inject into the stratosphere tens of teragrams of chemically and microphysically active gases and solid aerosol particles that can affect the Earth's radiative balance and climate and disturb the stratospheric chemical equilibrium. The volcanic aerosol cloud forms in several weeks by the conversion of sulfur dioxide (SO_2) to sulfate aerosol and its subsequent microphysical transformations. The resulting cloud of sulfate aerosol particles, with a residence time of a couple of years, has important impacts on both shortwave and longwave radiation. The

resulting disturbance to the Earth's radiation balance affects surface temperatures through direct radiative effects as well as through indirect effects on the atmospheric circulation. These aerosol particles also serve as surfaces for chemical reactions that can deplete stratospheric ozone.

*Volcanism has long been implicated as a possible cause of weather and climate variations. Even 2000 years ago, Plutarch and others pointed out that the eruption of Mt. Etna in 44 BC dimmed the Sun and suggested that this caused crops to shrivel and produced famine in Rome and Egypt. Because of their large effects in the English-speaking world, the largest eruptions of the past 250 years have each drawn attention to the atmospheric and potential climatic effects. The 1783 eruption in Iceland produced large effects all that summer in Europe. Benjamin Franklin, the US ambassador to France published the first paper on the subject in more than 1800 years, suggesting that the Lakagigar eruption in Iceland in 1783 might have been responsible for the abnormally cold summer of 1783 in Europe and the cold winter of 1783- 1784 (*see *Franklin, Benjamin, Volume 1). If an eruption identical to the 1783 Laki eruption took place today, air traffic in the Northern Hemisphere would be disrupted for six months or more. The 1815 Tambora eruption produced the year without a summer in 1816 (*see *Volcanic Eruption, Tambora, Volume 1) and inspired Mary Shelly to write Frankenstein that summer while vacationing on the shores of Lake Geneva, Switzerland. She and her husband, Percy Bysshe Shelley and their friend Lord Byron had a contest to see who could write the scariest ghost story, inspired by the cold, gray weather that kept them housebound. Mary Shelley won.*

On average, major volcanic eruptions have occured about every 20 years over the last few centuries (see Table 1). The most extensive study of the impacts of a single volcanic eruption was carried out by the British Royal Society examining the 1883 Krakatau eruption (*see* Volcanic Eruption, Krakatau, Volume 1). The Society produced a beautiful volume including watercolors of the volcanic sunsets near London. This eruption was probably the loudest explosion of historic times, and the book includes color figures of the resulting pressure wave s four circuits of the globe as measured by microbarographs.

The 1963 Agung eruption produced the largest stratospheric dust veil in the Northern Hemisphere (NH) in more than 50 years, and inspired many modern scientific studies. While the Mt. St. Helens eruption of 1980 was very explosive, it was a lateral blast and did not inject much sulfur into the stratosphere, where aerosol particles can remain several years and have a world-wide effect on global average temperature. Because no materials reached the stratosphere, this eruption had very small global effects and its tropospheric effects lasted only a few days. However, it occurred in the US, and so received much attention. In contrast, the subsequent 1982 El Chichón and 1991 Mt. Pinatubo eruptions produced very large stratospheric aerosol clouds and large climatic effects (*see* Volcanic Eruption, El Chichón, Volume 1; Volcanic Eruption, Mt. Pinatubo, Volume 1). Despite their different climatic influences, quantification of the size of these eruptions has proven difficult because different measures reveal different information. For example, one could examine the total mass ejected, the explosiveness, or the sulfur input to the stratosphere.

Table 1 Major volcanic eruptions of the past 250 years

Volcano	Year of eruption
Grimsvotn (Laki or Lakagigar), Iceland	1783
Tambora, Sumbawa, Indonesia	1815
Cosiguina, Nicaragua	1835
Askja, Iceland	1875
Krakatau, Indonesia	1883
Okataina (Tarawera), North Island, New Zealand	1886
Santa Maria, Guatemala	1902
Ksudach, Kamchatka, Russia	1907
Novarupta (Katmai), Alaska, US	1912
Agung, Bali, Indonesia	1963
Mt. St. Helens, Washington, US	1980
El Chichón, Chiapas, Mexico	1982
Mt. Pinatubo, Luzon, Philippines	1991

Volcanic eruptions inject several different types of particles and gases into the atmosphere (Figure 1) (*see* Aerosols, Stratosphere, Volume 1). In the past, it was only possible to estimate these volatile inputs based on measurements from active, but not explosive, eruptions and from remote sensing of the resulting aerosol clouds using lidar, radiometers, and satellites. The serendipitous discovery of the ability to monitor SO_2 using the Total Ozone Mapping Spectrometer satellite instrument, however, has given us a new tool to directly measure stratospheric injection of gases from eruptions.

The major component of volcanic eruptions is magmatic material, which emerges as solid, lithic material or solidifies into large particles that are referred to as *ash* or *tephra*. These particles fall out of the atmosphere very rapidly, on time scales of minutes to a few days, and thus have no climatic impacts. However, this temporary large atmospheric loading can reduce the amplitude of the diurnal cycle of surface air temperature in the region of the tropospheric cloud, and this material is very dangerous for aircraft. But these effects disappear as soon as the particles settle to the ground. When an eruption column still laden with these hot particles descends down the slopes of a volcano, the resulting pyroclastic flow can be deadly to those unlucky enough to be at the base of the volcano. The destruction of Pompeii and Herculaneum after the 79 AD Vesuvius eruption is the most famous example.

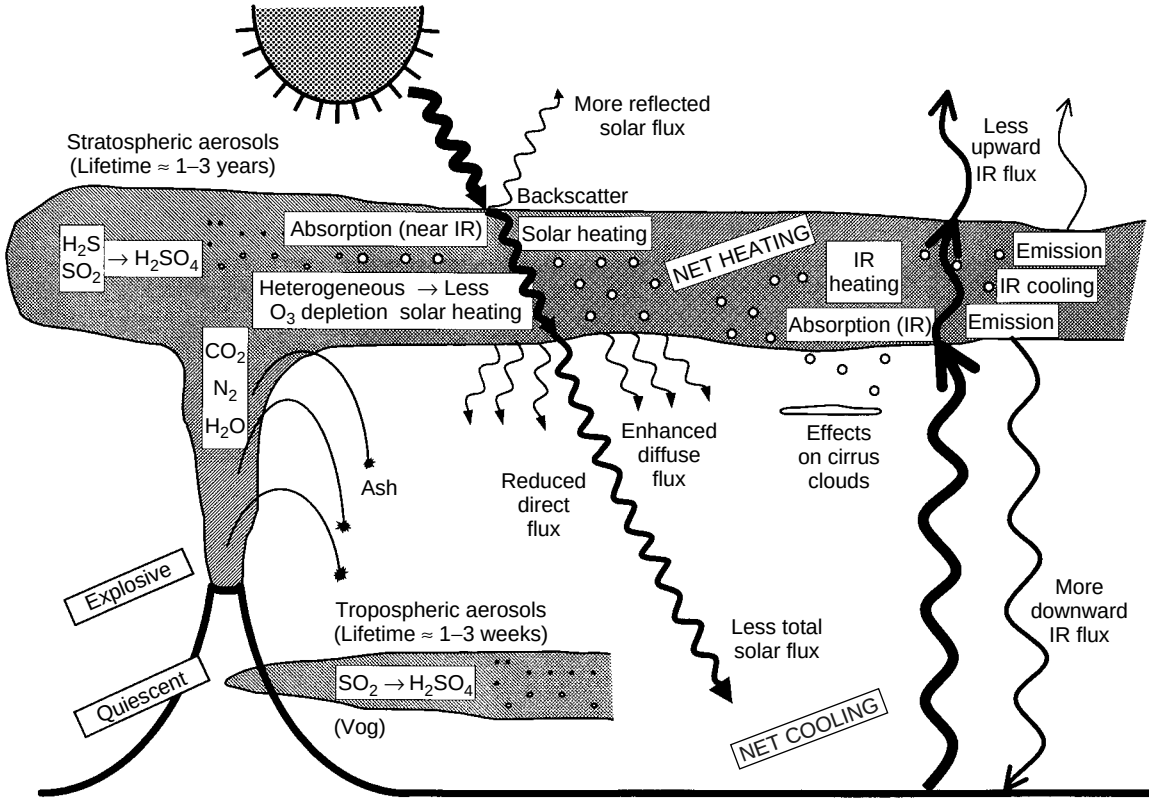

Figure 1 Schematic diagram of volcanic inputs to the atmosphere and their effects. (Adapted from Plate 1 of Robock, 2000, © Copyright, American Geophysical Union)

Volcanic eruptions typically also emit gases, with water (H_2O), nitrogen (N_2) and carbon dioxide (CO_2) being the most abundant. Over the lifetime of the Earth, these gases have been the main source of the planet s atmosphere and ocean, once the primitive atmosphere of hydrogen and helium was lost to space. The water has condensed into the oceans, the CO_2 has been changed by plants into oxygen (O_2), with some of the C turned into fossil fuels. Of course, we eat the plants and animals that eat the plants, we drink the water, and we breathe the oxygen, so each of us is made of volcanic emissions. The atmosphere is now mainly composed of N_2 (78%) and O_2 (21%), both of which had sources in volcanic emissions.

Of the less abundant gases, both H_2O and CO_2 are important greenhouse gases; however their atmospheric concentrations are so large (e.g., CO_2 is at only 370 ppm and growing) that individual eruptions have a negligible effect on their concentrations and do not directly impact the greenhouse effect. Rather, the most important climatic effect of explosive volcanic eruptions is through their emission of sulfur species to the stratosphere, mainly in the form of SO_2, but sometimes as hydrogen sulfide (H_2S). These sulfur species react with H_2O to form sulfuric acid (H_2SO_4) on a time scale of weeks, and the resulting H_2SO_4 aerosols produce the dominant radiative effect from volcanic eruptions. For example, the 1982 El Chichón eruption injected 7 megatonnes (Mt) of SO_2 into the atmosphere, and the 1991 Pinatubo eruption injected 20 Mt.

Once injected into the stratosphere, the large aerosol particles and small ones being formed by the sulfur gases are rapidly transported around the globe by stratospheric winds. Observations after the 1883 Krakatau eruption showed that the aerosol cloud circled the globe in two weeks. Both the 1982 El Chichón cloud and the 1991 Pinatubo cloud circled the globe in three weeks. Although El Chichón (17 °N) and Mt. Pinatubo (15 °N) are separated by only 2° of latitude, their clouds, after only one circuit of the globe, ended up separated by 15° of latitude, with the Mt. Pinatubo cloud straddling the equator and the El Chichón cloud extending approximately from the equator to 30 °N. Subsequent dispersion of a stratospheric volcanic cloud depends heavily on the particular distribution of winds at the time of eruption. For those trying to reconstruct the effects of older eruptions, this factor adds a further complication, as the latitude of the volcano is not sufficient information.

Quiescent, continuous volcanic emissions also add sulfates to the troposphere, but their lifetimes in that part of the atmosphere are much shorter. Global sulfur emission by volcanoes to the troposphere is about 14% of the total natural and anthropogenic emission, thereby leading to a

cooling influence at the surface. Only if there is a long-term trend in these emissions, however, will they be important contributors to climate change; nevertheless, they must be considered when evaluating the effects of anthropogenic sulfate emissions.

Figure 1 indicates the major radiative processes resulting from the stratospheric aerosol cloud from a major volcanic eruption. The most obvious and well-known effect is on solar radiation. Because the sulfate aerosol particles are about the same size as the wavelength of visible light, with a typical effective radius of 0.5 μm, and they have a single-scatter albedo of about 1, they strongly interact with solar radiation by scattering visible light. Some of the light is backscattered, reflecting sunlight back to space, increasing the net planetary albedo and reducing the amount of solar energy that reaches the Earth s surface. This is the dominant radiative effect at the surface and results in a net cooling there. Much of the solar radiation is forward-scattered, however, resulting in enhanced downward diffuse radiation that somewhat compensates for the large reduction in the direct solar beam.

The longest record of the effects of volcanic eruptions on atmospheric transmission of radiation is the apparent transmission record from the Mauna Loa Observatory in Hawaii (see Figure 2). The effects of the 1963 Agung, 1982 El Chichón, and 1991 Mt. Pinatubo eruptions can be clearly seen. Although the Mt. Pinatubo eruption produced the largest stratospheric input of the three, the center of the El Chichón cloud went directly over Hawaii, while only the edge of the Mt. Pinatubo cloud was observed. The Agung cloud was mostly in the Southern Hemisphere, so only the edge was seen in Hawaii.

The reflection of the setting Sun from the bottom of stratospheric volcanic aerosol layers produces the characteristic red sunsets that are used as one means of detecting past eruptions. The famous 1893 Edvard Munch painting, *The Scream*, shows a red volcanic sunset over the Oslo harbor produced by the 1892 Awu (Indonesia) eruption.

Volcanic eruptions can affect the climate system over many time scales (Table 2). The largest known eruption of the past 100 000 years was the great Toba (on Sumatra, Indonesia) eruption about 71 000 years ago, which occurred intriguingly close to the beginning of a major glaciation (although a cause and effect relationship has yet to be established). Volcanic aerosols can be important causes of temperature changes for several years following large eruptions, and, even on a 100-year time scale, they can be important when their cumulative effects are taken into account. This is a very significant consideration when analyzing the extent of global warming, because the impacts of anthropogenic greenhouse gases and aerosols on climate must be evaluated against a background of continued natural forcing of the climate system from volcanic eruptions, solar variations, and internal random variations from land–atmosphere and ocean–atmosphere interactions. New analyses of the volcanic loading of the atmosphere, based on ice core records, have helped

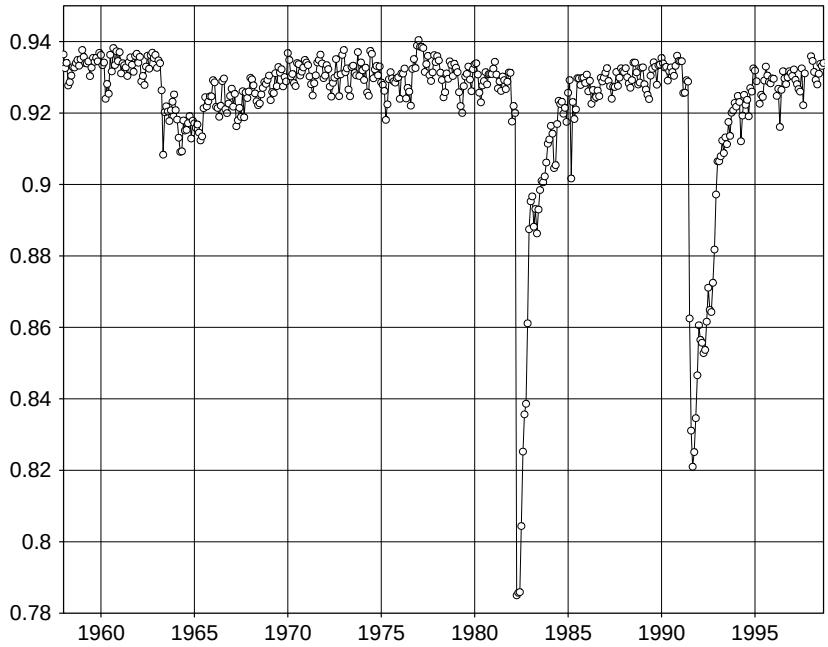

Figure 2 Broadband spectrally-integrated atmospheric transmission factor, measured at the Mauna Loa Observatory, Hawaii (19 °N). Effects of the 1963 Agung, 1982 El Chichón, and 1991 Mt. Pinatubo eruptions can clearly be seen. Years on abscissa indicate January of that year. (Data courtesy of E Dutton, NOAA CMDL, Boulder)

Table 2 Effects of large explosive volcanoes on weather and climate

Effect/mechanism	Begins	Duration
Reduction of diurnal cycle Blockage of shortwave and emission of longwave radiation	Immediately	1–4 days
Reduced tropical precipitation Blockage of shortwave radiation, reduced evaporation	1–3 months	3–6 months
Summer cooling of NH tropics and subtropics Blockage of shortwave radiation	1–3 months	1–2 years
Reduced Sahel precipitation Blockage of shortwave radiation, reduced land temperature, reduced evaporation	1–3 months	1–2 years
Stratospheric warming Stratospheric absorption of shortwave and longwave radiation	1–3 months	1–2 years
Winter warming of NH continents Stratospheric absorption of shortwave and longwave radiation, dynamics	6–18 months	1 or 2 winters
Global cooling Blockage of shortwave radiation	Immediately	1–3 years
Global cooling from multiple eruptions Blockage of shortwave radiation	Immediately	Up to decades
Ozone depletion, enhanced ultraviolet (UV) radiation Dilution, heterogeneous chemistry on aerosols	1 day	1–2 years

identify the effects of volcanic eruptions in the climate record.

Individual large eruptions certainly produce global or hemispheric cooling for two or three years, and this signal can now be more clearly in climate records. It has also been found that the winter following a large tropical eruption is warmer over the NH continents. This counter-intuitive effect is due to a nonlinear response through atmospheric dynamics. It has also recently been realized that volcanic aerosols provide a surface for heterogeneous chemical reactions that destroy ozone. Indeed observations following the Mt. Pinatubo eruption have documented midlatitude ozone depletion caused by volcanic effects.

The winter warming pattern is illustrated in Figure 3, which shows the global lower tropospheric temperature anomaly pattern for the NH winter of 1991–1992, following the 1991 Mt. Pinatubo eruption (*see* Tropospheric Temperature, Volume 1). This pattern is closely correlated with the surface air temperature pattern where the data overlap, but the satellite data allow global coverage. The temperatures over North America, Europe, and Siberia were much higher than normal, and those over Alaska, Greenland, the Middle East, and China were lower than normal. In fact, it was so cold that winter that it snowed in Jerusalem, a very unusual occurrence. As another example of the extreme conditions, Coral at the bottom of the Red Sea died that winter because the water at the surface cooled and convectively mixed the entire depth of the water. The enhanced supply of nutrients produced anomalously large algal and phytoplankton blooms, which smothered the coral. This coral death had only happened before in winters following large volcanic eruptions.

At the tropopause, the boundary between the troposphere and stratosphere, the strongest winds are found in the midlatitudes in the winter and are called the jet stream or polar vortex. The strength of the jet stream depends on the temperature difference (gradient) between the tropics and the polar region, which is largest in the winter when the polar regions cool. For a tropical eruption, the stratospheric heating from volcanic aerosols is larger in the tropics than in the high latitudes, producing an enhanced pole-to-equator temperature gradient, and in the NH winter, a stronger polar vortex and winter warming of NH continents. The stronger jet stream produces a characteristic wind pattern in the troposphere, which warms some regions and cools other ones. This indirect advective effect on temperature is stronger than the radiative cooling effect that dominates at lower latitudes and in the summer.

Because volcanic aerosols normally remain in the stratosphere no more than two or three years, with the possible exception of extremely large eruptions such as that of Toba approximately 71 000 years ago, the radiative effect of volcanoes is interannual rather than interdecadal in scale. A series of volcanic eruptions can, however, significantly raise the mean optical depth of the atmosphere over a longer period and thereby give rise to a decadal-scale cooling. If a period of active volcanism ends for a significant period, such as for the 50-year period from 1912 to 1963, the adjustment of the climate system to an absence of volcanic forcing can (and apparently did) contribute to warming over this period. Furthermore, it is possible that feedbacks involving ice and ocean, which act on longer time scales, can transform the short-term volcanic forcing into a longer-term effect. As a result, the possible role of volcanoes in

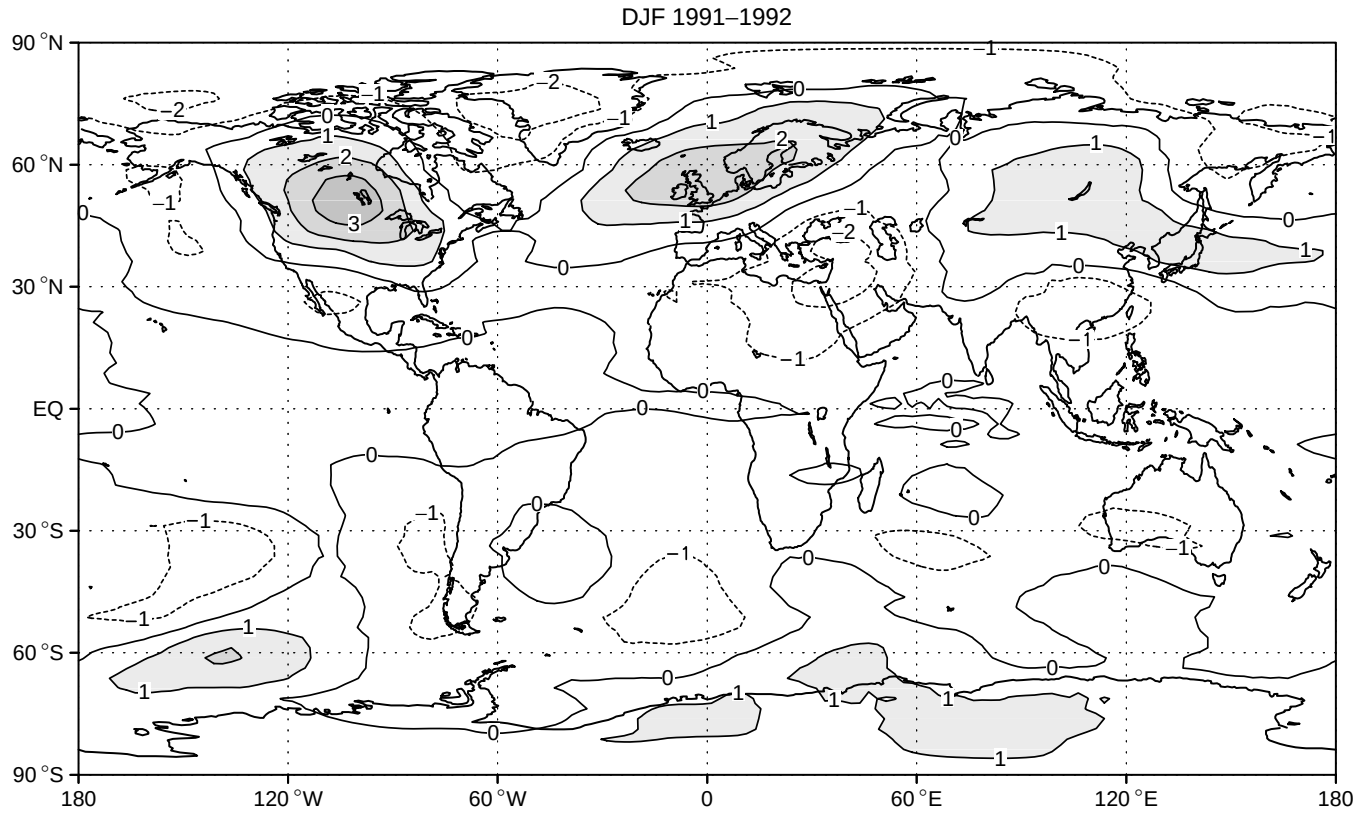

Figure 3 Winter (December January February, DJF) lower tropospheric temperature anomalies (K) (with the non-volcanic period of 1984–1990 used to calculate the mean) for the 1991–1992 NH winter (DJF) following the 1991 Mt. Pinatubo eruption. This pattern is typical of that following all large tropical eruptions, with warming over North America, Europe, and Siberia, and cooling over Alaska, Greenland, the Middle East, and China. (Data from Microwave Sounding Unit Channel 2LT, courtesy of J Christy, University of Alabama, Huntsville. Adapted from Plate 8, Robock, 2000, © Copyright American Geophysical Union.)

decadal-scale climate change remains unclear (*see* Natural Climate Variability, Volume 1). In particular, the current century is the warmest of the past five, with the early part of this period earning the moniker of the Little Ice Age due to its coldness (*see* Little Ice Age, Volume 1). Volcanic eruptions and solar variations are both likely to have been important contributors to the cooling of the Little Ice Age.

Volcanic aerosols have the potential to change not only the radiative flux in the stratosphere, but also its chemistry. The most important chemical changes in the stratosphere are related to ozone (O_3) which has significant effects on ultraviolet (UV) and longwave radiative fluxes. The reactions that produce and destroy O_3 depend on the UV flux, the temperature, and the presence of surfaces for heterogeneous reactions, all of which are changed by volcanic aerosols. The heterogeneous chemistry responsible for the ozone hole over Antarctica in October each year occurs on polar stratospheric clouds of water or nitric acid, which only occur in the extremely cold isolated spring vortex in the Southern Hemisphere (*see* Ozone Hole, Volume 1; Depletion of Stratospheric Ozone, Volume 1). These reactions make anthropogenic chlorine available for chemical destruction of O_3. Sulfate aerosols produced by volcanic eruptions can also provide these surfaces at lower latitudes and at all times of the year. In fact, after the 1991 Mt. Pinatubo eruption, a column O_3 reduction of about 5% was observed in midlatitudes, ranging from 2% in the tropics to 7% in the midlatitudes. Ozone depletion in the aerosol cloud is much larger and reaches 20%. The chemical ozone destruction is less effective in the tropics, but lifting of low ozone concentration layers with the aerosol cloud causes a rapid decrease in ozone mixing ratio in the low latitudes. Decrease of the ozone concentration reduces UV absorption in the stratosphere, which modifies the aerosol heating effect. The net effect of volcanic aerosols on the surface UV flux is to increase it because the aerosols backscatter less UV than the subsequent O_3 depletion allows through (*see* Ultraviolet Radiation, Volume 1).

The significant volcanic effect on O_3 chemistry is a new phenomenon, depending on anthropogenic chlorine in the stratosphere. While we have no observations, the 1963 Agung eruption probably did not deplete O_3, as

there was little anthropogenic chlorine in the stratosphere. Due to the Montreal Protocol and subsequent international agreements, chlorine concentration has peaked in the stratosphere and is now decreasing (*see* Stratosphere, Ozone Trends, Volume 1). Therefore, for the next few decades, large volcanic eruptions will have effects similar to Mt. Pinatubo, but after that, these O_3 effects will be significantly decreased and volcanic eruptions will have a stronger effect on atmospheric circulation without the negative feedback produced by O_3 depletion.

While the large 1982–1983 El Niño occurred just after the 1982 El Chichón eruption in Mexico, there is no evidence of a cause and effect relationship for this or any other eruptions. There is also no evidence that volcanic eruptions produce El Niño events. Because they can occur simultaneously, the climatic effects of El Niño and volcanic eruptions must be carefully separated to understand the climatic response to each.

Because volcanic eruptions and their subsequent climatic response represent a large perturbation to the climate system over a relatively short period, observations and the simulated model responses can serve as important analogs for understanding the climatic response to other perturbations. While the climatic response to explosive volcanic eruptions is a useful analog for some other climatic forcings, there are also limitations. The theory of nuclear winter, which focuses on the climatic effects of a massive injection of soot aerosols into the atmosphere from fires following a global nuclear holocaust, includes upward injection of the aerosols to the stratosphere, rapid global dispersal of stratospheric aerosols, heating of the stratosphere, and cooling at the surface under this cloud (*see* Nuclear Winter, Volume 3). Because testing this theory in the real world would involve global destruction, volcanic eruptions serve as analogues supporting various aspects of the theory.

While we have no idea when the next large tropical eruption will occur, our current understanding of the climatic impacts of volcanic eruptions suggest a likelihood of global cooling lasting about two years, and winter warming of the NH continents for one or two years.

Vostok, Subglacial Lake

J Cynan Ellis-Evans
British Antarctic Survey, Cambridge, UK

A vast lake, thought to be millions of years old, has been discovered beneath the Antarctic ice sheet. The deep sediments of Lake Vostok may contain a unique high-resolution record of climate change and continental-scale glaciation in Antarctica over the past 15- 30• million years. This extreme sub-glacial environment is also likely to contain novel microbiota, long isolated from the Earth's atmosphere and entirely dependent on geochemical energy. Lake Vostok

could feasibly provide a modern analogue for the Snowball Earth event some believe occurred during the neo-Proterozoic period (560- 700 million years ago) and which may have led to the subsequent enormous evolutionary radiation seen in the fossil record.

The presence of a water layer, due to geothermal heat production, beneath thick Antarctic ice sheets was predicted by Russian scientists almost 50 years ago and proven by airborne radio-echo studies in the vicinity of the Russian Vostok Station during the 1970s. By 1993, first evidence was emerging for the scale of water accumulation beneath the ice at Vostok and, in 1996 (Kapitsa *et al.*, 1996), it was confirmed that an enormous freshwater lake (over 280 km long and up to 1 km deep) was present beneath 4 km of glacial ice. Where the topographical ice sheet passes over the lake, surface features entirely flatten out and satellite radar altimetry (ERS-1 and RADARSAT) was used to map, at high resolution, the outline of the lake and its drainage basin (Figure 1). The lake has proved to be one of the largest freshwater bodies on the planet and represents a new extreme environment for humankind to explore. Subsequent coarse radio-echo surveys within a survey area that covers roughly half the Antarctic ice sheet have indicated in excess of 60 additional subglacial water bodies within this area. These additional lakes are significantly smaller than Lake Vostok (though many are around 20 km in length) and the majority are associated with ice sheet divides (start points for ice flow, equivalent to catchment boundaries) near Dome C and Ridge B in East Antarctica where the ice sheet is thickest (Figure 2).

Antarctica was separating from the other southern continents by 34 million years ago, and the resulting thermal isolation as the circum-polar Southern Ocean formed promoted development of the first ice sheets (Figure 3). Subglacial lakes formed in large rock depressions after the ice sheet had reached a thickness of at least 2 km. It is thought that the smaller subglacial lakes are perhaps a few million years old, but recent evidence increasingly points to a much older origin, and even to pre-glacial links, for Lake Vostok. With the Gamburtsev Mountains being the main point of glacial origin at the center of East Antarctica, the surrounding highland areas would have become ice covered at the outset of continent-wide glaciation and likely retained a thick ice sheet throughout the various glacial/interglacial events of the past 15–20 million years. A subglacial lake would have formed early and been maintained throughout this period in such a setting. The depth of sediment (up to 500 m) seen in Lake Vostok is also far greater than might be predicted from a few million years accumulation of glacial scour, which supports an earlier development.

Recent geophysical data have confirmed that the lake is associated with a major tectonic boundary, possibly still active, in the Vostok highlands, between the subglacial Gamburtsev Mountains to the west and the Aurora lowlands to the east (R Bell, personal communication). The current

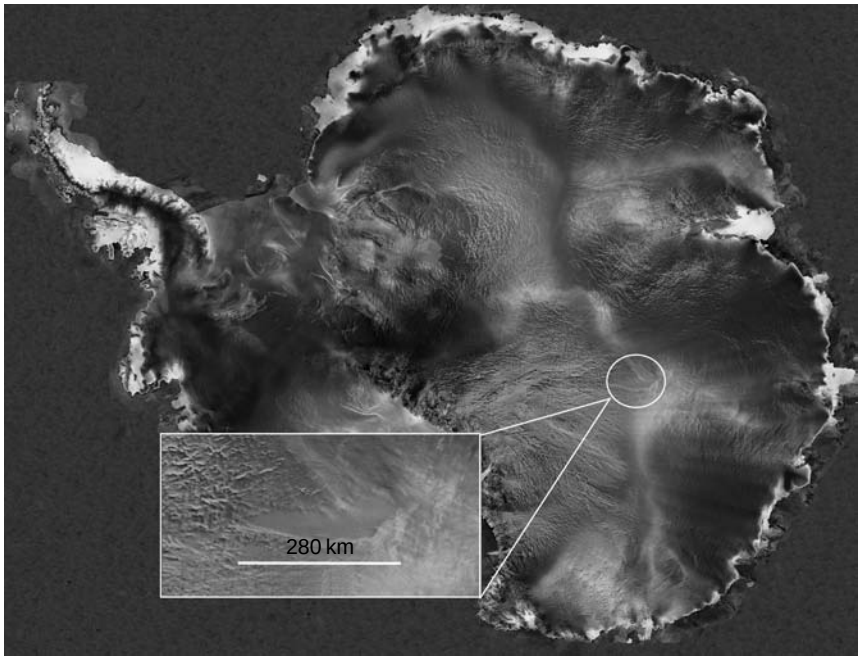

Figure 1 RADARSAT imagery, using radar altimetry data, clearly demonstrates the presence of Lake Vostok – seen as a very large area with an unusually flat surface on the East Antarctic ice sheet where the ice flows over the subglacial lake. (Image credits: NASA – Goddard Space Flight Center Scientific Visualization Studio)

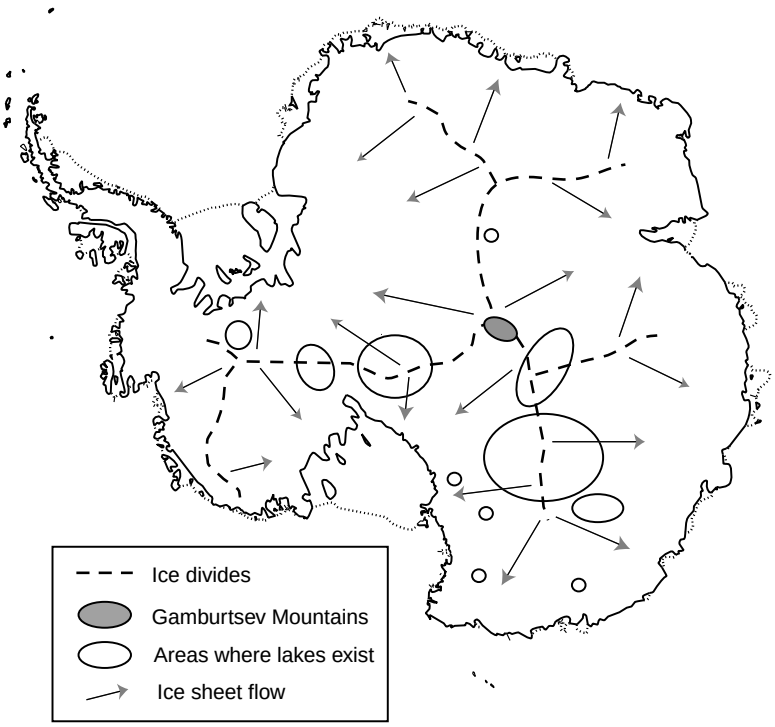

Figure 2 Dotted lines show the ice divides separating Antarctic ice catchments. Most of the subglacial lakes are located in close proximity to these ice divides where the greatest ice thickness occurs. (Modified from Barrett, 1999)

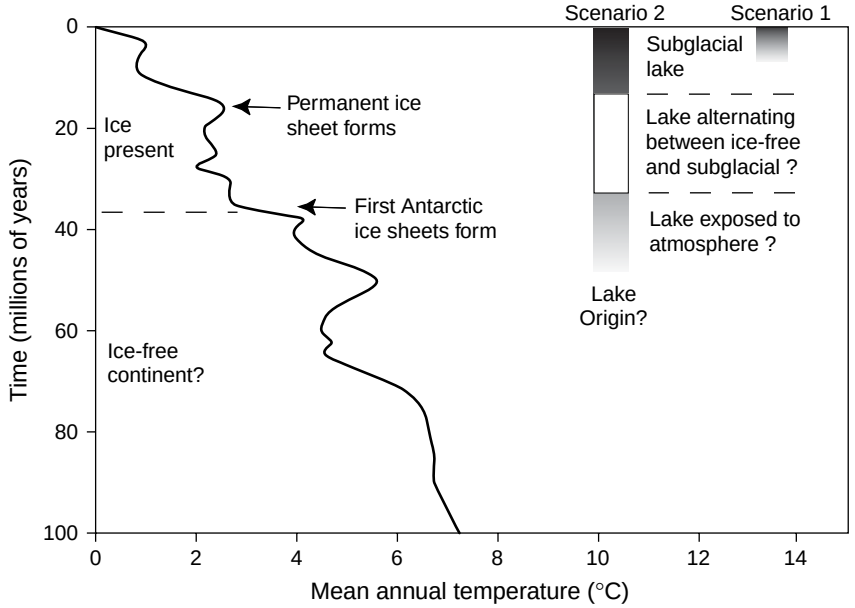

Figure 3 Time-temperature diagram illustrating the changes in mean annual air temperature in Antarctica over the past 100 million years and possible scenarios for the development of subglacial lakes over this time scale. (Modified from Barrett, 1999)

view is that Lake Vostok uniquely occupies an ancient rift valley basin. This raises the tantalizing possibility that a large lake may have occupied this basin before glaciation. A pre-glaciation Lake Vostok would likely have existed in a cold, temperate climate, similar to those now seen in southern Chile and Argentina, with diverse aquatic flora and fauna and a relatively barren catchment due to its alpine location. However, if the rift valley is comparatively

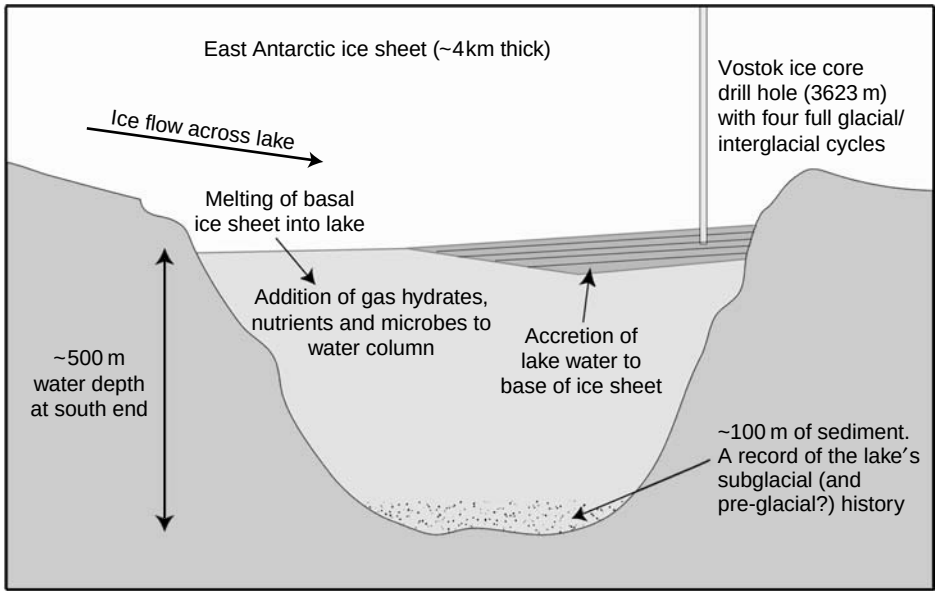

Figure 4 Vertical section through Lake Vostok (not to scale) illustrating salient features including the presence of areas of ice sheet melting, ice accretion and sediment accumulation

old, a lake could possibly have existed at that location for a substantial period extending into times of much warmer climate. Basal sediments in the current Lake Vostok would hopefully include sediments from any pre-glaciation lake. Lake Vostok would therefore appear to be unique, even amongst sub-glacial lakes, potentially containing a sediment record of the geological and climatic history of Antarctica extending throughout the period of glaciation and possibly further back into the pre-glacial Antarctic history. With this possibility, it is not surprising that the scientific community has become enormously interested in studying this particular lake.

The significance of Lake Vostok lies not only in its potential long sediment record but in the existing climate record serendipitously provided by the Vostok ice core which has drilled to within 150 m of the lake (Figure 4) and provided the longest ice climate record (four full glacial/interglacial cycles or 420 000 years) yet obtained. This exquisitely detailed record (Petit *et al.*, 1999) offers a means of cross-checking the responsiveness of a previously unexamined form of lake sediment record, though ice-covered surface lakes from polar regions are already known to record climate changes with great sensitivity.

The enormous catchment area associated with this lake constitutes a giant trap for terrestrial and extra-terrestrial material, which deposits on the ice sheet surface, migrates through the ice sheet and contributes to the sediments at the bottom of the lake. Examination of dust particle records in the ice sheet has demonstrated a previously unrecognized 100 000 year record that linked to climate changes over the past half million years. The lake sediments may not only contain this same record but also feasibly extend it through the millions of years of glaciation.

The ice record has also shown that viable microorganisms exist within the ice profile and could potentially seed the lake. The bottom of the Vostok ice core penetrated into ice that had been formed by freezing of lake water (accretion) to the base of the ice sheet. Within this accretion ice, recent studies have revealed viable microorganisms that in all probability came from the lake. Molecular fingerprinting (Priscu *et al.*, 1999) shows these bacteria to be identical to existing microorganisms, suggesting that they originated from aero biota that were carried through the ice sheet, deposited in the lake and subsequently trapped in accreted ice. However, the lake sediments may contain organisms derived from scoured bedrock and possibly from a pre-glaciation lake. Such organisms would potentially have had a longer period in which to adapt and evolve so could possibly prove to differ markedly from modern microbes. Information on such organisms could provide insights to the evolution of life on Earth and particularly as to how evolution might occur in a cold climate, whereas previously studies of the evolution of life have tended to be based on hot climate scenarios.

A recently presented and still controversial theory of evolution of the early Earth (the neo-Proterozoic period, 750–530 Ma) suggests that the Earth at that time was not simply cooling down from a hot start point, but instead went through cycles of hot climate (greenhouse) and cold climate (freezer) over periods of more than 10 million years. The *snowball Earth* theory is based on observations of extensive bands of carbonate cap deposits in ancient

rocks as the world s CO_2 became tied up during global glaciation and was subsequently released during greenhouse conditions (Hoffmann *et al.*, 1998). The switching between hot and cold climate has been proposed as a trigger for the enormous evolutionary radiations in biodiversity seen in the fossil record at the end of the Proterozoic. An old Lake Vostok would offer the only analogue possibility for a snowball Earth likely to be found on the planet, and would provide the opportunity to study microbial life at the limits of existence in a cold dark world.

To date very little is known about Lake Vostok and even less about other subglacial lakes, but the information already obtained hints at a potentially important role for Lake Vostok in deciphering the climate changes and evolutionary patterns of microbial life on Earth over the past tens of millions of years.

It would have been comparatively simple to have continued the Vostok ice core drilling project the last 150 m and penetrated to the lake. But the drilling operation uses a kerosene/antifreeze mixture as the drilling fluid, which would have risked contaminating this unique pristine environment, so drilling was stopped at a safe distance above Lake Vostok. Plans to penetrate to the lake in the latter half of this decade are now based on drilling new bore-holes with contamination-free technology currently under development. Initial entry will probably involve a non-return trip by robotic probes, which will set up monitoring observatories in the lake to characterize the environment s physical and chemical characteristics. A second drilling system will be deployed to obtain water and sediment samples for life detection studies and the final challenge will be to drill through the sediment profile and return a full sediment record to the surface without significantly disturbing the lake environment.

Walker Circulation

The atmospheric circulation near the equator varies strongly in longitude over scales of thousands of kilometers. A useful but perhaps oversimplified conceptual model of this variation is one of overturning cells in the longitude/height plane, along with associated patterns of surface temperature, sea level pressure and precipitation. The name given to this conceptual model is the *Walker Circulation* in honor of Sir Gilbert Walker, a Director-General of British observatories in India in the early part of the 20th century, who conducted much research directed at understanding and prediction of the Indian Monsoon. He also identified a number of relationships between seasonal climate variations in Asia and the Pacific region, notably the quasi-periodic variation known as the Southern Oscillation, which is associated with the El Niño.

The current widely used conceptual model and the term Walker Circulation both arise from the work of Jacob Bjerknes in the 1960s (*see* Bjerknes, Jacob, Volume 1). The Walker Circulation is comprised of rising motion in regions of high surface temperature (which in turn leads to low sea level pressure and high precipitation coming from deep convective clouds) and sinking motion in regions of low surface temperature (which in turn leads to high sea level pressure and low precipitation). The rising and sinking regions are connected by east/west motions in the upper and lower troposphere, forming the Walker Cells. The east/west motions near the surface are directed from regions of high to low surface pressure, and motions in the upper troposphere at the same longitude are in opposite directions to the surface flows, thereby closing the cells.

The Walker Circulation varies seasonally, but in the mean it has three important rising regions, located in the western Pacific near Indonesia, in equatorial Africa, and over equatorial South America. Following the Pacific cell as an example, the low-level, easterly trade winds form the base of the Walker Circulation, bringing warm moist air from over the Pacific Ocean towards the Indonesian region. Here, moving over normally very warm seas, intense convection takes place, and moist air rises to high levels of the atmosphere. The air then travels eastward before sinking over the eastern Pacific Ocean. The rising air is associated with a region of low air pressure, towering cumulonimbus clouds and rain. High pressure and dry conditions accompany the sinking air. Because this circulation takes place near the equator, the Coriolis force is absent or weak, and a direct zonal (i.e., east–west) circulation spanning the ocean is possible (*see* Atmospheric Motions, Volume 1).

Shifts in the location of the Indonesian rising region and the associated large scale changes in the Walker Circulation are a key feature in interannual climate variability associated with El Niño/Southern Oscillation, (*see* El Niño and La Niña: Causes and Global Consequences, Volume 1). The strength of the Walker Circulation over the Pacific is conventionally measured by a simple Southern Oscillation Index (SOI), which is essentially the difference in atmospheric pressure between Tahiti and Darwin. During El Niño years, the SOI becomes negative, the Walker Circulation is weakened or even reversed, with suppressed convection in the west and enhanced precipitation in the east over the warm waters characteristic of the El Niño. Positive values of the SOI are associated with stronger Pacific trade winds, warm sea surface temperatures in the western Pacific, and enhanced precipitation in Indonesia and eastern and northern Australia.

Water Cycle

see Hydrologic Cycle (**Volume 1**)

Water Vapor: Distribution and Trends

Dian J Seidel
NOAA Air Resources Laboratory, Silver Spring, MD, USA

Water in the gaseous phase, water vapor, is the most signi cant atmospheric trace constituent vis-à-vis climate, weather, hydrology, and atmospheric chemistry. Water vapor is the most abundant atmospheric greenhouse gas, and without it the planet's surface temperature would be well below freezing. Phase changes involving water vapor - the condensation and evaporation processes - involve exchanges of latent heat energy that affect the vertical stability of the atmosphere, the structure and evolution of storm systems, and the energy balance of the global climate system (Chahine, 1992). Water vapor is also the prime source of the atmospheric hydroxyl radical, an oxidizing agent that cleanses the atmosphere of many air pollutants.

The total amount of water vapor in the atmosphere is about 13 • 10^{15} kg. For reference, oceans hold about 100 000 times as much water, and the total amount of water on land (as ice, snow, surface and ground water, and in living organisms) is about 4000 times as much as in the atmosphere. Nevertheless, changes in the amount and distribution of atmospheric water vapor, which can happen relatively quickly, both cause and provide evidence of other global environmental changes. For example, temperature and water vapor changes often go hand in hand, so that increases in water vapor can be indirect evidence of warming. As changes in climate are accompanied by changes in atmospheric circulation and the transport of water vapor, the patterns of precipitation will also change. The extent of such changes could be similar in magnitude to the shifts associated with the El Niño- Southern Oscillation phenomenon, which leads to droughts and ooding in various locations around the world.

The weight of the atmosphere s water vapor contributes to only about one-quarter of 1% of the total sea level pressure of all gases. If all the water vapor in the air were to condense and fall as rain, it would cover the Earth with a layer about 25 mm (or 1 inch) deep on average. This is called precipitable water. Since water vapor is not evenly distributed over the globe, there would be about 50 mm near the equator and less than one-tenth as much near the poles, as shown in Figure 1 (Randel *et al.*, 1996). The general decrease of precipitable water from equator to poles is a reflection of the global distribution of temperature, because warm air is capable of holding more moisture than cold air. There are exceptions in the major desert regions, where the air is very dry despite its high temperature. The most humid region is in the western equatorial Pacific, above the so-called oceanic warm pool, where the highest sea surface temperatures are found.

The average precipitation over the globe is about 1 m annually, so there must be swift transfer of atmospheric water vapor to the surface via precipitation and back again to the atmosphere via evaporation; the average water molecule spends about 9 days in the air before returning to the surface. This rapid turnover, combined with the variation of temperature with height and geography, causes water vapor to be distributed unevenly in the atmosphere, both horizontally and vertically. The map in Figure 1 is a 10-year average depiction that is smoothly varying. On any given day, water vapor exhibits much more complex patterns associated with storm systems and wind patterns.

The uneven distribution of water vapor is even more pronounced in the vertical dimension. Water vapor concentrations (expressed as the ratio of the volume occupied by water vapor to the total volume of air, most of which is nitrogen and oxygen) decrease rapidly with height, varying over four orders of magnitude, from a few percent near the surface to a few parts per million in the lower stratosphere. Nearly half the total water in the air resides below an altitude of about 1.5 km. Less than 5% is in the upper troposphere (above 5 km), and less than 1% is in the stratosphere, nominally above 12 km. This wide range of concentrations presents challenges in designing instruments for atmospheric water vapor measurements. Therefore, a plethora of technologies exist, from low-cost, expendable balloon-borne sensors designed for daily weather observations, to research-quality aircraft- and satellite-borne instruments.

Variations in atmospheric water vapor occur on timescales from milliseconds to decades. The fastest fluctuations are due to turbulence, and near the surface they

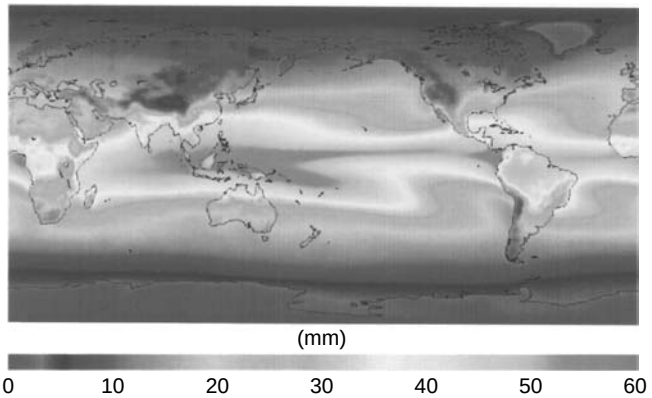

Figure 1 The global distribution of total atmospheric water vapor (precipitable water) above the Earth's surface. This depiction includes data from both satellite and weather balloon observations and represents an average for the period 1988–1997

are associated with changes in the vertical component of the wind and in evaporation. At higher altitudes, air currents generated by atmospheric instability redistribute water vapor and influence cloud formation over periods of minutes or hours. Land and sea breezes cause water vapor concentrations in coastal regions to vary considerably over the course of a day. The distribution of water vapor changes with seasonal changes in temperature and atmospheric circulation patterns. As with temperature, seasonal changes in water vapor appear to be stronger in the Northern Hemisphere than in the Southern Hemisphere. Since the Northern Hemisphere has more land, with lower heat capacity than the ocean, it shows faster temperature and water vapor changes.

On longer time scales, water vapor changes are thought to contribute to an important positive feedback mechanism for climate change, as follows. Warming of the surface, particularly the sea surface, leads to enhanced evaporation. Since warmer air requires more moisture to reach saturation, atmospheric temperature increases allow for increases in atmospheric water vapor. Due to the fact that water vapor is a greenhouse gas, enhanced water vapor in the lower troposphere results in further warming, allowing a higher water vapor concentration, thereby creating a positive feedback. This mechanism is well represented in global climate models, and observations of year to year variations in temperature and water vapor show high correlations (Wentz and Schabel, 2000). However, it is less clear whether this mechanism operates in the upper troposphere, where, despite its relatively low concentrations, water vapor has a more powerful greenhouse effect (Harries, 1996). The variability of upper-tropospheric water vapor with surface temperature is not well documented, mainly because of the lack of long-term measurements in this region (Rind, 1998). Mechanisms have been proposed by which upper-tropospheric water vapor changes, particularly in the tropics, may lead to negative feedbacks on surface temperature (Lindzen, 1990), but overall water vapor changes are thought to contribute to a positive feedback to global warming (Stocker, 2001).

With global warming, an increase in the rate of evaporation must be matched by an increase in the rate of precipitation, because the atmosphere holds so little water. This acceleration of the global hydrological cycle seems likely to lead to an increase in the frequency of extreme precipitation events, and an increase in the proportion of precipitation falling in extreme events (Trenberth, 1998, 1999), which has been observed in some regions (Folland and Karl, 2001). Such changes would have important consequences for agriculture, flood control, and other aspects of human society. Water vapor feedback may also be amplifying atmospheric temperature changes, suspected to be the primary driver of the observed rapid retreat, and in some cases the disappearance, of ice caps and glaciers at high elevations in the tropics and subtropics (Thompson, 2000). Evidence for long-term changes in atmospheric water vapor is limited by the availability and quality of measurements. However, data for the last three or four decades of the twentieth century indicate an increase in water vapor in the lower troposphere over parts of the Northern Hemisphere (Ross and Elliott, 2000).

Measurements are so limited in the stratosphere that detecting changes in stratospheric water vapor is very difficult. Although the spatial representativeness of the observations remains a question, observations made over Boulder, Colorado, in the 1980s and 1990s show an upward trend in water vapor concentration (Oltmans *et al.*, 1995). Unlike the troposphere, the stratosphere is not well mixed, and stratospheric water vapor is not controlled by the same processes operating in the troposphere. The observed stratospheric water vapor increases are larger than can be attributed to increases in methane, which is a chemical source of stratospheric water vapor, and do not appear compatible with the current understanding of changes in the temperature of the tropical tropopause, where tropospheric water vapor enters the stratosphere. Circulation changes are hypothesized to be a contributing factor. Changes in stratospheric water vapor, and related changes in stratospheric clouds, could alter the chemistry of the stratospheric ozone layer and contribute to a cooling of the stratosphere.

Thus, water vapor, a natural and familiar atmospheric constituent, plays many important roles in the global environment. In the greenhouse effect, the global water cycle, and global air chemistry, water vapor both brings about, and is a manifestation of, global environmental change.

WCC (World Climate Conferences – 1979 and 1990)

Two international conferences, convened a decade apart by the United Nations World Meteorological Organization (WMO) in cooperation with a number of other international bodies, played a major role in rallying world support for international efforts in climate research and services.

The First World Climate Conference (FWCC), held in Geneva in 1979, was motivated by a number of growing concerns. Drought in Africa and fisheries collapse in South America had seriously disrupted international trade in food, causing significant price increases. At the same time, international conferences had called attention to the threat of human-induced climate change. With the availability of improved observing, data processing, and dissemination systems, the National Meteorological Services saw opportunities for providing greatly enhanced support. Finally, the Global Atmospheric Research Programme was drawing to a close, and ambitious plans were being developed to continue its research efforts relating to the climate system.

This convergence of motivations prompted the organization of the FWCC under the leadership of Dr Robert M White (US) as Conference Chairman and Sir David Arthur Davies, Secretary-General of the WMO. The week-long conference brought together hundreds of scientists and senior representatives from most of the world s nations and international bodies. The conference s recommendations formed the basis for establishment of the World Climate Programme (WCP), and firmly placed climate issues on the international agenda.

The Second World Climate Conference (SWCC), held in 1990, again in Geneva, assembled an expanded group of international representatives, including many ministers and several heads of state. It reviewed the very considerable progress of the WCP, strongly reaffirmed concerns for human influences on global climate, and made a number of important recommendations for the development of the WCP, notably in strengthening systems of observing and monitoring. In accord with the recommendations of the SWCC, the WCP now includes the four sub-programs dealing respectively with data and monitoring, applications and services, research, and impact assessment and response strategies.

JOHN S PERRY *USA*

WCP (World Climate Programme)

The WCP is a cooperative international scientific program whose goals are to improve understanding of the climate system and to apply that understanding for the benefit of societies coping with climate variability and change. The WCP was established following the staging of the First World Climate Conference in Geneva, Switzerland in February 1979. The major sponsoring organizations of the WCP at the international level are the World Meteorological Organization (WMO), the United Nations Environment Programme (UNEP), the Intergovernmental Oceanographic Commission of United Nations Educational, Scientific and Cultural Organization (UNESCO) and the International Council for Science (ICSU). The four components of WCP and their respective primary objectives are:

- World Climate Data and Monitoring Programme (WCDMP): to facilitate the effective collection and management of climate data and the monitoring of the global climate system, including the detection and assessment of climate variability and changes.
- World Climate Applications and Services Programme (WCASP): to foster the effective application of climate knowledge and information for the benefit of society and the provision of climate services, including the prediction of significant climate variations, both natural and as a result of human activity.

- World Climate Impact Assessment and Response Strategies Programme (WCIRP): to assess the impacts of climate variability and changes that could markedly affect economic or social activities. To advise governments thereon, and contribute to the development of a range of socioeconomic response strategies that could be used by governments and the community.
- World Climate Research Programme (WCRP): to improve the understanding of climate processes for determining the predictability of climate, including its variability and change, identifying the extent of human influence on climate and developing the capability for climate prediction (*see* GCOS (Global Climate Observing System), Volume 1).

The WCP and the Global Climate Observing System (GCOS) are the major international programs contributing to the implementation of Agenda 21.

MICHAEL COUGHLAN *Switzerland*

WCRP (World Climate Research Programme)

The WCRP was established in 1980, under the joint sponsorship of the International Council for Science (ICSU) and the World Meteorological Organization (WMO), and has also been sponsored by the Intergovernmental Oceanographic Commission (IOC) of the United Nations Educational, Scientific and Cultural Organisation (UNESCO) since 1993. The objectives of the program are to develop the fundamental scientific understanding of the physical climate system and climate processes needed to determine to what extent climate can be predicted and the extent of the influence of human activities on climate. The program encompasses studies of the global atmosphere, oceans, sea and land ice, and the land surface, which together constitute the Earth s physical climate system. WCRP studies are specifically directed to provide scientifically founded quantitative answers to the questions being raised on climate and the range of natural climate variability, as well as to establish the basis for predictions of global and regional climatic variations and of changes in the frequency and severity of extreme events.

WCRP activities thus forcefully address outstanding issues of scientific uncertainty in the Earth s climate system, including transport and storage of heat by the ocean, the global energy and hydrological cycle, the formation of clouds and their effects on radiative transfer, and the role of the cryosphere in climate. These activities match the scientific priorities identified by the Intergovernmental Panel on Climate Change (IPCC), and provide the basis for responding to issues raised in the United Nations Framework Convention on Climate Change (UNFCCC) (*see* Intergovernmental Panel on Climate Change (IPCC): an Historical Review, Volume 4). WCRP also lays the scientific foundation for meeting the research challenges posed in Agenda 21 (*see* Agenda 21, Volume 4). Together with the International Geosphere–Biosphere Programme (IGBP) and the International Human Dimensions of Global Environmental Change Programme (IHDP), WCRP provides the international framework for scientific cooperation in the study of global change (*see* IGBP (International Geosphere- Biosphere Programme), Volume 2; IHDP (International Human Dimensions Programme on Global Change), Volume 4).

In addition, WCRP organizes and/or sponsors *ad hoc* meetings to consider scientific and planning issues, and participates as appropriate in the planning of the ICSU/WMO/IOC/UNEP Global Observing System (GCOS). In contributing to the planning and oversight of GCOS and the Global Ocean Observing System (GOOS), WCRP cosponsors the Ocean Observation Panel for Climate (OOPC), which oversees the implementation of an ocean observation system for GCOS (or, equivalently, the climate component for GOOS). With GCOS, WCRP also oversees the Atmospheric Observation Panel for Climate (AOPC) and collaborates with IGBP and IHDP in the development of the System for Analysis, Research and Training (START).

Scientific guidance for the program is provided by a Joint Scientific Committee (JSC), which consists of 18 scientists selected by mutual agreement between the three sponsoring organizations. The scientists are selected so as to represent climate-related disciplines in atmospheric, oceanic, hydrological and polar sciences. Implementation of the program takes place through the Joint Planning Staff (JPS) in Geneva and the International Project Offices (IPOs).

WCRP has formulated a broad-based inter-disciplinary science strategy offering the widest possible scope for investigation of all physical aspects of climate and climate change. This strategy is reflected in the ongoing WCRP core projects. All projects are led by scientific steering or working groups, normally meeting once a year.

The Arctic Climate System Study (ACSYS), concentrating on the understanding of Arctic Ocean variability and change including sea ice processes, is being expanded into the Climate and Cryosphere Initiative (CLIC), which will investigate the role of the entire cryosphere for global climate and as an early indicator of change.

Climate Variability and Predictability (CLIVAR) is the main focus in WCRP for studies of climate variability, extending effective predictions of climate variation and refining the estimates of anthropogenic climate change.

CLIVAR is particularly attempting to exploit the memory in the slowly changing oceans and to increase understanding of the coupled behavior of the rapidly changing atmosphere and slowly varying land surface, oceans and ice masses as they respond to natural processes, human influences and changes in the Earth s chemistry and biota. CLIVAR will advance the findings of the successfully completed Tropical Ocean and Global Atmosphere (TOGA) project, and will expand on work now underway in WCRP s World Ocean Circulation Experiment (WOCE).

The Global Energy and Water Cycle Experiment (GEWEX) is the scientific focus within the WCRP for studies of atmospheric and thermodynamic processes that determine the global hydrological cycle and water budget and their adjustment to global changes such as the increase in greenhouse gases. One of the main thrusts of GEWEX is the implementation of a series of atmospheric/hydrological regional process studies, including the GEWEX Continental-scale International Project (GCIP) that embraces the whole Mississippi River basin, the GEWEX Asian Monsoon Experiment (GAME), and the Baltic Sea Experiment (BALTEX). Observational projects undertaken in order to satisfy specific and evolving scientific needs include the International Satellite Cloud Climatology Project (ISCCP), the International Satellite Land-Surface Climatology Project (ISLSCP), the Global Water Vapor Project (GVaP), and the Global Precipitation Climatology Project (GPCP). Progress has also been made in the GEWEX Cloud System Study (GCSS), which aims to develop improved parameterizations and models of cloud systems used in climate and numerical weather prediction studies.

Another WCRP research activity playing an important role in better understanding the climate system is the Stratospheric Processes and their Role in Climate (SPARC) study, which investigates the interaction of dynamical, radiative and chemical processes. Activities organized by SPARC include the construction of a stratospheric reference climatology and the improvement of understanding of trends in temperature, ozone and water vapor in the stratosphere. Gravity wave processes, their role in stratospheric dynamics and how they may be parameterized in models are also being investigated.

The WOCE is a fundamental element of the WCRP scientific strategy to understand and predict changes in the world ocean circulation, volume and heat storage that would result from changes in atmospheric climate and net radiation. WOCE is conducted by means of a combination of *in situ* oceanographic measurements, observations from space, and global ocean modeling.

The development of global climate models is an important unifying component of WCRP, building on scientific and technical advances in the more discipline oriented activities. These models are the fundamental tools for understanding and predicting natural climate variations and providing reliable estimates of anthropogenic climate change. Models also provide the essential means of exploiting and synthesizing in a synergistic manner all relevant atmospheric, oceanographic, cryospheric and land surface data collected in WCRP and other programs. The Working Group on Numerical Experimentation (WGNE), jointly sponsored by the JSC of WCRP and the WMO Commission for Atmospheric Sciences (CAS), leads the work on the development of atmospheric circulation models for both climate studies and numerical weather prediction. Each project has a numerical experimentation group, that supports the respective WCRP components.

In addition, the Working Group on Coupled Modelling (WGCM), jointly sponsored by JSC and CLIVAR, leads the development of coupled ocean/atmosphere/land models that are used for climate studies on longer time-scales. WGCM is also WCRP s link to the Earth system modeling in IGBP s Global Analysis Integration and Modelling (GAIM) and to the IPCC. Activities in this area concentrate on the identification of errors in model climate simulations and exploring the means for their reduction by organizing coordinated model experiments under standard conditions. Under the auspices of WCRP, the Atmospheric Model Intercomparison Project (AMIP) has been set up in which the 10-year period 1979–1988 has been simulated by 30 different atmospheric models under specified conditions. The comparison of the results with observations has shown the capability of many models to adequately represent mean seasonal states and large-scale interannual variability for several basic climate parameters. A similar Coupled Model Intercomparison Project (CMIP) is in progress.

Further information on many of these research programs are covered in separate articles in this volume. In addition, information may be obtained from the WCRP Joint Planning Staff, c/o World Meteorological Organization, 7 bis, Avenue de la Paix, Case Postale 2300, 1211 Geneva 2, Switzerland, email: dwcrp@gateway.wmo.ch.

Weather

Weather is the state of the atmosphere as perceived by a person: hot or cold, humid or dry, rain or snow, windy or calm, clear or cloudy, etc. Each of these weather elements has quantitative measures, e.g., temperature, humidity, precipitation amount, wind speed and direction, and cloud cover. *Climate* was once defined as the average of the various weather parameters. Climate was viewed as a static

measure of long-term conditions. In the past decade, however, the extension of the forecast period of long-range weather forecasting and the improved understanding of seasonal to interannual climate fluctuations has blurred the distinction between weather and climate. Climate may be viewed as what one would expect, whereas weather is what happens.

Weather prediction is made possible by observing the various atmospheric parameters, analyzing the resulting data by assimilating them into a comprehensive picture of what is occurring at a specific time, and using known relationships or models to project the changes in the initial parameters. These resulting values then must be related to the conditions that will be felt by human senses, i.e., weather. The weather observations may be direct, *in situ* measures of atmospheric parameters, such as in the case of thermometers and anemometers, or remotely sensed, and indirect measures, such as those taken by weather radars or environmental satellites. The challenge to the weather forecaster is to have sufficient information of the required accuracy to be able to specify the initial state of the atmosphere. The data assimilation process is crucial in this regard; it must blend varied types of data with varied degrees of accuracy and varied frequencies of observation. The challenge of the weather forecasting models is to be able to adequately represent the resolution of the weather events, as well as to represent the various physical, chemical, and dynamic processes that influence the future evolution of the state of the atmospheric system.

ELBERT W (JOE) FRIDAY, JR *USA*

Weathering

Weathering is the major force operating on the Earth s surface in opposition to mountain building. Weathering processes are the main agents of decay and disintegration of rocks at the surface of the Earth. Weathering processes include the effects of gravity but do not include significant sediment transport (such as occurs in rivers and streams, glaciers and aeolian environments). Weathering is caused by both physical and chemical processes and is commonly biologically mediated. The physical processes of weathering cause rocks to disintegrate via mechanical mechanisms. Mechanical disintegration can be caused by the freeze/thaw of water in cracks, roots expanding into cracks during plant growth, varying expansion rates of the component minerals during diurnal heating and cooling cycles (insolation), and salt precipitation and hydration in cracks. In contrast chemical processes cause rocks to decay by dissolution and re-precipitation processes. Chemical weathering is controlled by the composition of the parent material, climate, presence of water, rate of transport of solutes away from the site of weathering, redox potential (i.e., whether the pore waters are either relatively reducing or oxidizing; *see* Redox Potential, Volume 2), acidity of the ground water and kinetics of the reactions between the different minerals present and the ground water. Chemical weathering is particularly intense in soils where the combination of elevated (relative to the atmosphere) carbon dioxide (CO_2) concentrations resulting from microbial decay processes and acid ground waters cause minerals, which were stable in igneous settings, to be unstable in the weathering environment. Individual minerals are variously susceptible to weathering, with the common igneous minerals forming a weathering series (in which minerals such as olivine are much more susceptible to degradation than feldspar and quartz). During weathering some minerals (e.g., calcite) dissolve completely (congruent reactions), which liberates their component elements to the pore waters, while others partially dissolve (e.g., forsterite), which liberates material to the pore waters and leaves solid residues (incongruent reactions). In soils, the dissolved components commonly reprecipitate and form new mineral assemblages including clays, carbonate minerals, soil sesquioxides [aluminum (Al), iron (Fe), and manganese (Mn) oxides]. The chemical weathering of silicates and subsequent precipitation of carbonate minerals remove significant carbon from the atmosphere and is a major sink of carbon in the global carbon cycle. Weathering exerts a long-term (10^5–10^6 years) control on global warming.

See also: Geological Cycling, Volume 1; Soil Mineralization, Volume 2.

JOE MACQUAKER *UK*

Wegener, Alfred

(1880- 1930)

Wegener was born in Berlin on 1 November, 1880. From 1899 he studied astronomy and meteorology at Heidelberg, Innsbruck and Berlin. Whilst at university he also became very interested in geology. He received his doctoral degree

on 24 November 1904 for his thesis *Die Alfonsischen Tafeln für den Gebrauch des modernen Rechners* supervised by Wilhelm Foerster and Julius Bauschinger. From 1905/1906 he worked at the Aeronautical Observatory in Lindenberg (near Berlin) and participated in the Danish expedition for exploration of the northeastern coast of Greenland. In 1917 he became a professor of meteorology and practical astronomy at the University of Marburg and in 1924 he was appointed professor of meteorology and geophysics at the University of Graz.

Wegener s main work dealt with the physics of the upper atmosphere, especially the aurora, the so-called geo-corona, the nature of noctilucent clouds and the link between cyclones and Helmholtz s air billows. Another interest was in atmospheric optics in which he studied various aspects of halos. The main results of this work were published in his book on the physics of the atmosphere (1911).

In the 1920s, Wegener worked on the results of his exploration of Greenland, and he made plans to mount a new expedition to examine the inner ice shelf of Greenland. In 1929 he departed on a preparatory expedition to Greenland but died there from an illness on 1 April 1930.

The other major aspect of Wegener s work was his contribution to the theory of continental drift (*see* Continental Drift, Volume 1). The possibility of such drift had been proposed by H Wettstein as early as 1888. Wegener, in his well-known textbook of 1915, gave reconstructions of the distribution of the continents at various earlier geological epochs such as the Carboniferous (beginning about 362 million years ago) and Eocene (a geological epoch, subdivision of the stratigraphic column), supported by geological and other evidence. He envisaged continental drift as a flight from the Poles (Polflucht) due to gravitational attraction exerted by the Earth s equatorial bulge. This force, although real, is much too feeble and his theory was rejected by many scientists of the time for lack of a viable geophysical mechanism. Wegener s concept of continental drift has, however, been accepted since 1950 as a result of conclusive evidence from the new field of palaeomagnetism, and the hypothesis of convection in the Earth s mantle, which was made possible by solid-state creep. (It is of interest that Wegener, in 1929, discussed the role of convective streaming in the magmatical core as a possible source of drift). In recent years all this has been integrated neatly into a comprehensive theory of plate tectonics (*see* Plate Tectonics, Volume 1) and seafloor spreading, which explains much of the dynamic behaviour of the Earth s surface features.

WGNE (Working Group on Numerical Experimentation)

The WGNE is an international group of experts concerned with the mathematical and physical aspects of atmospheric modeling for both weather prediction and climate simulation. The WGNE is jointly sponsored by the Joint Scientific Committee for the World Climate Research Programme (*see* WCRP (World Climate Research Programme), Volume 1) and the Committee on Atmospheric Sciences of the World Meteorological Organization. Originally established in the 1970s to support the Global Atmospheric Research Program (*see* GARP (Global Atmospheric Research Program), Volume 1), the WGNE has examined a wide variety of questions related to the formulation and solution of numerical atmospheric models, as well as questions related to the performance of the atmospheric components of climate models. The WGNE publishes an annual survey of international activities in atmospheric and oceanic modeling, and is the international host of the Atmospheric Model Intercomparison Project (AMIP) (*see* AMIP (Atmospheric Model Intercomparison Project), Volume 1).

W LAWRENCE GATES *USA*

Wind Chill

Wind chill is the effective temperature experienced by a person under a given combination of air temperature and wind speed. Wind chill is different than temperature in that it attempts to consider the additional cooling effect of wind

on the human body. Moving air can carry away heat from a person at a rate that increases with the wind speed, thus causing the person to perceive a lower temperature than actually exists. A person exposed to cold temperatures will be in more danger from hypothermia or frostbite as the wind speed increases.

A chart of wind chill factors may be found at *http://www.nws.noaa.gov/er/iln/tables.htm#wind chill*

The present wind chill values were determined in 1939 by experiments conducted in Antarctica. Containers of water were placed in sub-freezing temperatures and varying wind speeds. The time required for the water to freeze was recorded as a function of temperature and wind speed. The results were used to determine the empirical relationship that defines wind chill.

In the last few years, the use of the wind chill as a measure of the impact of the weather conditions on human health has come under criticism. Some scientists consider the index to be too simplistic because actual cooling is a function of other meteorological factors, such as humidity and solar radiation.

ELBERT W (JOE) FRIDAY, JR *USA*

WMO (World Meteorological Organization)

The WMO is a specialized agency of the United Nations (UN) system, whose purposes are to facilitate international cooperation in the establishment of networks of stations for making meteorological, hydrological and other observations; and to promote the rapid exchange of meteorological information, the standardization of meteorological observations and the uniform publication of observations and statistics. It also furthers the application of meteorology to aviation, shipping, water problems, agriculture and other human activities, promotes operational hydrology and encourages research and training in meteorology.

The WMO was created in 1947 by the World Meteorological Convention adopted at the Twelfth Conference of Directors of the International Meteorological Organization (IMO), which had carried out similar functions before World War II. It commenced operations in 1951 in Geneva with the late Sir David Arthur Davies (UK) as its first secretary general. There are at present 185 Members, each of which maintains its own Meteorological and Hydrological Service.

The WMO s supreme body, the World Meteorological Congress, meets every four years to determine policies, approve the program and budget, and adopt regulations. The executive council meets at least every year to provide timely review and guidance. Members of the WMO are grouped in six regional associations (Africa, Asia, South America, North and Central America, South-West Pacific and Europe), which meet regularly. Eight technical commissions are responsible for: aeronautical meteorology; agricultural meteorology; atmospheric sciences; basic systems; climatology; hydrology; instruments and methods of observation; and marine meteorology.

The WMO secretariat, numbering just under 250 international civil servants, is headed by the Secretary General, currently Professor G O P Obasi (Nigeria). Housed in an innovative modern building near other international bodies in Geneva, it serves as the administrative, documentation and information center of the organization.

The WMO has long played a central role in international environmental research and protection efforts, actively collaborating with other intergovernmental and non-governmental organizations. An early initiative in which WMO played an important role was the International Geophysical Year (1957–1958), which laid the groundwork for current WMO programs in ozone and air pollution monitoring. The WMO also contributed significantly to preparations for the 1972 UN Conference on the Human Environment in Stockholm, Sweden, which led to the establishment of the United Nations Environment Programme (UNEP). In 1975, WMO issued the first scientific statement on the modifications of the stratospheric ozone layer, which led to the formulation in 1977 of the first International Plan of Action for the Protection of the Ozone Layer. Subsequent assessments by WMO provided the basis for the 1985 Vienna Convention on the Protection of the Ozone Layer, the 1987 Montreal Protocol and subsequent amendments, bringing hope for the recovery of the ozone layer by the middle of the 21st century. Through the ongoing Global Atmosphere Watch, WMO is providing a vital input to the United Nations Framework Convention on Climate Change (UNFCCC).

One of the most massive international scientific undertakings of the 20th century was the Global Atmospheric Research Programme (GARP), a worldwide collaborative effort led by WMO, the International Council of Scientific Unions (now the International Council for Science), and the Intergovernmental Oceanographic Commission (*see* GARP (Global Atmospheric Research Program), Volume 1). Responding to a mandate from the UN, GARP sought to improve weather prediction capabilities and advance understanding of the physical basis of climate. A series of field observing experiments laid the groundwork for a Global Weather Experiment in

1979, in which the global atmosphere was, for the first time, observed in full detail for a meaningful period of time. The resulting data sets provided the basis for research that has greatly increased the accuracy and time range of weather prediction. WMO collaboration with other international organizations such as UNEP, the Food and Agriculture Organization, etc., has continued strongly with the establishment of the World Climate Programme (WCP) in 1979. Today, this program provides much of the scientific and administrative infrastructure supporting the UNFCCC, through which the nations are seeking to deal with the threat of human-induced climate change.

The WMO currently carries out a diverse suite of major programs of vital importance to science and society:

- The World Weather Watch (WWW) coordinates the gathering and dissemination of worldwide weather information through surface and space-based observing and communications systems. The global system comprises about 10 000 surface stations, hundreds of radiosonde stations, about 7000 ships, about 300 buoys, and a suite of four polar-orbiting and five geostationary satellites, all operated by national or regional organizations under complex international agreements on standards, codes, measurements and communications. The WWW also includes special activities on methods of observation and tropical cyclones.
- The WCP seeks to use existing climate information to improve economic and social planning; to improve the understanding of climate processes through research, so as to determine the predictability of climate and the extent of human influence on it; and to detect and warn governments of impending climate variations or changes, either natural or human-induced, which may significantly affect critical human activities. Established in 1979, the WCP comprises: the World Climate Data and Monitoring Programme; the World Climate Applications and Services Programme; the World Climate Impact Assessment and Response Strategies Programme; and the World Climate Research Programme. The WCP supports the Global Climate Observing System, encompassing all components of the climate system, atmosphere, biosphere, cryosphere and oceans.
- The Atmospheric Research and Environment Programme coordinates and fosters research on the structure and composition of the atmosphere, on the physics and chemistry of clouds and weather modification research, on tropical meteorology research and on weather forecasting. The Programme comprises the Global Atmosphere Watch – which incorporates long-standing WMO work on ozone and air pollution monitoring, the Weather Prediction Research Programme, the Tropical Meteorology Research Programme and the Physics and Chemistry of Clouds and Weather Modification Research Programme.
- The Applications of Meteorology Programme aims to help members in the application of meteorology and climatology to social and economic development, protection of life and property, and the well-being of humankind. It comprises the Agricultural Meteorology Programme, the Aeronautical Meteorology Programme, the Marine Meteorology and Associated Oceanographic Activities Programme and the Public Weather Services Programme.
- The Hydrology and Water Resources Programme concentrates on promoting worldwide cooperation in the evaluation of water resources and the development of hydrological networks and services, including data collection and processing, hydrological forecasting and warnings and the supply of meteorological and hydrological data for design purposes. It comprises the Operational Hydrology Programme–Basic Systems; the Operational Hydrology Programme–Applications and Environment; and the Programme on Water-related Issues.
- The Education and Training Programme encourages the exchange of scientific knowledge through special courses, seminars and training materials through advanced courses, surveys of personnel training requirements, development of appropriate training programs, establishment and improvement of regional training centers, and organization of training courses, seminars and conferences.
- The Technical Cooperation Programme seeks to bridge the gap between developed and developing countries by the systematic transfer of meteorological and hydrological knowledge and information, and by assisting members, especially developing countries, in obtaining the technical expertise and equipment for the development of their national meteorological and hydrological services. It works with major international partners such as the UNEP, the Global Environment Facility and regional development banks.
- The Regional Programme supports the regional associations in implementation of WMO programs and other activities through a network of regional offices.

Operational WMO activities are primarily funded by national members, which, for example, operate observing, communication and data-processing systems within the WMO framework. Members also contribute dues currently totaling about 255 million Swiss francs per year to support the organization s central activities. Additional funding for specific projects is provided by other national and international organizations.

WOCE (World Ocean Circulation Experiment)

The WOCE is a component of the World Climate Research Programme and is the most ambitious oceanographic experiment undertaken to date. In addition to global observations furnished by satellites, conventional *in situ* physical and chemical observations have been made by nearly 30 nations in four of the world s oceans. At the same time, global numerical ocean models are being developed to assimilate these measurements.

WOCE has two goals:

1. To develop models useful for predicting climate change and to collect the data necessary to test them. This will require determining and understanding on a global basis a number of aspects of the World Ocean Circulation (WOC) and their relation to climate:
    - the large-scale fluxes of heat and fresh water, their divergences over five years, and their annual and interannual variability;
    - the dynamical balance of the WOC and its response to surface fluxes;
    - components of ocean variability on scales of months to years and thousands of kilometers, and the statistics on smaller scales;
    - the rates and nature of the formation, ventilation and circulation of water masses that influence the climate system on time scales from 10–100 years.
2. To determine the representativeness of the specific WOCE data sets for the long-term behavior of the ocean, and to find methods for determining long-term changes in the ocean circulation. Specific objectives are:
    - to determine the representativeness of specific WOCE data sets;
    - to identify those oceanographic parameters, indices and fields that are essential for continuing measurements in a climate observing system on decadal time scales;
    - to develop cost-effective techniques suitable for deploying in a climate observing system.

WOCE used resources from nearly 30 countries to make unprecedented *in situ* and satellite observations of the global ocean between 1990 and 1998 and to observe poorly-understood, but important, physical processes. In parallel, great advances have been made during WOCE in the ability of ocean models to reproduce the known characteristics of the ocean and its circulation. Analysis, interpretation, modeling and synthesis of WOCE data will continue to 2002 but a prerequisite for its success will be the continuing assembly and quality control of WOCE data. The diverse WOCE data sets will serve as a unique resource for climate researchers and marine scientists for decades to come.

Y

Younger Dryas

Dorothy Peteet
Lamont Doherty Earth Observatory, Palisades, NY, USA and NASA/GISS, New York, NY, USA

With the dramatic rise in anthropogenic greenhouse gases over the past 100 years and evidence of recent global climate warming, questions have risen about the potential for triggering climate changes that might be very rapid. One of the best-studied examples of past climate change that was extremely rapid is the Younger Dryas (YD) interval. This pronounced cold event occurred about 13 000 calendar years ago and lasted over 1000 years. The YD was one of several climatic reversals in the warming trend that occurred as the world emerged from the last ice age. This period has generated considerable interest because evidence suggests that the close of this interval took place in a particularly short time interval in Greenland, with most of the change occurring in one to three years. This termination of the event indicates that it is possible for the climate to ip from a cold to a warm state very rapidly. Various physical and biological indicators reveal how rapidly plants and animal responded to this change.

The YD cold period was first discovered about 1900 as a result of an examination of plant macrofossils in a stratigraphic section in Denmark. The tiny leaves of *Dryas octopetala* (Rosaceae family) were found in layers above remains of shrubs and trees that indicated the climate was warming after the ice age. This return to Dryas, which is an indicator of climate conditions conducive to an arctic-alpine tundra environment, indicated that the vegetation was responding to a dramatic cooling. By the 1940s as the science of *palynology* (the study of pollen and spores) was established, investigations at many sites all over Europe showed signs of this pollen change from shrub/tree to tundra and then back again. Evidence for glacial advances during the cold snap was mapped in Scandinavia and even in Scotland, where glaciers actually reappeared after having melted away. By the early 1980s, scientists recognized the YD as a significant event that took place 11 000 to 10 000 carbon-14 (^{14}C) years ago throughout Europe. When looking for the event elsewhere in the world, this ^{14}C time interval was used as a radiocarbon *chronozone* (time slice).

Complications with these correlations have occurred with the recent discovery of differences between the radiocarbon time scale and the calendar time scale (a result of variations in the formation rate of ^{14}C because of variations in solar radiation). Several radiocarbon plateaus exist in the interval, and thus the YD interval actually spans more than 1400 calendar years. Thus, in calendar years, it is considered to have occurred between about 13 000 and 11 600 years ago. The estimates of the magnitude of the cooling range from • 10 °C in northern Europe to • 2 °C in southern Europe. Recent palaeoclimatic research based on the Greenland ice cores has also shown this as a major climatic event, resulting in a cooling estimated to be between • 7 and • 15 °C.

Evidence for the YD in the record of North Atlantic sea surface temperatures was found during the 1980s, as well as confirmation of its signature in eastern North America. Accelerator mass spectrometry (AMS) has been used to date lithologic, pollen, and macrofossil records from Atlantic Canada, southern New England, and New Jersey. The cooling in the eastern US is estimated to have ranged from • 3 to • 6 °C based on pollen/macrofossil and oxygen isotopic evidence from lake diatoms. Evidence indicates that the change from cold to warm conditions at the end of the YD in eastern North America occurred in less than 50 years.

The changes in the ocean and atmosphere have been linked to changes in the terrestrial system through modeling of this period and through data-model comparisons. Using general circulation models (GCMs), several research groups in the US and Europe have attempted to simulate the rapid cooling by experimenting with different climatic forcings. Colder ocean temperatures in the North Atlantic have been found to lead to colder air temperatures downstream in Europe and Asia, but not elsewhere around the globe. The subsequent discovery of the YD cooling through pollen and glacial records on the western coast of North America, and a coincident change in ocean circulation or

upwelling indicated in sedimentary records from the North Pacific Ocean (i.e., Santa Barbara Basin, Sea of Japan, Gulf of California), suggest that the North Pacific Ocean must be connected as a link in the causal sequence. GCM experiments forced by a slightly cooled North Pacific Ocean result in a significant cooling of the entire Northern Hemisphere because the North Pacific Ocean is such a large source of water vapor to the atmosphere (water vapor being the most important greenhouse gas). However, whether the Pacific change is caused by a change in the North Atlantic thermohaline circulation change (possibly as a consequence of the changes induced in the atmospheric circulation) or whether it is somehow generated independently, but at the same time, is still not resolved. Recent indications of changes in upwelling in the Cariaco Basin, Gulf of Mexico imply that the tropics also were involved.

The high-resolution Greenland ice cores indicate that the YD is just one of the dozens of pronounced and rapid climate changes that have occurred in the last 50 000 years. These abrupt events are indicated by such observations as an increase in the deposition of dust, a decline in annual snowfall, and a decrease in methane concentration. While some Antarctic ice cores show an asynchronous response between the Northern and Southern Hemispheres, with a lead of about 1000 years in the Southern Hemisphere, new results from the Taylor Dome in East Antarctica exhibit an apparently synchronous response.

Although significant progress has been made in recent decades in improving understanding of the YD event, the greater, spatial and temporal detail now being sought in terrestrial, sedimentary, and cryospheric domains promises significant advances in the decades ahead. These advances should improve understanding about how rapidly the climate can change and whether human activities (or natural events) might trigger such changes in the future. Higher resolution cores throughout the cryosphere, terrestrial, and marine realms will be the key to gaining new perspectives on the YD event.

Preface to the Encyclopedia of Global Environmental Change

THE ENVIRONMENT

The word *environment*, whose dictionary meaning is simply that which surrounds, has in the last few decades become a buzzword , encompassing an exceedingly diverse array of elements and social issues. Taking the original meaning as a point of departure, it is clear that we humans depend totally on the environment provided by planet Earth for the food we eat, the water we drink, and the air we breathe. Thus changes in this environment must be of vital concern. Will Earth continue to sustain humans in a way that also encourages the ourishing of the other living things with whom we share the planet? This question has loomed ever larger as it has become more evident that human activities have been inducing major changes in all of the compartments of the global environment. We have converted forests and savannas to farms and cities; we have exhumed ancient treasures of fuels and minerals; we have used the rivers and winds as convenient sewers; and we have released entirely new chemical compounds and organisms into the environment. In the 1960s, the scienti c community began to use the word *environment* in this new non-specialist sense. Soon too, Departments of the Environment were created by many governments, and new scienti c journals began publication while others were re-named. For example, the *International Journal of Air Pollution* became *Atmospheric Environment*! In the ensuing decades, the world community has come to see the environment in many different ways, as a life-support system, as a fragile sphere hanging in space, as a problem, a threat and a home.

GLOBAL ENVIRONMENTAL CHANGE

A broader and deeper understanding of the global aspects of environmental concerns emerged in the 1970s and 1980s, and a new phrase *global environmental change* acquired popular currency. Paleoresearch had revealed that environmental change was far from new, and by no means the sole result of the actions of heedless humans. Since the planet s formation, virtually every element of its environment has been undergoing massive changes on all space and time scales. Oxygen waxed and carbon dioxide waned in the atmosphere. Continents moved about the planet s surface like scum on a soup kettle. Great ice sheets grew and shrank. Above all, the force of life (the biosphere) emerged as a dominant driver of planetary change.

However, another vital insight began to emerge about 1980: the inescapably interlinked nature of these many environmental changes. On the very longest time scales, continental drift moved lands into different climates but also changed the climate of the globe itself. Photosynthetic life changed the atmosphere but also made possible more advanced life forms that could take advantage of the new environment. On shorter time scales, atmosphere and ocean often interact to produce the massive changes in the Southern Paci c that we term El Niño and La Niña, whose consequences extend across the planet, and profoundly affect even our socioeconomic systems. Indeed, we have come to realize that human-induced perturbations in the environment are becoming increasingly large, and are potentially coming to dominate the natural workings of the complex and interdependent global system that sustains life on Earth. Humans and their global environment are no longer independent; they are ever-increasingly becoming interdependent components of a single global system.

Thus, the term *global environmental change* has come to encompass a full range of globally signi cant issues relating to both natural and human-induced changes in Earth s environment, as well as their socioeconomic drivers. This implicitly includes concerns for the capacity of the Earth to sustain life that have motivated the development of studies of global change and sustainable development in the last few decades. Analyses of global environmental change therefore demand input from the social sciences as well as the natural sciences (and indeed also from the engineering and health sciences) necessitating an inescapably interdisciplinary approach.

Scientists from many disciplines have been attracted to this growing eld of global environmental change. This is particularly noticeable in the biological sciences through the encouragement of IGBP (International Geosphere Biosphere Programme), which invites ecologists to expand their eld of vision from the plot and landscape scales to the regional, continental and global ones, and to interact with scientists from other disciplines in exploring environmental change at these larger scales. Indeed this trend has encouraged publishers and scienti c societies to introduce new journal titles, and these publications from all accounts appear to be ourishing.

At the same time, human social, economic, and cultural systems are rapidly changing under the in uence of growing globalization. In the economic sphere, for example, today s discourse centers on multinational corporations, the Global

Economy, and the Globalization of Trade. Thus, the agendas of most of the physical, life, and social sciences increasingly focus on global-scale changes.

THE EVER-CHANGING ENVIRONMENT

Since the launching of Earth-viewing satellites, we have been able to see a constantly updated moving picture of our planet. Great weather systems sweep around the globe, waves of green and brown ebb and ow over the continents with the seasons, as do white waves of ice and snow. Nevertheless, a remarkable feature of the Earth system has been its relative stability. Since the dawn of life, the planet's environment has remained within a range of conditions that has supported life. Moreover, with some notable and perhaps cautionary exceptions, changes from year to year, decade to decade, millennium to millennium, have been modest, particularly during the last 10 000 years. Many features of human society exhibit similar behavior. Civilizations and cultures evolve slowly for the most part in response to environmental, economic, and social driving forces over their long lives. Great cities like Rome endure through the ages. A citizen of ancient Babylon probably would have little difficulty understanding the politics of modern Toronto.

But today we appear to be entering an era of change unprecedented since Babylon was a cluster of mud huts. There are many reasons to believe that changes greater than humankind has experienced in its history are in progress and are likely to accelerate.

Virtually every measure of human society – numbers of people and automobiles, airplanes, energy consumption, generation of waste – is increasing exponentially. While the values of a few indicators are leveling off, the magnitudes of annual increases of others remain immense.

Major changes are becoming evident in many critical elements of the environment – increasing carbon dioxide concentrations, stratospheric ozone depletion (not to mention the stratospheric Antarctic ozone hole and the possibility of a similar Arctic event), rising sea level, declining productivity of soils, widespread collapses of fisheries, dramatic declines in biodiversity, destruction of tropical forests, etc. Within living memory, the countryside around large cities has been swallowed up by suburban developments and highways. Humans are stepping on the gas pedal of the planet's environment, and perhaps recklessly breaking the survivable speed limit of global change.

Paleoclimatological studies have shown that the stable environment that we take for granted has not always prevailed. Indeed, the relatively brief period in which human civilization has developed is somewhat unusual in its equable stability. Neolithic hunters in Europe some 13 000 years ago saw their climate shift from temperate to glacial in a single short lifetime. The evolution of human society is punctuated by wars, pestilence, and technological revolutions. Major – perhaps even catastrophic – change could occur in the future, because we know it has occurred in the past.

Rapidly advancing understanding of both natural and human systems – and above all the ability to translate that understanding into quantitative models – has enabled us to explore the future of our global society and its global climate with unprecedented realism. Although prediction of the single future path that we will follow is inherently unpredictable, it is possible to map a broad range of future environmental trajectories that we might take, each completely consistent with our understanding of how the system works. Such scenario-building exercises amply confirm our concerns that the changes of the 21st Century could be far greater than experienced in the last several millennia. Business-as-usual for human society appears to imply business-as-highly-unusual for the global environment.

THE INTERLOCKING BIOGEOPHYSICAL – SOCIOECONOMIC SYSTEMS

Recognition came in the 1970s that many of the environmental issues are inter-connected through the biogeochemical cycling of trace substances, especially carbon, sulfur, nitrogen and phosphorus. In fact, in a prescient statement on the main environmental research priority of the 1980s, Mostafa Tolba (then Executive Director of the United Nations Environment Programme) and Gilbert White (then President of the Scientific Committee on Problems of the Environment) drew the attention of both the scientific and the science-policy communities to the need to understand the major global biogeochemical cycles in order to maintain the global life support systems in a healthy state (Tolba and White, 1979). Quoting from that statement,

> We draw attention to the fundamental scientific importance of understanding the biogeochemical cycles which link and unify the major chemical and biological processes of the Earth's surface and atmosphere. The results will have practical significance for all of us who inhabit an Earth with limited resources and who, by our actions, increasingly affect the quality of the human environment.

So it is that many of the global environmental issues – acid rain, stratospheric ozone depletion, climate change, nitrogen over-fertilization – are inter-related through the global biogeochemical cycles.

One of the interesting results of the study of the Earth's history has been the discovery of the global teleconnections of the Earth system, with some major climatic shifts occurring simultaneously in the two hemispheres. In an analogous way, there has been recognition for a long time that human social, economic, and cultural systems are globally inter-related. That these are connected in turn to the

Earth system was implicitly recognized as early as the 1972 Stockholm Conference on the Human Environment.

To manage the human responses to this enormously varied but at least moderately coupled world system in an era of increasing global change through the diverse array of local, national and international organizations is indeed a daunting challenge. An essential first step is to describe past and present states, then to explain the various phenomena observed, and finally to develop predictive models (or at least a range of scenarios) describing the future behavior of this total Socioeconomic–Cultural–Environmental system. In this process, environmental scientists must learn how to assimilate better the new information constantly being received, although uncertainties, often large, will continue to exist. Within this mix, rational and effective policies must be developed that will balance the risks and costs of global environmental change in an adaptive way. Only then will we be able to even formulate, much less start to implement, rational and effective policies that cope effectively with global change. The prospect of change tempts us to think in terms of winners and losers. However, such analyses often do not play out in simple ways. For example, a modest increase in rainfall would cause farmers to rejoice while vacationers would despair. However, greater farm production can lead to lower commodity prices, thereby reducing farm incomes while making vacation food purchases less expensive. Human society is pretty well adapted to the present environment, so change is necessarily a challenge.

In the longer-term, much depends on the ability of societies to respond, to adapt. Societies will differ in the resources – natural, human, and technological – that are available to them. They will also differ in terms of the values and priorities they attach to physical, social, and environmental goals, and in the social and political mechanisms that they employ to seek these goals. These differences in the human world of generations yet unborn may be as great – and as significant – as the changes in the global environment. A major challenge for our times is to develop frameworks for understanding complex interdisciplinary issues of this complexity.

No discussion of change and the future can be complete without consideration of risk. Projections of the future, however imaginative or soundly based, necessarily center on plausible, surprise-free scenarios – population will increase, economies will advance, climate will change – all typically slowly and smoothly. However, such projections made at the beginning of the 20th Century would have missed two World Wars, the automobile, aviation, space travel, television, and McDonald's in Beijing. By definition, genuine surprises cannot be predicted. However, an understanding of the impacts of past surprises may help us to make our society and our world somewhat more robust in the face of the unknown surprises that await us.

THE HUMAN DIMENSIONS OF GLOBAL ENVIRONMENTAL CHANGE

The human dimension of global change has been defined as the ways in which individuals and societies contribute to global environmental change, are in uenced by it, and adapt to it. Many empirical studies have been undertaken that describe human activities in physical terms, based on various kinds of indicators. Rates of deforestation, urbanization, and changing levels of emissions of greenhouse gases are only some measurable contributors to environmental change. But the dynamics of human activities and global change are much more complex, and they re ect the complexities of the human–nature relationship.

While the sheer burden of human activity on the planet is important, we know that the major forces at work are human beings operating together through political systems, corporations, interest groups, and beliefs that sway whole peoples. These raise questions about the nature of choice, about the hopes, dreams, and frustrations that impel people forward, or block them. At the moment, for instance, the dream of the good life – which has been a critical element of every religious tradition in the world – is increasingly being defined in terms of material possessions and powerful images that are shown on global media. Can this particular version of human happiness be sustained on a limited planet? Some people say that it can; others say that it cannot.

The central questions about the role of human beings in global environmental change revolve around social, cultural, economic, ethical, and even religious issues. These are becoming more and more pressing, and more and more foundational as human beings deliberately or inadvertently modify more and more of the planet. It is also obvious that in this generation the modification of organisms and ecosystems may well extend to the modification of human beings themselves. Among the fundamental questions are: What motivates us towards saving or harming the environment? How do we see ourselves with regard to nature? What is our responsibility to this and future generations? Who do we think we are, and who would we like to become? Appropriately enough, Volume Five of this Encyclopedia wrestles, in many different voices, with these ultimate questions that remain intimately linked with the sweep of physical, chemical, biological, geographical, and institutional changes documented and discussed throughout the earlier four volumes.

The Brundtland philosophy urges us not to reduce options for future generations. Implementation of this idea is, however, difficult. For example, it often seems more compelling to alleviate current poverty than to protect the environment and renewable resources for future generations. Many scientists agree that new approaches are needed to meld the social with the natural sciences in the policy arena. Some of the new methodologies that go beyond the physical sciences

are described in Volumes Four and Five of this Encyclopedia, e.g., post-normal science, integrated environmental assessment, and the precautionary principle.

In a commentary in which he described the 21st Century as the century of the environment, Edward O. Wilson began by referring to the growing *consilience* (the interlocking of causal explanations across disciplines) so that the interfaces between disciplines become as important as the disciplines themselves. He then stated that this interlocking amongst the natural sciences will in the 21st Century also touch the borders of the social sciences and humanities. In the environmental context, environmental scientists in diverse specialities, including human ecology, are more precisely defining the arena in which that species arose, and those parts that must be sustained for human survival (Wilson, 1998).

This is a major challenge for environmental scientists. Already through DNA techniques, for example, it is possible to trace back connections amongst prehistoric peoples through the last Ice Age to modern times.

THIS *ENCYCLOPEDIA OF GLOBAL ENVIRONMENTAL CHANGE*

More than two million papers are published every year in science and medicine, a twentyfold increase since 1940 that taxes the resources of concerned citizens, scientists, university departments, research institutes and libraries. At the same time, many policy-motivated organizations find it difficult to draw together the necessary expertise for resolving the newly emerging environmental issues. The scientific literature relating to the environment is burgeoning. However, research syntheses are in general still scattered across a broad spectrum of journals and books, and information on global environmental change is not readily available in an inter-related way. In particular, it is quite uncommon for contributions from the natural sciences to appear in the same journal or workshop proceedings as contributions from the social sciences and the humanities.

This *Encyclopedia of Global Environmental Change* is a comprehensive and integrated reference in the broad area of global environmental change that will be conveniently accessible and productively usable by students, managers, administrators, legislators, and concerned citizens. The Encyclopedia consists of five volumes of interrelated material:

Volume 1 The Earth system: physical and chemical dimensions of global environmental change (Michael C MacCracken and John S Perry, editors)

Volume 2 The Earth system: biological and ecological dimensions of global environmental change (Harold A Mooney and Josep G Canadell, editors)

Volume 3 Causes and consequences of global environmental change (Ian Douglas, editor)

Volume 4 Responding to global environmental change (Mostafa K Tolba, editor)

Volume 5 Social and economic dimensions of global environmental change (Peter Timmerman, editor)

The first four volumes cover the broad issues of the science and politics of global environmental change. Volume Five adds an often understated but extremely important aspect, linking as it does, global environmental change to the socioeconomic, cultural and ethical dimensions of human societies. Here will be found a rich panoply of writings by people who are not natural scientists but who have thought deeply about the environment. It places global environmental change in a refreshing historical, sociological and cultural context. In many contributions, the time horizons of most interest are the last hundred and the next hundred years. However, some contributions dip backward millions of years. Throughout, the emphasis is upon the dynamics of the various processes discussed – how and why did they change? A second recurrent theme is the interconnection of processes and changes – What produces change? What is impacted by change? Finally, we attempt to deal even-handedly with natural and human-induced change, and with impacts on both the natural world and human society. From the numerous diverse articles in the Encyclopedia, we believe that the user can obtain a coherent picture of this complex and dynamic system of which we all are a part.

To assist in promoting this coherence, each volume begins with a group of extended essays on major topics that embrace the field covered in that volume. These are intended to provide an introduction to the topic, a convenient road map through cross-references for exploring the Encyclopedia. Then there follows, in alphabetical order, shorter articles on a variety of scientific topics, descriptions of scientific programs, definitions, acronyms, and biographies of leading contributors to the field – from Charles Darwin, through the Russian ecologist Vernadski, to the three most recent environmental Nobel Laureates – Crutzen, Rowland and Molina. Indeed, these definitions, biographies and acronym definitions are, we believe, a uniquely valuable feature of the Encyclopedia. In the case of acronyms of international organizations and programs, it is no exaggeration to state that a young environmental scientist requires not only a good understanding of science, but also a good knowledge of acronyms, if they are to follow the discussions taking place at many international meetings! Also included in the alphabetic listings are abundant cross-references to related topics in the same or other volumes.

The substantive scientific articles that comprise the meat of the Encyclopedia are original contributions by active scientists from around the world, and thus

represent authoritative and up-to-date summaries of the state of current knowledge, direct from the producers of this knowledge. A number of these articles break new ground in synthesizing and summarizing our understanding from novel viewpoints and in unconventional ways. Thus, readers will find a wide variety of styles and approaches within the articles, re ecting in a unique way the rich diversity of today's world science. The articles have also had the benefit of careful reviews, particularly by our Editors.

The scientific essays and some of the program descriptions begin with a few italicized paragraphs written for non-specialists. These are not intended to be abstracts of the paper to follow, but rather are aimed at providing the reader with an introduction into why the topic is important and where it fits into the broader aspects of global change – a kind of encouragement to read on. Reading on should not be too difficult a task, since most of the scientific essays are written at the level of journals such as *Scienti c American* and *AMBIO* that are intended for the non-specialist. The Encyclopedia will be a valuable source of information for everyone with a general interest or a need-to-know in the various environmental fields (the natural sciences, socio-economics, engineering, the health sciences, and policy analyses) particularly as they relate to global-scale environmental change, its drivers, and its consequences. It is also expected that among the audiences for each volume will be practitioners and researchers in the fields covered by the other four volumes. We believe that this rather unusual – indeed unique – Encyclopedia will be used in a variety of ways.

1. Some people will employ it simply as a convenient source of information on specific topics – What has been happening recently to the sea ice in the Arctic Ocean? Who was Roger Revelle? What is soil mineralization? What is ICSU or IGBP? What is the Kyoto Protocol? What is deep ecology?
2. Serious students in the environmental sciences may begin by reading one or all of the introductory essays, which present highly compressed crash courses in a range of central topics.
3. We believe that the substantive specialized articles that constitute the bodies of the volumes are productively and enjoyably readable in their own right.
4. Finally, a case has been made by one of the volume editors (Peter Timmerman) for encyclopedia browsing as an enjoyable and productive pastime (*see* Encyclopedias: Compendia of Global Knowledge, Volume 5).

We believe that these five volumes are in the tradition of the human aspiration towards the compilation of global knowledge that sparked the preparation of the first encyclopedias in the 18th Century.

Our Editors have had the benefit of a marvellous postgraduate education in the course of the Encyclopedia's evolution! We are immensely grateful to the many, many authors in our virtual university who have contributed their wisdom to this project.

ACKNOWLEDGMENT

Many helpful comments and draft paragraphs were received from the Volume Editors during the preparation of this Preface.

Preface to Volume Two

The rapid evolution of the science of global change over the last 15 years has provided major insights on the functioning of the biosphere and its interaction with the physical environment. As the realization grew that major changes of key environmental drivers were taking place, such as increased global temperature and atmospheric CO_2, Earth system science was challenged to better understand the function of the Earth system as a whole, with the biosphere both as a major driver and recipient of those environmental changes.

This volume of the *Encyclopedia of Global Environmental Change* deals with the fundamental science that underpins the understanding of quantities and processes that control the basic biogeochemical cycles such as carbon, nitrogen, and phosphorus, and the associated changes in ecosystem physiology and structure under current and predicted human-driven global environmental change. These changes also include the dramatic loss of species, and the world's reorganization of biota towards higher homogenization. Here we cover major themes relevant to various spatial scales of the biosphere including species, populations, communities, ecosystems, biomes, and the Earth system as a whole. In addition, this volume provides an important account of new research tools that are allowing the science of global ecology to quickly develop. Finally, a number of international programs have been fundamental in the development of thinking in this new field of science; and a description of the most important efforts is included.

The new understanding provided in this volume forms the basic building blocks which will allow us to (i) integrate the biospheric processes and quantities with the Earth's physical system into one single Earth system, (ii) detect changes in the world's ecosystems' function and structure, both as already visible impacts of global change and also as indicators of change, and (iii) develop the capability to predict impacts on the biosphere brought about by global environmental changes over the next few decades to century. This information, in turn, will form the basis to develop the technical capabilities and policy tools to mitigate and adapt to undesirable changes.

Volumes One and Two deal with the fundamental science that allows the development of capabilities to assess global change and its impacts on ecosystem goods and services critical to human well being (the latter largely dealt with in Volume Three). Both the realization that global change is happening now and its already noticeable impacts on terrestrial and aquatic ecosystems have prompted the action of new policies and institutions dealt with in Volumes Four and Five.

A HUMAN DOMINATED WORLD

Humans have populated the Earth for thousands of years but not until the last few centuries have they played a major role in influencing the structure and metabolism of the global biosphere. Human-induced changes have today reached such an extent that, in some cases, they are as important or even more important than those caused by the geological and climatic forces that shaped the Earth's environment over the previous thousands of years.

There is no doubt that the growth of human populations and associated resource consumption have been the major drivers behind the large biospheric transformations that have occurred, particularly in the last few decades. Both the total and the *per capita* exploitation of the Earth's resources have been nearly exponential for some time now. The human population has increased tenfold to 6 billion over the last three centuries along with, for example, the growth in the number of cattle (to 1.4 billion) as well as in the number of automobiles. Figure 1 provides a vivid illustration of the extent of large-scale human interference with the natural environment.

Many changes are currently taking place (and at an accelerating pace) in the biosphere. See, for example, Vitousek *et al.* (1997) and Figure 1. These changes include:

1. The historic transformation, to various degrees of intensity, of 30–50% of the land surface, particularly the 10% converted from natural vegetation into cropland. Twenty percent of existing forest and woodlands has disappeared in the last three centuries (Figure 2).
2. Over the last four glacial periods, the atmospheric concentration of carbon dioxide oscillated between 180 and 280 ppm and not until recently have human activities (mainly industrialization and deforestation), driven carbon dioxide concentrations above this narrow window. The biogeochemical cycle of carbon is consequently perturbed on a grand scale, which must affect world vegetation patterns and climate likewise.
3. While carbon is the largest contributor to plant living matter, with about 45% of dry weight, no single life process would be possible without the action of highly specialized proteins (enzymes) for which nitrogen is the key element. Nitrogen is now being added to the biosphere by chemical synthesis (fertilizer production) and expansion of nitrogen-fixing crops at a similar rate to that of nitrogen produced naturally, thus doubling the planet's nitrogen production. The single largest change has resulted from the increased use of synthetic inorganic fertilizers in agriculture; half of the amount that has ever been used on Earth has been applied during the last 15 years. In some areas (with poorly buffered lakes and soils), the net result is acidification. In other areas, the net result is nitrogen over-fertilization, with the risk that the assemblage of species in whole biomes may change radically.
4. Humans use about 50% of the runoff that is fresh and reasonably accessible, irrigated agriculture being the most important single user. In the Northern Hemisphere, 77% of the water flowing into the oceans comes from rivers that have been regulated by dams or manipulated in other ways. This has had large impacts on the transport of sediment to the oceans and in the salinity of coastal waters.
5. Extinction rates of species due to human activities, and particularly due to changes in land use and cover, are calculated to be between 100 and 1000 times greater than in pre-human days. For instance, up to 25% of bird species have been driven to extinction. The current loss of species is comparable to those occurring during the five great extinction events of the geological past. *See*, for example, **Extinctions and Biodiversity in the Fossil Record**, Volume 2; **Extinctions (Contemporary and Future)**, Volume 2.
6. Invasive species are reshaping the biotic composition of the world's ecosystems. In just six nations studied, there have been over 100 000 introduced species (plants, animals and microbes) about 2000–50 000

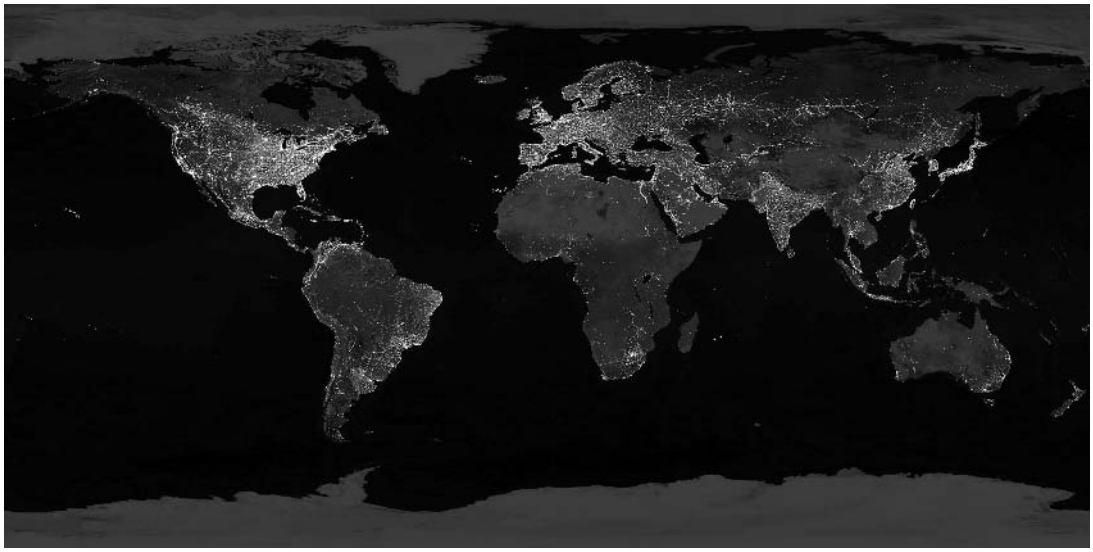

Figure 1 Earth city lights. (Image by Craig Mayhew and Robert Simmon, NASA GSFC, based on data courtesy of Christopher Elvidge, NOAA National Geophysical Data Center)

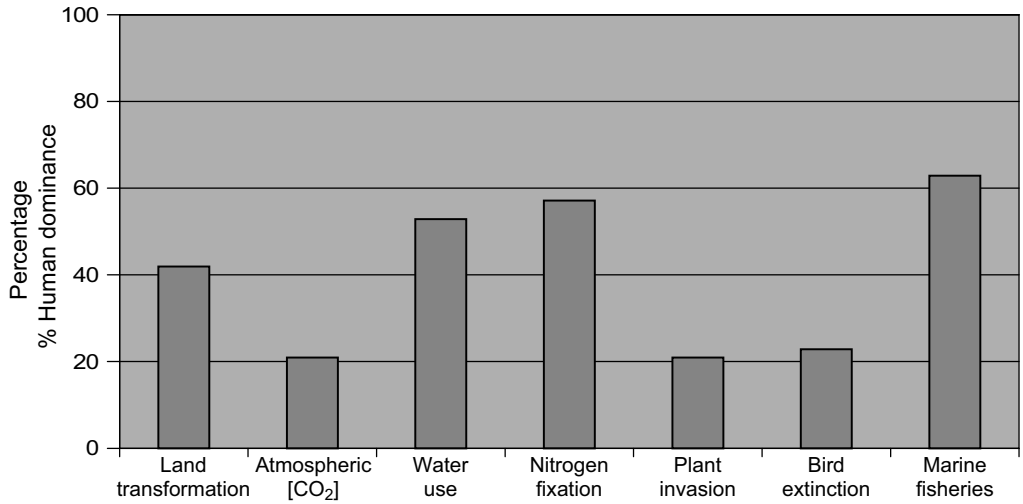

Figure 2 Human alteration of various biospheric compartments. (after Vitousek *et al.*, 1997)

species per country (*see also* **Biological Invasions**, Volume 2). Biological invasions are now considered the second largest threat to biodiversity losses in terrestrial ecosystems after habitat destruction (see for example Figure 3).

7. Fisheries around the world are known to be in trouble with about 22% of recognized fisheries being overexploited or already depleted (see Vitousek *et al.*, 1997). Global fish catches have leveled in recent years.

These examples illustrate the extent of human interventions in many of the Earth's key compartments and processes. Recognition of this situation has led Nobel Laureate Paul Crutzen (2000) to propose that mankind has entered a new biogeophysical era that he has called the *Anthropocene* (*see* **Anthropocene**, Volume 1). This idea is intended to sharpen the distinction between the current human-dominated world (starting around the 1800s) and the previous Holocene era that spanned the post-glacial period of the past 10 000–12 000 years when the Earth's climate and metabolism were exclusively controlled by geological forces. In this respect, *anthropocene* refers not only to the large scale of human interventions but also to the fact that these various drivers affect all terrestrial and aquatic ecosystems on Earth.

Finally, we should draw a distinction between biospheric changes due mainly to continental- and global-scale modifications of the chemical and radiative properties of the environment (climate greenhouse warming, stratospheric ozone depletion and acid deposition) with the direct changes

Figure 3 Invasion rate in San Francisco Bay (data from Cohen and Carlton, 1998). Image courtesy of MITI, ERSDAC, JAROS and the US/Japan ASTER Science Team

in the characteristics of the physical environment (forest clearing, urbanization, irrigation, etc.). The emphasis in this volume is on the former but in the real world, several stresses operate simultaneously on the biosphere. This kind of behavior will be considered in volume three, and the consequences for policy formulation will be discussed in volume four. The Intergovernmental Panel on Climate Change (IPCC) process (*see* **Intergovernmental Panel on Climate Change (IPCC): an Historical Review**, Volume 4) is a shining example of how to move from science to policy, certainly to be emulated with respect other biospheric changes in coming decades. To cite three examples,

1. How will wheat yields be affected over the next several decades, as a result of increasing frequencies and intensities of both ground-level ozone episodes, and of increasing heat waves and droughts? (not to mention globalization of markets, bioengineering, and changes in food preferences).
2. How will salmon and cod stocks respond to changes in technology, sea temperatures and ocean currents, and national and international regulations?
3. How will ecosystems respond to rising carbon dioxide concentrations and climate warming? (This question is addressed in several papers in this volume.)

THE CHANGING METABOLISM AND STRUCTURE OF THE BIOSPHERE

Over the last two centuries, the extraordinary changes that have taken place in the land surface and in the atmosphere

over the land have had large impacts on biospheric structure and metabolism. From an Earth metabolic perspective, the large conversion of land since the early 19th century has reduced the terrestrial biosphere's capacity to produce organic matter (amount of carbon stored in plants per year) by 5% and has released 182–199 Pg of carbon (1 Petagram is 1 billion tonnes) to the atmosphere. Changes in land use and cover have been responsible for 33% of the increased concentrations of carbon dioxide observed in the atmosphere.

Earth observing systems can already detect the changing metabolism and structure of the biosphere. For instance, analyses of monthly air samples around the world for carbon dioxide and other chemical species have shown that the difference between the higher concentrations in the winter, when carbon dioxide release from respiration is the prevailing process, and the lower concentrations in the summer, when carbon dioxide uptake is the prevailing process, has increased between 20 and 40% over the last two decades. This is the result of changes in the strength of key metabolic processes such as photosynthesis (carbon dioxide uptake) and plant and microbial respiration (carbon dioxide emissions), and the length and intensity at which these processes operate in different parts of the planet. Satellite-sensed canopy development (greening) at the beginning of the growing season shows an increased length of this biologically active season in the Northern Hemisphere, specifically an advance of about one week in the onset of the spring drawdown of carbon dioxide. Using similar techniques, it has been shown that terrestrial net primary productivity of some regions in the world has increased over the same period.

The primary driver of these changes is thought to be increased air temperature although higher photosynthesis rates due to carbon dioxide fertilization and nitrogen deposition may have also contributed to some degree.

Changes in the metabolism and structure of the biosphere may well be the best proof that global change is taking place. A large body of evidence on the existence of these changes has been compiled over the past few years, including changes in key physiological processes as well as species redistribution in land and aquatic systems.

As indicated above, changes in plant and animal phenology have also been linked to changes in temperature around the world but most especially at high latitude sites where temperature changes have been the largest. Earlier timing of reproduction has been found for many bird species in a number of countries, as well as advances in the arrival time of migratory birds. In the last few decades, an increase in forest production in several countries in Europe has been related to changes in climate. The lengthening of the growing season is the most common response found, particularly in cold ecosystems of high latitudes.

Changes in phenology and physiology ultimately result in changes in plant and animal abundance and distribution. These changes have been well documented in coastal communities of macro-invertebrate species and with plankton and fish species in the open ocean (increasing abundance of southern species and a decrease of northern species in the Northern Hemisphere). Poleward shifts and movement towards higher elevations of plant and animals have been associated with warming trends regionally with well document shifts in the ranges of many species, including American, British, and European butterflies and insects. Species shifts also include viruses and parasites harmful to human health.

Coastal zones are also undergoing multiple changes, some linked to increased frequency of the El Niño Southern Oscillation (ENSO), with effects on species distribution and stability of coral reefs around the world. Equally important, leveling of fishery harvests and loss of biodiversity is spreading in coastal zones due to dead zones caused by nitrogen pollution. Accelerated nitrogen cycling on land produces NPP (net primary production) decline and forest dieback under chronic heavy nitrogen loads.

Finally, land transformation affects the water cycle and land surface properties. Both have major feedbacks to local and regional weather and climate, which in turn influence the type of vegetation structure that can exist. To put this effect in perspective, catchment studies indicate that water yield decreases 25–40 mm for each 10% increase in tree cover while increases in transpiration of water taken up by deep roots may account for as much as 50% of the observed responses.

Many contributions in volumes 2–5 elaborate on these themes, but of special relevance are the following in Volume 2:

- A series of essays on many of the world's biomes – e.g., the boreal forest, temperate deciduous forests, temperate grass lands, etc. . . .
- **Natural Systems: Impacts of Climate Change**;
- **Plants – from Cells to Ecosystems: Impacts of Global Environmental Change**;
- **Biological Invasions**;
- **C_3 and C_4 Photosynthesis**;
- **Carbon and Energy: Terrestrial Stores and Fluxes**;
- **Carbon Cycle**;
- **CO_2 Enrichment: Effects on Ecosystems**;
- **Nitrogen Cycle**;
- **Nitrogen Deposition on Forests**;
- **Phenology**;
- **Plant Growth at Elevated CO_2**;
- **Plants – Carbon Balance and Growth**;
- **Remote Sensing, Terrestrial Systems**;
- **Temperature Increase: Effects on Terrestrial Ecosystems**.

THE EMERGING SCIENCE OF GLOBAL ECOLOGY

Realization of the existence of global environmental problems such as increasing atmospheric carbon dioxide, the stratospheric ozone hole, and other changes more continental in nature, such as nitrogen deposition and acidification of land and aquatic systems, has extended the ecological sciences towards the new field of *global ecology*. In this connection, the global environmental issues mentioned above have been found to be related through the global biogeochemical cycles. Thus understanding the interactions amongst these cycles is fundamental to human attempts to preserve global life-support systems. There is therefore an obvious practical need to develop a new type of global science.

The new global ecology saw its beginnings during the International Biosphere Programme (IBP) during the late 1960s with a focus on primary productivity of the earth's ecosystems (*see* **International Biosphere Program (IBP) – a Foundation for Global Studies**, Volume 2). It was not until the onset of the International Geosphere–Biosphere Programme (IGBP), however, that the ecological sciences together with other disciplines began to develop a more integrated bio-geophysical Earth system science. This new program also focused on the nature of the human perturbation and how it is changing the Earth's functioning. The IGBP has operated in more than 60 countries and has led the thinking on global change research for more than 10 years. It is now entering phase II with a further emphasis on integration and interdisciplinary research (*see* **IGBP Core Projects**, Volume 2).

Some of the developments in global change research have been accompanied by technological innovation that has allowed measurements to be made over large regions of the globe, over the entire Earth for that matter. One such technological tool has been the satellite with the capacity to measure variables related to biospheric metabolism such as NPP and evapotranspiration (*see* **Global Ocean Observing System (GOOS)**, Volume 2; **Global Terrestrial Observing System (GTOS)**, Volume 2). The wide coverage and the high frequency of measurements has made it possible to track the phenology of plant cover (*see* **Phenology**, Volume 2) as well as historical changes in land surfaces.

New technology (e.g., eddy covariance, and free air carbon dioxide enrichment technology (FACE)) has also enabled us to manipulate and measure ecosystem quantities and processes at larger scales (dozens of m^2 to several hectares, and small watersheds) than previously in order to study the effects of present and future environmental conditions (Figure 4) (*see* **Long-term Ecological Research (LTER) System**, Volume 2). New knowledge resulting from observations and ecosystem experiments using these new technologies has been fundamental to increasing our understanding of ecosystem controls and the processes involved. This type of information is also the basis for the development and validation of biospheric models that simulate key functional and structural parameters of the Earth's ecosystems. *See*, for example, **Biome–BGC Ecosystem Model**, Volume 2.

The new Earth system science, fundamental to global change research, includes a large body of disciplinary work but the greatest challenge is in integrating research from multiple disciplines and developing appropriate linkages and constraints using both bottom-up and top-down approaches.

A good example of how such an integrated approach has been successful is the research done to explain the changes in interannual variability of atmospheric carbon dioxide concentrations. First, there is the global network of surface-based carbon dioxide monitoring stations, which provides the data on global trends in carbon dioxide concentrations. Then there is an integrated suite of top-down satellite data, plot-level bottom-up flux measurements (eddy covariance), and ecosystem experiments, which can explain why interannual variability occurs (Figure 5). The satellite-based normalized difference vegetation index (NDVI), for instance, might indicate earlier leaf-out in temperate and boreal forests. Ground-based measurements of leaf area document the phenomenon locally, and temperature measurements yield its probable cause. Eddy flux can then be used to measure the consequences of earlier leaf-out on the annual carbon balance for the ecosystem. Finally, ecosystem manipulative experiments (e.g., elevated carbon dioxide and temperature experiments) can provide the mechanistic information necessary to forecast changes under simulated global environmental change. Information on other intermediate-scale processes such as disturbances, succession and dispersion are also needed to understand the full range of controls on functioning and structure at multiple scales of space and time (*see also* **CO_2 Enrichment: Effects on Ecosystems**, Volume 2).

Global change research is also moving quickly towards better understanding of the nonlinear nature of the biosphere's behavior. Systems at any level of organization often display surprising and unexpected changes in response to continuous or sudden changes in the environment. Questions such as: Will NPP of terrestrial ecosystems change proportionally to changes in atmospheric carbon dioxide and temperature or are there thresholds, switch points or flip flops? Will the gradual deforestation of the tropics incrementally reduce biodiversity or are there fragmentation thresholds beyond which species extinction takes place more rapidly? The implications of nonlinear responses to global change are critical for the design of new research (*see* **Chaos and Cycles**, Volume 2; **Non-equilibrium Ecology**, Volume 2) and the development of suitable policies to deal with unexpected system behavior (*see* **Monitoring in**

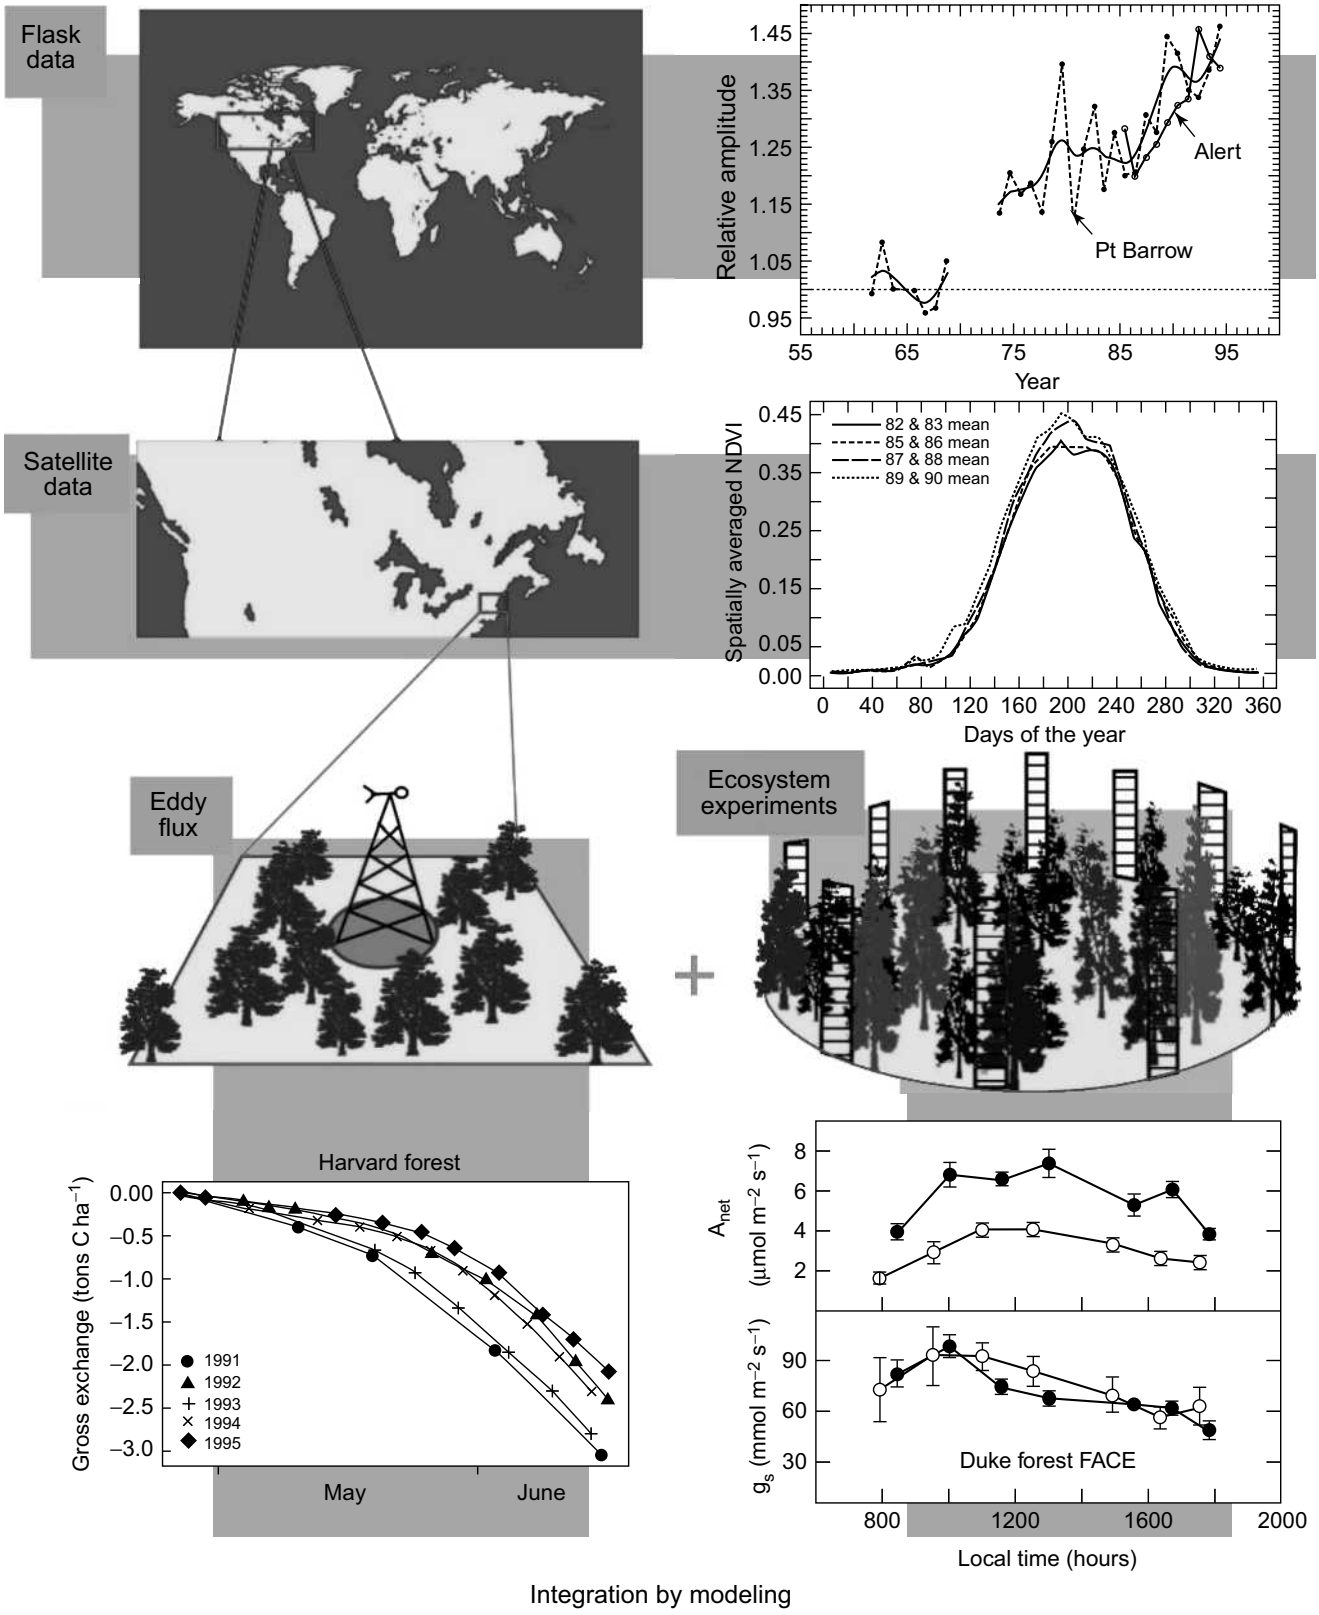

Figure 5 Measuring the carbon metabolism of the biosphere with a multi-technique approach (Canadell *et al.*, 2000)

Support of Policy: an Adaptive Ecosystem Approach, Volume 4).

Global change research also encompasses an understanding of the richness of the world's biota and its role in ecosystem functioning and stability. The diverse assemblages of organisms that dwell in the various components of terrestrial and aquatic systems perform critical functions such as decomposition of plant and animal detritus, nitrogen fixation, and a myriad of other essential functions. However, a large fraction of living species still remains unknown, particularly in oceans and soils (e.g., only 0.025–5% of nematode species have been described). This lack of information on the elemental constituents of an ecosystem poses large impediments to further understanding the role of biota on the functioning of the world's ecosystems. As loss of species continues, one could ask how many species are needed to maintain appropriate functioning and long-term stability of an ecosystem. In other words, from a functional point of view, how many species can we afford to lose? This challenge becomes even more complex when adding the rapid redistribution of the world's biota due to the increasing levels of material flows among many parts of the world, that is, the expansion of biological invasions (*see* **Biological Invasions**, Volume 2). Thus, a main challenge is the need for the development of new science and testable hypotheses linking biodiversity and ecosystem functioning (*see also* **Biodiversity in Soils and Sediments: Potential Effects of Global Change**, Volume 2; **Functional Biodiversity**, Volume 2).

CONCLUDING REMARKS

This volume contains a series of articles on the basic science that underpins current understanding of the functioning and structure of the biosphere and how it interacts with the physical environment. This knowledge allows us to evaluate the extent that the effects of global environmental change will have on the world's ecosystems and provides information on the development of concepts, theory, and tools that are used for simulating future trajectories under various scenarios of global change.

When individual species are grouped together into populations and communities, new processes shape their composition and structure such as herbivory, pollination, competition, succession, nitrogen fixation, and a critical understanding of life cycles as nonlinear and often chaotic systems.

The next level of biological organization and complexity concerns ecosystems with assemblages of multi-species, above and below ground interactions, and spatially explicit resource distributions. Contributions in this volume that provide understanding of ecosystem structure and functioning include: mineral cycling, disturbances, resilience, ecosystem invasions, and carbon and energy storage and fluxes. The volume also includes the latest understanding on current and future effects on the biosphere of increasing atmospheric carbon dioxide, nitrogen deposition, and rising air and soil temperatures.

Landscapes are the most common scale at which humans perceive and manage ecosystems. They comprise a mosaic of patches reflecting physical constraints, natural disturbance history, and land use patterns. This heterogeneity alone necessitates the use of approaches that account for the diversity of land surface properties and resulting fluxes, in addition to basic processes involved in landscape dynamics such as disturbances and dispersal, and dynamics at the interfaces (ecotones) in fragmented landscapes.

Landscape richness and distribution of species also have implications for the structure and functioning of ecosystems. Information on species richness and functional attributes is provided for some of the less studied components of the biosphere such as soils and freshwater sediments. Species assemblages sometimes change rapidly due to species extinctions and invasions of exotic species. Several contributions in this volume provide critical information on past, present, and expected future species extinctions with an analysis of what makes species most vulnerable. For individual plant and animal species, information on physiology, growth, and reproduction is also provided as key controls of structure and functioning.

The volume also reviews the major characteristics of a number of representative biomes across the world's climatic belts and their sensitivity to global environmental change (e.g., tundra is very sensitive to temperature changes). Special attention is given to some of the most vulnerable systems within biomes such as intertidal communities and coral reefs.

The highest level of complexity is the Earth system itself. This is the level at which some of the most fundamental life engines operate, particularly the various global biogeochemical cycles; carbon, nitrogen, iron. It is also the level at which major biosphere–atmosphere feedbacks take place with large impacts on regional and global climate.

The development of new tools has been critical to the advancement on global change research. The need to scale up to large regions and to the globe, and to project future trajectories of ecosystem functioning and structure has been a challenge. This volume describes some of these advances ranging from remote sensing techniques, ecosystem flux measurements (e.g., eddy covariance), manipulation experiments (e.g., FACE), the use of stable isotopes, ecotrons and other experimental facilities, etc. The information generated from the use of these techniques directly feeds into the development and testing of ecosystem and biospheric models also included in this volume.

The new research issues dealing with global environmental change have fostered the development of a new

type of science, a new type of scientist, and a new way to structure and coordinate research. The volume describes some of the international programs that have been critical to the development of the science of global change such as IGBP (*see* **IGBP Core Projects**, Volume 2), and how other international and regional programs and networks have played critical role in shaping the research agenda over the last decade. Such as the European Network for Research in Global Change, the Inter-America Institute for Global Change Research, the Asian Pacific Network for Global Change Research, the International Long Term Ecological Research network, and the International Global Observing Systems. Examples of regional research projects are also described such as the Boreal Ecosystems Atmosphere Study (BOREAS) and the Large-scale Biosphere–Atmosphere experiment in Amazonia (LBA) for their importance at pioneering integration within a large region (*see* **Boreal Ecosystem–Atmosphere Study (BOREAS)**, Volume 2; **European Network for Research in Global Change (ENRICH)**, Volume 2; **Inter American Institute for Global Change (IAIGC)**, Volume 2; **Large Scale Biosphere–Atmosphere Experiment in Amazonia (LBA)**, Volume 2; **Long-term Ecological Research (LTER) System**, Volume 2).

Biological Invasions

W M LONSDALE

CSIRO Entomology, Canberra, Australia

The world's natural and agricultural ecosystems are being invaded by a growing number of destructive species. Such invasive species are important agents of global change (Vitousek et al.*, 1996; Williamson, 1996; Simberloff, 1997a), and ecologists now believe that biological invasions are second only to habitat destruction as a threat to biodiversity (Walker and Steffen, 1997). Invasive weeds reduce agricultural productivity and out-compete the native ora, feral animals consume and degrade the resources that support our native animals and livestock, and insect pests and diseases threaten our natural vegetation and crops. Increasing numbers of exotic marine pests are invading our sheries and coastal environment. There are major impacts on animal health from exotic diseases, and on human health from allergies due to weeds. One of the main drivers of change through invasion has been trade. World trade grew 16-fold between 1950 and 1998 (The Economist, 1998), and although increasing globalization of trade represents great economic opportunities, there are increased risks to biodiversity from increasing movement of pests, weeds and diseases.*

DEFINITIONS

For Williamson (1996, 58–59), an *invader* or *invasive species* is any non-indigenous species – thus, it is a purely geographical term. Here, however, the terms *invader* and *invasive* are reserved for non-indigenous species that are in the process of increasing in range (Pysek, 1995). A further useful term is *cryptogenic*, defined as species that are neither clearly indigenous nor non-indigenous, and which may in some communities far outnumber the non-indigenous species (Carlton, 1996).

From a management point of view, it is useful to classify non-indigenous species by their population status. In ascending order of population size and stability (see Table 1), exotic species may be *adventive*, *naturalized*, or *invasive*. Each of these status groups has its counterpart for indigenous species.

A further classification, applying to both indigenous and non-indigenous species, is by function (*colonizers*, *dominants*) or by impact (*pests* or *weeds*). It is likely that most invasive species as defined above (i.e., non-indigenous species undergoing a range expansion) will have an economic or ecological impact. Indigenous species can cause damage, but a disproportionate amount of damage is caused by non-indigenous species, and they are major agents of global change. For example, in Australia, many of the pests and most of the weeds are non-indigenous.

Some other terms used in invasion studies include:

- *Disturbance*: removal of competing vegetation (Hobbs, 1991). Often regarded as the precursor to invasion.
- *Native species resistance to invasion*: competitive ability of native species with respect to invaders.
- *Resistance to disturbance*: ability of native ecosystems or species to recover from disturbance – often regarded as the inverse of invasibility.
- *Invasibility*: susceptibility of sites to invasion (e.g., Lonsdale, 1999).
- *Ecosystem resistance to invasion*: intrinsic resistance of native ecosystem to invasion through community structure (Williamson, 1996, 193–196). Probably the inverse of invasibility.
- *Invasion potential*: intrinsic ability of species to invade (di Castri, 1989).
- *Propagule pressure*: number of propagules arriving at a site (Williamson, 1996, 45).

THE INVASION PROCESS

Modes of Introduction

Many invasive species arrive as intentional introductions that then go awry. The proportion of harmful species that were introduced intentionally varies, however, between taxa. For weeds, 49% of Australian noxious weeds (Panetta, 1993) and at least 40% of invasive plants in North

Table 1 Population status of indigenous and non-indigenous species, and the words used to describe them

Population status	Indigenous	Non-indigenous (exotic, alien)
Uncommon, survival uncertain	Endangered	Adventive, casual, escaping
Stable	Stable	Naturalized
Range increasing	Expanding	Invasive
Capable of establishing in sparsely occupied habitats	Colonizers	
Most abundant species in community	Dominants	
Causing damage	Pests and weeds	

Eastern US (Mack and Lonsdale, 2001) were introduced intentionally. Similarly, most harmful fishes and terrestrial vertebrates in the US were intentional introductions (OTA, 1993, Figures 2–5). Invasive plants have been brought in as ornamentals, as pasture species, for erosion control, for afforestation, and as curiosities by botanic gardens (Mack and Lonsdale, in press). Mammals and fish are introduced for hunting and fishing. Although many are intentionally introduced, accidental introduction of fish, terrestrial vertebrates and plants also occurs.

By contrast, plant pathogens, mollusks and insect pests were mostly accidentally introduced (OTA, 1993, Figures 2–5). Pathogens and insect pests can arrive borne on air currents, or as unwanted passengers on imported plant material. Forest pests arrive on unprocessed timber imports. Mollusks frequently arrive in ballast water in ships, to be evacuated at the port of entry.

Rates of Incursion

Data on rates at which organisms become naturalized are quite scanty. For a range of organisms (Figure 1), the rate of establishment of species for the US, Australia and New Zealand varies between 16 species per annum (p.a.) (plant pathogens in Australia) to 0.5 species p.a. (fish in the US).

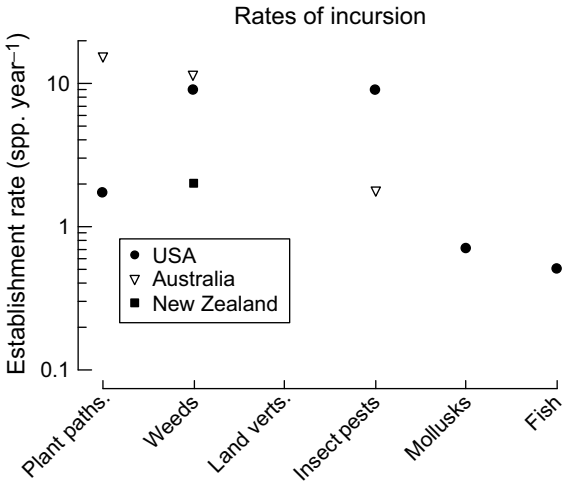

Figure 1 Rates of incursion of various exotic organisms (Plant paths are plant pathogens, Land verts are land vertebrates) into the USA, Australia and New Zealand (recalculated from data in OTA, 1993, Nairn *et al.*, 1996 and Buddenhagen *et al.*, 1998 respectively)

Lag Phases

Classically, invading populations have been characterized by a sigmoidal curve growth curve. This involves a delay, known as the lag phase, in the onset of the invasion process, followed by a phase of exponential increase until the system is saturated with the invader and the population size stabilizes. Cousens and Mortimer (1995, 25–27) have shown that the early stages of an exponential increase would, in many cases, be indistinguishable from a lag phase. Nevertheless, there are undoubtedly real cases of the phenomenon, e.g., the Brandenburg exotic ora (Kowarik, 1995), where the average time lag between introduction and invasion was 147 years. How general lag phases are for different organisms, and why they occur, remains the subject of conjecture. It seems, by contrast, that marine organisms have little lag phase, and that once introduced, rapidly move to pest status, with little wastage of species (J Carlton, personal communication, see section on rates of conversion to pest status herein).

Rates of Spread

Invaders exhibit a huge range of spread rates, over six orders of magnitude (Mack and Lonsdale, 2001). Most of this variation is found amongst invertebrates, which range in velocity of spread from 260 km year^{-1} (the Africanized honey bee in America; measured from Figure 6.2 of Williamson, 1996) down to 3 m year^{-1} for an introduced earthworm in Ireland (*Aporrectodea rosea*; Wellings, 1994). The highest spread rates are exhibited by diseases (Mack and Lonsdale, 2001) with in uenza the fastest at 1200 km year^{-1} (Williamson, 1996, 155). Amongst plants, tree spread rates are very much lower than those of herbs. This might be attributable to the greater maturation time of trees, though this perhaps cannot entirely account for

the two orders of magnitude of difference seen. Marine organisms are among the higher spread rates (Mack and Lonsdale, 2001), though not as high as might be expected given the velocity of surface currents (Grosholz, 1996). A considerable amount of effort has gone into the prediction of spread rates in invading organisms (see Shigesada and Kawasaki, 1997 for a review). However, analyses of the spread of invading organisms frequently use simple reaction–diffusion models that ignore the typically leptokurtic dispersal of propagules and tend to grossly underestimate the potential rate of spread (Kot *et al.*, 1996). Kot *et al.* (1996) showed that the rate of spread is extremely sensitive to the shape of the dispersal curve – for example, fat-tailed distribution curves can generate accelerating rates of spread. Similarly, Higgins and Richardson (1999) showed that a small proportion (0.001) of seeds moving long distances (1–10 km) can lead to an order of magnitude increase in predicted spread rate.

Rates of Conversion to Pest Status

Rates of conversion to pests can be termed *base rates* (Smith *et al.*, 1999) or *prevalences* (from epidemiology; see Lonsdale and Smith, 2001). Williamson (1996) and Williamson and Fitter (1996) have proposed a broad generalization, the *tens rule*, suggesting that roughly 10% of imported species become adventive, 10% of these become naturalized, and 10% of these become pests. Thus, about 0.1% of imported species become pests. The rule is useful as a reminder of the rarity of successful invaders, but in reality, insights will probably emerge from considering these rates as variable, and exploring the causes of variation.

The data analyzed so far (Williamson and Fitter, 1996) may in fact re ect the two aspects of the transitions. On the one hand, there are the transition rates between the pools of adventive, naturalized, and pest species and on the other, the ratio of the sizes of the pools. These are obviously two very different things. There is no reason why the transition rates should center on 10%, and indeed one would expect them to vary greatly, especially with the degree of assistance given to the arriving species (Simberloff, 1989; Williamson and Fitter, 1996). Data to test this critically are scarce because we can rarely follow a cohort of species from start to finish through the invasion process. However, for the biocontrol insects analyzed by Williamson and Fitter (1996), the rates are in fact quite high (averaging about 35% but varying between 20–60%).

On the other hand, the ratios of the sizes of the pools may possibly re ect the typical hierarchy of species abundance seen in communities (i.e., there are large numbers of less abundant species and a few very abundant ones). It is possible that these ratios may perhaps have predictable tendencies for different communities (cf. Sugihara, 1980), but again the data are lacking to test this idea. However, the ratio of the number escaping to the number imported is unlikely to exhibit any natural regularity at all, since it would be very dependent on the number imported, which could have almost any value.

INVASIBILITY

The idea that some communities are more invasible – i.e., more intrinsically susceptible to invasion – than others, has exercised the minds of invasion ecologists since Elton's classic book (Elton, 1958). Others have emphasized propagule pressure as the overriding factor in determining the degree to which systems are invaded, rather than the properties of ecosystems themselves (e.g., Newsome and Noble, 1986).

Analyses of global patterns of plant invasions (Lonsdale, 1999) showed that the Old World is less invaded than the New. Contrary to expectation, communities richer in natives had more, not fewer, exotics, while the temperate zone generally was more invaded than the tropics. While islands are more invaded, this is apparently not because of low native species diversity as the islands were no less rich in natives than mainland sites of similar size. Amongst continents, North America ranked as most invaded and Africa least, while temperate forest was the most invaded biome and savanna the least. However, there was considerable within-group variation in the mean degree of invasion. Incomplete as the data are for plants (little having been published on South American and Asian ecosystems), the data for other taxa are still less adequate.

However, it is difficult to conclude anything about relative invasibilities from this. This is because the number of exotics in a region must be the result of a ux between immigration and extinction. Comparisons between regions of invasibility, are, in fact, impossible to make, unless one can control for all the other variables that in uence exotic richness, including the rates of immigration of species, and the characteristics of the invading species themselves (Simberloff, 1989; Williamson, 1996; Lonsdale, 1999). This suggests that a true understanding of invasibility is likely to come only from experimentation, or from comparing rates at which groups of organisms become pests in different environments.

EXPLANATIONS FOR THE SUCCESS OF INVADERS

The asymmetry of transfer of weed species between the Mediterranean basin and the rest of the world is an interesting case study to explore the reasons for the success of invaders relative to native species. The five regions of the world sharing a mediterranean climate (Mediterranean basin, South Africa, southern Australia, California and Chile) have exchanged many weed species. There

was a primary invasion of mostly annual weeds from the Mediterranean basin to the other four regions, and a subsequent secondary invasion of woody species between the four regions and back to the Mediterranean basin (Fox, 1990). Overall, there has been a considerable asymmetry in this ux, with the species balance being outward from the Mediterranean (or at least from Europe) to the other four regions (di Castri, 1989; Fox, 1990; Groves, 1991). Even now, the degree to which the Mediterranean has been invaded is much less than that of the other regions. This has been attributed to a variety of causes including:

1. that the European species are inherently superior competitors to those elsewhere (di Castri, 1989);
2. that the European species had left behind their pests and diseases in the home range, and thus became superior competitors in moving overseas;
3. that the non-European ecosystems are more invasible (see section on Invasibility) or less resistant to disturbance than the European (di Castri, 1989);
4. that the package of grazing animals, plants, and diseases brought by immigrants from Europe proved, in combination, an unstoppable ecological juggernaut (Crosby, 1986);
5. that the propagule pressure was overwhelmingly outward from the Mediterranean;
6. that the invaders were ooding into vacant niches in the new range, especially the spring growing Mediterranean annuals moving into Australia and South Africa, which had largely summer-growing annuals (Fox, 1990);
7. that the Mediterranean species were in reality an assemblage of all-conquering cryptogenic (for meaning of this word, see line 6 of section on DEFINITIONS) species that had previously invaded the Mediterranean and were now moving on to overwhelm new territories.

These arguments have all been variously applied to other situations to explain the superior performance of invaders. It is nearly impossible to test the relative merits of these hypotheses critically. The fact that invasions are now occurring back towards the Mediterranean basin (Fox, 1990) demonstrates that the other regions' plants are not necessarily all ecological wimps. Moreover, there seems little doubt that propagule pressure was largely outward with the vast post-Columbian exodus of peoples and agricultural technologies, and could explain much of the observed variation between regions.

INVASIONAL MELTDOWN

Does the rate of acquisition of new species accelerate as the ecosystem becomes more invaded (Simberloff and von Holle, 1999)? The answer to this is likely to be scale dependent (at the local scale, saturation will occur, leading to deceleration, while at the geographical scale, no feedback will occur). It is not yet clear how many harmful invasive species can be tolerated in a region before the system collapses – if indeed this will happen – in a process of invasional meltdown (Simberloff and von Holle, 1999).

INTERACTIONS WITH OTHER AGENTS OF GLOBAL CHANGE

Climate change, nitrogen deposition, and elevated carbon dioxide concentration are all likely to favor range expansion of some invasive species while causing contraction of others, and it is not clear whether this will, in the end, increase or reduce the global pool of invasive species. However, the most important driver of global change – habitat destruction and land-use change – will probably increase the susceptibility of ecosystems to invasion. Thus, the interaction between invasive species and habitat destruction is likely to be positive.

WHAT ARE THE CONSEQUENCES OF BIOTIC INVASIONS?

The impact of an invader can be measured at five levels: (1) the phenotypic characteristics of individuals; (2) the genetics of populations; (3) population abundance and dynamics; (4) the structure and function of communities; and (5) abiotic ecosystem processes (Parker *et al.*, 1999). The least studied impacts are those of genetic changes and long-term evolutionary effects (Parker *et al.*, 1999), but most effects of invaders are not well documented, perhaps because of the inherent difficulties and expense of undertaking environmental assessment. These have been summarized by Underwood (1994). The two paramount problems in designing sampling programs to measure ecological impacts (including those of invasions) are that there is a large temporal variance in many populations, and that many populations show a marked lack of concordance in their temporal trajectories from one place to another (Underwood, 1994). It is clear that any invasion impact study will require substantial resources if it is to be authoritative.

Components of Impact

Overall impact I can be defined as the product of the range size of the species (R), its average abundance per unit area across that range (A), and the impact per individual (E), such that:

$$I = R \times A \times E \quad (1)$$

Clearly, all three of these entities are likely to vary over orders of magnitude between species, and have potentially very large associated errors of estimation (see also Parker *et al.*, 1999). *R* is probably the easiest component of overall impact to measure, and has potentially the smallest estimation error. *A* is more problematic, having a fairly wide range and a large estimation error. Perhaps the most important variable to focus on, however, in terms of the interspecific range in values, and the potential for enormous errors in estimation, is *E*. Although we lack data on *E*, we can draw on food web studies for insights. Studies where large numbers for food web links have been assessed (e.g., Wooton, 1997) suggest that interspecific interaction strengths in communities may vary over six or seven orders of magnitude. The variation for invasive species may be rather smaller (though we, as yet, have no data to test this) but will still be substantial: compare the likely *per capita* impact (not the impact across the region) of a herbaceous weed like purple loosestrife with that of an invasive tree like *Melaleuca*. So, if we are ever to be able to compare overall impact across a range of species, it seems likely that we must understand how *E* varies between species, as well as its presumably complex relationship with *R* and *A*.

Thresholds

Are there threshold densities below which an invasive organism is effectively harmless? Panetta and James (1999) conclude that, while thresholds may exist for invaders of natural ecosystems, experience from weeds in cropping systems suggests that even where damage thresholds do exist, they are of limited value for management purposes. Furthermore our ability to quantify thresholds in natural ecosystems is limited. Panetta and James argue instead that control measures for invaders of natural ecosystems are best determined by their cost and efficacy, rather than by waiting for some damage threshold to be measured (Panetta and James, 1999).

Environmental Consequences

Invasions that have the worst impacts are those that alter ecosystem function, alter the disturbance regime, or that facilitate other *invaders* (for a table of case studies of invasion impact, see http://www.ento.csiro.au and search on invaders).

Alteration of Ecosystem Function

The invasion of Hawaii Volcanoes National Park by *Myrica faya*, a small tree native to the Canary Islands, is transforming an entire ecosystem by fixing nitrogen in nitrogen-poor volcanic soils at a rate 90 fold greater than that added by native plants and over four times the rate at which precipitation adds nitrogen. Nitrogen fixed by *M. faya* is available to other non-indigenous plants, which favor fertile soils. Thus, *M. faya* is altering the course of succession in these communities (Vitousek *et al.*, 1987).

Ecosystem effects usually have economic consequences. The invasion of alien plants, especially acacias, pines and eucalypts, into South African native ecosystems, has caused loss of water (estimated at 3×10^9 m^3 year^{-1}; van Wilgen and van Wyk, 1999) from catchments through excessive transpiration rates, and the consequent loss of ow in rivers throughout the country, with many rivers ceasing to ow at all, or owing only infrequently. This has caused a loss of agricultural production as well as risking the loss by extinction of species from the unique Cape Flora.

Alteration of Disturbance Regime

It is argued that invaders that alter the disturbance regime are the most serious (Mack and D'Antonio, 1998), because they alter the rules of the game for all species in the ecosystem. Many invasive species cause change in ecosystems by fostering more frequent or intense fires, or both, to which key native species are not adapted. The paperbark tree has this effect in Florida (Schmitz *et al.*, 1997), as do numerous grasses worldwide (D'Antonio and Vitousek, 1992). In northern Australia, the native savanna vegetation has an annual grass understory that is being replaced by African perennial grasses of much higher biomass. These cure later in the dry season than the annual grasses they replace, thus promoting more intense fires. Although the native vegetation has evolved to cope with frequent fires, it is not certain that the increase in intensity is sustainable.

Facilitation

Given an invasion with *facilitation* (where one invader facilitates the invasion of another; see Simberloff and von Holle, 1999), the rate at which a species can swamp and transform an ecosystem can be dramatic. *Mimosa pigra* (mimosa), a tropical American shrub that invaded northern Australian wetlands in the late 1970s, expanded from a few hectares (ha) to an infestation that occupied about 30 000 ha of the Adelaide River oodplain between 1978 and 1984 (Lonsdale, 1993), and subsequently about 80 000 ha across the Northern Territory's wetlands. The expansion was all the faster because of facilitation by the Asian Water Buffalo, which had undergone a population explosion since 1970, and was overgrazing the native vegetation, reducing competition for mimosa seedlings and accelerating establishment. When the buffalo were largely removed, the rate of creation of new mimosa outbreaks slowed markedly (Lonsdale, 1993).

Economic Consequences

It has been estimated that invasive species in the USA cause economic damage of $138 billion p.a. (Pimentel *et al.*,

2000), roughly 2% of the gross domestic product. Some examples of economic costs from around the world include:

- Weeds cost Australian agriculture $3 billion p.a. in 1995 (Anon, 1999).
- Feral pigs cause $800 million in damages in the US annually (Pimentel *et al.*, 2000).
- $1.3 million was spent to control feral cats on Prince Edward Island, South Africa (Huntley, 1996).
- Estimated US losses to Russian wheat aphid from 1987–1989 exceeded $600 million (OTA, 1993).
- The estimated damage to livestock, wildlife and public health in Texas caused by the fire ant *Solenopsis invicta* is $300 million p.a. (Allen *et al.*, 1995).
- Bovine tuberculosis causes losses in the order of $63 million p.a. to Latin American countries (Cosivi *et al.*, 1998).

HOW ARE INVASIONS CONTROLLED?

Quarantine Methods

The ability of a nation to restrict the movement of invaders across its borders is governed by international treaties, of which a key agreement is the agreement on the Application of Sanitary and Phytosanitary Measures (SPS agreement; Anon, 1994). This agreement allows World Trade Organisation (WTO) members to take measures to restrict movement of species that may pose a threat to human, animal or plant life (Anon, 1994). The International Plant Protection Convention (IPPC) of 1951 deals with plant quarantine, and the IPPC secretariat coordinates phytosanitary standards (Anon, 1994). The SPS agreement requires WTO members to base any SPS measures on internationally agreed guidelines. Within these guidelines, countries like Australia have operated quarantine controls that have taken an innocent-until-proved-guilty approach, e.g., allowing new plant species in unless they are known weeds. This approach has been subjected to con icting pressures in recent years, with a movement to liberate trade and remove non-tariff trade barriers seeking to ease quarantine controls, and an opposing body of opinion that argues that the precautionary principle should apply, and that a guilty-until-proven-innocent approach should be used in quarantine protocols. The Australian Quarantine Inspection Service in 1997 adopted a risk assessment system for screening new plant imports based on their biological attributes and the consequent risk of invasiveness that they pose (see http://www.agric.wa.gov.au/progserv/plants/weeds/Weedsci.htm).

However, prediction of successful invaders from their biological attributes either has low predictive power (e.g., Perrins *et al.*, 1992) or, if high, has more limited applicability (e.g., to specific regions or taxa; Rejmanek and Richardson, 1996). In general, there is a tension here between quarantine risk assessment procedures that must be scientific, transparent, and of general application, supported by recent research that suggests that this may be achievable (e.g., Rejmanek and Richardson, 1996), and those who argue that the prediction of invasiveness will always be extremely difficult (Simberloff, 1989; Williamson, 1996).

Clearly, much research on accuracy of prediction remains to be done. In applying a risk assessment screening procedure as government policy, however, it is not just the accuracy that has to be considered. The rates at which species become naturalized, and the rate at which naturalized species become pests, are quite low. This low base rate for pests means that predictive power of any risk assessment has to be very high in order to reliably identify pests (Smith *et al.*, 1999). For example, a screening system of high accuracy (85%) will reduce the rate of ingress of pests from 1% of introductions to about 0.2%, but in doing so, it will exclude large numbers of non-pest species – 95% of the rejected species would not have been pests. This suggests that a quarantine system will risk causing intersectoral con ict between environmentalists desiring that the precautionary principle apply, and industries such as horticulture desiring free movement of species. It remains to be seen whether the effects of this degree of restriction on trade will be sustainable in the long run. It is also not yet known whether genetically modified organisms will be more or less predictable than unmodified organisms.

Pesticides

Pesticide trade and usage globally is growing – pesticide exports grew 28 fold between 1961 and 1997 (Food and Agriculture Organization, 1999). This is in itself an agent of global change – pesticides persisting in ground water, for example, had polluted 10% of wells in the US by 1991 (Environmental Protection Agency, 1991). Pesticides remain useful tools in the pest control armory, but research is often necessary to adapt them for use in natural ecosystems, since they are as a rule devised and tested for use in agro-ecosystems. Resistance of insect pests to insecticides emerged in the 1940s, while weeds started to show resistance to herbicides somewhat later, in the 1970s. The occurrence of pesticide resistance has increased the urgency to seek ways of minimizing chemical pesticide use. These include biological control, microbial pesticides, pheromones to alter pest insect behavior, novel technologies such as sterility vaccines for feral pests, and the general approach known as integrated pest or weed management (*see* Integrated Pest Management (IPM) in an Era of Global Environmental Change, Volume 4). On the other hand, enzyme systems that have evolved to break down pesticides are being extracted from pest organisms and adapted for use in bioremediation.

Biocontrol

Biocontrol is a form of planned invasion. It is an extraordinarily powerful tool when effective, particularly in its classical form. Recent successes have included the control of the oating fern Salvinia in southeast Asia (Room, 1990) and of water hyacinth in Lake Victoria. It has been used in the control of weeds, insect pests and vertebrates, and has a good reputation in Australia where strong legislation ensures a transparent release procedure for new agents in which a high degree of host specificity must be demonstrated (see Cullen and Delfosse, 1985). In the US, by contrast, there is no Federal statute that requires that biological control agents be reviewed before release, and the credibility of biological control in the US is under attack from environmentalists. This is despite the excellent quality of much of the science (e.g., McEvoy *et al.*, 1991), and the fact that many of the practitioners regard themselves as environmentalists reducing the use of pesticides. Well-publicized examples of off-target damage (e.g., Louda *et al.*, 1997) have added to the pressure. Testing of post-release host expansion, to verify that the host specificity claimed in pre-release studies has been maintained in the field, has been little studied in the US, and indeed anywhere in the world. This should be redressed as an aid to future risk assessments.

Eradication

Eradication of a non-indigenous species is sometimes feasible, particularly if it is detected early and resources can be applied quickly. However, many regulatory agencies tend to view a non-indigenous species as not worth the bother and expense of attempting to control, until it becomes so widespread that eradication is probably not an option (Simberloff, 1997). There are examples of successful eradication programs, however – one such was the recent program against the introduced black-striped mussel in Darwin harbor, in northern Australia. The infestation was small, and was discovered early, was contained within a marina, and control measures had strong government support because of the risk to fisheries posed by the pest. All these factors favored success. Eradication using chemicals succeeded, at a cost of A$1.5 million (R Thresher, personal communication).

Strategic Approach to the Control of Invaders

It is being increasingly recognized that a strategic approach is needed for the control of invaders (e.g., Luken and Thieret, 1997). Much pest control thinking, by contrast, has been short-term and limited to the immediately visible problems. The underlying philosophy of a pest management strategy should be to establish why pests are ourishing in a region, and address the underlying causes rather than just killing pests *per se*. System management, rather than species management, is the focus. For example, in a region where weed species are ourishing in multi-species stands, the introduction of control measures against one species only may be a waste of resources, unless there is a strategy in place for dealing with the remaining species. It is an approach that is particularly appropriate for conservation areas, but is seldom undertaken. Related concepts (generally used in agricultural systems) are integrated pest management (IPM) or integrated weed management, which involve combining control measures, crucially, with a knowledge of the pest or weed's ecology to reduce pesticide use and maximize impact of control. It is claimed that IPM measures have reduced pesticide use in Indonesia by 60% and increased rice yields by 40%, for example.

The strategic approach to the control of invaders has begun to be used at the national level. Australia, for example, has recently adopted a national weeds strategy aimed at reducing the impact of weeds (Anon, 1999). Similarly, in a project of extraordinary scale, South Africa has decided to clear the exotic woody weeds from its river catchments in a 20-year program (van Wilgen and van Wyk, 1999). The strategy involves manual clearing of thickets to allow native vegetation to re-establish, treatment of cut-stumps with mycoherbicides, and the use of biological control to prevent reinvasion. Although this will cost R900 million, this is still far cheaper than the alternative, a massive dam-building program (R12 000 million; van Wilgen and van Wyk, 1999).

CONCLUSION

Biological invasions are major agents of global change, possibly second only to habitat destruction, through their impact on managed and unmanaged ecosystems. This impact is likely to intensify as conservation areas become fragmented, and as disturbance increases. Trade, agriculture and forestry all play a part in the intentional or unwitting movement of species globally, and regulating this movement is problematic. Control of invasives is often subject to market failure as it can be expensive and others than those carrying out the control measures often experience the benefits. This implies that governments must increasingly shoulder the burden for the assault on invasive species.

Functional Biodiversity

SHAHID NAEEM

University of Washington, Seattle, WA, USA

One of the many values of biodiversity, such as untapped genetic resources and aesthetic values, is biodiversity's role in regulating environmental conditions such as atmospheric composition, water quality, and soil fertility. The biota move enormous quantities of elements, compounds, aerosols, and particles through the earth's atmosphere, hydrosphere and lithosphere every year and in so doing, modify the chemical and physical conditions of Earth's surface, creating an environment that sustains life. All species contribute to this environmental conditioning, but each in different ways. Some species are critical to the functioning of an ecosystem while others play minor or intermittent roles. Current limited evidence suggests that intermediate levels of biodiversity yield more ef cient ecosystems than depauperate systems while even higher levels of biodiversity provide even greater versatility and predictability in ecosystem response to environmental change. Our current knowledge of the functioning of biodiversity suggests that increasing loss of biodiversity may qualitatively and quantitatively change the way ecosystems contribute to environmental processes. Elucidating the functional roles of species and their contributions to ecosystem processes will be fairly important to better understand the environmental consequences of biodiversity loss.

BIODIVERSITY, ECOSYSTEMS, AND BIOGEOCHEMISTRY

Gigatons of elements such as carbon (C), hydrogen (H), nitrogen (N), oxygen (O), phosphorus (P) and sulfur (S) (Schlesinger, 1997) and teragrams of aerosols and particles are annually cycled among the atmo-, hydro-, and lithospheres by an extraordinarily diverse assemblage of species (Figure 1). Some cycling occurs passively, by geochemical and geophysical processes, but a significant portion, known as *biogeochemical cycling* (Schlesinger, 1997), is done by earth's biota. The earth's ecosystems and the biota within them modify the planet's surface conditions through a rich variety of biogeochemical activities, whether it is the production of stratospheric ozone, the cycling of greenhouse gases, nutrient cycling, or the production of aerosols that affect climate. These activities are sometimes referred to as *ecosystem services* (Daily, 1997) because they directly impact human economies and human welfare (Costanza *et al.*, 1997).

The function of the earth's extraordinary diversity in these biogeochemical processes is an important but difficult question. Ecologists began addressing the ecosystem consequences of biodiversity decline in the 1990s, motivated in part by dramatic declines in global biodiversity (Schulze and Mooney, 1993; Heywood, 1995; Mooney *et al.*, 1996). Three functional roles of biodiversity have been identified. First, high levels of biodiversity mean that biogeochemical processes occur over a wide range of habitats. Second, higher numbers of species potentially provide greater short-term efficiency of biogeochemical processes if species use their resources in complementary ways. Third, higher biodiversity may ensure greater reliability or predictability of ecosystem response to disturbance. Each of these functions is explained in greater detail later in this article.

Scientists have identified over 50 hypothetical ways in which biodiversity loss may impact ecosystem functioning (Schlapfer and Schmid, 1999), but most of these revolve around three basic ideas. First, beyond some minimum number of species necessary to carry out basic ecosystem processes, most species are equivalent (redundant) and their loss is of little significance. Alternatively, reductions in biodiversity may have significant but unpredictable (idiosyncratic) effects on ecosystem functioning. The third, and perhaps most widely cited idea, is that loss of a few species (like loss of a few rivets in a large machine) may at first have no apparent affect, but if loss continues unabated, the system eventually fails to function, much the way a machine would fail if it lost too many rivets (Ehrlich and Ehrlich, 1981).

The functioning of biodiversity therefore concerns whether depauperate ecosystems are functionally different from

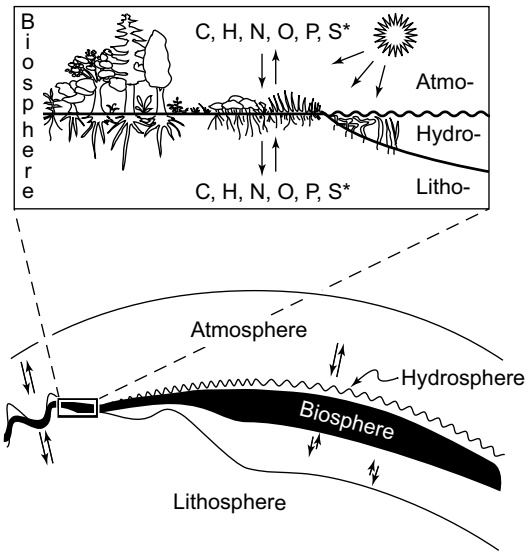

Figure 1 The role of the biota in biogeochemical processes. The bottom portion of the figure represents a cross section of the earth in which the atmo-, hydro-, and lithosphere are shown in relation to the biosphere. Note that this illustration is not to scale, (were the figure to scale the biosphere would be barely visible as a very thin line). The top part shows a section of the biosphere (shown as a rectangle on the lower figure) is expanded showing how the collective metabolic activities of the earth's biota move elements among the various spheres. This activity is referred to as biogeochemistry. The prefixes, atmo-, hydro-, and litho- refer to the major spheres illustrated in the bottom figure. Important organisms, such as microbes and animals, are not shown. Many other elements, including Fe, Mg, Ca, K, and more, are cycled but not illustrated

species-rich ecosystems. Large-scale human transformations of habitats into managed ecosystems have invariably led to the substitution of species-rich ecosystems with human-dominated, depauperate systems. For example, vast areas (about 99%) of North American prairie grasslands, once containing hundreds of plant species are now farms, pastures, urban areas, or other human-dominated ecosystems which contain relatively few species. Like prairies, crop farms and pastures are also temperate, herbaceous ecosystems, so these ecosystems may be similar in many respects to the prairies they replaced. Thus, the central issue is not so much the loss of species *per se* as it is the replacement of once species-rich ecosystems with modern species-poor systems.

To understand the possible consequences of such reductions in biodiversity over large stretches of habitat requires an understanding of the functioning of biodiversity. This article summarizes how scientists address this issue and reviews the functional classification of species and its use in understanding the functioning of biodiversity.

OBSERVATIONAL AND EXPERIMENTAL METHODS

Basic Approaches

Understanding the functioning of biodiversity involves the same approaches used to understand the functioning of any system's structure and parts. When faced with the task of understanding the functioning of a novel system, we begin by observing its activity and exploring its response to various manipulations. We then methodically disassemble the system and examine its parts and the relationship among its parts. If successful in our research, we can construct a blueprint for the structure of the system, explain its functioning and the role of its parts. We could also predict which parts are critical to functioning and how the system might respond to perturbations.

Ecologists approach ecosystems in much the same way. They begin by observing ecosystem activity, such as rates of energy ow and material cycling. They methodically explore the system to uncover the many species residing within the system and learn how these species interact with one another. They conduct experiments on the functional role of species by deleting certain species or groups of species and monitoring system response. Finally, they use this information from observations and experiments to predict how the ecosystem might respond to perturbation such as loss or addition of species or changes in environmental conditions. All these activities lead to the construction of a blueprint of the pattern of interactions among species and the ow of nutrients and energy through them.

Although the study of ecosystems and human engineered systems may seem similar, they are quite different in a number of respects. The first important difference is that parts and the relationship among parts in engineered systems generally re ect purposeful design. We therefore expect all parts to serve some function and our task is to identify that function. Purposeful design enormously simplifies the process of determining the functioning of a system and the functional role of its parts. Ecosystems, however, have no purposeful design. Species within ecosystems and the interactions among them are the result of evolution, biogeography, chance events, and other processes, none of which re ects deliberate design. Therefore, we should not expect that all species present serve roles in overall ecosystem functioning.

A second important difference is that engineered systems often exhibit some degree of economy or parsimony in design. Parts are seldom duplicated if they are costly, complexity is avoided, and efficiency of energy use is often maximized. Again, this human engineered economy of design simplifies analyzing functioning in machines. In contrast, there is no reason for, nor is there currently evidence that supports similar economy in ecosystem design.

Finally, the structure of an engineered system is generally static, whereas ecosystem structure is dynamic. Immigration, extinction, colonization, and evolutionary change are all important, dynamic properties of communities within ecosystems.

We should also note the way in which the words *function* and *functioning* are used in ecology. *Function* has two meanings, one referring to purpose and the other to activity. The term *functioning of biodiversity* may be misinterpreted as the purpose of biodiversity. Ecologically, however, the *functioning of biodiversity* refers simply to the role diversity plays in environmental processes, such as how biodiversity contributes to biomass production, nutrient cycling, soil acidity, soil water content, water quality, trace gas emissions, carbon dioxide (CO_2) ux, and many other processes. Similarly, the design of a natural ecosystem does not imply purposeful design, only the existence of structure and pattern. Managed ecosystems, however, can re ect considerable purpose in their design. In a farm, for example, the species composition, density, spatial arrangements, energy, water, and nutrient cycling may all be part of a manager's strategy to maximize production and yield.

Empirical Approaches

The functioning of biodiversity is determined by a variety of empirical methods. Observation of ecosystem behavior and dynamics, on the surface of the earth or from space through remote sensing, have provided ecologists with considerable knowledge about typical or average ecosystem behavior and activity for a large number of systems over many regions. These observations form the basis for expected or predicted ecosystem biogeochemical activity given geography, climate, and habitat.

Biodiversity, however, covaries with many environmental variables; the direct role of species in these observed ecosystem processes being best studied with experiments. For example, microbial biomass, pH, nitrogen content of litter, and other ecosystem properties show a variety of relationships with plant diversity in Swedish boreal forest islands (Wardle *et al.*, 1997). Plant diversity in these islands, however, is also associated with island size and fire frequency. Thus, in this system, like most natural systems, it is not possible without direct experimentation to determine whether biodiversity and ecosystem processes are associated because of confounding factors such as covarying island size and fire frequency. The primary value of such descriptive, observational studies is to establish the basic correlational pattern between biodiversity and ecosystem functioning as we move from habitat to habitat or ecosystem to ecosystem. Experimental approaches (discussed later) can then be used to determine how diversity affects ecosystem functioning within a particular habitat or ecosystem.

EXPERIMENTAL TESTS OF THE FUNCTIONING OF BIODIVERSITY

Experimental examinations of the functioning of biodiversity have focused on manipulating diversity and monitoring biogeochemical responses. This approach avoids the problems created by covarying or confounding factors typical of strictly observational studies. Any measure of the collective metabolic activities of species within a community represents a suitable measure of response, and may include production, nutrient retention, water retention, rates of decomposition, ux rates of oxygen (O_2), CO_2, or nutrients, or other biogeochemical processes.

Currently, the most common approach has been to create replicate ecological communities, varying the number of species among replicates and monitoring ecosystem response variables. Emphasis has been placed on plants because they acquire the energy and supply the organic material needed by all the organisms in an ecosystem (discussed later). A frequently used method is to clear the ground of vegetation, divide the cleared ground into equal-sized plots, then add plant species randomly to create monocultures, two-species plots, four-species plots, and so on. Once plants are established, production, decomposition, and other ecosystem measures are made on every plot. Averages for each level of species richness are calculated and compared.

Experiments come in a variety of shapes and sizes and have been conducted in growth chambers, greenhouses, in bottles and Petri dishes in the laboratory, in experimental plots in a single field, and in experimental plots established in replicate fields in different countries. Replicates have been as few as 14 growth chambers to as many as 460 microcosms. The majority of these experimental studies have shown that ecosystem processes respond in a variety of ways to experimental manipulations of species composition among replicate, model ecosystems (i.e., plots, pots, microcosms). A representative sample of results from some of these experiments is shown in Figure 2.

Most of these experiments have shown that ecosystem processes, especially the production of plant biomass, increases rapidly as one increases plant species richness from one species (monocultures) to multiple species (polycultures). In many cases, the increase in biomass diminishes as the number of plant species gets much higher than 5 or 10, suggesting ecological equivalency (redundancy) among species. This pattern can be seen quite clearly in Figure 2(a,b) which shows results from plant experiments using prairie grassland and English meadow species, respectively.

When one looks below ground, other interesting patterns are likely to emerge. For example, the biomass of microbes in the soil may show an increase with plant diversity (Figure 2c) and the number of mycorrhizal fungal species may affect plant production (Figure 2d). There are intimate

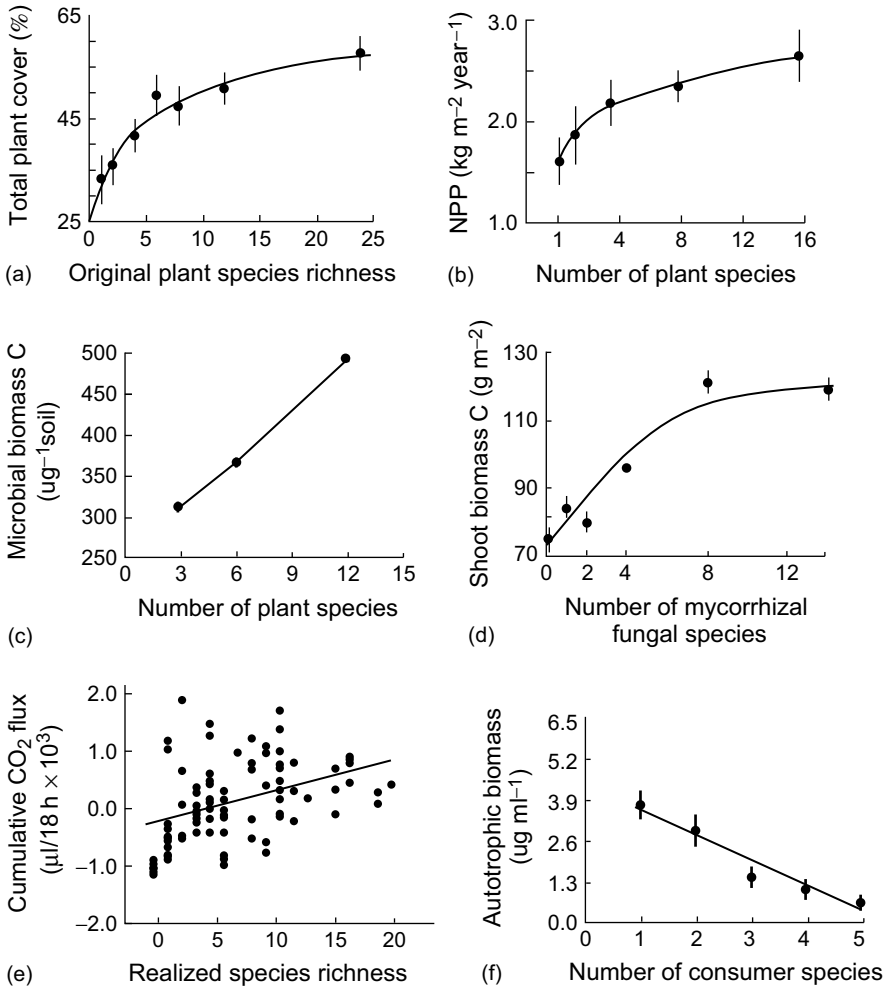

Figure 2 Experimental evidence that the diversity of an ecosystem's biota affects ecosystem processes. (a) The relationship between plant species richness of experimental grassland plots in Minnesota to percent of the ground covered with vegetation, a proxy measure for plant production (Tilman *et al.*, 1996). (b) The relationship between plant species richness of experimental old-field ecosystems and net primary production (NPP) (Chapin, III *et al.*, 1998). The ecosystems were modeled after English old-fields and maintained in controlled environmental chambers. (c) The relationship between plant species richness in Mediterranean, herbaceous ecosystems and microbial biomass, a proxy measure for microbial production. The experimental systems were intact sections of natural communities removed from the field and established in growth chambers within greenhouses in France (Chapin, III *et al.*, 1998). (d) The relationship between the number of mycorrhizal fungal species and shoot biomass, a proxy measure of plant production. The experimental systems were potted plants grown in greenhouses, modeled after North American and European plant communities (Van der Heijden *et al.*, 1998). (e) The relationship between CO_2 flux and microbial species richness. The experimental systems were modeled after microbial communities of protists and bacteria found in a local pond in New Jersey and maintained in bottles (McGrady-Steed *et al.*, 1997). Realized species richness is the actual number of species observed in the microcosm at the time of measurements (the initial diversity was higher, but local extinction occurred). (f) The relationship between heterotrophic protists, either bacterivores, algavores, or omnivores, and autotrophic (green alga) biomass, a proxy measure of production (Naeem and Li, 1997). The experimental systems were modeled after freshwater microbial communities and maintained in Petri dishes

connections between microbes in the soil and plants that suggest changes in diversity of one or the other will affect ecosystem functioning.

Microcosm experiments have shown that results from plant experiments may underestimate the complexity of ecosystem response to biodiversity loss. Microcosm experiments have the advantage that they can manipulate not just plant-like species (algae), but other trophic groups as well, such as herbivores (protists that eat algae), predators (protists that eat other protists), and decomposers (bacteria). Such experiments better capture the true complexity of natural ecosystems when compared

to plant-only experiments. Their smallness and artificiality, however, limit their applicability to predicting the response of much larger natural systems. Thus, microcosm experiments serve primarily as tests of basic ideas about the relationship between biodiversity and ecosystem functioning. For example, CO_2 flux is much higher with greater numbers of species in a microcosm containing many kinds of microbial species (Figure 2e) and algal biomass declines with greater numbers of protistan species as diversity increases (Figure 2f). These experiments point to the importance of distinguishing between plant, animal, and decomposer diversity when examining the relationship between biodiversity and ecosystem functioning, a fact that is often missed in plant-only experiments.

Why Does Biodiversity Affect Ecosystem Functioning?

These recent experiments have generally confirmed a variety of functional relationships between biodiversity and ecosystem processes, but causes for these relationships remain elusive. Three mechanisms have been proposed to explain such associations. One mechanism, commonly referred to as the *sampling effect*, is a probability-based explanation for the patterns observed. If a regional species pool contains a large number of species, some of which have strong impacts on ecosystem processes, then there is a high probability that replicate or local ecosystems which draw their biota from this pool (which sample the pool) will contain species with strong effects. If the species richness of the regional pool declines, then the probability that local systems get recolonized with strong-impact species declines, affecting ecosystem functioning.

Second, *species complementarity*, or species differing in the way they use resources, can create a positive relationship between diversity and functioning by leading to more thorough use of local resources in species-rich communities. For example, greater numbers of plant species, each with different rooting depths, may increase the thoroughness with which water and nutrients are used in a given volume of soil compared to monocultures that only root to one depth. Such principles of complementarity are well known and have been used in agroecological studies of intercropping. Temporal complementarity, in which certain species function only during certain environmental conditions, is known for microbes that appear at different times in degradative processes. Likewise, temporal complementarity may be found in stream invertebrates that form a shredder chain in which one group of species shreds incoming leaf litter into smaller pieces that are in turn consumed by other species. Similarly, temporal complementarity between early- and late-season owering plants can sustain needed pollinators throughout the year.

A third mechanism is that increasing the numbers of species increases the number of mutual, facilitative, or positive indirect effects among species in an ecosystem. This mechanism is poorly studied, so it remains unclear if such positive interactions are responsible for observed, positive effects between biodiversity and ecosystem functioning.

In most ecosystems, both the presence of species that have strong impacts on ecosystem processes and complementarity, may be important. In some cases, species may have such strong impacts on ecosystem functioning that complementarity may be less important than the presence or absence of strong-impact species.

Limitations in Experimental Approaches

Experimental approaches must contend with several problems all related to the practical difficulties associated with biodiversity research. First, the number of replicates required for statistical rigor is often prohibitive. Even small numbers of species provide for hundreds to thousands of possible combinations. Researchers invariably choose manageable numbers of species rather than representative numbers of species. Inferences from such experiments are therefore limited to cases in nature where severe reductions in biodiversity have already occurred, such as where natural habitats have been transformed to managed ecosystems. Second, experiments are small and short compared to the natural world. Third, additional factors, such as soil fertility, CO_2 concentrations, temperature, or other factors associated with global environmental change, are seldom manipulated in these experiments even though these factors interact with biodiversity and one another. As research programs grow in size and scope, many of these limitations may be minimized or overcome.

THE FUNDAMENTAL STRUCTURE (BLUEPRINT) OF ECOSYSTEMS

As in the exploration of any system, constructing a blueprint of system structure is a necessary step for understanding the functional significance of its parts. Evaluating the functioning of biodiversity, where we consider species to be the relevant parts or components of an ecosystem, involves the same exercise. Experimental and observational evidence already demonstrates that biodiversity is associated with ecosystem functioning. We know that the parts (species) are necessary. We do not know, however, if all the parts are necessary or if some parts are more important than others are. We address these issues by constructing the fundamental structure or blueprint of an ecosystem from which we can evaluate the relative importance of species found within it.

Evaluating the relative importance of species in ecosystem functioning is similar to evaluating the importance of

parts in an engineered system. In an engineered system, an important part is considered as one whose removal results in serious alteration of system performance or functioning. In ecological research, parts (or species) that are unique and represent critical steps in a series of linked, interdependent processes, are indispensable. Unnecessary parts (or species) are those whose removal or loss do not seriously compromise system functioning. Unlike parts in engineered systems, determining which species are critical or which species are expendable is quite difficult in ecological systems.

The relative importance of species in ecological processes is a well-developed research topic in ecology. Some species have long been recognized to be keystone species because their presence suppresses competitive dominants and permits greater diversity to persist within an ecosystem. Others consider the relative impact of the removal of a species to be a good measure of the relative importance of species to system functioning (Power *et al.*, 1996). By this approach, the species whose removal results in the largest change in the ecosystem is considered to have the highest *community importance value* (CIV) while all other species are given lower CIVs. For example, if the removal of one species leads to a dramatic reduction in production while the removal of another does not, we consider the first species to have a high CIV while the other species has a low CIV.

Other approaches consider those species most important whose activities modify the physical or chemical nature of the ecosystem (ecosystem engineering) such that the system supports many other species (Jones *et al.*, 1994). Beavers are considered a classic example of ecosystem engineers, building ponds within which many other species live. Clearly, the beaver is the most important species in the community as its activity, in large part, creates the ecosystem within which others live.

One final approach to assessing the relative importance of species is based on the impact a species has on the population dynamics of others. Some species are strong interactors, like top predators whose change in abundance has strong effects on the dynamics of other populations, while others are weak interactors, such as a rare, inferior competitor whose change in abundance has little effect on other populations (McCann *et al.*, 1998).

This variety of methods for evaluating the relative importance of species has a common theme. All these classification schemes, keystone versus non-keystone species, high versus low CIVs, ecosystem engineers versus non-ecosystem engineers, and strong versus weak interactors, imply that some species are indispensable in maintaining an ecosystem while others are potentially dispensable.

Identifying the Functional Roles of Species

Because all species contribute to ecosystem processes, these processes represent clear measures of the functioning of biodiversity. Organisms grow by the assimilation of elements and compounds. Either they assimilate materials from inorganic sources and convert them to organic materials or they assimilate materials from organic sources produced by other living organisms. Species acquire the energy they need for metabolic processes either from external sources such as light or energy stored in chemical bonds in organic or inorganic material. Regardless of how organisms acquire material and energy, or what their sources are, the end result is that all organisms of all species within an ecosystem chemically transform and physically move elements such as C, H, N, O, P, S, potassium (K), silicon (Si), calcium (Ca), magnesium (Mg), iron (Fe), and many others, into and out of the atmosphere, hydrosphere (e.g., lakes, streams, oceans), lithosphere (e.g., rocks or the mineral components of soil), and biosphere (Figure 1). The functional roles of species are therefore closely associated with their effects on these biogeochemical or ecosystem processes.

The functional roles of species are not necessarily related to taxonomic identity, thus taxonomy is of less interest in assessing the functioning of biodiversity. Taxonomic classification schemes are based on similarities of genetic information among groups of organisms reflecting shared evolutionary histories. Classification by genetic similarity, however, may show no correlation with classification by functional similarity. Two species in the same genus may not be similar in their contributions to biogeochemical

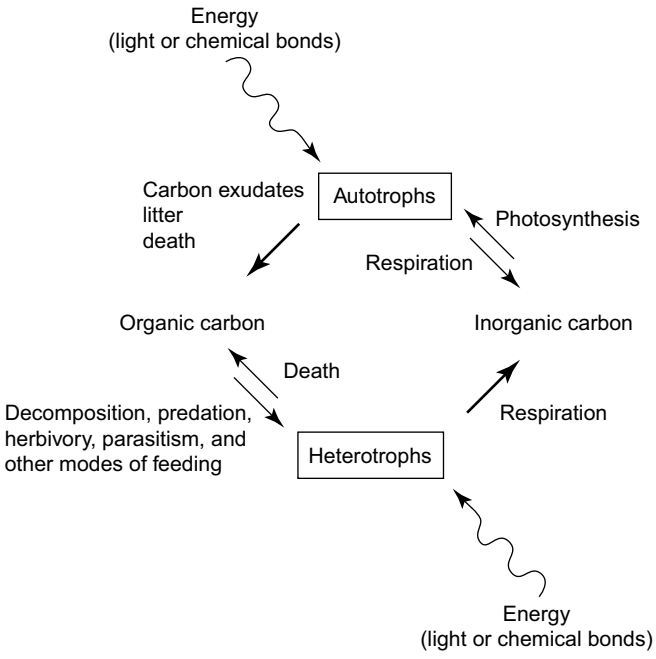

Figure 3 Fundamental trophic groups. All species can be divided into four fundamental groups distinguished by their source of carbon and their source of energy

cycles. Conversely, two species that are evolutionarily unrelated may be functionally quite similar. For example, the largest taxonomic division is that of the biological domains known as Eukarya, Bacteria, and Archaea, yet the ability to fix atmospheric nitrogen (convert N_2 to NO_2 or NO_3) is found in both Bacteria and Archaea, but not in Eukarya. In contrast, many species in the bacterial genus *Pseudomonas* do not fix nitrogen while some do (e.g., *Pseudomonas diazotrophicus*).

Source of Carbon versus Source of Energy as a Major Functional Distinction

To live and grow requires the acquisition and assimilation of carbon in one of two ways. First, one can acquire carbon by taking the carbon off of CO_2 and adding it to one's existing stock of organic carbon compounds. Alternatively, one can acquire carbon by consuming extrinsic sources of organic compounds. Acquiring carbon from CO_2 or other inorganic forms defines *autotrophy*. Acquiring carbon from organic or biological sources defines *heterotrophy*. These functional traits are illustrated in Figure 3.

This division is sometimes confused with the secondary division that concerns energy acquisition. If a species' source of energy for the acquisition of carbon from CO_2 is light, the species is a *photoautotroph*. If its source of energy is from chemical bonds it is a *chemoautotroph*. If the species is a heterotroph, but acquires its energy from light it is a *photoheterotroph*. If the species is a heterotroph but acquires its energy from chemical bonds, then it is a *chemoheterotroph*.

With respect to prokaryotes (Bacteria and Archaea) there are at least seven distinct kinds of autotrophic bacteria (Brock and Schlegel, 1989). Classification of the Eukarya, however, is less complex. The Eukarya consist of the protists (generally single celled organisms), fungi, metaphyta (multicellular organisms generally called plants) and metazoa (multicellular organisms generally called animals). The fungi and animals are heterotrophic because they obtain their carbon and energy from organic compounds. The protists can be photoautotrophs or heterotrophs or sometimes myxotrophic when their carbon may come from both CO_2 and organic material. Plants are generally photoautotrophic and obtain their carbon from CO_2 via photosynthesis. A more detailed functional classification of the earth's biota is provided at the end of this article.

Linkages Among Functional Groups

The construction of a general blueprint of ecosystem structure requires determining how many functional groups are necessary for an ecosystem to function and how many species are available to carry out each function. The majority of ecosystems have the essential features discussed in the simple terrestrial ecosystem portrayed in Figure 4. This figure can serve as a general blueprint of an ecosystem. Whether it is a grassland, savanna, forest, pond, lake, or marine ecosystem, they all contain living biomass, dead organic matter, and inorganic matter. We can therefore simplify Figure 4 by dividing ecosystem materials into two organic pools (living biomass and dead organic matter) and two inorganic pools (carbon and mineral or nutrient pools such as nitrogen, phosphorus, or sulfur). This simplification yields Figure 5, a generic model for an ecosystem more universal in its features than that shown in Figure 4. For simplicity, we have left out uptake facilitators (e.g., mycorrhizal fungi in terrestrial ecosystems and bacteria in aquatic systems) though they are commonly found in ecosystems.

Figure 5 shows six functional groups with each group occupied by a single species. In Figure 5, there are six serially dependent functional groups (autotrophs, decomposers, and two groups each of consumers of autotrophs and consumers of decomposers) each with a single species. *Serially dependent* means that one group cannot persist without the other because each is dependent on the functioning of the other. Autotrophs and decomposers, for example, cannot persist without each other because they are dependent upon one another for nutrient cycling. Similarly, consumers cannot persist without their prey. Each of these serially dependent groups is most likely occupied by many species. To produce a more useful blueprint, we can modify the model system in Figure 5 by adding a modicum of biodiversity and more clearly illustrating the serial dependency among the functional groups (Figure 6). Such a block diagram (Figure 6) provides a blueprint for an ecosystem in which each of six serially dependent functional groups is populated by six different species. In this hypothetical system, species are considered fully substitutable, though in real systems many species, even though occupying the same functional group, may not be so equivalent.

It is important to note that natural systems are likely extraordinarily complex compared to that shown in Figure 6. Even in the overly simplistic portrayal of an ecosystem in Figure 6, which contains only 36 species, there is already considerable complexity in the way species are linked to one another by nutrient and energy ows. In natural systems, however, there may be tens to hundreds of autotrophic species, hundreds to thousands of animal species, and thousands to tens of thousands of microbial species or strains. Nevertheless, the overall structure may still be understood in terms of functional groups and species within functional groups.

The generic blueprint of an ecosystem (Figure 6) reveals two major properties of ecosystems. First, the more serially dependent functional groups in an ecosystem process, the more likely functioning will not be achieved. Clearly the more groups of species dependent upon one another, the

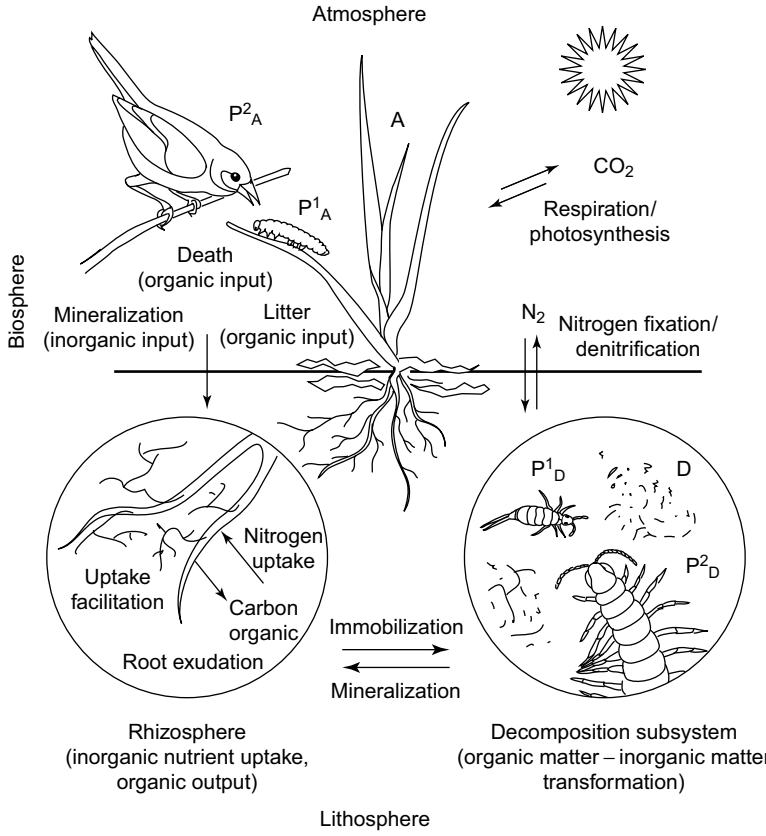

Figure 4 Common structure of an ecosystem as reflected in a model terrestrial ecosystem. This figure illustrates the core features of a simple terrestrial ecosystem. For simplicity, many processes and other functional groups of organisms are not illustrated. Circles represent magnified regions. The rhizosphere is illustrated by roots (larger, branched structure) and mycorrhizal fungi (thin lines entering roots). Root carbohydrate exudation and mycorrhizal facilitation of nutrient uptake are illustrated as arrows. The decomposition subsystem shows bacteria, fungi, a collembolan insect feeding on microbes and a small predatory centipede. Above-ground animal ecosystem processes are illustrated as mineralization, such as excretion of inorganic compounds, the entry into dead organic matter by death, or litter inputs from plants. A, photoautotrophs (e.g., plants). D, decomposers (e.g., bacteria and fungi). P^1_D, primary consumers of decomposers (e.g., bacterivores or fungivores). P^2_D, secondary consumers, decomposer-derived. P^1_A, primary consumers of autotrophs. P^2_A, secondary consumers, autotroph-derived. The atmosphere, lithosphere, and biosphere are illustrated to facilitate comparison with Figure 1. This figure should also be compared with Figures 5 and 6

more places functioning could change because one group is lost or adversely affected by environmental change. The second attribute apparent in the generic blueprint of an ecosystem (Figure 6) is that the more equivalent or redundant species one finds within a functional group, the greater the reliability of system functioning over long periods of time. More redundant species, like more redundant parts, means greater system reliability because loss of one or a few species is compensated for by the presence of other, substitutable species.

Difficulties in Determining Functional Groups and Species Redundancy

A strict definition of functional groups, one in which functional groups are serially dependent, is often not practical for ecosystems. Ultimately, the only truly serially dependent functional groups in continuously functioning ecosystems are likely to be decomposers dependent on organic carbon from autotrophs and autotrophs dependent on decomposers for material recycling. Most other species occupy two or more functional groups or their functional identity changes when conditions change. A rare herbivore, for example, may become a dominant regulator of plant biomass if the top predator vanishes. A weak interactor during one year may be a strong interactor when community composition or environmental conditions change.

FUNCTIONAL GROUPS AND FUNCTIONAL CLASSIFICATION OF SPECIES

As shown above, identifying functional groups and classifying species into functional groups provides an important

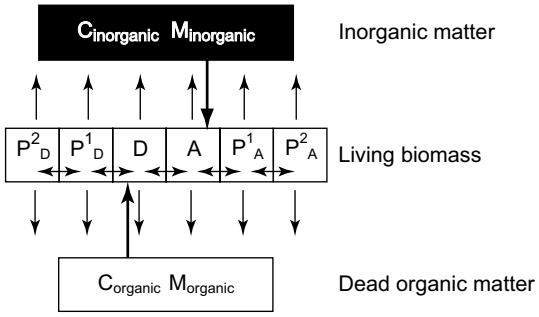

Figure 5 Common structure of ecosystems. This schematic portrays the common structure of an ecosystem by compartmentalizing material into common pools (organic and inorganic) and trophically-defined functional groups. Biological matter consists of living biomass and dead organic matter. Living biomass consists of autotrophs (A) and heterotrophs (see Figure 3), the latter of which consist of consumers (P^1_D, P^2_D, P^1_A or P^2_A) that are either derived from the consumption of decomposers (D) or the consumption of autotrophs (see Figure 4). Materials are divided into nutrients and mineral (M) or carbon (C), either bound in organic or inorganic compounds. Arrows indicate the flow of materials among the different compartments. Note that most ecosystems contain species that may exhibit complex feeding modes, such as omnivores that might feed on both autotrophs and decomposers or myxotrophs that are photoautotrophic but also consume other organisms. This figure should be compared with Figure 6

means for assessing the functioning of biodiversity. As discussed earlier, the major functional divisions of species are based on the different ways in which species acquire carbon and energy. Secondary and finer divisions are based on additional differences among species concerning their roles in other ecosystem processes. Following are two examples of functional group classification and then a full, but brief classification scheme is provided for the earth's biota.

Functional Groups of Plants

Many schemes exist for classifying plants into functional groups. Here, we consider major divisions based on how different groups of plants contribute to carbon cycling. We divide plants first into aquatic forms that generally acquire carbon in the form of HCO_3^- (carbonic acid or CO_2 dissolved in H_2O) versus terrestrial forms that fix atmospheric CO_2. We further divide plants into C_3, C_4 and Crassulacean acid metabolism (CAM) (*see* C_3 and C_4 Photosynthesis, Volume 2). Each of these groups of distinctly different plant physiologies (often associated with anatomical and taxonomic differences) leads to fixation or use of carbon dioxide in distinctly different ways (Pearcy *et al.*, 1989). C_4 plants, for example, are photosynthetically more efficient than C_3 plants whereas CAM plants fix CO_2 at night. Plants can be further divided into woody and herbaceous types. Woody plants produce compounds such as lignin that do not decompose readily and so remove carbon from the atmosphere for longer periods than herbaceous plants whose tissues are more readily decomposed.

We further divide plants into those that are associated with nitrogen-fixing symbionts and those which are not so associated. The rationale for this finer division is based on the observation that nitrogen-fixing plants, such as legumes, can have different C : N ratios, thereby producing litter that may decompose faster and tissues that are potentially more susceptible to herbivory. Nitrogen-fixing plants also have higher energy demands because they must use some of their photosynthate to support their energetically demanding nitrogen-fixing symbionts.

In functional groups, as in taxonomic groups, distinctions are not always clear and some groups have more representatives than others. For example, at least 22 species in eight different genera have been identified as intermediate between C_3 and C_4 and only one tree and a few bushes have been identified as woody C_4 plants.

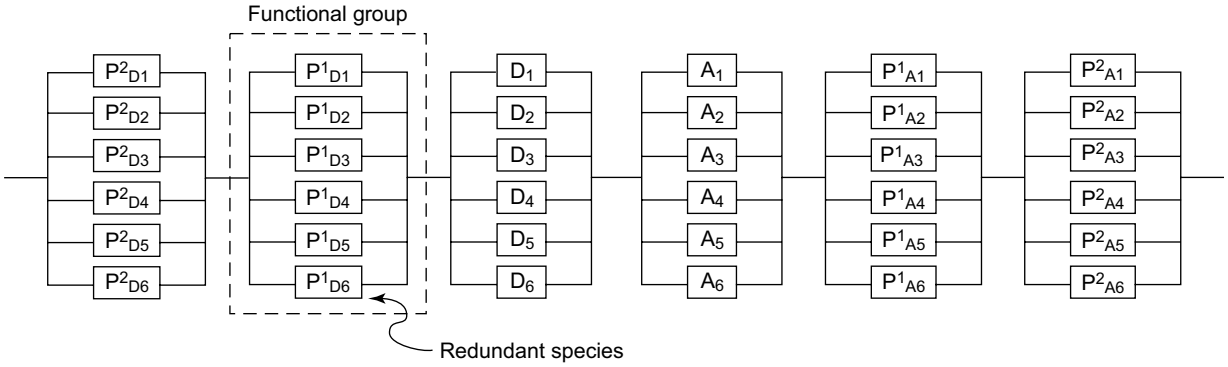

Figure 6 A block diagram or blueprint of an ecosystem ignoring material pools. Species are divided into six serially dependent functional groups within which redundant species are represented. As constructed in this ecosystem, normal functioning would only be obtained if at least one species in each functional group was present. Greater numbers of species insure that the system functions normally. See caption of Figure 5 for explanation of terms in boxes

Functional Groups of Nitrogen Cycling Organisms

Nitrogen cycling represents a good example of the lack of correspondence between taxonomic and functional classification schemes. Atmospheric nitrogen (N_2) is fixed only by prokaryotes (Bacteria and Archaea). Similarly, nitrification (the conversion of ammonia or NH_3 to NO_3^-) which can be taken up by plants and denitrification (the conversion of NO_3^- to atmospheric N_2), are both accomplished by prokaryotes. Thus, with the exception of lightning, which can convert N_2 to NO_3^-, the bulk of nitrogen cycling is accomplished by prokaryotes. Among these few functional groups (e.g., nitrogen-fixers, denitrifyers, and nitrifyers), however, many taxonomically distant species are involved. Over 20 families containing over 120 species, some more distantly related from one another than plants are from animals (i.e., Bacteria versus Archaea), exhibit N_2 fixing capabilities.

If we consider eukaryotic, symbiotic hosts of nitrogen-fixing prokaryotes, there is again an enormous diversity even though we lump them into a few functional groups. Among protists, some diatoms show symbiotic associations with cyanobacteria. Among plants, the cycads, liverworts, ferns, and *Gunnera* (an angiosperm) show symbiotic associations with cyanobacteria. Some fungi show associations with cyanobacteria yielding nitrogen-fixing lichens. Legumes show symbiotic associations with bacteria in the genus *Rhizobia*. A diverse array of terrestrial plants (greater than 200 species) show symbiotic associations with the bacteria in the genus *Frankia*. A few animals, including a ship worm (mollusk), have also been shown to exhibit symbiotic associations with nitrogen-fixing bacteria. Thus, although we can reduce the diversity of species associated with nitrogen-cycling to a small number of functional groups, taxonomic diversity is not only much greater, but shows little correlation with functional groups. Indeed, in the case of nitrogen-fixation, it is often necessary to classify symbiotic pairs of species (the nitrogen-fixing prokaryote and its host) as a single functional species.

A Brief Functional Classification of the Earth's Biota

The following is a brief functional classification of the earth's biota derived from the observations of how species affect ows of energy and materials as described in the previous sections. The classification is described in Table 1 and illustrated in Figure 7. Figure 7 also presents a contemporary taxonomic classification of biodiversity so that it can be compared with a functional classification.

Three things emerge from this simple functional classification. First, it is evident that many of the biogeochemical processes used in the classification are conducted predominantly by prokaryotes (Bacteria and Archaea). Second, it is also clear that there is no necessary correlation between functional groups and taxonomic groups (compare the top and bottom portions of Figure 7). Third, every group may be divided further. For example, within the chemoheterotrophs, sarcodinid protists may be divided into those producing calcium carbonate tests that serve as skeletons (foraminiferans) versus those that produce siliceous skeletons (radiolarians). Each of these subgroups significantly affects different elemental cycles (i.e., Ca, C, or Si). Other animal groups show such differences in use of elements. For example, arthropods primarily use chitin in their exoskeletons (an organic, carbon-based compound) sometimes fortified by calcium compounds, shelled mollusks use protein and calcium carbonate in their shells, vertebrates use protein and calcium salts in their bones, sponges use protein and spicules of either silica (e.g., certain *Demospongiae* and *Sclerospongiae*) or calcium carbonate (e.g., calcareous sponges), and corals use calcium carbonate. These organisms classified here simply as chemoheterotrophs would need further classification if calcium or silica were important in the functions being examined.

CONCLUSION

There is little doubt that the Earth's biota function critically in conditioning global environmental conditions. Historically, the appearance of oxygenic photosynthetic microorganisms 2.7 billion years ago led to the transformation of the earth's atmosphere from an anoxic environment to an oxygen-rich one. Later in the Permo-Carboniferous period (300 million years ago) the terrestrial invasion of photosynthetic organisms may have contributed to the draw-down of atmospheric CO_2 that led to global cooling and glaciation in the Southern Hemisphere. Currently, biogeochemistry provides abundant evidence for the role of the Earth's biota in governing cycles that affect greenhouse gases, soil fertility, and water quality. Without the biota, which means without biogeochemical processes, geochemical and physical processes would eventually transform the earth to an inhospitable planet (Lovelock, 1979). In fact, the foundation of the Gaia hypothesis (Lovelock, 1979) is based on the notion that this feedback between biogeochemistry and the biota creates a homeostatic regulation of earth's environment, an interesting hypothesis that is under investigation by many researchers (*see* Gaia, Volume 2; Gaia Hypothesis, Volume 5).

The role of the earth's extraordinary diversity, ranging from 10–100 million species, is only recently unfolding. Three important functions of this diversity have been identified. First, whereas the biota function as a whole in the transformation and movement of material among the earth's major spheres (hydro-, litho-, atmo-), it is the breadth of diversity within the biota that permits these cycles to occur over a physically and chemically heterogeneous planetary surface. The Earth's many biomes are defined

Table 1 Major functional divisions of the biota. See Figure 7 for illustration

Primary functional group	Secondary functional group	Finer divisions					Comments (examples)
Autotrophs: species that acquire carbon from inorganic sources	Photoautotrophs: acquisition of carbon from inorganic sources using light energy	Anoxygenic – photosynthesis					Species that do not produce oxygen as a by-product of (purple and green sulfur bacteria)
		oxygenic					species that produce oxygen as a by-product of photosynthesis
			Photosynthetic prokaryotes				(blue green algae)
			Photosynthetic protists	Without cell walls			(Example: cryptomonads, euglenids)
				With cell wall	Cellulose or organic material in cell wall or outer covering		(Some dinoflagellates)
					Siliceous cell walls		(Silicoflagellates)
					Calcified cell walls		(Some green and red algae)
			Green plants				
				Aquatic plants			Aquatic macrophytes
				Terrestrial plants	Grasses		Generally recover from above-ground grazing more readily, many species use silica to strengthen tissues
						C_3	Less efficient use of CO_2
						C_4	More efficient use of CO_2

Forbs, ferns and non-vascular plants		These organisms use less carbon, but require locally sufficient nitrogen
	C_3 forbs not associated with nitrogen-fixing symbionts	Less efficient use of CO_2
	Nitrogen fixers associated with nitrogen-fixing symbionts	These organisms use some of their acquired carbon to support symbionts, but have nitrogen supplied for them by their symbionts
	C_4	More efficient use of CO_2
Woody plants		Carbon used in structural compounds such as lignin that are more resistant to decomposition
	C_3 without nitrogen-fixing symbionts	Less efficient use of CO_2
	Associated with nitrogen-fixing symbionts	These organisms use some of their acquired carbon to support symbionts, but have nitrogen supplied for them by their symbionts
	C_4	Rare
CAM		Sequester CO_2 at night

(*continued overleaf*)

Table 1 (*continued*)

Primary functional group	Secondary functional group	Finer divisions		Comments (examples)
	Chemoautotrophs			Acquisition of carbon from organic material using inorganic chemical bonds (bacteria using energy stored in hydrogen, carbon monoxide, iron, sulfur, and nitrogen chemical bonds)
Heterotrophs	Photoheterotrophs: acquisition of carbon from organic sources using energy from light energy			(Examples: halobacteria and heliobacteria)
	Chemoheterotrophs: acquisition of carbon from organic sources using energy from organic compounds	Decomposers	Organic–inorganic transformers	Movement of nutrients to and from dead organic matter to (mineralization) and from (immobilization) inorganic pools (examples: many bacteria, fungi, including gut endosymbionts of herbivorous animals such as termites and ungulates)

	Uptake facilitators			Microbes that locally concentrate or mobilize nutrients which are taken up or supplied directly to autotrophs (examples: mycorrhizal fungi that facilitate uptake in terrestrial plants and bacteria that locally concentrate nutrients near phyto-plankton)
Consumers: direct consumption of living biomass	Decomposer-derived (examples: bacterivorous nematodes, nemato-phagous mites, predatory soil micro arthropods)	Primary: consume decomposer bacteria or fungi	Bacterivores	Consume bacteria
			Fungivores	Consume fungi
			Detritivores	Consume particulate matter containing microbes
		Secondary		Consume primary consumers in decomposer food chains
		Tertiary (and higher)		Consume secondary consumers in decomposer food chains

(*continued overleaf*)

Table 1 (*continued*)

Primary functional group	Secondary functional group	Finer divisions				Comments (examples)
				Omnivores		Consumes organisms from two or more trophic groups
			Autotroph-derived	Primary: consume autotrophic species such as plants or algae	Herbivores	Consume photosynthetic tissue
					Frugivores	Consume reproductive tissue
					Pollinators	Consume nectar and/or pollen
				Secondary		Consume autotrophic-derived primary consumers
				Tertiary (and higher)		Consume autotrophic-derived secondary or higher consumers
				Omnivores		
Myxotrophs						Acquires energy from inorganic and organic sources (example: photosynthetic protists that also consume bacteria such as euglenoid protists)

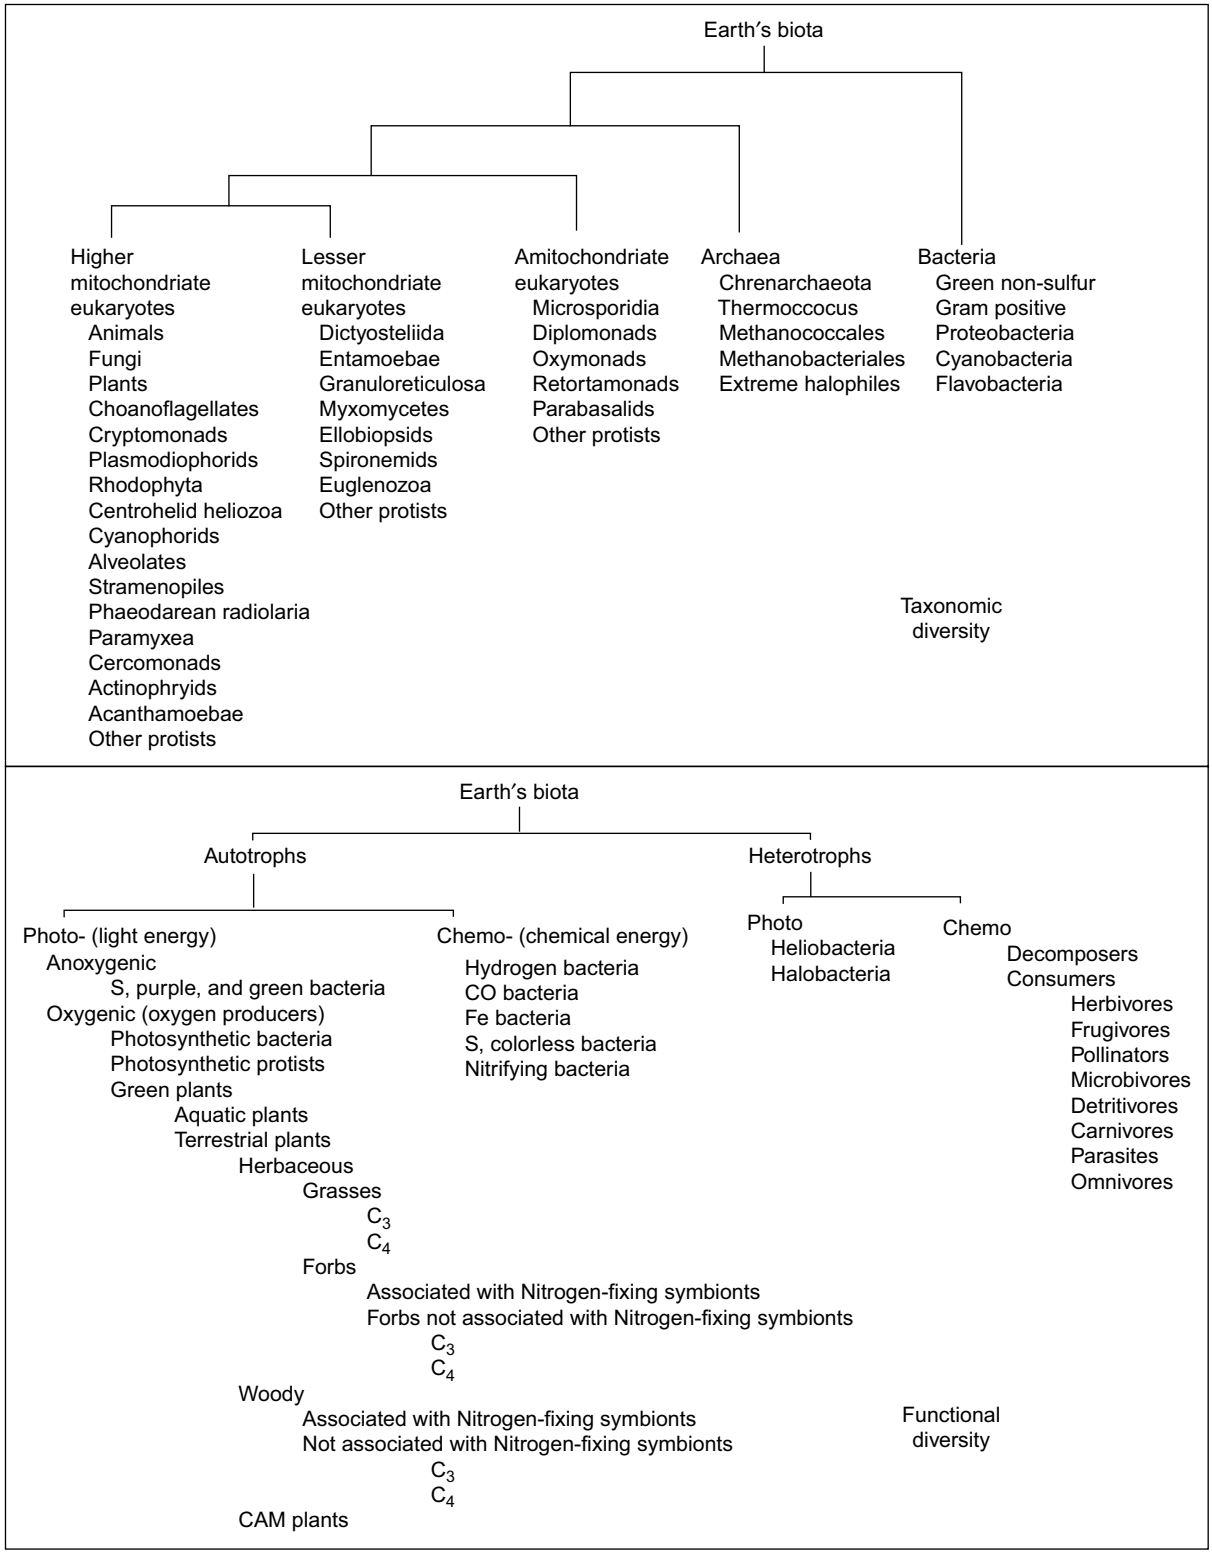

Figure 7 Taxonomic versus functional classifications of the biota. The top dichotomous tree represents species grouped by genetic or taxonomic similarity whereas the bottom represents species classified by their contributions to biogeochemical cycles (focusing primarily on carbon and nitrogen cycles). See text and Table 1 for further explanation

by climatically distinct regions, each containing numerous uniquely adapted species. Deserts, for example, contain drought-resistant plants, whereas tundras contain cold hardy plants and salt marshes contain halophytic or salt-loving plants. Such a diversity of differently adapted species permits carbon cycling and other biogeochemical processes to occur over much of the earth s surface.

Second, the ef ciency, in the sense of maximizing use of local resources, occurs when many complementary species are present, each using slightly different versions of a resource (e.g., different kinds of organic substrates) or each exploiting resources in slightly different ways (e.g., plants rooting at different depths). The rich variety of organic carbon sources, for example, that make up dead organic matter, is used the most when a wide diversity of species representing a wide diversity of enzymes for breaking down different kinds of organic compounds, is present in the decomposer functional group. This is the foundation of *bio-remediation*, which seeks to maximize the necessary microbial diversity to break down the complex milieu of organic compounds that comprise oil and other pollutants. *See* **Bioremediation**, Volume 3.

Third, having several species per functional group, or having greater redundancy of species, provides greater reliability of ecosystem functioning over a wide range of varying environmental conditions. For example, drought-tolerant plants may dominate communities during drought, thereby ensuring continued carbon cycling and production during drought years. By a functional classi cation, many species may appear redundant, but this redundancy is one of the most important values of diversity.

Interestingly, we tend to be disinclined, for whatever reasons, to consider familiar species as redundant even if they are functionally equivalent and taxonomically similar. Many, for example, would nd it worrisome to group zebra, wildebeest, giraffes, reed bucks, and elephants into a functional group called herbivores even though they are all members of a single, narrowly de ned taxonomic class and narrowly de ned functional group. On the other hand, species of microbes, which are less familiar to us, are frequently grouped into a microbial black box in ecological studies. Yet microbes in the microbial black box typically represent hundreds to thousands of species belonging to several phyla and representing all three biological domains (Eukarya, Bacteria, and Archaea). Awareness of the functional role of biodiversity draws attention to the importance of preserving both taxonomic and functional aspects of biodiversity.

The functioning of biodiversity is an inseparable issue from other topics in global environmental change. Certainly global environmental change affects biodiversity, but the converse, that changes in biodiversity may affect global environmental processes, is a rapidly growing research frontier.

IGBP Core Projects

WILL STEFFEN

IGBP Secretariat Royal Swedish Academy of Sciences, Stockholm, Sweden

The overall goal of the International Geosphere–Biosphere Programme (IGBP) is to describe and understand the interactive physical, chemical and biological processes that regulate the Earth System, the unique environment it provides for life, the changes that are occurring and how they are influenced by human actions. To achieve this goal, the IGBP has organized its research effort into a number of core projects and framework activities. The core projects, largely oriented around broad disciplinary groupings, carry out the bulk of the scientific research within IGBP. The framework activities are designed to support the scientific endeavor carried out in the core projects by providing Global Analysis, Interpretation and Modeling (GAIM) data and information as required and the regional perspective on global change science.

Beyond the scientific research that is carried out within the core projects themselves, IGBP is a coherent scientific effort in its own right. To achieve its ultimate goal of understanding the changing Earth System as a whole, especially human perturbations to this system, requires that the work of the core projects be integrated and synthesized at a higher level. This task is tackled jointly by a suite of inter-core project activities, by the GAIM framework activity, and by the Scientific Committee of the IGBP and its executive body, the IGBP Secretariat.

THE CORE PROJECTS: OBJECTIVES AND STRUCTURE

The eight core projects of the IGBP (Figure 1) represent various ways of viewing the Earth System. Five of them – Global Change and Terrestrial Ecosystems (GCTE), Land–Ocean Interactions in the Coastal Zone (LOICZ), International Global Atmospheric Chemistry Project (IGAC), Global Ocean Ecosystem Dynamics (GLOBEC) and Joint Global Ocean Flux Study (JGOFS) – represent the land, coastal, atmospheric and oceanic compartments of the Earth System, respectively. Land-Use/Cover Change (LUCC) studies a global change driver, Biospheric Aspects of the Hydrological Cycle (BAHC) analyzes an Earth System cycle and Past Global Changes (PAGES) takes a time slice perspective on the changing Earth System as a whole.

The IGBP core projects also vary in their historical development. Two of them – IGAC and JGOFS – were initiated independently of IGBP, in fact before IGBP was conceived, and were later adopted by IGBP. Three of them – BAHC, GCTE, and PAGES – joined IGAC and JGOFS as the original core projects, all of which launched their implementation phase around 1990 or earlier. LOICZ, LUCC and GLOBEC were phased in throughout the 1990s, as their respective scientific communities developed coherent international frameworks, and resources were found to begin and coordinate the implementation phase. The scientific objectives of the core projects have evolved throughout the development of IGBP. The work of the five original core projects is strongly oriented towards basic Earth System science, with only GCTE featuring a strong effort on the impacts and consequences of changes in the Earth System. The three newer core projects – LOICZ, LUCC, and GLOBEC – all have a balance between basic Earth System science and impacts or consequences. In all core projects, there is a balance among the physical, chemical and biological sciences, but IGBP's strength lies in its ability to fully integrate the biological aspect into Earth System science.

Several core projects have co-sponsors. The Scientific Committee on Oceanic Research (SCOR) jointly sponsors both JGOFS and GLOBEC; the latter is also sponsored by the Intergovernmental Oceanographic Commission (IOC). IGAC is co-sponsored by the Commission on Atmospheric Chemistry and Global Pollution (CACGP) of the International Association of Meteorology and Atmospheric Science (IAMAS). LUCC is co-sponsored by the International Human Dimensions Programme on Global Environmental Change (IHDP).

Biospheric Aspects of the Hydrological Cycle (BAHC)

Understanding the biospheric controls on the hydrological cycle, and how changes to that cycle affect water quantity

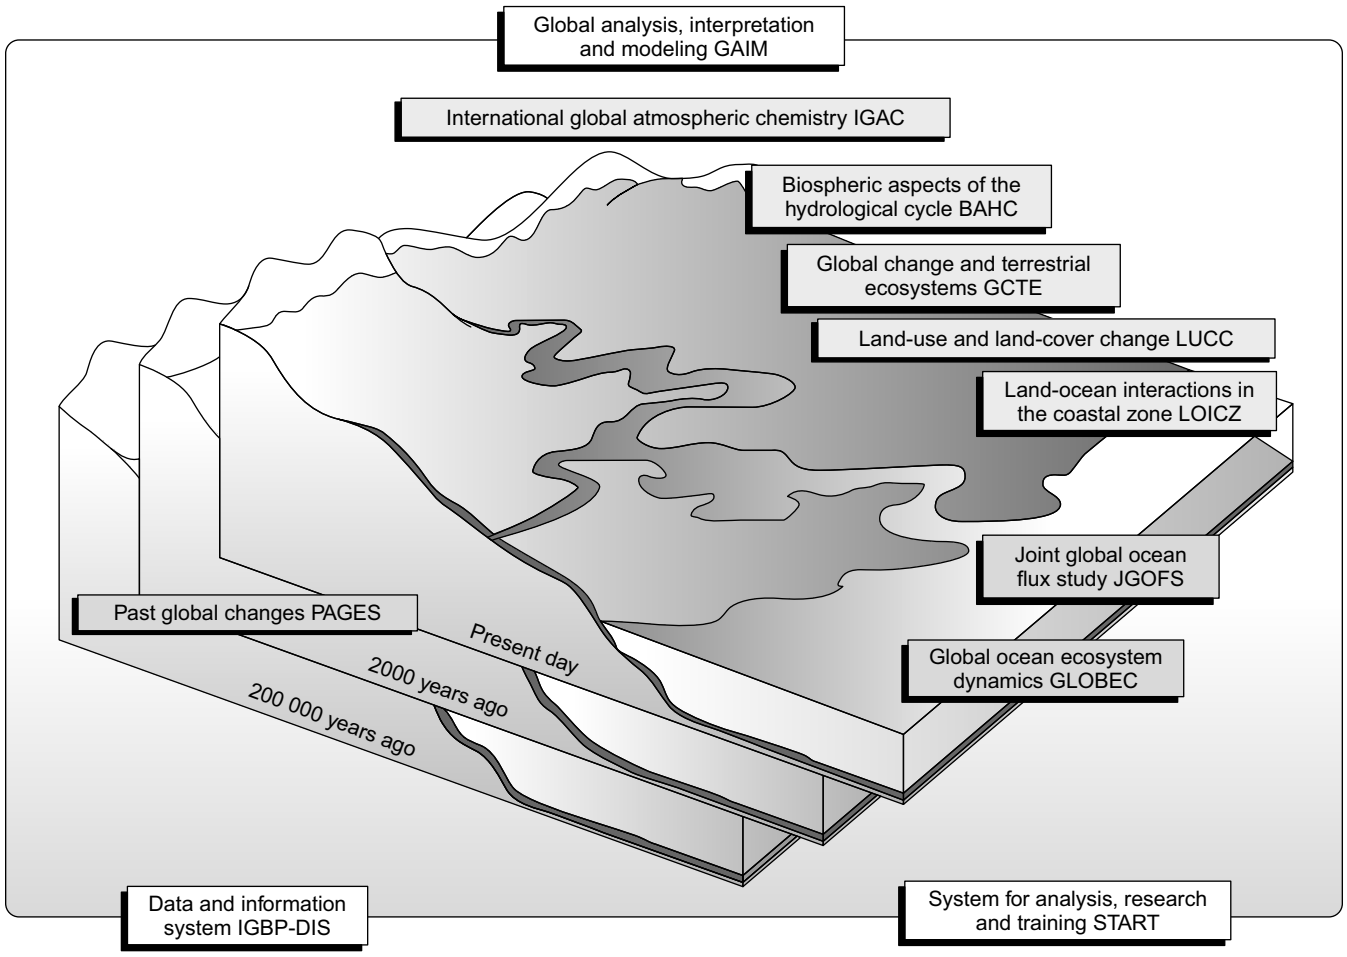

Figure 1 The IGBP core projects and framework activities

and quality, is crucial for sustainable development. BAHC's objectives are:

- to determine the biospheric controls of the hydrologic cycle through field experiments, for the purpose of developing models of energy and water fluxes in the soil–vegetation–atmosphere system at temporal and spatial scales ranging from vegetation patches to general circulation model (GCM) grid cells;
- to develop appropriate databases that can be used to describe the interactions between the biosphere and the physical Earth System, and to test or validate model simulations of such interactions.

BAHC is organized into 10 major areas, or key themes:

1. FLUXNET (a global network of stations for the routine measurement of water, energy and CO_2 fluxes – see the section on FLUXNET);
2. below-ground hydrological processes;
3. land-use change – climate/hydrology interactions at regional scales;
4. parameterization of land/atmosphere interactions;
5. global terrestrial–climate interactions (see the section on BAHC Earth System Modeling);
6. water transport/riverine systems;
7. contributions to developments of global databases;
8. mountain ecohydrology;
9. integrated terrestrial experiments;
10. impacts–feedbacks–vulnerability–water resources.

Global Change and Terrestrial Ecosystems (GCTE)

The health and productivity of the terrestrial biosphere is essential for human well-being; in addition, the terrestrial biosphere plays an important role in the dynamics of the Earth system. GCTE's objectives are:

- to determine the effects of changes in climate, atmospheric composition and land use on terrestrial ecosystems, including agriculture, forestry, soils, and ecological complexity;
- to determine the feedback of these changes to the atmosphere and the physical climate system.

GCTE's research effort is organized into four foci:

1. ecosystem physiology and global change;
2. ecosystem structure;
3. global change impact on agriculture, forestry and soils;
4. global change and ecological complexity.

In addition, GCTE has established a global change impacts center in Bogor, Indonesia, as the first in a set of such centers to help apply the results of its research to policy and resource management issues in the developing world.

Global Ocean Ecosystem Dynamics (GLOBEC)

The most extensive ecosystem on Earth is the marine, and the ocean is inextricably involved in the physical, chemical and biological processes that regulate the total Earth System. GLOBEC's objective is:

- to advance our understanding of the structure and functioning of the global ocean ecosystem, its major subsystems, and its response to physical forcing so that a capability can be developed to forecast the responses of the marine ecosystem to global change.

GLOBEC is organized into four foci:

1. retrospective analyses in the context of large-scale climatic changes;
2. process studies;
3. predictive and modeling capabilities;
4. feedbacks from changes in marine ecosystem structure.

International Global Atmospheric Chemistry Project (IGAC)

Human activities are now changing atmospheric composition rapidly compared to the past, and are significantly perturbing the natural processes operating in the atmosphere. IGAC's objectives are:

- to develop a fundamental understanding of the processes that determine atmospheric composition;
- to understand the interactions between atmospheric chemical composition and biospheric and climatic processes;
- to predict the impact of natural and anthropogenic forcings on the chemical composition of the atmosphere.

The implementation of IGAC is built around three foci:

1. biosphere–atmosphere interactions
2. oxidants and photochemistry
3. atmospheric aerosols

and two framework functions:

1. fundamental and cross-cutting activities;
2. capacity building.

Joint Global Ocean Flux Study (JGOFS)

Oceans are the sleeping giants in the uptake of increasing CO_2 in the atmosphere. The objectives of JGOFS are:

- to determine and understand on a global scale the processes controlling the time-varying fluxes of carbon and associated biogenic elements in the ocean, and to evaluate the related exchange with the atmosphere, sea floor and continental boundaries;
- to develop a capacity to predict on a global scale the response of oceanic biogeochemical processes to anthropogenic perturbations, in particular those related to climate change.

The implementation of JGOFS is built around large-scale surveys, process studies, time series, sedimentary record studies, and continental margin boundary fluxes, with data base development and management and global synthesis playing central roles. JGOFS has adopted a strongly regional approach to implementation, with work in the North Atlantic, equatorial regimes, the Southern Ocean, monsoon regimes, eastern and western boundary regimes and central gyres.

Land-Ocean Interactions in the Coastal Zone (LOICZ)

The coastal zone is a relatively small but highly dynamic and sensitive area that is coming under increasing pressure from population growth, urbanization and industrialization. The objectives of LOICZ are:

- to determine at global and regional scales:
    1. the fluxes of material between land, sea and atmosphere through the coastal zone;
    2. the capacity of coastal systems to transform and store particulate and dissolved matter;
    3. the effect of changes in external forcing conditions on the structure and functioning of coastal ecosystems.
- to determine how changes in land use, climate, sea level and human activities alter the fluxes and retention of particulate matter in the coastal zone, and affect coastal morphodynamics;
- to determine how changes in coastal systems, including responses to varying terrestrial and oceanic inputs of organic matter and nutrients, will affect the

global carbon cycle and trace gas composition of the atmosphere;
- to assess how responses of coastal systems to global change will affect habitation and usage by humans of coastal environments, and to develop further the scientific and socio-economic bases for the integrated management of the coastal environment;

LOICZ is structured around four foci:

1. the effects of changes in external forcing or boundary conditions on coastal fluxes;
2. coastal biogeomorphology and global change;
3. carbon fluxes and trace gas emissions;
4. economic and social impacts of global change in coastal systems.

Land-Use/Cover Change (LUCC)

For the Earth's land surface, the most important component of global change for the next several decades at least is land-use and land-cover change, more important than either changes in atmospheric composition or in climate. LUCC's objective is:

- to improve understanding and projections of the dynamics of LUCC as inputs to and consequences of global environmental change and as elements of sustainable development.

LUCC is organized into three foci:

1. land-use dynamics – comparative case study analysis;
2. land-cover dynamics – direct observation and diagnostic models;
3. regional and global models – framework for integrative assessments.

Past Global Changes (PAGES)

Paleo studies are powerful tools for understanding the natural variability of the Earth system, and for discerning human impacts on the system in the recent past. The objectives of PAGES are:

- to determine how global climate and the environmental systems linked to it changed in the past, the factors responsible for those changes, and how knowledge of past changes can be used to improve insight into likely future climate and environmental change;
- to determine the extent to which human activities have modified climate and the global environment, and to disentangle anthropogenically-induced change from natural responses to external forcing mechanisms and internal system dynamics;
- to determine the limits of natural greenhouse gas variation in the atmosphere, the natural feedback to the global climate system, and the sequence in which changes in greenhouse gas concentrations, surface climate and ecological systems occur;
- to determine the important forcing factors that produce climate change on societal time scales, the causes of abrupt climatic and environmental events and of the transitions between quasi-stable climatic states that occur on decade to century time scales.

The PAGES implementation is built around five foci:

1. palaeoclimates of the Northern and Southern Hemispheres;
2. palaeoclimate and environmental variability in polar regions;
3. human interactions in past environmental changes;
4. climate system sensitivity and modeling;
5. cross-project analytical and interpretive activities.

THE FRAMEWORK ACTIVITIES: OBJECTIVES AND STRUCTURE

The IGBP framework activities were all initiated at the beginning of IGBP in the late 1980s. More recently, Global Change System for Analysis, Research and Training (START) has become a jointly shared activity with the World Climate Research Programme (WCRP) and the IHDP.

Data and Information System (DIS)

Global change research requires global data, and an international research effort requires an integrated and efficient information system. The objective of DIS is:

- to improve the supply, management and use of the data and information that are needed to attain IGBP's scientific goals.

DIS is organized into three foci:

1. data set development;
2. data management and dissemination;
3. data coordination in an international context.

The data needs of IGBP, and the most appropriate structure required to meet them, were reviewed in 1998/1999 and a restructured DIS became fully operational in 2000. The main change in DIS was the new emphasis on service rather than system, and a more user-driven approach in response to the data needs of the core projects.

Global Analysis, Interpretation and Modeling (GAIM)

The work of IGBP is not complete without understanding the interactions between the core projects – the flows and feedbacks, the thresholds and non-linearities which are characteristic of complex systems. The goal of GAIM is:

- to advance the study of the coupled dynamics of the Earth System using as tools both data and models.

GAIM's implementation is based on a task force approach, engaging scientists who are involved in IGBP core projects and focusing on topics which involve more than one core project. GAIM activities to date have included intercomparison projects on ocean carbon models, atmospheric transport models, and models simulating net primary production of terrestrial vegetation; regional interaction of climate and ecosystems; climate–biosphere model studies of 6 k and 18 k years before present; a global carbon cycle model linkage project; and the characterization of global wetland distribution and functioning.

Global Change System for Analysis, Research and Training (START)

Increasing emphasis is being placed on the regional perspective of global change, dealing with the heterogeneity of the planet in terms of both Earth System processes and global change impacts. START employs a system of regional networks to meet its objectives:

- to conduct research on regional aspects of global change;
- to assess the impacts of regional findings;
- to provide regionally important integrated and evaluated information to policymakers and governments.

In its implementation START places emphasis on the development of regional networks in developing countries. It seeks to mobilize the resources required to augment existing scientific capabilities and infrastructures in developing countries.

IMPLEMENTATION STRATEGIES: THE VALUE-ADDING OF IGBP SCIENCE

Understanding the changing Earth System is beyond the capacity of the scientific communities of individual countries; it requires a coordinated international effort of unprecedented interdisciplinarity and cooperation. The implementation of IGBP's research program is based on voluntary contributions from a large number of national and regional global change research projects and the promotion and initiation of new work where critical gaps exist. The core projects knit these contributing projects together into a coherent effort, using a variety of value-adding activities. The basic principles on which the IGBP core projects undertake these activities are:

1. They must address questions which can only or best be answered through collaborative, interdisciplinary international research;
2. They must ensure that the scientific output of the activities is greater than what could be achieved by the individual contributing projects working on their own – the whole is more than the sum of its parts.

The most important of the value-adding activities are described below, with examples given for each.

Agreed International Framework

The first task of each of the core projects is to develop an agreed international framework under which the collaborative work will be undertaken. This in itself is a complex task, involving extensive consultation with the science and policy communities in many regions of the world. This process enables a wide range of ideas and hypotheses to be incorporated into the science plan, and entrains a large number of scientists into the implementation phase. The agreed framework ensures that a strong focus is maintained during the implementation of the research and facilitates the synthesis of results at regular intervals and the reformulation of the scientific agenda based on work completed under the agreed framework.

The LUCC Science Plan

The science plan developed by the land-use and land-cover change research community demonstrates not only the development of a widely accepted framework for international research, but also how that process of developing such a framework can itself promote interdisciplinary research. As noted earlier, the LUCC science plan is organized into three broad thematic areas, land-use dynamics – comparative case study analysis, land-cover dynamics – direct observation and diagnostic models; and regional and global models – framework for integrative assessments. Traditionally the theme of land-use dynamics has been the territory of the social sciences while the second theme, with its strong emphasis on remote sensing as a research tool, has been dominated by the natural sciences. However, in carefully developing a single, coherent science plan for the LUCC core project, the process of integrating the social and natural sciences had begun. For example, Figure 2 shows the numerous social and biophysical driving forces which affect land-use and land-cover change at a variety of scales. Such a conceptual framework in itself drives collaboration. Even more striking is the interaction between the natural and social sciences in the

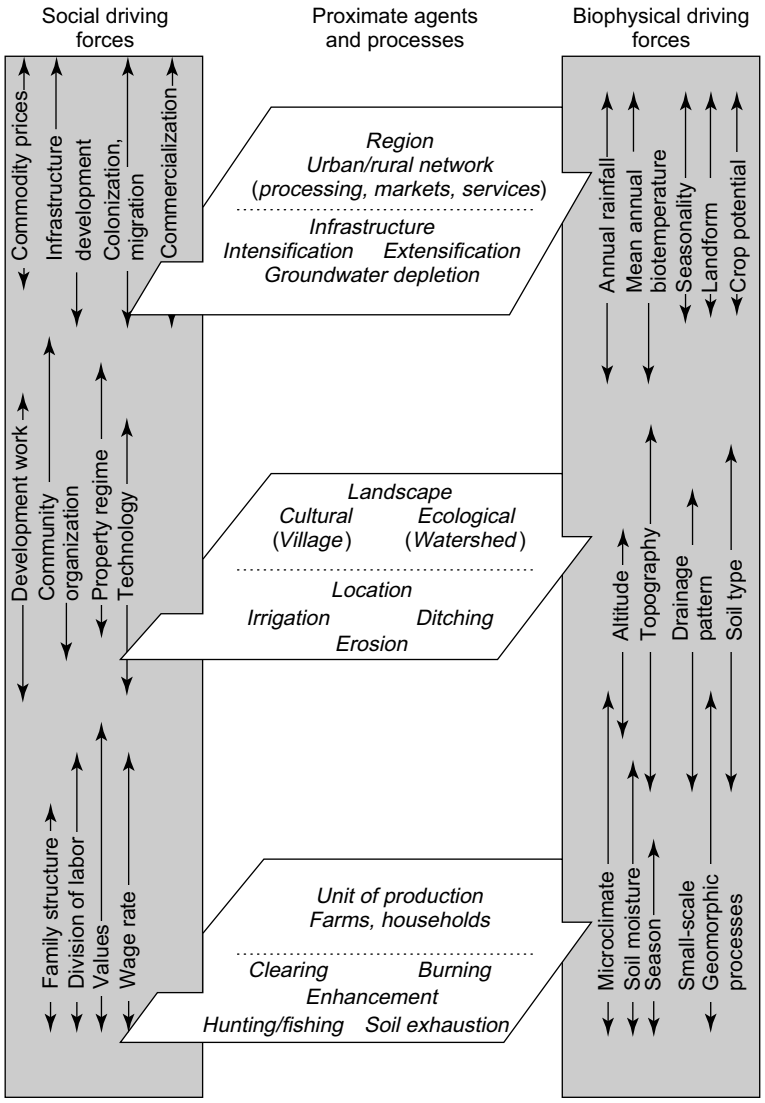

Figure 2 Multiscale driving forces in land-use and land-cover change

implementation of the LUCC Science Plan. An excellent example is the pioneering work on merging traditional social science research with remote sensing imagery, that is, LUCC's first two research themes. One of the concepts around which this interdisciplinary work is built is socializing the pixel, in which the biophysical data of a pixel (grid cell of a remotely sensed image) are interpreted in ways that yield social meaning or insights, or are used as a basis for social science modeling. A companion concept is pixelizing the social, in which social, political and economic data, which are usually aggregated by political unit (e.g., state or country) are disaggregated and made spatially explicit (Geoghegan *et al.*, 1998).

The Miombo Network Plan

At a regional scale, science plans are evolving to address regional issues specifically, but they are usually built around an integration of components of several IGBP (and WCRP and IHDP) core projects. The development of the Miombo Network, a study of global change in the seasonal woodlands of central and eastern Africa, is a good example of this approach. This framework adopts a modular approach in which work is organized around seven core studies: land-use dynamics, land-cover dynamics, ecosystem dynamics and disturbance, nutrient limitation in Miombo, biogeography and distribution of Miombo, regional primary production and carbon balance of Miombo, and sustainable natural resource management. The strengths of the Miombo Network plan include its broad community consensus and hence wide acceptance in the region, its emphasis on sustainable development–global change linkages, its explicit provision for activities in integration and synthesis and its incorporation of much existing appropriate research in

the region, thereby identifying where scarce new scientific resources are best placed.

Ef cient Use of Resources

A very practical benefit of IGBP research is the use of the agreed frameworks to make the most cost-effective use of scarce resources in achieving scientific results. This value-adding characteristic is most evident when large and expensive facilities, such as oceanographic research vessels, aircraft, or large *in situ* installations (e.g., free-air carbon dioxide enrichment (FACE) experiments) are required to carry out the work.

Aerosol Characterization Experiment

A good example of the coordination of scarce scientific resources is the series of Aerosol Characterization Experiment (ACE) campaigns carried out under the auspices of IGAC. For instance, the ACE-2 campaign was a major field effort over the North Atlantic in 1997 to study the radiative effects and controlling processes of anthropogenic aerosols from Europe and desert dust from Africa as they are transported over the North Atlantic Ocean (Raes and Bates, 1998). The campaign involved 60 coordinated aircraft missions with six aircraft, one ship, and ground stations on Tenerife, Madeira and mainland Portugal and over 250 scientists from the United States, five European countries and the European Union. ACE-2 was only possible through international collaboration, and was well beyond the scope of any of the individual countries or agencies.

Preliminary results from ACE-2 include:

- A wide variety of aerosol types was observed in the region studied, including background marine aerosols, European pollution-derived aerosols and African mineral dust. The last was encountered less frequently than expected.
- Aerosols originating over Europe and Africa and transported more than 3000 km from the source still impact on the chemistry and radiative properties of the atmosphere. For example, observations from a mountain ridge on Tenerife showed that the pH of cloud water was typically 5.5 during clean periods, but dropped sharply to 3.5 during polluted periods, with a substantial contribution of nitric acid to the acidity.
- Pollution from Europe and dust from Africa were transported in distinct layers, the optical depth of which varied over a wide range.

JGOFS pCO_2 Measurements

Another example of more efficient use of scientific resources is the suite of oceanic cruises undertaken by JGOFS, in collaboration with the WCRP's World Ocean Circulation Experiment (WOCE), to measure the exchange of CO_2 between the oceans and the atmosphere. If JGOFS and WOCE, with their detailed plans for international collaboration, did not exist, there likely would be a strong bias towards sampling the North Atlantic Ocean, around which much of the world's oceanographic research resources are concentrated. Instead, about 90% of the planned cruises over the past decade have actually been implemented, with a representative coverage of all of the world's oceans in all seasons of the year. The result is a vastly improved understanding of ocean–atmosphere carbon exchange – the breathing of the oceans.

At a broad scale the work has shown that the oceanic sink for atmospheric CO_2 is not quite as strong as estimated earlier by global models. The estimate has been reduced from about 2.0 Gt C annum^{-1} (e.g., IPCC, 1994) to about 1.6 Gt C annum^{-1} (Takahashi *et al.*, 1997). But the work also shows some fascinating details of oceanic exchange. For example, there is a large out-gassing of CO_2 in the equatorial Pacific Ocean, caused by strong upwelling in this region coupled with a lack of biological activity. The JGOFS work also shows that there is considerable variability in the strength of this source, with the almost complete disappearance of the source during El Nino years. In contrast to the equatorial Pacific, the North Atlantic Ocean is the most intense marine carbon sink on Earth, due to both physical and biological factors. As a result of the this research, the pattern, both in space and time, of oceanic exchange of CO_2 with the atmosphere is now much better known, yielding valuable insights into the nature of the processes responsible for this exchange and into the reliability of the oceanic sink into the future.

Network Approach

The backbone of IGBP's value-adding activities is the establishment and operation of international research networks (Ingram *et al.*, 1998). All core projects use this approach to varying degrees. Networks generate research which could not be done by the constituent groups acting independently (e.g., experiments where many individual sites or studies are required, yielding results and insights greater than the sum of the parts) sharing data, models and facilities as well as sharing costs. Experience in GCTE has shown that networks need a number of requirements for successful operation:

- The goals of the network must be clearly stated and scientifically exciting.
- The individuals in the network must themselves benefit in addition to the network as a whole.
- Success is maximized when there is a sense of ownership of the network by the members, which is best achieved by jointly designing network

Table 1 Key stages in the development of the GCTE Soil Erosion Network (from Ingram *et al.*, 1998)

Date	Event	Outcomes/product	Ongoing activities commenced
January 1991	GCTE Open Meeting (Brighton, UK); GCTE general planning	Draft GCTE Operational Plan	
September 1991	Focus 3 Open Workshop (Lunteren, NL): Focus 3 general planning/scoping exercise	Draft Focus 3 Operational Plan	
March 1993	Internal planning meeting (Oxford UK)	Task 3.3.2 (Soil Degradation) Inaugural Workshop designed	Inaugural Workshop planning
March 1994	Inaugural Workshop (Paris, France)	Task's major objectives agreed; major erosion models and monitoring projects identi ed; metadatabase structures developed; Task Working Group convened	Metadatabase structure developed for models, manipulative experiments and monitoring programs; invitation to join network widely distributed; follow-up workshop preparation
	Publication of Paris Workshop Report (GCTE Working Document II, Ingram, 1994)		
February 1995	Network Planning Workshop (Corvallis, US). Task Working Group meeting	Model sensitivity analysis planned for water erosion at plot scale. Four Core Research Projects (CRPs) planned; criteria for network membership established; inaugural membership agreed; Special Issue of *J. Soil & Water Conservation* designed	Preparation of inaugural members' metadata for submission to GCTE Scienti c Steering Committee for rati cation as GCTE Core Research; plot scale model sensitivity analysis workshop planning; JSWC Special Issue editing
April 1995	GCTE Scienti c Steering Committee meeting (Bariloche, Argentina)	Soil Erosion Network (GCTE-SEN) formally recognized as GCTE 'Core Research'	
September 1995	Network Workshop: 'Global Change: Modeling Soil Erosion by Water' (with NATO; Oxford, UK). Task Working Group meeting	Results of model sensitivity analysis reported and outlines of NATO ASI book chapters produced. Model sensitivity analysis planned for water erosion at catchment scale	Editing NATO ASI book chapters; catchment scale model sensitivity analysis workshop preparation
September 1995	Publication of revised Focus 3 Operational Plan including revisions to Task		
January 1996	Network Workshop:		
	'SALT' Experimentation Planning (Senegal, Burkina, Faso & Niger). Task Working Group meeting	Field collaboration planned along SALT transect (see Chapter 4)	
April 1996	Publication of Soils Activity (Activity 3.3) Implementation Plan (GCTE Report 12)		Editing metadata. Distribution of A3.3 Implementation Plan to current and prospective

Table 1 (*continued*)

Date	Event	Outcomes/product	Ongoing activities commenced
			members of GCTE-SEN; selected projects invited to contribute to GCTE-SEN; detailed planning for Utrecht workshop
October 1996	Publication of ve papers as Special Issue of *Journal of Soil and Water Conservation*, 51		Collaborative work on water erosion at eld-scale started in Senegal
December 1996	Publication of metadata for models, experiments and modeling programs (GCTE Report 6)		
Early 1997	Publication of Oxford NATO workshop book in NATO-ASI Series		
April 1997	Network Workshop: 'Modeling water erosional at catchment scale' (Utrecht, NL)	Series of papers for publication in book or journal special issue anticipated	Editing Utrecht papers. Detailed planning of GCTE presentations at Wind Erosion Congress, GCTE/LUCC Open Science Conference, Activity 3.3 Session at ISSS Congress, and Focus 3 Science Conference
November 1997	Network Workshop: 'Erosion Thresholds' (Almeria, Spain)	Erosion thresholds Core Research Project (CPR2) launched. Detailed plans for GCTE Erosion Network input to GCTE/LUCC Open Science Conference and GCTE Special Session at ISSS Congress; and proposals for input to Focus 3 Conference	
March 1998	GCTE/LUCC Open Science Conference (Barcelona, Spain)		Focus 3 session to include reporting of Soils Activity results
August 1998	ISSS Congress: GCTE Activity 3.3 Session (Montpellier, France)	Series of papers as Journal Special Issue	Editing ISSS Special Session papers
September 1999	Focus 3 Science Conference (Reading, UK)	To include a full review and synthesis of GCTE soil erosion research	Editing Focus 3 Conference papers

activities and by maximizing participation in synthesis workshops and publications.

- Both benefits and responsibilities of network membership must be clearly stated.

Table 1, based on the work of the GCTE Soil Erosion Network, is an excellent example of the activities and products of a successful network (Ingram *et al.*, 1998).

The examples below show the types of networks being used, some of the activities which networks use to meet their objectives, and the enhanced scientific understanding achievable through the network approach.

FLUXNET

Determining the pattern, strength and variability of the terrestrial sources and sinks of CO_2 is much more difficult

than for the ocean, due to the natural heterogeneity of the land surface as well as to human disturbances of the structure and functioning of terrestrial ecosystems. An IGBP initiative, led by the BAHC core project and involving GCTE and IGAC as well, aims to measure the exchange of water, energy and carbon between the land surface and the atmosphere at representative sites around the world, that is, to monitor the breathing of the planet's terrestrial biosphere. The project, called FLUXNET, is built around major independent flux-measuring networks being developed in Europe and North America, together with stations being established in other parts of the world. Figure 3 shows the current international array of flux-measuring stations (Baldocchi *et al.*, 1996).

FLUXNET demonstrates the utility of the network approach as a value-adding tool within IGBP. By forming an international network rather than operating as independent national or regional networks, several important advantages have been realized. First, a common measurement methodology, that of the EUROFLUX network (see http://www.unitus.it/eflux/euro.html for more information on EUROFLUX) has been adopted worldwide, thus greatly enhancing the intercomparability of network results. Second, a single international network will lead to a much more effective placement of future measuring sites, especially in the developing regions of the world. Choice of sites can more readily be based on scientific criteria, rather than on bilateral aid arrangements or more narrow national or regional considerations. Third, establishment and maintenance of an active international network promotes analysis and interpretation based on the results of the entire network, rather than on results of national or regional components of it.

The IGBP framework has added value to the FLUXNET enterprise in other ways as well. For example, collaboration with GCTE is leading to the choice of more representative sites in terms of ecosystem types, successional stages of vegetation, and degrees of human disturbance. In addition, the addition of ecological expertise to the network enhances the analysis and interpretation of results, especially with respect to the time dimension. Fluxes based on only a few years of measurements cannot usually be extrapolated to decade, or longer, fluxes in a straightforward fashion. Collaboration with IGAC will facilitate the use of the results in atmospherically based inverse calculations of carbon sources and sinks, which currently suffer from a lack of surface measurements to constrain the models.

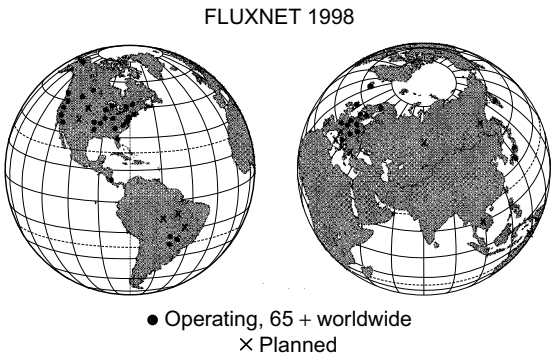

Figure 3 Location of FLUXNET sites (Baldocchi *et al.*, 1996). ●, Operating FLUXNET stations in 1998; ×, planned stations

LOICZ Biogeochemical Model Project

Another good example of the power of the networking approach, especially in terms of the adoption of common methodologies, is the LOICZ biogeochemical model project (Gordon *et al.*, 1995). This initiative demonstrates how a network based on a large number of individual investigators working at the site-specific level can, by the use of agreed techniques, yield results that can be readily scaled to yield regional and global understanding of the dynamics of biogeochemically important elements in the coastal zone. The common methodology was developed through a consensus process of all of the participating scientists in a series of international workshops. Although a suite of modeling techniques could have been adopted, the group opted initially for a simple approach based on stoichiometrically linked carbon, nitrogen and phosphorus budgets requiring relatively little data. This allows many more scientists and sites around the world to be included in the project. These simple but robust budget models of carbon, nitrogen and phosphorus fluxes can be used as the basis for developing more complex dynamic simulation models that can be used to explore the impacts of global change on important biogeochemical fluxes in the coastal zone.

GCTE Elevated CO_2 Network

Of the various IGBP core projects, GCTE has made the most extensive use of the network approach (Ingram *et al.*, 1998). One of the earliest networks to be formed in GCTE is that of researchers studying the effects of elevated CO_2 on terrestrial ecosystems, a network which has produced an impressive list of results in just seven years of operation. Established in 1991, the focus of the network is on ecosystem-level experiments and the analysis and interpretation of their results. Prior to the 1990s, there had been a large body of research on the effects of elevated atmospheric CO_2 on individual plants and small stands of plants, almost always in laboratories, greenhouses or other enclosures, but very little work on whole ecosystems *in situ*. The GCTE network aims to redress that balance.

Undertaking ecosystem-level elevated CO_2 experiments is challenging technically, and one of the first tasks of the GCTE network has been the evaluation and promotion of methodologies for undertaking such work,

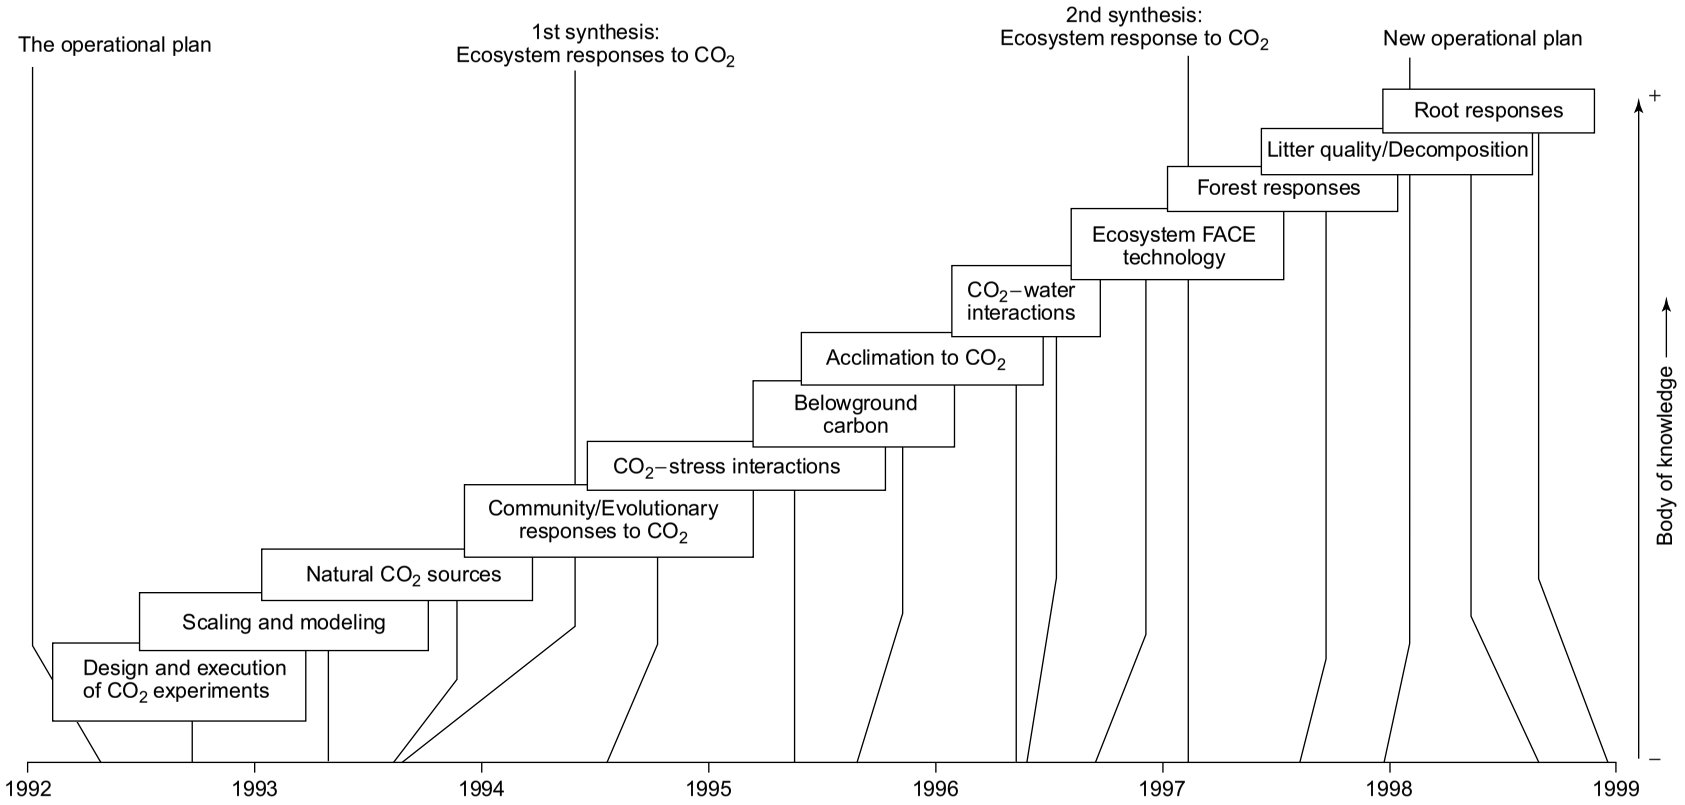

Figure 4 GCTE sponsored or co-sponsored activities in elevated CO_2 research, 1992- 1999. The increase in knowledge over time is enhanced by network activities; the network as a whole is greater than the sum of its constituent research projects. (Figure courtesy of Josep Canadell)

especially the FACE (Free Air Carbon Dioxide Enrichment) approach. This method does not use an enclosure of any kind and thus allows the ecosystem to interact with the ambient atmosphere without obstruction. FACE technology is complex and expensive, so the GCTE network has worked with principal investigators and agencies to move towards a more representative system of FACE sites around the world.

The elevated CO_2 network has operated in a rather less tightly organized way compared to FLUXNET in that no standardized methodologies have been prescribed. Nevertheless, as the network has developed, individual research groups have voluntarily moved towards more readily comparable experimental protocols and practices. The voluntary nature of network activities has worked remarkably well in terms of producing integrated scientific results. Network members have taken turns in hosting workshops on various focused aspects of elevated CO_2 effects, leading to a significant number of books and special journal editions based on network activities. The overall result is that the community's knowledge base has improved rapidly during the 1990s, much more rapidly than if the individual projects in the network had carried out their research independently (see Figure 4).

The most important findings include (Mooney *et al.*, 1998):

- Most whole ecosystems show a higher peak season net carbon uptake under elevated CO_2 compared to current ambient conditions. Above-ground productivity of grasslands increased by an average of about 15%, although there was wide variation among individual grassland communities, with some responses negative (Figure 5).

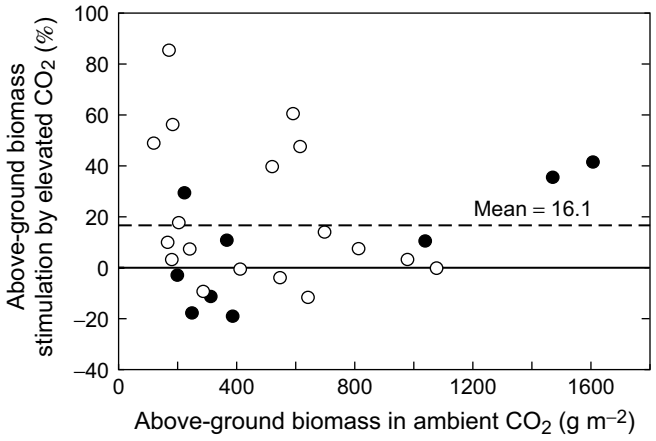

Figure 5 Stimulation of above-ground biomass of herbaceous systems by elevated CO_2 with and without addition of nitrogen (Reproduced by permission of Cambridge University Press in Mooney *et al.*, 1998). ●, Nitrogen addition; ○, no nitrogen addition

- Litter from plants grown under elevated CO_2 does not necessarily decompose more slowly. The ratio of carbon to nitrogen in the litter generally is not higher under elevated CO_2, as earlier predicted. This result has important implications for the terrestrial carbon cycle in general, as an important process in the cycle is the decomposition of soil organic carbon, derived from plant litter.
- Herbaceous plants show a reduced loss of water through transpiration under elevated CO_2 compared to current ambient conditions. This results in reduced loss of soil moisture, which in turn increases water availability to the vegetation. This secondary effect of elevated CO_2 is the dominant driver for increased carbon uptake in water-limited grassland systems.

Core Project Integration and Synthesis Activities

As the core projects progress further into their implementation phase, they are beginning to undertake within-project integration and synthesis activities. These represent significant leaps in understanding, and the examples described below have all had significant impacts on their own research areas.

PAGES Synthesis of Temperature Trends and Forcing Functions

One of the most intriguing questions in global change science is whether human perturbation of the climate is discernable. A synthesis of paleo-records provides some of the strongest evidence yet that humans are having a direct and measurable impact on climate (Mann *et al.*, 1998). The work is centered on integration of multi-proxy records – from tree rings, coral, ice core/melt and instrumental records – of Northern Hemisphere temperature from 1400 to the present, as shown in Figure 6. One of the most striking features of this record is the sharp increase in temperature in the 1990s. The three hottest years since 1400 occurred in this decade; their mean annual temperatures are greater than those of any other year since 1400 at a 99.7% level of certainty. Even more striking is the correlation of this temperature record with a corresponding record of three climatic forcing functions – atmospheric CO_2 concentration, solar irradiance and DVI, the latter an indication of aerosol inputs to the atmosphere from explosive volcanism (*see* **DVI (Dust Veil Index)**, Volume 3). Using a 200-year moving window to correlate the response of the climate to each of the three forcing variables, Mann *et al.* (1998) show that until the second half of the 20th century, solar irradiance was the primary driver of climate variability, with the dips in solar irradiance in the late 1600s and early 1800s and the rise through the first half of the 20th century clearly evident

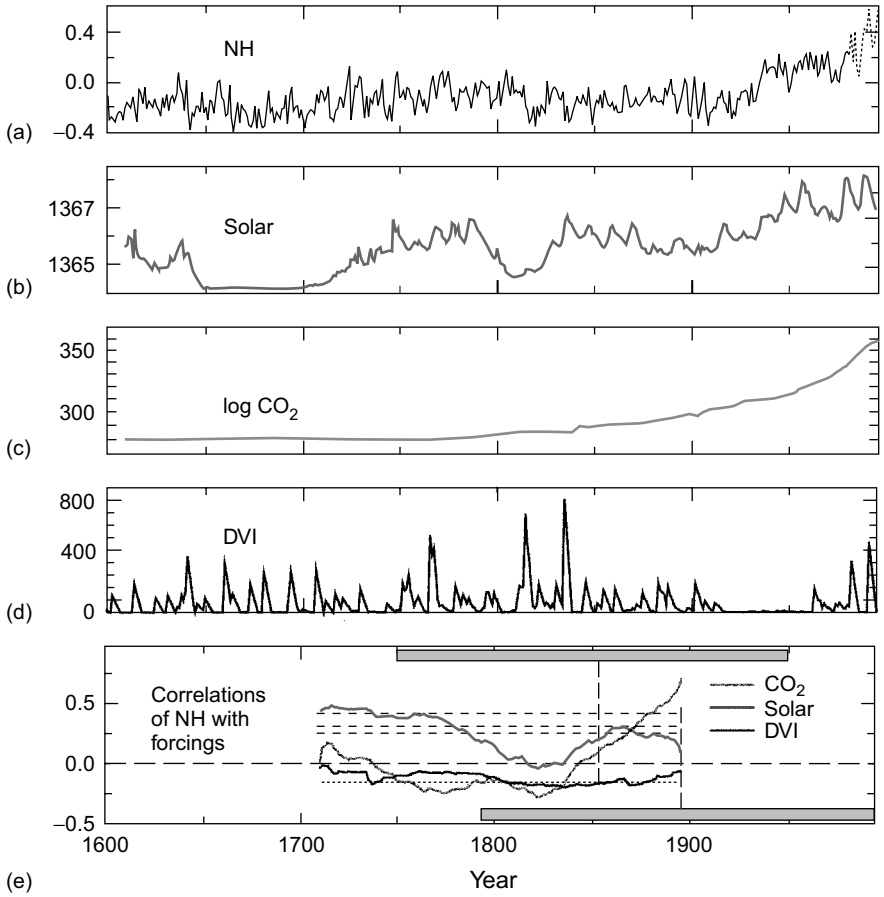

Figure 6 Relationships of Northern Hemisphere (NH) mean temperature with three candidate forcings between 1610 and 1995. (a) Reconstructed NH temperature series from 1610- 1980, updated with instrumental data from 1981- 1995. (b) Reconstructed solar irradiance. (c) Greenhouse gases represented by atmospheric CO_2 measurements. (d) Weighted volcanic dust veil index (DVI). (e) Evolving multivariate correlation of NH series with the three forcings solar, log CO_2, DVI. (Reproduced by permission of *Nature* in Mann *et al.*, 1998)

in the temperature record. However, the sharp increase in temperature in the last two decades does not coincide with a period of increase in solar irradiance, but rather correlates strongly with the anthropogenically driven rise in atmospheric CO_2 concentration.

The GCTE Terrestrial Carbon Cycle Synthesis

As part of its project-wide synthesis effort, GCTE analyzed the key terms of the terrestrial carbon budget, based on work carried out within GCTE networks, and projected likely trends in the terms (Walker *et al.*, 1998b). Three major areas of research were considered:

- *Land-use/cover change*: with the human population expected to increase by a billion every 12 years or so for the next several decades, most projections of land-use and land-cover change (e.g., Alcamo, 1994; Alcamo *et al.*, 1996) show increasing conversion of natural ecosystems to agriculture. In most cases conversion of ecosystems to agriculture or intensification of agriculture on land currently used for production leads to increased emissions of carbon from the vegetation removed in the conversion process and subsequently from the soil (e.g., Donigan *et al.*, 1995). Thus, the overall rate of carbon emissions from LUCC is likely to be maintained at current levels or increase for the foreseeable future.
- *Ecosystem physiology*: the GCTE synthesis analyzed the following factors:

  1. CO_2 fertilization, which is not likely to be as strong as earlier predicted;
  2. nitrogen deposition, which is likely to continue to act as a fertilizer for northern hemisphere forests, enhancing carbon uptake;
  3. nutrient limitations, which could be relieved as temperature increases and mobilizes nutrients through decomposition;
  4. physiological saturation, which will lead to reduced carbon uptake as global change proceeds

through a diminishing response of photosynthesis to increasing atmospheric CO_2 concentration and an increased release of carbon through decomposition as temperature increases.

- *Ecosystem structural change*: under global change, biomes will likely change through enhanced mortality of their current vegetation followed by establishment of a new vegetation assemblage. Mortality results in a fast release of carbon to the atmosphere while uptake of carbon by the new vegetation assemblage is a slower process. This mismatch in rates may lead to a significant transient pulse of carbon to the atmosphere (e.g., Smith and Shugart, 1993).

Based on likely trends in these areas, GCTE argued that the present rate of carbon uptake by terrestrial ecosystems, on a global scale, would be difficult to maintain. It projected that the terrestrial biosphere as a whole, including land used for production systems, would decrease in its ability to absorb carbon and may even become a net source of carbon sometime in the 21st century (Walker *et al.*, 1998b). This projection generated considerable controversy in the global change research community, but the results of more recent modeling studies are consistent with the GCTE projections (Cao and Woodward, 1998).

GAIM Model Intercomparisons

GAIM aims to integrate new understanding on biogeochemical cycling across the core projects. As a necessary precursor to that challenge, GAIM has first focused on compartments of the Earth System, undertaking model intercomparisons that are designed to test and improve our understanding of how important processes respond to anthropogenic perturbations.

Model intercomparisons are one of the most important of IGBP's value-adding activities. They accelerate model development by contrasting the varying degrees of success of a suite of models, which in turn leads to the identification of the causes of strengths and weaknesses of individual models. This process drives a more rational model adjustment and reformulation. In addition, model intercomparisons provide improved estimates of the uncertainty of model projections.

Below three GAIM-led model intercomparisons are described.

- *Ocean Carbon–Cycle Model Intercomparison*: the oceans are potentially the largest carbon sink on Earth, and understanding the partitioning of carbon between the oceans and the atmosphere is crucial to projecting future radiative forcing of climate. GAIM's ocean model intercomparison aims to improve 3D marine carbon cycle models for use in predicting future ocean–atmosphere partitioning of CO_2, and provide estimates of important but poorly known quantities relevant to the marine carbon cycle, such as new production, aphotic zone remineralization, and anthropogenic CO_2 fluxes and inventories. The first phase of the intercomparison forced the models with the history of pCO_2 change from 1765 (pre-industrial) to the present, based on ice core records and direct measurements. The results of the four models which participated in the project showed a good agreement on the overall oceanic uptake of carbon (a range of $1.5–2.2\,Pg\,C\,year^{-1}$), but they differed by more than 100% in their simulation of uptake of anthropogenic CO_2 by the Southern Ocean. This is a crucial shortcoming as the Southern Ocean is the largest oceanic sink of carbon and a good understanding of the processes and patterns of carbon uptake in this vast region is essential for projecting future atmospheric concentrations of CO_2. Comparison of the model output with measurements of pCO_2 (see the section on JGOFS pCO_2 Measurements) will also be important in improving model performance.
- *Atmospheric Transport Model Intercomparison*: the ultimate aim of this model intercomparison is to diagnose and quantify the uncertainty in inversion calculations of the global carbon budget due to errors in simulated transport. The first phase of the project, involving 12 atmospheric transport models, simulated the response of atmospheric CO_2 to anthropogenic emissions and to seasonal exchange with the biosphere. The results showed surprising variation in the interhemispheric concentration difference (a measure of transport of CO_2 from the Northern to the Southern Hemisphere) and in the simulation of the annual mean response to the biosphere exchange. Phase 2 of the project was based on intercomparison of the distribution of sulfur hexafloride (SF_6), which has slowly varying sources, no sinks (unlike CO_2), and is fairly well observed around the world. Evaluation of the outcomes of both phases suggests that the variation of the North–South gradient at the surface (where CO_2 concentration is measured) is not controlled primarily by interhemispheric mixing but rather by vertical mixing, which occurs at unresolved spatial scales and must be parameterized in the models. The third phase will intercompare inversion calculations of the atmospheric CO_2 budget, which estimate carbon fluxes from the observed distribution of measured atmospheric CO_2 concentrations. In the post-Kyoto era with its emphasis on terrestrial carbon sinks, such inverse calculations can lead to controversial estimates of regional sink strengths (e.g., Fan *et al.*, 1998). The GAIM-led intercomparison of inverse calculations hopes to produce a reliable estimate of the uncertainty in these calculations, especially the degree

of uncertainty due to the modeling of atmospheric transport.

- *Global Net Primary Productivity*: although net primary productivity (NPP) cannot be easily equated to long-term carbon storage in terrestrial ecosystems, it is a critical process in evaluating the role of the terrestrial biosphere in Earth System functioning. The GAIM NPP intercomparison, carried out in conjunction with GCTE and DIS, is the largest and most ambitious model intercomparison carried out in IGBP. It involved 17 modeling groups, two intensive workshops (in 1994 and 1995) and extensive analysis and interpretation following the formal intercomparisons. The biospheric productivity models participating in the project are complex. They relate geographically specific and comprehensive estimates of solar radiation, temperature and precipitation to the basic biospheric processes of photosynthesis, growth and maintenance respiration, water and nitrogen fluxes, allocation of assimilates within ecosystems, and the production and decomposition of litter. In addition to the driving variables of climate and radiation, soil characteristics and vegetation structure also have strong influences on the simulation of NPP, and these must either be specified or, in the case of vegetation structure for some models, simulated. The models simulated a global NPP of the terrestrial biosphere from 39.9 to 80.5 Pg C year^{-1} with an average of 54.9 Pg C year^{-1}. Despite the very significant differences in model philosophies and formulations, there was surprisingly good agreement on this value, leading to speculation that perhaps explicit or unconscious calibration to an assumed global NPP has occurred. It was significant that four of the six models which included nutrient constraints on NPP predicted lower global NPP values than the other models, and four of the six models which used a vapor pressure deficit calculation to determine NPP projected a higher global NPP. An important next step is to compare the model output with measured NPP, and to facilitate this, GAIM has begun the global primary production data initiative to collect observed estimates of NPP and to develop improved methodologies for acquiring and distributing these data.

IGBP-wide Integration and Synthesis Activities

As IGBP matures and more pieces of global change research yield new understanding in specific areas, there is more incentive to put the pieces of the puzzle together in new ways. Thus, integration and synthesis activities among sets of core projects, and across the program as a whole, are playing an increasingly important role in IGBP science.

BAHC Earth System Modeling

A first attempt to integrate the major components of the Earth System within a modeling framework is the development of intermediate complexity models to simulate Earth System functioning, undertaken by BAHC in collaboration with GAIM (Ganopolski *et al.*, 1998). The initial model, developed at the Potsdam Institute of Climate Impact Research, consists of coarse resolution but fully coupled atmospheric, oceanic and terrestrial vegetation components. The model can be run holding each of the components static in turn to determine the impacts of each component individually, and of two and three components synergistically. The results for present-day climate forcing and for the orbital forcing of 6000 years ago are striking. They show that the earlier notion that the atmosphere and oceans together largely determine climate and that the terrestrial biosphere is mainly a recipient of, rather than a player in, climate change is most likely wrong. In both time frames, the climate simulated when all three components are fully dynamic and interactive is much closer to the observed climate than when any component is held constant. The terrestrial biosphere is thus an important player in global climate, synergistically with oceans and climate. In particular, the results show the importance of a warming-driven northward expansion of boreal forest in the northern high northern latitudes leading to further warming via vegetation–snow–albedo feedback, and strong positive feedback between vegetation and precipitation in the Sahara region. In a broader sense, the simulations suggest that the Earth system may exist in semi-stable states, with sharp transitions between the states, a phenomenon that also features in ice core records (e.g., Alley *et al.*, 1993).

IGBP Terrestrial Carbon Working Group

Comprised of representatives from BAHC, GAIM, GCTE, IGAC and LUCC, the IGBP Terrestrial Carbon Working Group is an example of IGBP's ability to assemble multi-disciplinary teams on short notice to tackle pressing problems integrating science and policy. The working group was formed in March 1998 at a joint GCTE/LUCC Open Science Conference, it met in Stockholm in late April 1998, and produced in May 1998 an authoritative commentary on the implications of the science of the terrestrial carbon cycle for the Kyoto Protocol (IGBP Terrestrial Carbon Working Group, 1998). The paper was produced on a rapid timeframe as input to an important meeting of the Subsidiary Body on Scientific and Technical Advice to the Framework Convention on Climate Change.

The objective of the working group was to analyze our current understanding of the terrestrial carbon cycle, and, based on that understanding, provide an informed commentary on the implications of the Kyoto Protocol. The

Table 2 IGBP/DIS Land Cover Classi cation

1. Evergreen needleleaf forests: lands dominated by trees with a percent canopy cover >60% and height exceeding 2 m. Almost all trees remain green all year. Canopy is never without green foliage
2. Evergreen broadleaf forests: lands dominated by trees with a percent canopy cover >60% and height exceeding 2 m. Almost all trees remain green all year. Canopy is never without green foliage
3. Deciduous needleleaf forests: lands dominated by trees with a percent canopy cover >60% and height exceeding 2 m. Consists of seasonal needleleaf tree communities with an annual cycle of leaf-on and leaf-off periods
4. Deciduous broadleaf forests: lands dominated by trees with a percent canopy cover >60% and height exceeding 2 m. Consists of seasonal broadleaf tree communities with an annual cycle of leaf-on and leaf-off periods
5. Mixed forests: lands dominated by trees with a percent canopy cover >60% and height exceeding 2 m. Consists of tree communities with interspersed mixtures or mosaics of the other four forest cover types. None of the forest types exceeds 60% of landscape
6. Closed shrublands: lands with woody vegetation less than 2 m tall and with shrub canopy cover >60%. The shrub foliage can be either evergreen or deciduous
7. Open shrublands: lands with woody vegetation less than 2 m tall and with shrub canopy cover between 10 and 60%. The shrub foliage can be either evergreen or deciduous
8. Woody Savannahs: lands with herbaceous and other understory systems, and with forest canopy cover between 30 and 60%. The forest cover height exceeds 2 m
9. Savannahs: lands with herbaceous and other understory systems, and with forest canopy cover between 10 and 30%. The forest cover height exceeds 2 m
10. Grasslands: lands with herbaceous types of cover. Tree and shrub cover is less than 10%
11. Permanent wetlands: lands with a permanent mixture of water and herbaceous or woody vegetation that cover extensive areas. The vegetation can be present in either salt, brackish, or fresh water
12. Croplands: lands covered with temporary crops followed by harvest and a bare soil period (e.g., single and multiple cropping systems). Note that perennial woody crops will be classi ed as the appropriate forest or shrub land cover type
13. Urban and built-up: land covered by buildings and other structures. Note that this class will not be mapped from the AVHRR imagery but will be developed from the populated-places layer that is part of the Digital Chart of the World (Danko, 1992)
14. Cropland/natural vegetation mosaics: lands with a mosaic of croplands, forests, shrublands, and grasslands in which no one component comprises more than 60% of the landscape
15. Snow and ice: lands under snow and/or ice cover throughout the year
16. Barren: lands exposed to soil, sand, rocks, or snow and never having more than 10% vegetated cover during any time of the year
17. Water bodies: oceans, seas, lakes, reservoirs, and rivers. Can be either fresh or salt water bodies

working group pulled together IGBP and related research on the terrestrial carbon budget, the processes that control the terms in the budget, methodologies for measuring changes in terms of the budget and their implications for carbon accounting techniques, and the long-term dynamics of the terrestrial carbon cycle.

The formation of the working group and the publication of the critique of the Kyoto Protocol was the first stage in the formation of an IGBP-wide working group on the carbon cycle, adding the coastal, atmospheric and marine components to the existing terrestrial group. The objectives of the combined working group are to produce an up-to-date understanding of the carbon cycle as a whole, emphasizing and synthesizing the work within IGBP core projects on the carbon cycle, and to develop an agreed framework for a coordinated international, long-term effort on the dynamics of the global carbon cycle.

DIS Land Cover Classi cation

An integrating activity of a different type is the production by DIS of a land cover classification scheme for wide use in IGBP's terrestrially-oriented core projects. The lack of a common classification scheme for vegetation (e.g., biome classification) or land-cover often vitiates global change research on the terrestrial surface. Global vegetation models often define their own schemes, which are different from those adopted for remotely sensed databases, which in turn are invariably different from those of *in situ* databases. Intercomparison of models or comparison of models with databases is virtually impossible. DIS is attempting to rectify this situation within the IGBP family by the development of a single classification scheme, based on broad consultation with IGBP core projects (see Table 2). As part of the GCTE synthesis, this new classification scheme was used to compare global vegetation

and land cover models with each other and with databases (Walker *et al.*, 1998b).

TRENDS IN IGBP SCIENCE

As the more mature IGBP core projects (BAHC, GCTE, IGAC, JGOFS, PAGES) reach a decade of research, some underlying trends in global change science are becoming apparent:

- The original IGBP core projects were largely organized around compartments of the Earth system – the atmosphere (IGAC), the oceans (JGOFS), the terrestrial land surface (GCTE) and the coastal zone (LOICZ). As the research has progressed, however, there is growing interest in the interfaces between these compartments and in processes that move materials and energy between the compartments. Examples include the exchange of trace gases between the lower atmosphere and upper oceans, a corresponding exchange between the terrestrial biosphere and the troposphere, and the lateral transport of materials from inland terrestrial ecosystems through the coastal zone to the coastal seas.
- The original emphasis within IGBP was almost exclusively on fundamental Earth System science; only GCTE had a significant component (Focus 3: Global Change Impact on Agriculture, Forestry and Soils) on the biophysical consequences of changes in the Earth System to sectors of importance for human well-being. As IGBP has evolved, there is now a stronger emphasis on impacts and consequences of global change, building on a continuing solid core of basic Earth system science. All of the newer core projects – LOICZ, LUCC, and GLOBEC – have major components on impacts, and two of the older core projects – BAHC and IGAC – are placing much more emphasis on impacts of changes to their components of the Earth System (on water resources and on the human and ecosystem health effects of global atmospheric pollution, respectively) as they restructure.
- WCRP was founded nearly a decade before IGBP, with an obvious focus on the climatic part of the Earth System. As the IGBP core projects have matured and the relationship of climate and Earth System science has been more clearly recognized, collaborative research between IGBP and WCRP core projects has intensified. Examples include the Global Energy and Water Cycle Experiment (GEWEX), the BAHC work on the hydrological cycle, the joint WOCE/JGOFS oceanic cruises, the rapidly expanding interaction between the SPARC (Stratospheric Processes and their Role in Climate) and IGAC, and the development of joint work on climate variability involving the CLIVAR (Climate Variability Research Project) and PAGES. See Box 1.
- At the inception of IGBP, the human dimensions were recognized as a critically important aspect of global change but the international framework for a social science global change research program was not yet in place. By the late 1990s, however, the IHDP had developed rapidly into a focused, well-defined international research effort. Interfaces between IGBP and IHDP have subsequently developed strongly.
- The regional perspective on global change has gained prominence in the last several years as the policy and resource management implications of global change research have become increasingly appreciated. Impacts and adaptation are largely considered at regional and national, not global, scales. See Box 2.

THE FUTURE OF THE IGBP CORE PROJECTS

Over the 1998–2001 period, IGBP undertook a major integration and synthesis of its first decade of research. Each of the mature core projects – BAHC, GCTE, IGAC, JGOFS and PAGES – completed a synthesis of its area of global change science, with GCTE's effort being an update of an earlier synthesis (Walker *et al.*, 1998a). In addition to the core project efforts, there was an IGBP-wide synthesis, on the theme of the Earth System as an integrated whole. In each of the themes, the synthesis addressed both the fundamental Earth System science and the impacts and consequences for human societies.

As an integral part of the synthesis effort, the structure of IGBP is evolving to address the needs of the first

Box 1 Collaborative programs between IGBP and IHDP

Examples include joint work between IHDP's Global Environmental Change and Human Security (GECHS) program and IGBP on water resources (with BAHC) and on food security (with GCTE, LOICZ and GLOBEC), as well as interaction between the Institutional Dimensions of Global Environmental Change (IDGEC) core project of IHDP and LUCC and GCTE. LUCC itself is jointly sponsored by IGBP and IHDP.

Box 2 Examples of integrated regional programs within IGBP

Many core projects are now involved in integrated regional projects under the auspices of START, and several of the core projects - LOICZ, LUCC and GLOBEC - have a strong regional orientation to their implementation strategies. The IGBP Terrestrial Transects program is a good example of a regional approach to global change research, employing many of the value-adding activities described above (Koch *et al.*, 1995; Steffen *et al.*, 1998).

decade of the 21st century. The restructure will evolve naturally as the synthesis proceeds, based on the new scientific understanding and the new questions and gaps generated by the synthesis, taking into account the trends described above. Thus in the coming decade, the core projects within IGBP will almost surely be considerably different from the configuration of the 1990s, reflecting the changing scientific demands of a dynamic research program.

Impacts of Global Environmental Change on Animals

JOEL G KINGSOLVER

University of North Carolina, NC, USA

Global change represents a diverse assortment of human-induced environmental changes that collectively impact animals around the globe. These diverse environmental changes will necessarily have diverse biological impacts on the millions of species of animals alive today. Recent studies of fossil vertebrates suggest that human colonization and population expansion has been causing extinctions over the past 10 000 years and more: even small human populations with stone-age technology can be suf cient to elevate extinction rates. These effects have been greatest for endemic and ecologically specialized animals; typically habitat destruction and introduced species rather than direct human exploitation have been the primary causes of extinction. Anticipated climate change during the 21st century will alter seasonal, diurnal and latitudinal patterns of variation in temperature and precipitation. Changes in seasonal components of climate will likely be most important in determining the extent of range shifts in animals, particularly by altering the relative seasonal timing of animals and their resources or enemies. Recent evidence from butter ies, birds and other systems suggests that decadal-scale climate changes during the past century have already caused range shifts or local extinctions in some cases. Climate change will likely negatively impact animal species that are localized or habitat specialists, but will cause expanded ranges towards the poles in many generalist species, including agricultural pests. Useful predictions of climate change impacts must incorporate simultaneous effects of changes in carbon dioxide (CO_2) and seasonal temperature and precipitation. The effects of changes in climate on vector-borne diseases may depend critically on how climate alters the seasonal patterns of interactions among parasites, vectors and hosts.

INTRODUCTION

Global change is a misnomer, implying some singular alteration of the earth's physical and biological characteristics. Instead, global change is an assortment of quite diverse changes – climate change, environmental toxins, habitat loss and alteration, invading pests and pathogens, harvesting of natural resources; the common attribute of these changes is that they are the direct or indirect products of human activities, and collectively their impacts are worldwide. Clearly these different environmental changes operate at quite different characteristic scales of time and space. For example, an application of insecticide may act over days to weeks at a spatial scale of hectares; loss of habitat for a rare or endangered species or community may occur over years at local to regional scales; atmospheric carbon dioxide (CO_2) increases globally over a time scale of decades. These diverse environmental changes will necessarily have diverse biological impacts.

Similarly, the term animals refers to a natural grouping (the Metazoa) of enormous diversity – perhaps 10–100 million distinct species, each representing a unique evolutionary lineage with a distinctive set of biological and ecological characteristics. Although collectively animals inhabit the entire globe, the distribution of particular species is typically local to regional: there are few truly global species, *Homo sapiens* being one notable exception. When we consider some particular aspect of environmental change, e.g., habitat fragmentation, the responses of different animal species to such change may depend on their particular biological, ecological and distributional characteristics. What is the appropriate level of detail needed to make useful predictions about animal responses?

In this essay we will take an ecological and population perspective on the responses of animals to global changes: on how global change alters the distribution and abundance of populations and species. Environmental changes will affect the development, physiology, behavior, growth or reproduction of individual animals, but our primary concern is how these effects will impact the persistence and distribution of a population or species into the future. In this sense we will consider the biology of individuals primarily

as potential mechanisms of population-level responses. An ecological perspective also emphasizes the relationship of animal populations to their resources and to other animal species: that is, the ecological community in which the population is embedded. How important are these species interactions for ecological responses to global changes?

In this essay we will not attempt to systematically cover all of the diverse aspects of the global environment that are changing as a result of human activities. Rather, we will explore two quite different case studies that provide distinct but complementary messages about the past, present and future responses of animals to global changes. First, we will examine the early history of one globally invading species – *Homo sapiens* – and its consequences for extinctions of birds, mammals and other vertebrates during the past 100 000 years. Here we will focus on recent fossil evidence to provide some historical perspective on the roots of human-induced (anthropogenic) environmental change. Second, we will examine in some detail how weather and climate impact the distribution and abundance of animals. Here we will focus on ecological field studies of animal populations during the past century, and combine these with scenarios of global climate change to explore our capacity to predict the ecological consequences of ongoing and future climate change. Throughout the discussion we will emphasize three general themes:

1. Generalist and widely dispersive species will fare better than more specialized species in the face of environmental changes.
2. Indirect effects of environmental changes as mediated through species interactions are frequently as or more important than direct effects on individual survival or reproduction.
3. The details of the time and spatial scale of environmental change and the biology of particular species may sometimes matter critically to understanding population responses of animals.

ANIMAL EXTINCTION AND HUMAN COLONIZATION

There is abundant historical evidence that colonization and settlement by Europeans during the past 500 years has greatly increased rates of extinction of animals, and rates of extinction have accelerated as human population size and technology have exploded during the past century (Wilson, 1992). But of course most regions of the globe had been colonized by human populations prior to the past half-millenium. Only recently have we begun to understand how these earlier events in human evolutionary history may have impacted animal extinction rates. What population sizes and level of technological sophistication in human populations are required to cause substantial extinctions of animals, and what sorts of species are most likely to go extinct?

Molecular and fossil evidence suggests that modern humans (*Homo sapiens*) first emerged 100 000–200 000 years ago in Africa, then migrated out to other areas of the world. It is clear that other forms of *Homo* occurred in Europe, the Near East, Asia as well as Africa by 500 000–1 million years ago; and modern humans inhabited each of these continents before 60 000 years ago. Humans and their hominid relatives have been a part of the biological landscape of these regions for a long time.

Human colonization has been more recent for the remainder of the globe, including New Guinea, Australia and New Zealand, the Pacific Islands, and North and South America. Human settlement of these differing areas occurred at different times, thus providing a series of natural experiments to explore the rates of extinction following the appearance of humans. We shall first consider recent evidence about extinctions of birds on Pacific Islands, and then examine extinctions of vertebrates more generally on the continents of Australia and North America.

Bird Extinctions on Pacific Islands

There are more than 800 major islands in the Pacific Ocean; nearly all of these were initially colonized by humans during the period from 35 000 to 1000 years ago. Many of these islands are small, and some island groups (e.g., Hawaii, Easter Island) are quite isolated. As a result, the land birds on many islands are highly endemic: many species occur on only a single island or island group. There have been repeated evolutionary radiations of finches (including the Hawaiian honeycreepers and the Galapagos finches), ibises, parrots, pigeons and doves, and ightless species of ducks, geese and rails. Many of the larger islands possess lava tubes or limestone caves as well as archaeological sites, that in the past two decades have provided a new picture of past and present bird diversity on Pacific Islands (Steadman, 1995).

Islands in the Kingdom of Tonga in western Polynesia were settled by humans before 3000 BP (before present). Caves on Eua and other islands within Tonga have yielded substantial bird fossils both before and after human settlement. During the 10 000 years prior to human settlement (a period of substantial climate and sea-level changes), there were virtually no changes or extinctions in bird species on Tonga. However, the majority of endemic birds went extinct in the period following human settlement: e.g., of 27 land bird species known from prehuman times, only six survived into the past two centuries (the historical period) (Steadman, 1995). The losses were particularly heavy among ground-dwelling and forest-dwelling species, probably re ecting predation by humans and by mammals introduced by humans, especially rats, dogs and pigs. In fact, archaeological sites suggest that native birds, especially pigeons,

doves and rails, were a major part of the diet for early human settlers on these islands. Similar patterns of extinction are seen on the Cook Islands and other east Polynesian islands; in addition, many species remaining today have much more restricted geographic distributions than prior to human settlement (Steadman, 1995).

The isolation and ecological diversity of the Hawaiian Islands generated many unique and endemic groups of plants and animals, including birds, which evolved quite independently from related groups in the Polynesian heartland. The prehistorical fossil record for land birds on Hawaii, which was first settled about 1500–2000 BP, is extensive and has been well studied (Olson and James, 1982). About 60 species of endemic land birds went extinct in the period following human settlement (1500–200 BP); another 20–25 species have gone extinct during the past two centuries. These losses were particularly great for ightless ducks, geese and rails and for the honeycreepers and other finches. The extinctions likely have a variety of causes, including predation or disturbance by humans and other introduced mammals (rats and pigs), deforestation and agriculture, and invasion by new diseases (including malaria) and generalized birds (including crows).

One thousand years ago, New Zealand possessed a diverse endemic bird fauna including kiwis, many waterfowl and 11 species of large, ightless moas. The earliest human settlements on New Zealand by Polynesian colonists date to the 13th century AD (Holdaway and Jacomb, 2000); European settlement began in the 19th century AD. At least 44 endemic land bird species have become extinct since human settlement, including 27 of the 50 land birds on the South Island. A recent analysis of archaeological sites and demographic modeling of the moas of New Zealand suggest that these large ightless birds went extinct only 100–200 years after Polynesian settlement, as a result of habitat destruction and human predation on moa eggs and adults (Holdaway and Jacomb, 2000). Some of the 14th century archaeological sites reveal large quantities of moa bones, representing several hundred tons of moa meat, during the first several decades after settlement. Demographic models suggest that moas were probably particularly susceptible to extinction, because they were long-lived, slow to reach reproductive maturity, and had long reproductive rates (Holdaway and Jacomb, 2000).

This pattern of human settlement followed by elevated extinction rates of endemic birds is largely from remote Pacific Islands (Steadman, 1995). However, there is also evidence that similar effects may occur in larger and less isolated islands. For example, New Ireland in Papua New Guinea is a large, heavily forested island off the Huon Peninsula of New Guinea. It has been occupied continuously by humans for the past 35 000 years. Recent archaeological studies suggest that 20–30% of the more than 100 endemic bird species of New Ireland went extinct since human settlement (Steadman *et al.*, 1999). Most of the extinctions occurred between 10 000 and 18 000 BP, though some extinctions were more recent (1000–5000 BP). Although much of the extinction occurred well after first human settlement, it is likely that humans played a major direct or indirect role in the extinctions, probably as a result of habitat disturbance and predation by humans, pigs, dogs, rats and other introduced mammals (Steadman *et al.*, 1999).

The clear picture that emerges from these studies is that the colonization of islands by prehistoric humans repeatedly accelerated extinction rates of endemic birds, even when human population sizes were quite small. In some cases direct human predation was a major factor, but in most cases indirect effects, primarily habitat destruction and the accidental or intentional introductions of rats, pigs, chickens, dogs and other animals, were probably the dominant causes. Extinction rates were highest, up to 50–90% of land bird species, in smaller and more remote island groups; however, there is some evidence that accelerated extinctions also occurred on larger and less remote islands.

Islands are special places, both ecologically and evolutionarily. Because of their small size and isolation, islands tend to have relatively fewer species and more endemic species than continental regions; they sometimes lack large predators and other key players that may have disproportionate effects on animal communities. In this sense, the ecological disruption and species extinctions on small, remote islands caused by small, prehistoric human settlements may not be so surprising; and perhaps these lessons about human colonization and extinction simply do not apply to large, continental regions. How could small bands of humans armed with stone tools cause widespread extinctions on a continent? To address this, we shall consider extinctions of large vertebrates on Australia and North America.

Late Pleistocene Extinctions on Continents

It has been known for more than a century that Australia suffered major losses of its terrestrial vertebrates during the Pleistocene. Larger species were particularly affected. Recent analyses suggest that more than 85% of all Australian land genera with a body mass exceeding 44 kg became extinct during the late Pleistocene, including all 19 marsupial species greater than 100 kg (Miller *et al.*, 1999). These large vertebrates are sometimes called the Australian megafauna. In total about 60 vertebrate species became extinct, including large varanid (monitor) lizards, horned tortoises, and an 80–100 kg ightless bird, *Genyornis newtonii*; two somewhat smaller ightless birds, the emu and the cassowary, survived.

Humans first settled parts of Australia by about 55 000 BP. However, the timing of the Pleistocene extinctions of

Australian megafauna was unresolved until the development of new methods for dating these fossils. One recent study used analyses of fossil eggshell fragments, which are easily identified to species, abundant, and readily dated, to explore changes in abundance of *Genyornis* and emus over time from three different sites in Australia (Miller *et al.*, 1999). Analyses of more than 1200 shell fragments show that *Genyornis* was abundant 60 000 BP, but declined and disappeared suddenly at ~50 000 BP at all three sites. By contrast, emus were present continuously throughout the period in which *Genyornis* became extinct. Because *Genyornis* fossils are often associated with some of the youngest deposits containing remains of other large vertebrates, Miller *et al.* (1999) argue that the extinction of the Australian megafauna also occurred ~50 000 BP.

The rapid extinction of *Genyornis* within a few thousand years following human settlement clearly supports the idea that humans directly or indirectly contributed to the extinction of *Genyornis* in particular, and perhaps the Australian megafauna in general. However, only a single archaeological site provides clear evidence for direct predation by humans on *Genyornis*; this is also the case for other Australian megafauna. The main alternative hypothesis proposed for these extinctions has been climate change. However, 50 000 years ago Australia was experiencing only mild climatic cooling. By contrast, the last glacial maximum occurred about 20 000 BP, during which temperatures in Australia were up to 9 °C cooler than present, and much of the Australian continent was very arid. If climate change led to the extinction of the large, ightless *Genyornis* in Australia 50 000 BP, then one must explain why the large ightless moas of nearby New Zealand were unaffected, and thrived until just 800 years ago.

Of course, Australia was not the only continent to suffer megafaunal extinctions during the Pleistocene: major mass extinctions of large mammals occurred in both North America and northern Eurasia at the end of the Pleistocene between 12 500 and 10 000 BP. The extinctions in North America have been particularly well studied (Pielou, 1991).

The Pleistocene climate was dominated by the wax and wane of glaciation, and for much of the past 100 000 years, most of northern North America was covered by two major ice sheets, the Laurentide in the east and the smaller Cordilleran in the west. South of the ice sheets, a diverse and abundant endemic fauna of large mammals ourished, including mammoths and mastodons, sabertooth cats and American lions, five species of endemic horses, and giant ground sloths and beavers. There was also a large ice-free region known as Beringia, in the area that is now Alaska and the Yukon Territory, to the north and east of the Cordilleran Ice Sheet; during this period this region was connected to eastern Siberia via the Bering Land Bridge.

The last glacial maximum occurred about 20 000 years ago. These ice sheets largely disappeared during the subsequent 10 000–12 000 years following the glacial maximum; the retreat of the ice sheets to the north was particularly rapid between 14–12 000 BP. The melting of the ice was associated with increasing average temperature and increasing atmospheric CO_2 during this time. However, there was substantial periodic variation in temperature during this overall warming, that generated alternating warming and cooling cycles with a period of about 2500 years.

The diverse megafauna south of the ice sheets suffered major extinctions between 12 000 and 10 000 BP. More than 70% of all mammal species larger than 44 kg – a total of 35 species – went extinct during this period. The dramatic changes in both climate and vegetation in North America between 20 000 and 10 000 BP may have caused extinctions of large mammals at the end of the Pleistocene. However, global climatic warming had another, more indirect effect: the melting of the ice created an ice-free corridor between the Cordilleran and Laurentide sheets about 14–12 000 BP, allowing migration of animals and plants between Beringia to the north and the areas south of the ice sheets. Among the early migrants were humans, who migrated from Beringia into North America by 11 500 BP. Did these early human settlers cause the mass extinctions of large mammals in North America 12 000–10 000 BP?

One proposal, sometimes called the overkill hypothesis, suggests that direct predation by human hunters on large herbivores caused the extinctions. Hunting of large game was an important aspect of the lifestyle and diet of these early American colonists. One intriguing pattern in the North American megafaunal extinctions is that most of the species that went extinct, including mammoths, mastodons, shrub oxen and woodland muskoxen, evolved *in situ* south of the ice sheets: these species did not share a recent history of exposure to humans (Martin and Klein, 1984). By contrast, most of the species that survived the extinctions, including elk, moose, deer, caribou and muskox, were species that had immigrated from eastern Asia during the late Pleistocene, and hence shared their evolutionary history with humans. One interpretation of this pattern is that species that had not been previously exposed to humans were more vulnerable to human hunting and were more readily driven to extinction.

A major challenge for the overkill hypothesis is the lack of late Pleistocene archaeological sites in North America that possess remains of extinct mammals. In addition, most estimates indicate that human population sizes south of the ice sheets during this time were quite small. How could a few thousand human hunters with stone tools exterminate millions of large mammals so rapidly, and without leaving extensive evidence of the slaughter? It is also possible that the effects of humans were more indirect, e.g., as a result of introducing new diseases or parasites. Although the precise

causes of these extinctions remain unclear, there is now strong evidence that the colonization of both Australia and North America by human settlers was quickly followed by widespread extinctions of large vertebrate species.

PAST AND FUTURE CLIMATE CHANGE: HOW WILL ANIMALS RESPOND?

While global climate change has waxed and waned over the past 100 000 years, the human population expansion and colonization has continued unabated. In the past several centuries, the biological consequences of human population growth have been amplified by technological changes that have greatly accelerated rates of habitat and natural resource exploitation by humans. One of the many consequences of this exploitation has been increases in atmospheric CO_2 and other greenhouse gases that are expected to increase global mean temperatures during the coming decades. Evidence that such anthropogenic climatic warming has already begun is increasing: more importantly, nearly all present data and models concur that global mean warming of $1-4\,^{\circ}C$ will occur during the 21st century. What will be the biological consequences of global warming, given the backdrop of other anthropogenic environmental changes?

Studies of past climate changes offer several important lessons for predicting animal responses. First, climatic warming and cooling have occurred repeatedly in most geographic regions during the past one million years, at a variety of time scales. Recent studies have demonstrated that regional climate may change very rapidly on the scale of decades to centuries. For example, oxygen isotope records from lake sediments and ice cores indicate a nearly $7\,^{\circ}C$ increase in mean temperature over a 50 year period about 10 700 years ago (Houghton, 1997). Thus, most current animal species have experienced rapid climatic changes during their recent evolutionary histories. Second, palaeontological studies suggest that species respond individualistically, not as communities, in response to climate change. For example, mammals in North America and beetles in Britain show complex patterns in changes in geographic distribution following the climatic warming that started about 18 000 years ago, rather than straightforward northwards shifts in all species. As a result, predicting responses to climate change must begin by considering the characteristics of species.

Another important lesson is that climate change is much more than a simple change in global mean temperature. The predictions from global circulation models (GCMs) are in general consensus about several key ways in which greenhouse gases will alter climate (Houghton, 1997). First, warming will be greater at higher northern latitudes than at lower latitudes. Second, warming will be greater in winter than in summer, especially at higher latitudes. Third, diurnal temperature variation will be reduced, primarily because of increased nighttime temperatures in most seasons and geographical regions. Fourth, the mean and variability of global precipitation will increase, with greater winter precipitation at higher latitudes.

The message from these consensus predictions is that climate change will have greater effects on low temperatures than high temperatures, and will generally reduce diurnal, seasonal and latitudinal variation in temperature. A main theme of the rest of this essay is that patterns of variation in temperature, rather than mean temperature *per se*, are key to understanding the effects of climate on animal distributions.

Climate and the Distribution and Abundance of Animal Species

The traditional approach to understanding plant and animal distribution involves mapping the geographic distribution of a species (or community) onto the distribution of environmental factors. These environmental factors may be either physical or biological. By identifying critical values of environmental factors that coincide with particular geographic boundaries, one can develop hypotheses about biological or ecological characteristics of the species in relation to environment that may limit the species at the boundary. Correlations between species distributions and climatic factors have been widely identified for animals. For example, Root (1988) noted that the northern limits of the winter distributions of many North American birds coincide with particular isotherms of average minimum winter temperatures. Root used these associations to propose that the energy balance between food intake and metabolic output at cold temperatures was a major determinant for northern winter range boundaries in such species. A variety of statistical approaches have been used to quantify the associations between species distribution and climatic variables for many animals (Dennis, 1993; Rogers and Randolph, 1993); and most quantitative predictions about the effects of climate change on species distributions are based primarily on such statistical associations.

Although this is an appropriate starting point for predictions, there are several important problems with this traditional approach (Crozier, 2001; Parmesan *et al.*, 2001). First, as noted above there are many components of climate at a location involving mean, extreme and patterns of variability in temperature, precipitation and radiation at diurnal, seasonal and annual time scales; in the absence of biological information about the species, it is not clear which (if any) of these many components should be considered. The problem is compounded by the fact that many aspects of climate are strongly correlated spatially. Because geographic distribution of a species is by definition limited spatially, spurious correlations between range boundaries and climatic factors are likely to occur in the absence of

any causal relationship. Second, the approach implicitly assumes the species boundaries are in fact limited directly by (and in equilibrium with) climatic factors, rather than by (for example) food resources, habitat requirements, or other biological factors. Put another way, it assumes that each species occupies its entire fundamental niche (with respect to climate), so that changes in climate should directly translate into changes in geographic distribution. As a result, predictions based on the traditional approach are likely to be in error if (as detailed above) different aspects of climate change in different ways, or if species and their limiting resources or habitats respond to climate in different ways.

How do we identify those aspects of climate that determine the geographic boundaries of a species? I suggest that in many animals, specific seasonal components of climate acting at key stages in the life cycle are frequently primary determinants of species boundaries (*see* Phenology, Volume 2). Let us explore this suggestion using several examples from studies with butter ies in Great Britain. Butter ies may be of particular interest for studies of climate change, because they are important ecological indicators of diverse habitats, they are quite sensitive and responsive to weather variation, and in many areas their distributions, abundance and ecology are well known and routinely monitored (Pollard and Yates, 1993). In the first half of the 20th century, the White Admiral Butter y, *Ladoga camilla*, underwent a substantial northern and western extension of its range in southern Britain (Dennis, 1993). The expansion into new areas occurred primarily during the 1930s, a decade which experienced unusually warmer weather during the months of May–July. Detailed population studies near the range edge suggested two main causes of this effect of weather on butter y abundance and range extension. First, warmer conditions in June accelerated rates of larval and pupal development, reducing predation and mortality during this period. Second, warm, sunny weather in July increased the time available for ight and oviposition, increasing the eggs laid by females. Importantly, other components of weather appeared largely uncorrelated with population abundance and the range extension of White Admirals.

Subsequent analyses suggest seasonal weather effects may be important for much of the British butter y fauna (Dennis, 1993). For example, mean daily temperatures during June and July were the best predictors of butter y abundance in more than 80% of species surveyed. Demographic studies that indicate the direct effects of temperature and solar radiation on oviposition rates are probably most important in determining population abundance. Similar effects of diurnal mean temperatures and sunshine on ight activity, oviposition and population abundance have also been documented for North American butter ies (Kingsolver, 1989).

Minimum winter temperatures may also be important in determining range boundaries in insects, especially in species that lack adaptations to extreme cold. For example, the Sachem Skipper is a generalist, southern species that lacks freeze tolerance (Crozier, 2000). It has shifted its northern range boundary northwards by ~500 km into the Pacific Northwest US during the past 50 years. During this time the mean minimum January temperature has increased by ~2.5 °C in the Pacific Northwest (Crozier, 2000). Recent laboratory and field experiments suggest that over-wintering mortality is a major factor limiting Sachem populations near the current range boundary (Crozier, 2000). Because minimum winter temperatures are expected to increase more rapidly than other aspects of climate, this may be a particularly important type of animal response to climate change in cold-sensitive species.

Another important way that climate affects distribution and abundance is through effects on the timing of key life history events in relation to environmental factors and limiting resources (Harrington *et al.*, 1999). For example, for herbivorous insects the phenological timing between insect life cycle and plant resources is critical. In temperate regions, many insects over-winter in a diapause stage, and emergence from diapause is cued by photoperiodic and temperature conditions. For herbivores, the timing between emergence from diapause and the growth and development of host-plant resources is a major determinant of population success. Demographic studies with temperate butter ies show that caterpillars are impacted by seasonal weather in three important ways: by weather effects on the early growth of host-plant resources, by the direct effects of temperature on caterpillar growth, and by the timing of host-plant senescence. Because weather variation can have differing effects on plant growth and senescence than on insect growth and development, this can lead to phenological mismatches between plant and herbivore and cause high larval mortality and even local population extinction (Harrington *et al.*, 1999; Singer and Thomas, 1996). Similarly, in winter moths, an important forest pest, temperature has differing effects on the timing of larval emergence and budburst in Sitka spruce, a major host-plant, that may lead to phenological mismatches in response to climate change. However, the effects of climate on the timing of plants and herbivores may vary markedly among systems. For example, orange-tip butter ies in Britain diapause as pupae, emerging in spring to lay their eggs on the ower heads of their main host-plant, garlic mustard. Long-term survey and climatic data from Britain show that spring temperature variation has very similar effects on the timing of butter- y emergence and host-plant owering (Harrington *et al.*, 1999).

Analogous effects of climate on the phenology of breeding and reproduction in birds in relation to their food resources are also likely. For example, studies of great

tits (*Parus major*) in Western Europe indicate that nestling survival depends strongly on the abundance of winter moth larvae during the nesting period (van Noordwijk *et al.*, 1995). However, at high temperatures larval development rates are accelerated such that caterpillar abundance and the nesting period do not coincide, leading to higher chick mortality. Similar effects are likely to be particularly important for migratory birds that breed at higher latitudes, where breeding seasons may be very short, and where climatic warming is predicted to be greatest.

Shifts in relative phenology can arise when the climate has differing effects on the life cycles of animals and their food resources. More generally, analogous effects can occur whenever animals and their natural enemies respond differently to climate. For example, field studies and models of aphid pests and their ladybird beetle predator indicate that the outcome of predator–prey interactions can depend on temperature (Kingsolver, 1989). At low temperatures, predation rate is low relative to aphid development and reproduction, leading to rapid increases, in aphid abundance. However, as temperature increases, predation rate increases more rapidly than aphid development, leading to a decline in aphid abundance. These kinds of effects may occur widely with sedentary prey and actively foraging predators, when temperature has differing effects on (prey) growth and development than on (predator) foraging and prey capture (Harrington *et al.*, 1999; Kingsolver, 1989). Similarly, laboratory microcosm experiments with *Drosophila* illustrate how temperature can also affect the outcome of interspecific competition in ways that cannot be predicted solely from the responses of individual species to temperature (Davis *et al.*, 1998).

Our discussion so far has focused on effects of seasonal temperature and precipitation on interactions of animals and their food resources. The direct effects of CO_2 on plants can also alter their interactions with insect herbivores (Lincoln *et al.*, 1993). Experimental increases in atmospheric CO_2 concentration increase photosynthetic and growth rates of plants; in many plants increased CO_2 also decreases the nitrogen concentration in leaves and other tissues by up to 20–40%. Because nitrogen is frequently the main limiting nutrient for growth in insect herbivores, this has major consequences for insect feeding and growth. Watt *et al.* (1995) recently reviewed studies with 15 insect species feeding on plants grown in elevated CO_2. These studies showed that elevated CO_2 dramatically increased consumption rates of insects, often by 40% or more. Elevated CO_2 tended to decrease developmental rates and larval and pupal weights. These effects can be largely attributed to effects of CO_2 on leaf nitrogen: those plant species for which leaf nitrogen declined most strongly in elevated CO_2 had the greatest impacts on insect growth and development. Significantly, four of the seven studies to date showed that elevated CO_2 significantly decreased insect abundance, often by 30–50%.

These studies suggest that elevated CO_2 may decrease growth and abundance of herbivores. There are several important caveats, however. First, plants may acclimatize to elevated CO_2, altering the effects of CO_2 on leaf nitrogen (Lincoln *et al.*, 1993; Watt *et al.*, 1995); the insect feeding studies to date have used unacclimatized plants. Second, most studies have used leaf-feeding insects on annual plants; impacts for trees, and for sap-sucking and gall insects remain largely unexplored. More generally, the combined effects of elevated CO_2, which tends to decrease insect development rates and abundance, and increased temperature, which tends to increase insect development rates and abundance, have not been examined.

Taken collectively, these studies illustrate how specific seasonal components of climate during key life stages can dominate the responses of many species to climate change. These effects on a given animal species may occur directly, through effects of temperature or precipitation on growth, development, survival and reproduction; or indirectly by altering the timing and interactions of populations with their food resources or natural enemies. Indeed, shifts in relative phenology of animals and their food resources or enemies may be one of the most common effects of climate change for animals in seasonal environments, especially at higher latitudes (Harrington *et al.*, 1999). As a result, predicting responses to climate change will require both seasonal and geographic details of climate, and biological information about how climate determines distribution and abundance. Approaches that combine quantitative associations between current geographic distributions and climatic variables with demographic and phenological models of key, climate-dependent life stages will be most valuable in making quantitative predictions about responses of animal populations to climate change.

Recent Distributional Shifts and Climate Change

Geographic ranges and local abundance of animals are dynamic and may change for a variety of reasons. In addition, climate may change at a variety of temporal and spatial scales. Attempts to show that the geographic distribution or abundance of a given species has changed in response to climate change must do so against the backdrop of other natural and anthropogenic changes that are occurring. Nevertheless, there are clear indications that climatic warming events during the past century have caused species shifts in some cases. Once again, the evidence is most abundant for butter ies and birds in North America and Europe, for which we have substantial long-term geographic databases at the species level.

Parmesan (1996) provided a detailed analysis of range shift in Edith's Checkerspot butter y, which occurs in discrete local populations in western North America from

Mexico to southern Canada. During the past century, the probability of successful establishment of new populations has been highest in the northern part of the range, whereas the probability of population extinction has been highest in the southern part of the range. As a consequence, both the northern and southern boundaries of this species have shifted to the north: the mean location of populations has shifted nearly 100 km northward. A similar shift to higher altitudes has also occurred. These distributional changes coincide with a mean annual temperature increase of about 0.7 °C for this region, which is consistent with the magnitude of the range shift. Increased frequency of drought events and shifts in relative phenologies of host-plant senescence and larval development may account for the extinctions of southern populations (Parmesan, 1996; Singer and Thomas, 1996).

A more recent analysis of range shifts of non-migratory European butter ies also suggests the effect of climate change (Parmesan *et al.*, 1999). Of 35 species whose northern and southern boundaries were considered, 63% shifted northwards; 29% were stable at both northern and southern boundaries, and only 6% shifted southwards. The northern shift is largely due to extensions of the northern boundary: only 20% of species both extended the northern boundary and retracted the southern boundary. As a result, 46% of the species considered expanded the size of their geographic ranges. Again mean annual temperature in the region has increased about 0.8 °C during the past century, which is consistent with the magnitude of range shifts in species that extended northwards. This study provides perhaps the best evidence to date that sets of animal species are shifting their geographic distributions in response to recent climate change; however the mechanisms underlying these shifts and the relevant components of climate involved are unknown.

It is important to recognize that these studies do not indicate that all temperate butter ies are shifting distributions in response to climate. For example, to focus specifically on the possible effects of climate change, the above analyses (Parmesan *et al.*, 1999) excluded the majority of European butter ies: in particular, species were excluded from consideration if they were clearly limited by narrow habitat requirements, habitat loss, low tolerance for anthropogenic habitat modification, or host-plant distribution. Detailed analyses of butter ies in Britain and Holland show that half of all species have declined in abundance and/or geographic range since the 1890s, which would not be predicted from increased mean annual temperature during this period (Dennis, 1993). One general pattern in the data from Britain is that the decline in rare or localized species is largely associated with habitat loss and degradation, whereas many common species have expanded in abundance and northern distribution (Crozier, 2001; Dennis, 1993). Indeed, some butter y species have expanded northward in Britain during the past 50 years despite a reduction in preferred habitats. The overall pattern is that rare species became rarer or more localized, whereas common species became more common and widespread.

Studies with temperate birds provide some limited evidence of range shifts in response to recent climate change. A recent analysis of distributional changes of breeding birds in Britain from 1970 to 1990 indicates that many species had shifted their northern range boundaries by an average of 19 km; southern range boundaries showed no significant shift (Thomas and Lennon, 1999). The short time period and modest extent of any range shifts limit what one can conclude from these analyses. Root (1988) and Root and Schneider (1995) examined winter distributions of North American birds during the past half century, and showed northern range expansions in many common species, particularly in the northeastern and western US. These expansions are consistent with relaxed energetic constraints associated with increases in mean January temperatures of 1–2 °C in the past half century. However, in many cases non-climatic factors are certainly involved, including habitat modification and supplemental winter feeding, making it difficult to ascertain the role of climate in these changes.

Nearly all of the research discussed thus far involves animals in temperate or high latitude regions, but several recent studies suggest effects of recent climate change in tropical mountain systems. In the Monteverde Cloud Forest Reserve in Costa Rica, 20 of 50 species of frogs and toads, including the locally endemic golden toad, abruptly declined and disappeared in 1987, following a year of unusually warm dry weather associated with the El Nino-southern oscillation (ENSO) (Pounds *et al.*, 1999). Climatic analyses suggest that increases in sea surface temperatures in the equatorial Pacific are associated with increased air temperature and decreased dry-season precipitation since 1976. During the past 15 years, multiple population crashes in frogs, toads and anole lizards, as well as changes in bird communities, have coincided with unusually warm and dry conditions during the dry season. Pounds *et al.* (1999) propose that atmospheric warming has raised the average altitude of the cloud bank for the cloud forest, reducing the frequency of mist in the dry season, and causing population declines in amphibians and some lizards. Whether these effects are due to direct effects of desiccation on mortality, or due to indirect effects from stress and susceptibility to disease, is unknown. These widespread declines in amphibians in a relatively undisturbed highland tropical forest in association with climate change are sobering, particularly in light of recent amphibian declines around the globe.

Changes in sea surface temperature associated with ENSO have been implicated in biological change in a number of marine animal systems, including reef corals, marine fisheries and pelagic birds (Lubchenco *et al.*, 1993). However, it remains unclear whether short time scale oscillations

such as ENSO provide a useful analog for predicting responses to sustained, directional climate change. Evidence from longer-term studies is now beginning to accumulate. Northward range shifts of pelagic fishes in the north Pacific over the past 30–50 years have been documented, coincident with increased mean sea surface temperatures (McGowan *et al.*, 1998). A study of intertidal invertebrates and zooplankton in the English Channel indicated that the relative abundances of warm- and cold-water species have changed with alternating periods of warming and cooling during the past 75 years (Southward *et al.*, 1995). Similarly, detailed analyses of intertidal invertebrates in California showed that the abundance of southern species increased and of northern species decreased between 1933 and 1996, associated with a nearly 2 °C increase in mean ocean shoreline temperatures during summer over the interval (Sagarin *et al.*, 1999).

This brief survey suggests that we now have widespread evidence of important changes in distribution and abundance of animals from a variety of systems that are coincident with recent climatic changes during the past 20–100 years. These studies clearly demonstrate that anticipated anthropogenic climate change in the coming century will likely have major effects on many animal species. It is important to note, however, that many of these studies have not clearly distinguished climatic effects from other anthropogenic and natural components of environmental change, and that many animals do not appear to respond substantially to decadal-scale climate changes.

Climate Change, Pests and Disease

One general pattern that emerges from the examples above is that many animal species have expanded their ranges towards higher latitudes during recent periods of climatic warming. Significantly, the majority of such cases involve relatively abundant, geographically widespread species that are not narrow habitat specialists. One important class of abundant, widespread organisms is agricultural, forest and medical pests. Weather and climatic variation is known to be important in the incidence of outbreaks of many pests and disease organisms; as a result there has been widespread interest in modeling the consequences of global climate change for pests and disease (Martens, 1998; Parry, 1990). Initial analyses suggest that under most climate change scenarios, many agricultural and disease organisms will spread into regions that are presently too cool to sustain them. For example, modeling of the European corn borer (*Ostrinia nubilalis*), a major pest of maize in Europe, predicts that climate warming could lead to northward range extensions of 200–1000 km during the next 50 years (Porter, 1995). Similarly, climate warming simulations predict that malaria, a major tropic disease transmitted by anopheline mosquitoes, could extend northwards into central or northern Europe and much of North America during the next 50 years (Martens, 1998). These and similar predictions have raised concerns about the expansion of agricultural pests and vector-borne diseases as a result of climate change.

An important caveat is that most of these predictions are based on simulated changes in temperature (and sometimes CO_2) and not other components of climate; in particular, seasonal precipitation patterns are often omitted from both parameterization and simulation of the models. Because temperature and environmental moisture may interact to affect animal distributions, this has major implications for predictions about climate change. For example, Rogers and Randolph (2000) recently estimated how the present-day geographic distribution of malaria is related to the mean, maximum and minimum values of temperature, precipitation and saturation pressure, then used the resulting statistical model to predict the future malaria distribution in response to climate change. In contrast to previous models based solely on temperature, Rogers and Randolph (2000) predict that climate change will produce only modest changes in the distribution and human exposure to malaria during the next 50 years. Their results also indicate that the covariation between temperature and moisture variables was critical in determining the distributional limits predicted by the model. A similar situation may occur for the distribution of tsetse ies, the vector for trypanosomiasis (sleeping sickness) (Rogers and Randolph 1993).

Recent detailed analyses of climate and tick-borne encephalitis (TBE) are enlightening (Randolph and Rogers, 2000). TBE is a major vector-borne disease in Europe and Eurasia which is transmitted by several *Ixodes* tick species. TBE is maintained by natural tick-rodent cycles; humans may become infected if bitten by an infected tick. The incidence of infection has increased markedly in many areas in Europe during the last decade. Studies in Sweden indicate a northwards expansion in the geographic range of the *Ixodes* vector during the past 20 years, that is correlated with increased minimum winter temperatures. Farther south in Sweden, increases in tick abundance and the incidence of TBE were also correlated with milder winters. These and similar observations have been used to suggest that future climate change may increase the range and prevalence of TBE (Martens, 1998).

However, recent analyses indicate that seasonal patterns of climate are key to the dynamics of TBE (Randolph *et al.*, 1999). TBE infection cycles are maintained by transmission between infected nymphal ticks and uninfected larval ticks that are feeding on the same rodent host; a sufficient transmission rate to maintain infection requires specific seasonal patterns of tick population dynamics that are controlled by climate. In particular, it requires relatively warm summer temperatures (to allow rapid tick development), rapid cooling in autumn (to induce synchronous larval diapause and spring emergence) and adequate soil moisture

levels (Randolph *et al.*, 1999). Randolph and Rogers (2000) estimated how the recent (1960–1990) geographic distribution of TBE is related to the mean, maximum and minimum values of temperature, precipitation and saturation pressure, then used the resulting statistical model to predict the future distribution of TBE in response to climate change. Their simulations predict that the distribution of TBE will contract substantially, remaining only in higher-latitude and higher-altitude regions in Europe, as a result of higher summer temperatures and decreased moisture. They suggest that this predicted contraction will occur because the seasonal pattern of tick population dynamics required for successful transmission is disrupted by climate change.

These results reinforce our suggestion that changes in the seasonal patterns of climate may be critical to understanding animal responses to climate change. This may be particularly true in host–vector–parasite and similar systems of strongly interacting species, each of which may respond to climate differently. These results also highlight the importance of incorporating both temperature and moisture variables into models and simulations to predict responses to climate change. An important limitation, however, is that predictions about future patterns of precipitation and moisture from GCM models are less reliable at the regional level than are those for temperature. Moreover, likely future patterns of spatial and temporal covariation between temperature and environmental moisture, which may be key to animal distributions in some cases, are even more uncertain.

PREDICTING ANIMAL RESPONSES TO GLOBAL CHANGES

In this essay we have explored two complementary aspects of global changes: the history of human colonization and animal extinction, seen against a backdrop of climatic change during the past 100 000 years; and the effects of recent climate change on distribution and abundance of animals, in the context of other aspects of environmental change. There are several general lessons that we can draw from these considerations, as we try to anticipate the responses of animals to global changes in the near future. Human population expansion has been causing the extinctions of animals throughout much of the history of *Homo sapiens*. What is remarkable is that quite small human populations can be sufficient to cause substantial extinction, especially for endemic, local or ecologically specialized species. The effects are of course strongest on small or isolated islands, but can be seen as well in larger areas as well. Recent human population expansions have amplified these effects a million-fold and more; and as endemic species become increasingly restricted to small, isolated islands, their extinction rates will continue to accelerate. In addition, it is usually the secondary effects of humans, most notably habitat destruction and invading species, which are the primary causes of extinction, rather than the direct exploitation of animal resources.

While climate change has been part of the evolutionary histories of most current species, anthropogenic climate change will rapidly create a new constellation of seasonal and regional climatic conditions during the 21st century. The responses of animals to these changes will be as diverse as the animals themselves, but a few general patterns are likely. First, geographically localized and ecologically specialized animal populations are less likely to be able to track rapid climate change, and are more likely to go extinct; this will be a particular problem for populations already largely restricted to (geographically fixed) nature reserves and other habitat islands. Second, many species may shift range boundaries to higher latitudes, increasing the size of their geographical ranges. This effect will be most common in species that are not too strongly tied to a single habitat or food resource. In most cases, particular seasonal components of climate will be most important in determining the extent of range shifts. Third, because there will be major changes in seasonal patterns of climate in different regions, climate change may alter the relative seasonal timing of key life history events of an animal and its resources or enemies. Such relative shifts in phenology may have positive, negative or no effects on a particular animal species depending on the system in question, but are most likely to be important in strongly interacting ecological systems including host–vector–parasite and specialized insect-plant interactions. These indirect effects of climate change are likely to be as or more important than direct effects on survival and reproduction in understanding animal responses. Fourth, many animal distributions are directly or indirectly determined by specific combinations of seasonal temperature and environmental moisture; predictions based on temperature alone should be viewed with caution. This may be particularly true when considering tropical or subtropical species potentially shifting into more temperate regions. Fifth, range expansions by many temperate agricultural pests into higher latitudes seem likely. However, because of the strong interactions among parasites, vectors and hosts, it is less clear whether range expansions in response to climate change will be typical for vector-borne human diseases.

Natural Systems: Impacts of Climate Change

S MARK HOWDEN AND GUY B BARNETT

CSIRO Sustainable Ecosystems, Canberra, Australia

*Climate is a key determinant of the location, structure and function of natural ecosystems. We see this in everyday observations of the landscapes in which we live; for example, progressive changes in vegetation up a mountainside or the relationship of forest types to rainfall. There have been many attempts to translate these types of observations into schemes that relate climate to vegetation at the global scale. One example is the Holdridge diagram, which relates the global distribution of natural vegetation in terms of temperature, precipitation and evaporation (*see *Holdridge Life Zone Classification, Volume 2). Similar attempts have been made with fauna, although mobility can make such analyses more complex. There are also many examples of how climatic change on geological timescales has impacted on ora and fauna populations and on survival and distribution of whole ecosystems. These observations lead us to predict that the climate changes forecast over the coming centuries will have profound impacts on natural ecosystems and their component species. This essay will review brie y these predicted impacts for natural systems, which here include managed, semi-natural systems such as grazed rangelands.*

UNCERTAINTIES

Climate change impacts on natural ecosystems will occur in conjunction with a host of other human-induced (anthropogenic) pressures. Land clearing for agriculture and urban development, intensification of use of other ecosystems, introduction of exotic plants, animals and diseases, nitrogen deposition, acid rain and atmospheric carbon dioxide (CO_2) increase are just a few of these stresses. It is the interaction between climate change and these other factors that will determine the nature and distribution of ecosystems in the future. These interactions are generally poorly understood but are thought to be important in that the effects of one source of change can be reinforced by the other stresses. For example, computer simulations of broadscale land clearing of tropical forests suggest that regional droughts will increase, leading to regional changes in ecosystem composition and function, threatening species and increasing susceptibility to climate change and other disturbances.

Some of these impacts have positive aspects. For example, increasing levels of atmospheric CO_2 can increase plant growth, particularly under dry conditions and ameliorate the deleterious effects of tropospheric ozone. Plant growth (net primary productivity) is positively related to the number of plant species per unit area and so at first glance this would appear positive for biodiversity. However, there is accumulating evidence that species differ in their response to increasing CO_2 levels, suggesting that changed competitive relationships may shift relative distribution and abundance of species. This could lead to changes in community composition that are difficult to predict, given the complexity of the interactions. Similar arguments for the likelihood of future alteration in community composition apply to many of the other factors listed above, including climate change. In addition to changes in community composition, there may be impacts on ecosystem function where the changes affect rooting depth, photosynthetic pathway, nutrient cycling or the structure of the community. Changes in ecosystem composition and function could impact on the free services we get from ecosystems such as fresh water, pollination and maintenance of soil structure and fertility. In agricultural systems, the impacts of increasing CO_2 are sufficiently large to justify their inclusion in any global change impacts assessments. However, for natural systems, the effects are less well known and often lead to uncertain assessments of the impact on individual species and their interactions, although the general impacts on growth can be estimated.

There are several other uncertainties in assessing potential impacts of climate change on natural ecosystems. Chief amongst these are:

- future emission trends (including global economic development pathways, population growth and resource-use equity, degree of technological change and other emission-reduction options and policies);

- the degree to which these emissions will affect global climate (including the cooling effects of sulfate aerosols, impacts on oceanic circulations, cloud and particulate dynamics, feedbacks between land cover changes from carbon sink activities and climate);
- the translation of global climate changes to regional climate effects (including impacts of topography, land cover, land-ocean interactions).

Additional important uncertainties relate to possible asymmetric warming (where night-time temperatures increase more than those in the daytime), changes in the variability of climate (e.g., increased frequency of El Nino events) and changes in climate extremes (oods, droughts, storms, heatwaves, cyclones). Changes in extremes can be particularly important as they may produce conditions that exceed critical environmental thresholds and trigger change in ecosystems by increasing mortality or enhancing reproductive success of species.

NATURAL SYSTEMS

Climate change impacts on natural systems are discussed below using a simple bio-regional ecosystem classification. The ecosystems used here are:

- grasslands and savannas;
- deserts;
- tropical forest;
- temperate forest;
- boreal forest;
- polar regions;
- alpine environs;
- oceans;
- coastal zones and small islands;
- freshwater and wetland systems.

The terrestrial bioregions represent latitudinal, rainfall and altitudinal gradients, as these factors strongly in uence biodiversity (as measured by species richness), productivity and ecosystem function, particularly water availability and water balance. However, natural systems within each of these regions interact strongly with other factors such as soils and so there can be large variation within regions.

Grasslands and Savannas

Grasslands and savannas cover approximately 15% of the world's land surface (*see* Temperate Grasslands, Volume 2; Tropical Savannas, Volume 2). This area is declining due to landuse change to cropping activities and in some locations substantial urbanization. Up to 71% of the grassland and savanna ecosystems are degraded to some extent as a result of overgrazing, salinization, alkalinization, acidification and other processes. The pervasiveness of human in uence means that in many cases grasslands and savannas can best be thought of as semi-natural ecosystems. Extensive clearing of the woody vegetation across landscapes and installation of artificial watering points has already had very significant negative impacts on the biodiversity of grasslands and savannas in some regions. High levels of sustained total grazing pressure by domestic livestock in conjunction with pest animals have further impacted on the native species through competition for food and occupation of habitat. The introduction of exotic predators and weeds in many locations has further reduced biodiversity. In many cases, the above changes have significantly altered the functioning of grasslands and savannas with decreased infiltration, greater run-off and erosion, more rapid cycling of nutrients and lowered carbon levels. In more humid climates, intensive pasture development has transformed these systems so that they have a marginal biodiversity value. The alteration in grassland function may produce secondary effects in adjacent regions through increased nutrient ows into groundwater and waterways and increased drainage components that can raise dryland salinity risk. In some locations, these systems are being impacted by increasing rates of nitrogen deposition (which can improve production in nitrogen-poor sites but also increase soil acidity) and increased exposure to ultraviolet-B (UV-B) radiation and tropospheric ozone. The impacts of climate change have to be viewed in the context of these existing pressures, which are expected to continue and grow rather than decline.

Many grasslands and savannas have already been exposed to climate changes over recent decades. Increasing temperatures, particularly at night, increases in rainfall intensity and changes in rainfall amounts (often upwards but sometimes downwards) have been observed. The impacts of such changes are hard to separate from the background noise caused by the high climate variability often found in these systems and the relatively indirect measures of production that arise from them. Increases in climatic variability are also suggested as a potential impact of climate change, making it even more difficult to separate a meaningful signal from the historical record. These trends in climate are expected to continue, and the location of many grasslands away from continental margins means that expected warming trends may be higher (1.4–6 °C by 2080 with significant variation by region and by scenario) than in areas adjacent to the coast.

Increased temperature will tend to reduce productivity in many locations. This occurs due to increased evaporation rates and lower water use efficiency, which can arise from lower relative humidity. For some species, temperature optima for photosynthesis may be exceeded. In contrast, in some locations where low temperatures limit growth in autumn or spring, but where soil moisture is available, there may be an increase in the length of the growing season. This can have significant positive impacts on

grazing animals. However, in already warm environments, increases in temperature will increase heat stress frequency in animals, reducing physiological activity, foraging levels, growth and reproduction rates but increasing water demand, thus limiting the extent of their range from watering points. If the water supplies themselves become more scarce or intermittent, there could be significant impacts on species distributions. Increases in temperature may also result in transient release of nutrients from soil pools as they adjust to higher temperatures and this may be important in nutrient-limited environments.

The water-limited nature of many grasslands and savannas means that they are sensitive to changes in effective rainfall. However, there is substantial regional variation in suggested rainfall trends. Many grasslands are assessed as likely to undergo small but significant (i.e., 0–10%) decreases in rainfall by year 2080. However, there are some regions such as in Central America and south–west Australia that, under high emissions scenarios, may have larger decreases (−25%) whilst others such as western China that could get much wetter (+25%). Whilst the implications of such changes on natural grasslands will be significant, improved regional scenarios are required to decrease existing uncertainties.

Atmospheric CO_2 levels are expected to rise rapidly over the next 100 years. This change will have profound impacts on these systems, particularly where they are water limited and warm. Grasses increase their water and nitrogen use efficiencies under higher CO_2 levels while cool season (C_3) grasses also increase their photosynthetic rate. Grasslands and savannas have been exposed to increases in atmospheric CO_2 over the past 100 years and this may have already enhanced production by up to 8%. Growth responses to doubling of current CO_2 levels may range from negligible in wet, cool grasslands to 45% in dry warm savannas. The level of this growth enhancement is also dependent on the nutrient status of the soil, with lower nutrients limiting the response. Increased CO_2 is likely to reduce the nitrogen content but increase the carbohydrate content of leaves. In the majority of savanna environments that are nutrient-poor, this will reduce growth and reproduction of grazing animals, affecting the whole food chain. Increases in temperature will also reduce the digestibility of savanna grasses. In both of these cases methane emissions from the animals will tend to increase, providing a positive feedback to climate change. In other more nutrient-rich environments, the increase in soluble carbohydrates may increase herbivore productivity.

The combined effects of increases in temperature and CO_2 may change both the grass composition and the structure of grasslands and savannas. Grasses are split into two groups based on their photosynthetic pathway; C_3 species, which tend to grow in cooler, moister climates, and C_4 species, which are found in warmer, drier climates (*see* C_3 and C_4 Photosynthesis, Volume 2). Both groups increase their water and nitrogen use efficiency under higher CO_2 levels, but only C_3 species increase their photosynthetic rates. The distribution of these two groups under current CO_2 levels is correlated with climatic parameters such as growing season temperature, which affects the relative productivity of the group. Thus, warming by itself would result in poleward migration of the component species, reducing the area occupied by C_3 species. However, increasing CO_2 levels will tend to counteract this movement because of the additional photosynthetic response of C_3 species to CO_2. The net effect is uncertain and appears to vary depending on the seasonality of rainfall against temperature and the nitrogen response of the species. In contrast, legume species that fix atmospheric nitrogen are considered likely to benefit from increasing CO_2 levels. If there are significantly different species responses, then there is likely to be a breakdown of the existing species assemblages and generation of new ones. This is likely to have biodiversity implications for associated vertebrate and invertebrate species.

Global change may also have implications for the structure of grasslands and savannas through changes in the dynamics of woody versus grass species. Vegetation structure is important as it affects biodiversity, animal productivity (as trees strongly depress grass productivity in savannas), carbon storage, nutrient cycling, hydrology and the interaction of the biosphere with the atmosphere. Woody species have the C_3 photosynthetic pathway. It has been suggested that this is a way to enhance their competitiveness over the C_4 grasses that currently dominate the understory in savannas. This would occur as increased CO_2 levels may give woody plants greater growth response, increased seedling survival due to improved soil water availability from lower transpiration rates and deeper rooting if climate becomes drier. However, where burning is practiced, CO_2-induced increases in grass fuel load may kill establishing cohorts of woody plants leading to long-term declines in the woody ecosystem component. Thus, the structure of these systems under global change is probably dependent on the disturbance or management regimes. Establishment of woody species is often critically dependent on a favorable sequence of seasons. Climate changes could either increase or decrease the frequency of such conditions, adding to the uncertainty of the outcomes.

Regional changes in rainfall are more uncertain than changes in CO_2 or temperature. In dry grasslands, plant productivity is often linearly related to rainfall; thus a 10% decline in rainfall translates to about a 10% decline in production. However, increases in CO_2 may be able to offset such small reductions in rainfall. Thus, in locations where climate changes are relatively favorable (i.e., a small decrease to an increase in rainfall), increased plant production may increase grass cover, thus providing lower

risks of soil erosion even whilst slightly increasing animal productivity and numbers. In wetter environments, other constraints limit growth and so there may not be the same sensitivity to rainfall. Some grasslands in Australia, Africa and the Americas are strongly in uenced by the El Nino/Southern Oscillation (ENSO) system which results in high rainfall variability. There have been projections that the frequency of El Nino events may increase with global warming. This could result in significant increases in the variability of climate, producing large impacts on the biodiversity, productivity and functioning of affected ecosystems. For example, migratory mammals and insects have movement patterns that are strongly linked to variability in seasonal climates which if altered may disrupt these movements. Such pressures for the mammals are likely to be compounded by increasing fragmentation of landscape, barriers such as fences and control of watering points.

In many of the world's grasslands and savannas, if there is an increase in biological productivity arising from global change, then economic and cultural pressures as well as natural increase in wild populations, will tend to increase herbivore populations thus maintaining pasture utilization and providing little benefit to the natural systems and their function. There may also be increased pressure to crop the land, and in some regions such as North America, large areas of grasslands may become suitable for cropping. In contrast, in areas where production may decline due to climate change, those cultural, economic and population pressures will tend to maintain previous grazing populations and so pasture utilization will tend to increase as has happened in the grasslands of temperate Asia. This will lead to increased pasture and soil degradation, increased invasion of unwanted grass and woody species and long-term decline in the productive capacity of these systems.

Desert

Deserts are characterized by low rainfall (<250 mm annual average), which is highly variable. They cover about 30% of the earth's land surface (*see* Deserts, Volume 1; Deserti cation, Volume 3). Most deserts are located in the mid latitudes between $20-40^{\circ}$ although at other latitudes deserts exist in rain shadows adjacent to mountains whilst others occur simply due to great distances from oceans. High levels of solar radiation and low relative humidity result in large daily temperature uctuations and high evaporation. Rainfall, when it occurs, is often intense and localized and is channeled into small parts of the landscape. This results in substantial variation in plant production over time and space because productivity is often linearly related to water use. This variation in productivity strongly in uences the distribution of fauna. Thus, water availability is often the dominant factor controlling ecosystem processes. Hence climate changes that in uence the availability or effectiveness of rainfall are likely to be the most critical in in uencing desert ecosystems. Changes in the effectiveness of rainfall may arise through changes in the amount, season and intensity of rainfall, temperature changes and the level of atmospheric CO_2.

Recent climate change scenarios suggest significant decreases in rainfall in many of the world's deserts over the next 100 years although there remains considerable uncertainty over such regional scenarios. One of the reasons for the projected decrease appears to be intensification and poleward movement of the mid-latitude high-pressure belts due to an intensification of the Hadley circulation whilst atmospheric concentrations of greenhouse gases are increasing. Reductions in rainfall will tend to result in approximately proportional reductions in plant productivity and this will tend to reduce the abundance of other organisms. In a few areas, such as the deserts of the western USA, there may be an increase in winter rainfall and a decrease in summer rainfall. Rainfall changes like this may not significantly alter total system productivity but may result in changes in species composition towards those plants that favor growth in cooler seasons. These plants often have the C_3 photosynthetic pathway rather than the C_4 pathway. Consequently changes in rainfall seasonality may result in a shift in the C_3/C_4 balance with consequent impacts on ecosystem functions due to changes in community structure, nutrient cycling and water use.

Increases in the intensity of rainfall may result in higher proportions of run-off, thus enhancing growth in those limited areas of the landscape that accumulate water. This will tend to focus biological activities on these small areas leading to possible increased threats to biodiversity from predators and from competition from domesticated livestock, as well as providing environments where pest animals and plants can establish themselves. In other environments, increased intensity of rainfall may enhance the establishment and survival of ephemeral species that grow after rainfall events and survive as seed until the next favorable growth opportunity. These changes in community composition have been observed over past decades in response to the increased intensity of rainfall in a range of environments. Increases in ephemeral species may affect the perennial species through competition for resources or by increasing fire frequency or grazing intensity. Many insects, such as locusts, have similar life cycles to ephemeral plants and they may be in uenced in a similar way by changes in the variability of climate.

Recent climate change scenarios suggest temperature increases in the range of $1-5\,^{\circ}$C for desert regions for the year 2080. Evaporation rates increase markedly with temperature and so a $2\,^{\circ}$C rise increases potential evapotranspiration by $0.2-2\,\mathrm{mm\,day^{-1}}$. By itself, this will result

in less efficient use of water by plants and more rapid depletion of water following rain, although in environments where cold weather limits growth in spring or autumn, warmer temperatures may extend the growing season provided water is available. For plants, the negative effects of such increases in temperatures on water use may be partly offset by the positive impacts of increasing levels of atmospheric CO_2, which increases plant water use efficiency and also increases photosynthetic rates in C_3 plants. By itself, doubling of CO_2 over current levels may increase plant growth by up to 50% in desert environments. However, these increases are likely to moderate the effect of temperature increases in combination with rainfall reductions so the net effect of global change on productivity may, on balance, be slightly negative, particularly in nutrient-poor environments where the CO_2 response will be limited. Furthermore, whilst the CO_2 response will tend to increase less rapidly with increased CO_2 levels, that due to climate change will not, thus suggesting possible early increases in productivity but increasingly negative responses over time. In deserts in which organisms rely on fog and dew deposition, temperature increases are likely to have particularly negative effects as fog frequency is likely to decline due to less frequent occurrences of the low temperatures which produce condensation. There are already strong reductions in fog frequencies in some environments, which are having demonstrated impacts on biodiversity.

Climate changes will not occur in isolation from existing pressures on biodiversity and natural systems in deserts. Unlike many other regions, pressures for landuse change are not strong; however, the existing land management has resulted in the majority of the world's deserts being classified as degraded to some extent. Important processes include overgrazing by domestic livestock, particularly near natural or manmade watering points, introduced feral predators and herbivores and weeds. The history of use of desert regions suggests that if there are any increases in productivity from climate change, corresponding increases in herbivore populations will occur, negating the benefits to the natural systems. In contrast, recent research suggests that declines in desert productivity will tend to result in transient increases in forage utilization until declining productivity or degradation causes adjustment in herbivore numbers or behavior. Thus, climate change may interact with other pressures resulting in even more rapid degradation and increased impacts on natural systems.

Many species of water birds, fish and invertebrates are highly attuned to ephemeral water storages in deserts. Moderate increases in the variability of the climate of desert environments are by themselves unlikely to affect these species negatively. Increases in the frequency of filling of such waterbodies could arise in some regions from a possible increase in ENSO events or from more poleward movements of tropical cyclones. However, if these changes in frequency are sufficiently great, then existing demands to use this water for irrigated agriculture may intensify, which may have serious, negative impacts on the natural ecosystems if development proceeds (*see* C_3 and C_4 Photosynthesis, Volume 2).

Tropical Forests

Tropical forests cover approximately 12% of the earth's land surface and 40% of the world's forested area, but contain almost half of the world's plant and animal species (*see* Tropical Forests, Volume 2). They are made up of a variety of different forest types, but the main ones are rainforest, drought–deciduous forest, and dry forest. They are found between 25 °N and 25 °S, distributed over five continents. Most of these tropical forests are located in the developing countries of the low latitudes, such as central Africa and much of southern America and southern Asia. These locations typically have high population densities and are undergoing rapid economic development, and thus predicting the impact of climate change requires consideration in the context of both current and future human activity. For instance, many tropical forests are currently being rapidly cleared, and if this continues, human-induced landuse change will have a much more significant impact on tropical forests than that of climate change. However, these impacts may interact to increase the hazard of losses in biodiversity.

Climate change projections for the year 2080 indicate that seasonal temperatures in tropical forests could increase by 1–4 °C, depending on scenario and location. This level of warming is unlikely to increase photosynthesis for any except tropical montane forests where low temperatures can limit growth. However, these higher temperatures will increase plant respiration, tending to lead to lower growth and increase rates of breakdown of litter, reducing ecosystem carbon levels. For cloud forests, which rely on droplet deposition for much of the water supply, increases in temperatures will tend to reduce the frequency of deposition events leading to substantial changes in the whole ecosystem. This already may be happening in forests such as the Monteverde forest in Costa Rica with impacts on birds, reptiles and amphibians.

Increases in temperature will increase evapotranspiration, leading to reduced soil water availability. The degree of this effect will be modified by any changes in rainfall patterns. Projected change in rainfall is highly regionally variable with expected increases (10–15%) in much of southeast Asia (but changes in seasonality), equatorial Africa and the Parana–Rio Grande region of South America but decreases for the Amazon and Central America. If these changes are coupled with possible changes in the frequency of ENSO events, the result could be prolonged dry seasons and drought in some regions, with more rains and ooding in others.

The impact of this potential change in soil water availability is likely to be most significant in those regions that contain boundaries of different biomes. In these areas, the impact could involve a shift in the current distribution and composition of tropical forest types. For instance, some research suggests that if precipitation in the seasonally dry deciduous forests decreases, then these forests will become drier, promoting the accumulation of organic matter and leading to a possible increase in the frequency of intense fires. Under this scenario, the seasonally dry deciduous forests would tend to be replaced by fire-tolerant savanna vegetation and those plant species that are sensitive to fire would be lost. The converse scenario might involve the expansion of those species that prefer moist and wet climates into regions from which they have been excluded in the past through a lack of soil water availability or low temperature. In either scenario, there would be subsequent impacts on vertebrates and invertebrates, many of which have life-cycles tightly linked to specific tropical forest plant species.

Tropical forests typically grow on infertile soils and, therefore, require efficient nutrient capture and cycling to ensure an adequate supply of plant-available nutrients. Phosphorus is the most limiting of these nutrients and it has been suggested that elevated CO_2 levels (which can enhance photosynthesis and water use efficiency), could increase both root growth and mycorrhizal development, thereby enhancing the ability of tropical forest vegetation to access soil phosphorus and to fix atmospheric nitrogen. In undisturbed tropical forests, it is likely that these effects may lead to a potential gain in productivity and net carbon storage, particularly where nutrient limitations are minimal. However, the degree to which these effects will occur in the wet tropical regions (particularly when subject to disturbance) is open to considerable debate. Nevertheless, in the drier tropical regions, elevated CO_2 levels are likely to increase water-use efficiency by plants, and hence potential vegetation productivity.

Given the tightly closed cycling of nutrients in tropical forests, it is clear that any disturbance could have a significant impact on nutrient status. Examples of how climate change may in uence disturbance include increased rainfall intensity leading to soil erosion, increased decomposition rates, altered leaching regimes, increased storms which cause wind-throw and increased drought frequency or intensity which enhances mortality rates from water stress or from drought-related fires. This, and the importance of the regeneration phase in determining forest composition, suggests that changes in disturbance regimes could in uence forest productivity and distribution.

Whether tropical forests as a whole will increase or decrease in area under climate change is unclear, although it is possible that the total area may not change, but rather the relative proportions and composition of each forest type.

Temperate Forests

Temperate forests are extremely diverse, sometimes being a transition zone between boreal and tropical forest and in other places being adjacent to semi-arid ecosystems (*see* Temperate Coniferous Forests, Volume 2; Temperate Deciduous Forests, Volume 2). They occur across wide spatial ($25-50\,^{\circ}$N and S) and climate ranges. The most extensive forest types include *Fagaceae*-dominated northern deciduous, temperate coniferous, and *Eucalyptus* and *Nothofagus*-dominated evergreen forests in the Southern Hemisphere. Temperate forests cover approximately 7% of the Earth's land surface and are primarily located in developed countries. Many have a significant history of human impact. They are now commonly fragmented or discontinuous vegetation blocks contained within a matrix of agricultural and urban landuse. However, many of these forests are presently undergoing significant regrowth following the cessation of clearing and wood removal, which is also being supplemented by reforestation. As a result, the area and biomass of temperate forest is currently increasing, and for this reason, temperate forests may act as a carbon sink over the forthcoming decades.

Climate change scenarios for the year 2080 are for increases in summer and winter temperatures of $1-5.5\,^{\circ}$C and generally small increases ($0-+10\%$) in rainfall, although some regions such as southern Canada and China are projected to have bigger increases, and some such as Spain, the southern United States and Australia may have decreases. The changes are highly variable between regions and scenarios. Due to increased evapotranspiration, many soils are expected to be drier in late summer even though annual rainfall may increase slightly. The frequency of summer droughts could increase, particularly for those regions with a continental rather than oceanic climate and where rainfall decreases. The result could include reductions in forest density, leaf area, growth and standing biomass, and ultimately the loss of some marginal temperate forests following repeated drought. For other forests, the end result could be earlier and warmer growing seasons (sometimes longer and sometimes shorter), with fewer cold temperature extremes and frosts in winter. But perhaps of more concern than the magnitude and direction of these changes is the speed at which this change is likely to occur. Many temperate forest species grow in a limited climatic range. For example, in Australia 25% of *Eucalyptus* species have mean annual temperature ranges spanning less than $1\,^{\circ}$C whilst 53% have a range less than $3\,^{\circ}$C and 23% have a range spanning less than 20% variation in rainfall. This limited climatic range suggests that many forest species may be vulnerable to climate change. The high rates of migration needed to stay in current climate envelopes seems unlikely, given habitat fragmentation and degradation due to clearing, introduced pests and diseases and changed fire regimes. The

net result is that significant changes in species composition may occur.

Other associated impacts of climate change might include an increase in the incidence of fire in response to drought, outbreaks of pests and pathogens that are advantaged by warmer climates, and limitations on reproduction in certain temperate forest plants. For the latter, this could involve inadequate chilling requirements that are needed to break dormancy in seeds, or a reduction in frost hardiness that leaves plants more susceptible to damage during extreme events.

The combination of climate change and elevated CO_2 are predicted to affect the net primary productivity of temperate forests, but the overall direction and magnitude of this affect are not always clear. For example, enhanced growth of young trees exposed to elevated CO_2 has been observed to occur in experiments, but the effects are less marked in longer-term experiments largely, it appears, due to other limitations to growth (e.g., low nutrient availability). Similarly, changes in net primary productivity remain sensitive to rainfall but the interaction with increased temperature and CO_2 levels are not fully understood.

Temperate forests are currently considered to be a carbon sink, but some temperate forests could potentially become a source of carbon if climate change results in forest decline or human activity causes forest degradation such as soil acidification. As most temperate forests are located in developed countries, there is at least some capacity and knowledge available to minimize climate change impacts. Such strategies could include the adoption of integrated fire, pest and disease management technologies, as well as the supplementation of existing forest through reforestation activities.

Boreal Forests

Boreal forests are dominated by evergreen, coniferous species (*see* Boreal Forest, Volume 2). They are found in the northern parts of North America, Europe and Russia and cover approximately 9% of the earth's land surface. They are constrained in the north by cold temperatures that limit tree height and reproduction, and in the south, by competition from broad-leafed and deciduous forests and savanna-woodland species, as well as water availability. Boreal forests are already experiencing a series of pressures. These include acid rain and soil acidification, increased tropospheric ozone exposure, increased UV-B exposure, increases in logging demands (e.g., 38–96% increase in logging from Asian forests projected over the next decades) and landuse change pressures from agricultural expansion. There have also been pressures on ora and fauna from overuse, increased wildfire frequency, habitat change and increased biotic invasions. Boreal forest growth rates have increased over recent decades due to warmer seasons, increased nitrogen deposition, increased CO_2 levels and changed management but there have also been increases in insect and disease attacks and damaging fires.

Climate projections are for significant warming over the boreal forest regions during the next 100 years, resulting in northwards expansion of boreal forest in excess of two–thirds of the area currently occupied by tundra ecosystems. These changes are due to increased reproduction and productivity in the warmer climate and longer growing seasons. This increased growth may be assisted by increased levels of atmospheric CO_2, in combination with enhanced nutrient availability from atmospheric deposition in some areas as well as transient nutrient release from the soil. However, on the southern margins there may be encroachment of broad-leaf, deciduous species and replacement by grasslands and shrublands due to warmer temperatures and reductions in summer rainfall. For North America this may result in about a 15% increase in total area of boreal forest but in Russia a 50% reduction in area has been suggested. Even in North America where net changes are positive, some 14–19% of boreal forests could undergo drought-induced biomass decrease. Palaeoecological evidence suggests that these forests may not be able to shift across the landscape as fast as climate may change. This may increase the likelihood of disruption, dieback and species extinction due to disequilibrium with climatic factors. If dieback in the south occurs faster than expansion in the north, then there may be a temporary decline in boreal forest area or a shift to drier types of boreal forest under warmer scenarios. Consequently, responses may vary with time as well as place.

Fire frequency and damage in boreal forests has been increasing over the past decades. This appears to be partly due to climatic effects but also from management that has tended to allow buildup of biomass in some regions. This buildup results in increased transpiration, increasing drought stress frequency and susceptibility to fire. Climate change is likely to increase the current fire risk in some regions (e.g., Russia and Canada) by prolonging the length of the season when fires can occur and increasing the frequency of climate sequences that generate larger, more intense and potentially destructive fires. This could result in replacement of existing stands by new species and in long-term negative impacts on soil properties, such as infiltration rates. There could also be significant, negative impacts on wildlife and biodiversity. Changes in fire regime may be moderated if rainfall increases as is expected under some scenarios in some regions.

Cold temperatures protect boreal forest trees from many insects and fungi that are prevalent farther south. Climate warming over past decades has increased the frequency and severity of insect attacks in boreal forest (e.g., budworms and bark beetles) by enabling more generations per year, increasing the physiological activity levels

and increasing over-wintering survival. These trends are expected to continue with climate change although the complex nature of interactions prevents firm prediction of the outcomes. These effects are more strongly felt on drought-stressed trees and increased drought frequency associated with warm temperatures; nitrogen overfertilization may also increase susceptibility to pest and disease attack.

Polar

The polar regions dealt with here are those land areas of the Arctic and Antarctic bounded by the Arctic Circle in the Northern Hemisphere and 58 °S latitude in the Southern Hemisphere, respectively. They are characterized by low temperatures, strongly seasonal radiation and the current dominance by ice and snow (*see* Tundra, Volume 2). There have been strong warming trends in both the Arctic and Antarctic during the past 50 years. These increases have been up to 5 °C, although some regions show neutral to cooling trends. In the Arctic, this has already enhanced the temperature environment for agriculture and forests with earlier springs and longer growing seasons, changing the reproductive cycles of some animals and encouraging the poleward movement of forests. In the Antarctic, this appears to have markedly increased growth and population sizes of both of the two vascular plant species that exist there. There have also been increases in rainfall in both these regions. In the Arctic, there is long-term decline in sea ice extent and the sea ice has thinned. In the Antarctic, there was a significant retreat of sea ice between the mid-1950s and early 1970s but subsequent changes have been regionally variable. However, there has been a marked collapse and retreat of ice shelves on the Antarctic Peninsula as a result of regional warming. Surface waters in both regions have freshened and warmed. Ground temperatures have increased, permafrost area has declined and there has been an increase in the number of melt days per summer. Glaciers, ice caps and snow-covered areas have generally diminished although in some areas there is expansion in the upper reaches due to increased precipitation. The above trends are expected to continue with global warming, with temperatures in the Polar Regions increasing more than other regions particularly in winter. Some projections indicate winter temperature increases in the Arctic of greater than 7 °C by 2080 under high greenhouse gas emissions scenarios. The Arctic region is likely to be impacted by climate change more rapidly and significantly than any other region on Earth, while the Antarctic may be less affected at least over the next 100 years.

Biological production in Polar Regions is temperature dependent, and therefore global warming is likely to generally increase productivity and abundance throughout the food chain, and earlier and longer growing seasons are likely to benefit many species. However, there are likely to be changes in species compositions due to the different competitive abilities. For example, the lichens and mosses of the tundra regions may be replaced by more productive, low-growing vascular plants. Exotic and other species such as insects, which cannot tolerate the current cold conditions, may start to colonize the Polar Regions whilst other species that already exist there may alter their relative abundances. These changes are expected to result in a general tendency for poleward migrations of species in the Arctic. For example, there may be gradual northward expansion of boreal forest into the tundra regions, affecting up to two–thirds of the tundra. Although more precipitation is generally expected, increases in evapotranspiration may lead to droughts late in summer that could place additional pressures on existing species that are not drought-adapted. In the Antarctic, warming may further diminish ice shelves, exposing more ground, resulting in significant changes in the terrestrial ecosystems, whilst in the Arctic, sea ice is expected to decline markedly. These changes may impact on terrestrial food chains through changes to predator and prey species, particularly where there is a substantial dependence on sea-ice for shelter, reproduction or feeding. Salinity and temperature changes will also have a dramatic effect on species composition, both in and out of the circumpolar oceans. Increased CO_2 levels will have only a limited affect in either of these regions due to the low temperature and nutrient availability. However, the increased frequency and intensity of stratospheric ozone depletion in both the Arctic and Antarctic is likely to increase UV-B radiation exposure and this may have negative impacts on many plants and animals. Limited evidence suggests that this may already be occurring in both plant and animal species.

The hydrology of polar regions is highly sensitive to temperature changes with increases in the proportion of rainfall compared with snowfall, increased and earlier melting events and increased infiltration in previously permafrost areas resulting in lower seasonal variations in runoff. Increase in winter flow under the ice may be beneficial to invertebrate and fish populations whilst reductions in ice-jam induced flooding may have serious negative implications on Arctic riparian ecosystems. Changes in total runoff are likely to be regionally variable, depending on the balance of increased precipitation and increased evapotranspiration. The thawing of large areas of permafrost soil, particularly in ice-rich areas, will change regional drainage, subsidence and hence vegetation (e.g., changes from forests to bogs) and landuse by increases in bog areas, and increase landscape erosion by slumping and landslides. If there are widespread increases in stream flow as a result of increases in rainfall and the above hydrological changes, there may be a freshening of the waters of the Arctic Ocean and the North Atlantic, reducing formation of deep ocean water and thus weakening the thermohaline circulation. If this circulation

undergoes rapid reorganization, then abrupt climate change may occur. Many of the above changes will have implications for atmospheric concentrations of greenhouse gases. For example, reduction of permafrost may release methane and weakening of ocean circulations will reduce oceanic carbon sinks.

Alpine

Alpine areas can be found scattered throughout the mountainous regions of the world. They are defined by the climatic limit of tree vegetation, referred to as the treeline, and the zone of permanent snow and ice. The altitude at which the treeline occurs varies around the world depending on latitude and proximity to the ocean. For instance, the treeline in the oceanic Kosciuszko Mountain Range of Australia is located at about 1800 m above sea level, while the treeline in the continental Rocky Mountains of the USA is around 3000 m above sea level.

Documented reductions in both alpine glaciers and permafrost ice provide some of the clearest scientific evidence for responses of natural ecosystems to recent climatic warming. Direct measurement shows a significant warming of the high latitude, mostly continental mountains of the European Alps and Asia, whilst upward movement of plant species has been widely reported. In the tropical alpine zone, evidence for responses to recent climate changes is less pronounced to date.

Climate change projections are highly variable and uncertain for the alpine zone due to the inherent complexity of mountain systems and the lack of appropriate spatial and topographic resolution in most climate models. However, it is generally considered that warming will reduce the period of time that snow cover persists, hence in uencing both the timing and amplitude of runoff during snowmelt. This shift towards earlier spring runoff may result in a prolonged summer, increasing the dryness of alpine vegetation and soil and consequently increasing the risk of fire. The seasonality and amount of precipitation may change, as might the proportion of rain to snow, but the magnitude and direction of this change will vary from region to region. These changes could be quite significant. For example, scenarios for the European Western Alps under doubling of CO_2 concentrations (about year 2080–2120) suggest an increase in winter precipitation of up to 15% but a decrease in summer precipitation and a warming of up to 4 °C. There could also be changes in the frequency of extreme climatic events (e.g., storms), but again, it is unclear how these changes will be manifested for each particular region.

Alpine zones are extremely vulnerable to the effects of climate change because they are generally characterized by specialized ora and fauna that have evolved to contend with harsh climatic conditions, such as intense cold, high winds and heavy snowfall. In the case of plants, these morphological and physiological adjustments often include the development of stunted growth forms and small leaves. With the onset of climate change, the unique environment to which these species are often restricted is likely to suffer from a reduction in extent and increased fragmentation. This will place added pressure and stress on a fragile alpine ora and fauna, much of which is already highly endemic and rare, due to a low ability to disperse or migrate. Alpine areas and other montane systems can be thought of as mountain islands. As temperature increases, species need to migrate higher and higher to stay in the same climatic zone resulting in progressive isolation of populations and reductions of suitable areas (as mountain tops are smaller than their bases). The end result could be the extinction of particularly sensitive alpine taxa, and a significant reduction in total alpine biodiversity. This process is already being observed widely with tree establishment at elevations above current treelines. In the European Alps, plant species richness has increased at 70% of the sites studied presumably from upwards colonization; some plant populations have migrated upwards at a rate of $1-4\,\mathrm{m\,decade^{-1}}$. However, even this rate may not be fast enough to maintain some species in their preferred environment as there is a general rule that a 1 °C rise in temperatures equates to about a 170 m increase in altitude. Extinctions have occurred in the past where plant species that were already restricted to high elevations have been exposed to environmental changes including warming.

For many alpine zones, predicting how the vegetation will be affected by climate change is complicated due to uncertainties about species-specific responses to increased CO_2 as well as regional uncertainties about the level of change in other important environmental variables. For instance, temperature, solar radiation, precipitation, wind speed and soil moisture will also in uence species responses, but the degree to which these factors change will vary considerably across regions. The overall effect may be an increase in competition between plant species as the ecological potential of sites change. For example, those plant species migrating upward in response to warming are likely to compete with other plant species that may be responding differently or more slowly.

In addition to the potential effect on biodiversity, climate change in the alpine zone could also affect the rate of land degradation. Alpine soils are highly susceptible to erosion, and it is possible that an increase in precipitation could also increase the incidence of debris ow, land slide and slope failure in many mountainous regions. This would obviously have many implications, but among the more serious for natural systems would be a potential deterioration of water quality in alpine lakes and streams, as well as a reduction in the overall productive potential of alpine soils.

While climate change is likely to have a significant impact on alpine biodiversity, it should be noted that many

of the alpine zones with greatest biodiversity, such as the Himalayas, are located in areas where human population pressures are also pronounced. Thus, the potential impact of climate change on the alpine zone must be considered within the context of other anthropogenic in uences, as well as the inherent fragility of alpine ecosystems.

See also: Mountain Climates, Volume 1.

Oceans

Oceans cover 71% of the earth. They are strongly in uenced by climate at small scales and over the short-term, through effects on waves and production and mixing of different water layers, and at larger scales through impacts on oceanic currents and heat storage. These factors in turn affect climate through redistribution of energy into the atmosphere and around the globe. For example, the ability of the oceans to store heat has mitigated the rate of recent climatic change. The ocean is also a major source and sink of greenhouse gases and aerosols containing some 60 times more carbon than the atmosphere. The strong linkages between the oceans and climate suggest that climate changes and oceanic changes will occur in tandem.

There are already many pressures on the world's oceans as a result of human activity. These include overfishing, population pressures in coastal zones, habitat destruction, increased pollution from atmospheric, terrestrial and oceanic sources and increased UV radiation. Climate change will add to these existing pressures. Climate change will affect the oceans through changes in sea surface temperature, sea level, ice cover, ocean circulation, and wave characteristics.

Ocean circulation is particularly important. Ocean currents transfer energy from the equatorial regions towards the poles and also vertically from the ocean surface into deeper waters; in this way these transfers also facilitate the movement of nutrients critical for many marine biological systems globally. For example, the highly productive areas of the Sargasso Sea, the eastern Pacific and the Southern Ocean are dependent on the nutrient transfers associated with these currents, and about 45% of the net primary production of the oceans occurs in the nutrient-rich upwelling zones of these currents. Changes in ocean currents have occurred over both historical and palaeological time frames, resulting in large impacts on marine ecosystems. One of the best-known examples of this is the impact of temporary cessation of the nutrient-rich cold-water upwelling off the South American coast during ENSO events, which results in large reductions in fish stocks. There are many other similar examples and these relationships are sufficiently strong, so that for many species, water temperature and current strength can be used to forecast abundance and distribution. A range of possible changes in oceanic currents could occur with climate change and all of these will have impacts on marine ecosystems. In the extreme, there is some concern about the stability of the largest current – the global conveyor belt or the thermohaline circulation – which sinks cold water in the North Atlantic which is carried through the Southern Atlantic, around the Southern Ocean and up the west coast of South America where it surfaces, to travel across the Pacific through the Indonesian Archipelago into the Indian Ocean, around the tip of South Africa and back up the Atlantic (*see* Atlantic Ocean, Volume 1). Breakdown of this current appears to have occurred previously from the incursion of large amounts of cold, fresh water in the Northern Atlantic – a possibility with melting of the northern ice stores and changes in Arctic hydrology and sea ice abundance under global warming. Such an event would, paradoxically, cool Western Europe by several degrees, but in the longer term may enhance atmospheric accumulation of greenhouse gases because of reduced CO_2 sequestration by the oceans. The impacts of such a breakdown on marine ecosystems would be immense but are difficult to predict with current knowledge. Even lesser changes may reduce the ow of oxygen-rich water to the deeper ocean resulting in anoxic conditions that will negatively affect those ecosystems.

There is growing evidence that marine mammal and seabird populations are strongly affected by climate variations, and thus there is growing concern in regard to the impacts of climate change. Whales and related species (Cetaceans) may be particularly vulnerable. Sea ice extent and thickness has already declined in the Arctic and Southern Ocean over the past few decades with, for example, Arctic sea ice thickness declining 40% and areal extent declining 6–9% over the past 20 years. These changes are projected to continue. The sea ice is particularly important because it can affect the abundance of krill, which is the main food source of cetaceans. Declines in sea ice may reduce food sources for krill during the winter, reduce suitable habitat, reduce protection from predators and increase competition from macrozooplankton. Reduced ice-edge foraging zones may also affect cetaceans. Commercial or other whaling operations, if continued, will add to any such pressures on populations. Similar negative impacts may also occur to polar bears and changes in sea ice may affect many other Arctic species with resultant impacts throughout the food chain.

Future changes in fisheries will be a combination of the impacts of climate change and fishing management practices, as well as other factors such as degradation of marine habitats. Observed declines in fish stocks and catches that have previously been ascribed to overfishing (e.g., the collapse of the Peruvian anchovy fishery from the mid-1970s to the mid-1980s) are now considered to have a climatic component. This sensitivity to climate emphasizes the possibility that climate change may have significant impacts on fishery productivity. Globally, sea surface temperatures

have increased along with air temperatures over the past century and increased ocean temperatures are considered one of the most likely future changes. Sea temperature is an important regulator of fish behaviors and is well known to affect species such as sardines, bluefin tuna, skipjack tuna, North Sea cod and also seabirds, sea mammals and zooplankton through impacts on spawning, larval and juvenile survival and growth. In some cases, changes in temperature can adversely affect one species in a location whilst favoring another. In other cases, adverse effects are seen for whole ecosystems. Hence, climate change is likely to result in both positive and negative impacts and these may vary substantially between species. Regional-scale predictions are not feasible at present. Where negative impacts occur, these may be particularly harmful if there is no corresponding reduction in fishery activity. Hence, more informed fisheries management will become even more critical.

Seabirds are an important component of marine ecosystems. For example, in some systems they can consume up to 20–30% of annual fish production. Their mobility and capacity to adapt to different feeding sources often allows them to avoid the consequences of short-term variations in climate. However, the observed sensitivity of seabird populations to longer-scale climate–ocean variability and, in particular, the associated changes in fish abundance, suggest that there could be considerable impacts of climate change on sea birds.

The ENSO system is an important feature of the global climate and oceans. The possibility of the intensity or frequency of ENSO changing with global warming has raised concerns. There remains considerable uncertainty about these changes as they can be in uenced by the strength of trade winds, latitudinal temperature gradients and decadal scale climate–ocean variations. It is becoming increasingly apparent that decadal-scale variations in ocean–atmosphere patterns occur, and that these have major impacts on the location and abundance of marine life. There is a need to better understand these patterns and how they may change with global warming.

Coastal Zones and Small Islands

The coastal margins of the oceans are very extensive (approximately 1 million km) and densely populated, with about 40% of the world's population living within 100 km of this margin. They are also biologically highly diverse and very productive. However, coastal zones and small islands are highly vulnerable to the effects of climate change through sea level rise, exposure to storm events and impacts from terrestrial catchments. Coral reefs, in particular, may be affected by sea surface warming and impacts, as well as increased CO_2 concentrations.

Global sea level is already increasing with average rises of between 1 and 2.5 mm year^{-1} although in some areas the effective sea level is falling due to geological uplift. This rate is anticipated to increase during this century, leading to sea level rises of 0.2–0.92 m by the year 2100. Continued rises are expected for several hundred years thereafter due to thermal expansion and ice sheet reduction even if atmospheric greenhouse gas levels are stabilized. Sea level rise will inundate coastal lowlands and wetlands, increase rates of coastal erosion and change coastal sedimentation patterns, increase saltwater intrusion into estuaries and fresh water aquifers, increase storm surge ooding risks, alter tidal ranges in estuaries and temporarily change the turbidity of the water, thus affecting light-sensitive organisms and degrading near-shore aquatic breeding areas and nurseries. Coastal ecosystems have the capacity to respond to some of these changes through increased growth or accretion rates for corals and mangrove communities where the rate of sea level rise does not exceed the response rate.

Coral reefs are very important biological systems, providing habitat for 25% of marine fish, and with more classes of organisms than rainforests. The high biological productivity of reefs and the physical protection they provide mean that they are important for adjacent ecosystems as well as for human use. Many reefs (58%) are currently considered to be threatened from existing human activities such as poor fishing practices, inappropriate tourism management, pollution and increased sedimentation and land reclamation. These stresses can increase the susceptibility of reefs to diseases and predators such as the crown of thorns starfish. Healthy coral reefs may be able to grow at up to 10 mm year^{-1} which will probably allow them to keep pace with sea level rise. However, these rates of growth may not be able to be achieved given the above stresses, which may predispose corals to damage from possible increase in coral bleaching events, changes in storm patterns and CO_2 increase. Coral bleaching is a normal event in reef ecosystems and occurs because many coral reefs exist at or close to temperature tolerance thresholds. It is enhanced by high levels of solar radiation and by in uxes of freshwater and riverine sediment. However, the frequency, extent and severity of bleaching events appear to be increasing already in response to general increases in ocean temperatures. The 1998 bleaching event was unprecedented historically and was associated with highest sea surface temperatures on record. Tropical oceans are expected to warm substantially and if 1998 was an indication of the possible future environment in tropical locations, then climate change may have significant biodiversity implications for coral reefs. This is because some coral groups and species such as the branching corals are more adversely affected than others, like massive brain corals. Corals affected by bleaching are more prone to attack from diseases and predators. The combination of these stresses is thought to potentially result in major

changes in community composition and function, such as reversion to soft coral growth forms, algae and sponges. Additional stresses may arise from increased rainfall intensity increasing freshwater out ow events from rivers and also from increases of atmospheric CO_2 potentially reducing reef calcification rates (by 17–35% with doubling of CO_2) as a result of increased sea water acidity. The combination of these factors suggests that in some areas, coral reefs may undergo significant changes in the future.

Mangrove and saltmarsh areas are also important, highly productive ecosystems that are critical for reproduction and growth of marine and estuary species as well as providing a buffer to adjacent terrestrial ecosystems. They occur between mean tide and high tide levels on coastlines where wave energy is low. In many regions, they are already under threat from economic development. These ecosystems will be directly affected by increases in sea level. Where there is low sediment supply and limited rates of organic matter accumulation, there may be landward retreat of the community, which if restricted by steep backshores, will result in reductions in community size and species diversity. In other areas where sediment supply is adequate and/or where organic matter accumulation is high, there may be opportunity for both seaward and landward expansions. Even where such conditions arise, increased storm activity and erosion rates from climate change may limit expansion.

Sea level rise and groundwater extractions may combine to significantly threaten underground fresh water storage in coastal and island environments. This could have significant impacts on the plant communities that grow in these areas, both from salinization in the root zone and from subsidence, which may increase exposure to inundation and wave activity. Similar increases in exposure and erosion may occur with other coastal ecosystems such as those existing on dunes and in deltas. In some cases, human infrastructure may increase impacts by not allowing movement of systems such as dunes or by reducing the energy-absorptive capacity of the shoreline, thus increasing erosive potential.

Aquaculture is a rapidly growing coastal zone industry approximately tripling in production from 1990 to the present. Further increases in demand are anticipated. These fisheries use large amounts of fishmeal and fish oil and the supply of these could be reduced from climate change impacts on the fish species used. Further impacts may occur through higher water and air temperatures in the feeding pens. In cooler climates there may be a lengthening of the growing season, increasing growth rates and feed conversion efficiency. However, warmer water and associated reductions in dissolved oxygen levels may increase the intensity and frequency of disease outbreaks and the occurrence of toxic algal blooms which, along with the increased nutrient loads may have adverse impacts on adjacent ecosystems. As with other coastal infrastructure there may be increased damage from climatic events.

See also: Aquaculture and Environment: Global View from the Tropics to High Latitudes, Volume 3.

Tropical cyclones have significant impacts on coastal zones. Recent analyses suggest little change in frequency or initial locations of storms, although the maximum intensities may increase by 10–20%. Increased ocean temperatures may allow the storms to intrude further into the mid-latitude belt and persist longer. Such storms will result in increased intensity of rainfall events in coastal catchments, which may increase sediment loads. Whilst this may reduce coastal erosion rates and in some areas increase coastal accretion, it could also reduce ecosystem productivity through reducing light penetration in coastal waters. This would particularly affect communities such as sea grasses, which are a significant habitat for many species. The impacts of such reductions in habitat quality from climate changes are likely to be enhanced by human activities such as the transfer of exotic organisms in bilge water, pollution and increased disturbance.

The fossil record suggests that poleward migration of the component species of terrestrial ecosystems has occurred in past global warming episodes. Migration may be feasible for some species over the next centuries. However, southerly or northerly coastal zones represent major migration barriers to many species. Thus, there could conceivably be a concentration of organisms along such coasts. This could present a significant challenge for biodiversity management given the array of new interactions that would happen in such cases and the high level of disturbance and fragmentation in coastal areas due to the generally high human population densities found in such environs. Regions particularly prone to such issues include the megadiverse Cape region of South Africa and southwest Western Australia.

Freshwater and Wetland Systems

Freshwater ecosystems such as streams, lakes and inland wetlands, cover only a relative small area of the Earth's land surface (wetlands are 2.3%). They account for only 0.009% of the total volume of water on Earth, with groundwater approximately 66 times more abundant than surface freshwater (*see* Marshes, Anthropogenic Changes, Volume 3). They have an enormous diversity of fish, amphibians, aquatic plants, invertebrates and microorganisms, as well as being an important refuge, feeding and breeding ground for birds and many other terrestrial fauna. They provide a fundamental resource for humans, and have significantly in uenced economic activity and the distribution of human

settlements. Human activities have profoundly impacted on these ecosystems through extractions, drainage, diversions, dams, pollution and species introductions.

Freshwater ecosystems are potentially very sensitive to climate change because of the strong linkages between climate and regional hydrology. Many of these linkages are well understood, but despite this, projections of climate change for freshwater systems remain very uncertain. This is primarily due to the coarse spatial resolution of most current general circulation models and the disparity between the timescales for which information is often provided and those that impact on hydrology (sub-daily). As a result, it is difficult to make broad generalizations about the impact of climate change on freshwater ecosystems without specific reference to particular studies, locations or ecosystem types.

Hydrological regimes are highly sensitive to changes in rainfall. Reductions in precipitation disproportionately reduce mean flows (e.g., a 1% reduction in rainfall results in a 3% reduction in flow in the Gambia River, Africa), increase frequency of low-flow events and reduce frequency of floods. Similarly, increases in rainfall tend to disproportionately increase the frequency of floods. Thus, a critical impact of climate change will be altering the variability of the flow regime and the impacts that this will have on the biology, biogeochemistry and hydrological functions of the associated ecosystems. The sensitivity of the system to such changes tends to be greater in dry environments than in wetter ones. Changes in the behavior of large-scale systems that cause climate variability, such as ENSO, will further affect hydrology. As noted previously, human activities have profoundly affected riverine systems through the construction of large in-stream water storages, small off-stream water storages (e.g., farm dams) and extractions for irrigation. These activities are expected to increase. For example, all the surface water of India will be needed for irrigated crops to just meet growing domestic food demands by 2040. These impacts will interact with any alterations in hydrology caused by climate changes.

The degree to which extreme events, such as floods and drought, impact upon a region is determined by the physical and biological characteristics of the catchment and the degree of human-induced change and not simply climate alone. For this reason, there is a need to consider the impact of climate change on the source/sink relationship between terrestrial and freshwater ecosystems, in order to gain a more holistic understanding of the full implications of climate change. Predictions for terrestrial ecosystems suggest that vegetation composition and distribution will be influenced by changes in temperature and rainfall. If terrestrial production increases, there will be an associated increase in the supply of detritus to adjacent aquatic systems via an effective riparian filter system, which may in turn increase aquatic productivity. Alternatively, decreases in terrestrial productivity caused by a loss of forest cover may degrade the capacity of riparian vegetation to filter out sediment and nutrients, increasing turbidity levels and creating nutrient imbalances that might result in a decrease in aquatic productivity or eutrophication and an increase in toxic algal bloom frequency.

Changes in water temperature and the thermal structure of water columns caused by climate warming are likely to have a major influence on the productivity, persistence and diversity of the species that inhabit these systems. This change might simply be caused by an increase in ambient air temperature, or alternatively, through a shift in the proportions of rain and snow in mountainous regions, resulting in a change in the timing and temperature of runoff. These changes are expected to be more intense at higher latitudes, but nevertheless, extinction of species may occur anywhere that dispersal requirements are prevented by physical or temperature-induced isolation within streams and lakes.

Climate change will affect the cycling of carbon within freshwater wetlands. Some wetlands currently acting as a CO_2 sink are likely to change to a CO_2 source in response to increased temperatures and/or a lowering of water tables. These changes may already be occurring in some high latitude regions. The magnitude and timing of methane emissions will change in response to changes in current wetting and drying regimes, with depletion of wetlands decreasing these emissions but with construction of more dams increasing them.

The distribution and area of wetlands are expected to change with greenhouse warming, but the direction and magnitude of this change are unclear. Any climate impacts will be an added stress as these systems are already under serious threat from human activity. For instance, half of the world's wetlands are estimated to have been destroyed since the beginning of the 20th century. This destruction is expected to increase, particularly in developing countries, and therefore any potential impact resulting from climate change must be placed within the context of further anthropogenic change.

ADAPTATION STRATEGIES

In almost all of the systems discussed above, climate change will occur in conjunction with a multitude of existing and growing pressures from human activities. Consequently, in many ecosystems, a prerequisite for adaptation to climate change is the development of more sustainable management regimes. Development of these regimes, as well as adaptation options to global change, need to take into account the institutional, legal, socio-economic and cultural context in which they will be applied. These are significant challenges. For example, climate change will possibly

make less relevant many of the world's existing biosphere conservation systems. Lack of connectivity between these areas means that, at best, they may become refugia for species that no longer are adapted to the local climate. Locations such as mountain tops, islands and coastal zones on poleward sides of continents will be particularly prone to becoming refugia. Over time, greater inputs will be needed to maintain the resident species against various threatening processes and there may be depletion of a diverse gene pool. Difficult decisions will arise over whether to transplant species from other refugia and what that would do to the existing resident species. The alternative of developing a substantial off-reserve conservation system is becoming more difficult as landuse intensifies, with competing priorities from different land users (e.g., tourism versus farmers with respect to the elephants in the Serengeti), with the continuing introduction of exotic plant and animal species, with growing political and institutional instability in some nations and with conversion of existing land-tenure arrangements.

Ecosystems will adapt to climate change and related factors. Actions can be taken that facilitate this adaptation (i.e., providing connectivity across landscapes for migration of species or emplacement of fish ladders across dam walls). There is also the possibility of more actively assisting these changes, such as transplanting species or attempting to ameliorate factors that may prevent some species from adapting (e.g., provision of environmental flows to wetlands). However, this can sometimes have unforeseen consequences (e.g., this may increase the threat to organisms which have adapted to the previous regime). These will only be understood and resolved by research into these ecosystems linked with appropriate monitoring and adaptive management.

Scenario analysis, which investigates impacts in, say, the year 2050 or 2100 has often resulted in climate change not being taken into account in conservation planning as it is beyond the planning horizon. However, in many ecosystems there is growing evidence that observed changes in climate are already having biological impacts that fit with *a priori* predictions of those under future climate change. At this stage it is not possible to attribute these climatic changes to human activities even though in many cases they are in accord with predictions of such changes. An argument can be made that these changes need to be considered in conservation planning regardless of whether they are due to longer-term variability or climate change. Furthermore, there are other factors, which are attributable to human activities (increased CO_2 levels, nitrogen deposition, tropospheric ozone and UV-B) that already are likely to be having impacts. Hence, global change should already be considered in the management of natural ecosystems both on the basis of the current changes listed above as well as anticipatory adaptation that addresses existing pressures, which will reduce vulnerability associated with climate change.

Plant Dispersal and Migration

JAMES S CLARK, B BECKAGE, J HILLERISLAMBERS, I IBANEZ, S LADEAU, J MCLACHLAN, J MOHAN, AND M ROCCA

Duke University, Durham, NC, USA

Although Americans may have first seen kudzu (Pueraria lobata) *on US soil at the Philadelphia Centennial Exposition of 1876, broad distribution throughout the Southeast did not come until decades later. Kudzu is known for its rapid growth, a potential to bury forest canopies in dense foliage in the course of a single growing season. It is natural to attribute its success as an alien invader to an aggressive habit that co-opts the light supply of native vegetation. But kudzu's inherent invasive potential may be overrated. The modern distribution is the result of a determined campaign to broadly disseminate the species (reproduction is almost entirely vegetative). Even retail (including mail order) sales of the curious ornamental during the early decades of this century might not have been enough to establish it as the dominant alien it has become. That dominance dates from the 1930s, when the Soil Conservation Service paid farmers $8.00 an acre to stabilize their fallow fields, and the Civilian Conservation Corps distributed kudzu widely to control erosion (Miller and Edwards, 1982). In the absence of detailed records of planting during the Depression and additional establishment since, history provides few insights regarding its potential for spread in the absence of intentional propagation by humans.*

Worldwide invasions of exotic plants, together with environmental changes that threaten native species, challenge ecologists to understand population spread in the context of dispersal potential. Many countries now support resident populations of hundreds to thousands of invasive exotic plant species. Exotics represent greater than 50% of the flora on many remote islands (Vitousek et al.*, 1996). Biological invasions by exotic species change the composition and community structure of invaded areas. In addition to the obvious effects of competitive exclusion, such as occurred with yellow star thistle's* (Centaurea solstitalis) *invasion of northern California grasslands, there are less direct effects. Some of the more devastating consequences of cheatgrass'* (Bromus tectorum) *invasion of the intermountain West came from increased fire frequency, which results in a loss of shrubs (Whisenant, 1989). Introduced cordgrasses* (Spartina *spp*) *on tidal flats around the globe have devastated shorebird populations that depend on tidal flats for food (Daehler and Strong, 1996). There is increasing evidence that alien invaders can alter properties of whole ecosystems, including productivity, nutrient cycling, and hydrology (Vitousek, 1990).*

INTRODUCTION

The globe's 250 000 extant species of seed plants have unique distributions and migration histories. *Plant migration* is defined here as a change in the distribution of mature plants that spans more than a generation. Distributions can be continuous or discontinuous. Changes in distributions include both expansions and contractions, but we focus here on expansions. Geographic distributions represent a balance between seed dispersal and vegetative spread, both of which tend to extend the range, and environmental constraints on survival that keep it in check. Population frontiers are static when dispersal does not bring propagules to areas outside the range where they currently survive. Migration occurs when there is a change in dispersal, the environment, or both.

Dispersal and the potential for population spread have dual implications for populations confronted by global change. On the one hand, migration potential, typically aided by human transport, has brought epidemics of exotic aliens with attendant costs in biodiversity loss, restructuring of ecosystems, and the burdens of control measures. Potential forage species, such as alien grasses introduced in the American West (Mack, 1986) and prickly pear (*Opuntia stricta*) in Australia (Parker, 1977) have had severe economic consequences. Aquatic ornamentals, such as water hyacinth (*Eichhornia crassipes*), clog waterways in the southeastern US. Pimentel *et al.* (2000) estimate that 35 billion dollars are spent annually on control of invasive plants in the US. Eradicating or delaying the spread produces unintended consequences, and success rate is low (Daehler and Strong, 1996). Educational activities aimed at

alerting the public to potentially dangerous exotics date to the 19th century, and include bulletins that would aid identifications of seed contaminants by farmers (Mack, 1986). Efforts to increase public awareness might help stiffen existing laws and policies aimed at reducing invasions (Vitousek *et al.*, 1996), but effective legislation requires an understanding of how migrations occur.

On the other hand, a potential to migrate has saved species from extinction during repeated climate changes of the past. The legacy of prehistoric and contemporary plant migrations includes many examples of environmental change, both natural and human-caused, that have led to continental-scale changes in species distributions. The migration potential required to survive past environmental change will be needed again as global change accelerates. Recognition of species threatened by rapid climate change requires an understanding of migration potential.

The history of kudzu spread in the southeastern US captures many of the frustrations of determining how dispersal figures in plant migration potential. Differential ability to invade new environments begs the question of just how important is dispersal. Of the 25 000 alien plant species in Florida, an impressive 900 have become established in native vegetation (Pimentel *et al.*, 2000). The flip side of this calculation is the $>24\,000$ species that can grow there but have not escaped to become components of unmanaged vegetation. Seed dispersal does not appear to contribute importantly to contemporary spread of kudzu. We do know that the modern dominance of this perennial vine began with a widespread planting campaign. Clearly, dispersal potential is only one of many factors that might ultimately predict the potential for and rate of spread.

Although we focus here on how dispersal affects the potential for migration, most of the examples we consider involve widespread changes in the environment, including climate, land cover, or trophic structure (e.g., introductions of other aliens or absence of natural enemies in novel environments). We begin with a brief summary of what we have learned from models of migration, all of which have dispersal at their core. We then summarize the state of our knowledge on dispersal biology, with special emphasis on long-distance events and how well we can estimate them. We then turn to past plant migrations, both prehistoric and contemporary, for the light they can shed on migration potential. Finally, we synthesize the overriding themes that emerge from theory, dispersal biology, and the prehistoric and historic record as a basis for some general guidelines that may help us forecast future migrations and areas needing further research.

THE ELEMENTS OF PLANT MIGRATION

The Dispersal Vectors that Account for Spread

Analyses of factors that might control migration potential identify as key variables total seed production and extreme dispersal events. These two variables go hand in hand, because extreme events become increasingly probable with increased seed production.

The scatter of seed about the parent plant is termed the *seed shadow*. The shape of the seed shadow is determined by the dispersal kernel, which describes the probability that a seed released from the parent plant will travel a given distance. The density of seed expected to settle a given distance from the parent is found by multiplying the dispersal kernel by total seed production, or fecundity. Dispersal kernels for seeds are termed *fat-tailed*, the tail referring to the few long-distance dispersal events. Although these long-distance events are rare, they can still dominate the rate of spread (Figure 1). One rare long-distance event can

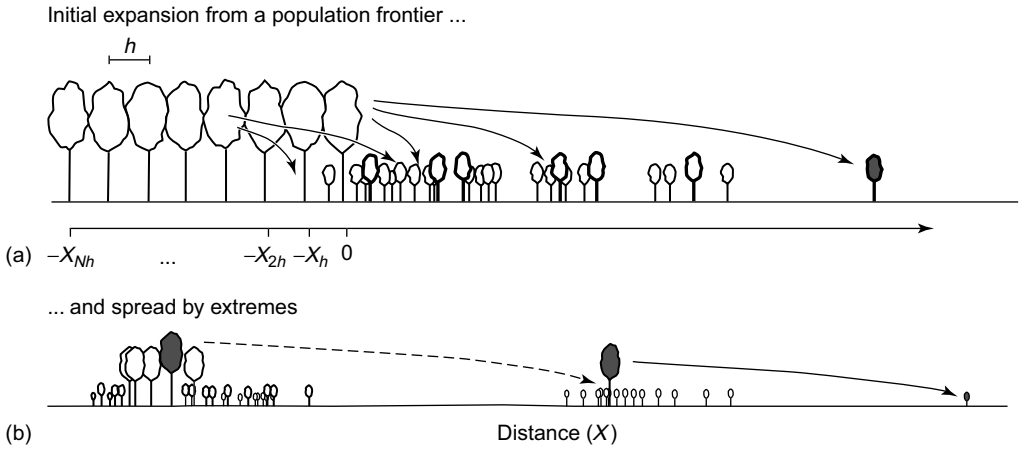

Figure 1 A plant migration includes both diffusive spread that results from local dispersal as well as rare, extreme events that can result in fast and erratic invasion. Spread from a coherent population frontier can proceed rapidly due to combined seed production of large numbers of adults (a), whereas total seed availability diminishes far from the population frontier (b). (Reproduced with permission of the University of Chicago Press from Clark *et al.*, 2001)

overshadow the contributions of the bulk of seeds that land near the parent.

To gain a rough idea of how fecundity interacts with the shape of the seed shadow, compare the velocities of spread predicted by simple models of diffusion and fat-tailed spread. Diffusion refers to a traveling wave of advance that results in the absence of rare, long-distance events. The velocity of this traveling wave is proportional to the square root of the log of lifetime seed production R_0, or net reproduction rate (Kolmogorov *et al.*, 1937; Skellam, 1951). Thus, the rate of spread is only weakly affected by total seed production. By contrast, the velocity of spread expected from dispersal kernels fitted to trees is proportional to the square root of lifetime seed production (Clark *et al.*, 2001).

These two results diverge as R_0 becomes large, because the tail of the dispersal kernel translates at least some of the increased seed production into long-distance events. Diffusive spread occurs when such events cannot occur, regardless of fecundity.

Despite a large dispersal biology literature, seed production and dispersal are poorly quantified for most species in most settings. In general, dispersal data tell us that plants tend to have fat-tailed dispersal kernels (Portnoy and Willson, 1993; Clark *et al.*, 1999a) and dispersal distance depends on aerodynamic properties of seed (Figure 2). Models tell us that when the kernel is fat-tailed, extreme dispersal events control the rate of spread (Kot *et al.*, 1996; Lewis, 1997; Clark, 1998), and total seed production has strong impact on the extremes (Clark *et al.*, 2001a,b). Especially high fecundity is a clue that extreme events can be particularly important. Thus, predicting migration potential by any dispersal mechanism depends on our ability to estimate extreme events and seed production.

Figure 2 The samaras of *Acer rubrum* seed are an example of specialized structures for wind dispersal

Dispersal by Wind

Long-distance dispersal by wind is poorly quantified, but seed trap studies combined with observational data suggest that it can range over many kilometers. Wind dispersal depends on aerodynamic properties of seed, which vary among species, and on wind fields, which vary in space and time. Many species have seeds that are highly specialized for wind dispersal. Plumed fruits and the parachutes of *Taraxacum* and other Liguliflorae (Compositae) provide for broad dissemination in wind velocities of less than $1\,\mathrm{m\,sec^{-1}}$ (Weaver and Clements, 1938). The spread of tumbleweed (including *Salsola kali*) through the Dakotas near the turn of the century was facilitated by saltation of dead plants that scatter seed in transit. Larger seeds have shorter extremes. The well-developed samaras of *Acer rubrum* (Figure 2) increase drag and, thus, reduce fall velocity. The few studies that have measured wind dispersal for multiple years at a single site report significant interannual (Houle, 1998; Clark *et al.*, 1999b) and stand (Clark *et al.*, 1999b) variability in seed production, but shape of the seed shadow is relatively consistent (Clark *et al.*, 1999a). Dispersal distances for temperate deciduous, mixed conifer, and lowland tropical forest species average less than 40 m, with highest mean values for species that produce especially small seeds (e.g., *Betula*) (Gladstone, 1979; Ribbens *et al.*, 1994; Clark *et al.*, 1998, 1999a). Wind-dispersal is more efficient in areas of limited vegetation cover, which reduces wind velocity near the ground.

Long distance dispersal is erratic and hard to predict. Extreme dispersal is not quantified, but fitted dispersal models are fat-tailed at distances of $<100\,\mathrm{m}$ (Clark *et al.*, 1999a), and there are examples of population spread due to seed movement in open environments that exceed 10^3 m. For example, colonization of Glacier Bay at rates of $300-400\,\mathrm{m\,year^{-1}}$ (Fastie, 1995) is comparable with rates inferred from fossil pollen data in the early Holocene (Ritchie and MacDonald, 1986). Storms can transport objects larger than seeds $>100\,\mathrm{km}$ (Snow *et al.*, 1995).

The importance of long distance dispersal for spread is evident on isolated islands, which cannot be reached by diffusive spread. For example, 30% of the seed-bearing plants on Krakatau ($\sim$30 km from Java and 12 km from the

nearest small island) 15 years after the 1883 eruption were brought by wind (Ernst, 1908). Although long-distance dispersal by wind was important, wind-dispersed taxa were underrepresented.

Extreme dispersal by wind is poorly quantified, but there is sufficient evidence to conclude that it is a plausible mechanism for rapid spread of relatively small-seeded species that release seeds in the canopy. It is a less plausible mechanism for especially large seed and for seeds released in dense understories.

Dispersal by Water

Seed transport by water (*hydrochory*) permits spread to islands, along coastlines, across large water bodies, and along river systems. Potential for long-distance dispersal by water is more readily estimated than for wind, because the direction of transport is more predictable, as are advection rates (flow velocities in rivers or ocean currents) and residence times in the water column, which depend on seed properties. For example, the tropical Atlantic shores of South America and Africa are linked by equatorial currents, and they share a common mangrove flora. This flora is distinct from the East Africa, India, and Malaya mangrove flora (Guppy, 1917). Lack of a connection between east and west African coasts, despite their proximity, explains their lack of common species. The efficacy of water transport is apparent from observational studies (e.g., Weaver and Clements, 1938; Craddock and Huenneke, 1997), and it is the only explanation for the presence of some species in remote sites (Godley, 1967).

Colonization of remote islands and spread along coastlines requires adaptations for flotation and salt tolerance. Transport is governed by ocean circulation and by local tidal currents (Huiskes *et al.*, 1995). *Cocos nucifera* (Arecaceae) with its corky husk withstands some exposure to salt water (Schimper, 1891). Small hairs on the seeds of *Salicornia*, a salt marsh chenopod, trap air and facilitate dispersal with tides (Dalby, 1963). Other adaptations involve enlargement of the diaspore surface (e.g., *Matricaria maritima*, Ridley, 1930) and buoyant structures that remain attached to seed, including carpels (Guppy, 1917), perianth bracts (König, 1960), and fragments of the inflorescence (Dalby, 1963). Many mangrove species (involving several angiosperm families) are viviparous, whereby seedlings develop while still attached to the parent plant. Seedlings photosynthesize and obtain nutrients and water while borne on ocean currents and can remain viable for a year or more (Davis, 1940). Seedlings of red mangrove (*Rhizophora mangle*) have a buoyant hypocotyl, whereas other species have buoyant pericarps, cotyledons, or entire embryos (Rabinowitz, 1978).

Extended viability in ocean currents can result in extreme long-distance colonization. The isolated estuaries of the Pacific coast represent islands of suitable habitat for introduced cordgrasses (*Spartina*) that are invaded by propagules borne on tidal currents (Daehler and Strong, 1996). Some mangrove species are capable of voyages spanning the largest oceans (including the Indian, western Pacific, and Atlantic, Sauer, 1988). Accumulation of species on remote oceanic islands is probably limited, in part, by water dispersal (Ernst, 1908).

Rivers can provide corridors for rapid migration. In riparian zones, some trees time fruiting to coincide with seasonal floods (Schneider and Sharitz, 1988; Kubitzki and Ziburski, 1994). Thebaud and Debussche (1991) suggest that water transport during autumn floods facilitates the spread of the typically wind-dispersed species *Fraxinus ornus*. Seeds dispersed by water first colonize littoral (Murray, 1986) or riparian zones, but a spread to upland areas can follow. North-flowing rivers of Eurasia might have accelerated plant migrations following the last ice age (Huntley and Birks, 1983).

Water dispersal can result in rapid spread, but it is limited by the distribution and velocity of water currents. For example, Eurasia contains many northward flowing rivers that might facilitate post-Glacial spread to high latitudes, whereas eastern North America does not.

Animals

Many of the hypotheses that concern rapid plant migration involve vertebrate vectors (Reid, 1899; Johnson and Adkisson, 1985). Vertebrates disperse seed by ingesting fruits and passing or regurgitating seeds intact (endozoochory), by caching (dyszoochory), and by carrying seeds that adhere to fur or feathers (epizoochory) (Howe and Westley, 1997). The most important vertebrate dispersal vectors are: (i) hoarding mammals and birds; (ii) arboreal frugivorous mammals that consume fruits with arils or pulps containing protein, sugar, or starch; (iii) bats that feed on pulps rich in lipids or proteins; and (iv) frugivorous birds (Howe and Westley, 1997). Birds and mammals are the most common vertebrate dispersal agents, but other vertebrate vectors include fish (Goulding, 1980), turtles (Moll and Janzen, 1995), and lizards (Nogales *et al.*, 1998). Ants disperse large quantities of seed, but dispersal distances are typically small, averaging perhaps one meter and ranging to 10 m (Hughes and Westoby, 1992). Vertebrates can process a large portion (e.g., $>70\%$) of a plant's seed or fruit production (Herrera *et al.*, 1994; Vander Wall, 1994) and, therefore, may have a large impact on dispersal. Dispersal is further influenced by birds that prey on other vertebrates that have consumed seed (Reid, 1899; Nogales *et al.*, 1998).

Plant adaptations that facilitate spread by vertebrates have probably contributed to past invasions. Darwin (1859) reports >80 seeds of several species in dried mud taken from a partridge leg. Elaborate adaptations to attract frugivores include thickened seed coats surrounded by brilliant, multicolored fleshy pericarp (Howe and Westley, 1997). Reproductive structures that adhere to animal fur may have

facilitated 20th century invasion of the intermountain West by cheatgrass. Barbs of *Xanthium* and *Bidens* fruits allow for similar mobility. Remote sites may be especially dependent on vertebrate vectors. Birds may have brought >75% of the flora to the Galapagos (Porter, 1976) and smaller fractions of total floras to islands that are less remote (Ernst, 1908). Vertebrates as large as elephants are important dispersers for some plant species today (Chapman *et al.*, 1992), and loss of Pleistocene megafauna may have subsequently limited spread of these species (Janzen and Martin, 1982).

The benefits of animal dispersal can be overemphasized, because losses are typically large (Schupp, 1993). Spread is facilitated not only by transport (Janzen, 1971; Harper, 1977) but also by scarification (pregerminative influences that make seed coats permeable to water and gases) (Fenner, 1985; Chapman *et al.*, 1992) and provision of concentrated resources, such as in animal dung high in nitrogen and phosphorus (Bazzaz, 1991; Chapman *et al.*, 1992). But most vertebrate vectors are seed predators. As little as 1% of seed handled by vertebrate seed predators may escape eventual consumption (Cahalane, 1942), although it can range as high as 15 to 75% (Forget, 1990; Steele and Smallwood, 1994), particularly in years of high seed production. Even frugivores, which pass seed through the intestinal tract intact, can lower viability (Murray, 1988).

Vertebrate dispersal can be more directed than wind dispersal in ways that might have particular significance for migration. Seeds are moved to microsites or habitats that may be especially suited to seedling survival (Hulme, 1997; Hoshizaki *et al.*, 1997; Vander Wall, 1994). Seed burial within specific habitats (Yasunda *et al.*, 2000) can promote establishment success (Forget, 1990, 1991). In one study, common ravens dispersed numerous seeds and placed 75% in habitats favorable for germination (Nogales *et al.*, 1999). Blue jays preferentially cache seeds in regenerating woodland and edge habitats, which may have facilitated spread in the past (Johnson *et al.*, 1997; Kollmann and Pirl, 1995). Herrera *et al.* (1994) found that birds tend to disperse seeds to forest–gap interfaces. Transport to favorable habitats not only increases establishment success, but can also affect dispersal distance, depending on the distribution of land cover.

Dispersal distances vary greatly among vertebrate vectors. Rodents move seeds 10^0 to 10^1 m (Forget, 1990; Kollmann and Schill, 1996) with maximum recorded distances ranging from 20–70 m (Forget, 1990; Tamura and Shibasaki, 1996; Yasunda *et al.*, 2000). Rodent seed caches are repeatedly moved and sometimes robbed by other rodents, potentially increasing the distance seeds are dispersed beyond a single individual's home range (Tamura and Shibasaki, 1996; Vander Wall, 1994). Foxes and bears, which consume fruits, may travel 10 km in a day (Storm and Montgomery, 1975) suggesting potential for long-distance dispersal. Old World frugivorous bats have the potential to disperse small seeds hundreds of kilometers (Shilton *et al.*, 1999). Primate seed dispersal in a Columbian forest ranged from 218 ± 82 to 354 ± 199 m (depending on species) with maximum values exceeding 600 m (Yumoto *et al.*, 1999). Birds commonly move seeds 10^2 to 10^4 m (Kollmann and Schill, 1996; Webb, 1986; Murray, 1988; Johnson and Adkisson, 1985; Vander Wall and Balda, 1977).

Despite obvious potential for long distance dispersal by large vertebrates, there are few quantitative data on extremes. As with other vectors, the most important dispersal events, i.e., the long distance ones, are most likely to be missed. Most of reported extreme distances by birds and large vertebrates are less than 10 km. But storms can disperse birds over large areas resulting in extremes that are difficult to quantify.

LESSONS FROM THE PAST

Recent global warming does not represent the first time that survival of plant species has depended on migration. Ice ages saw repeated and sometimes rapid climate changes. In regions of steep climate gradients and topographic complexity, such as the Atherton Tableland of northern Queensland, declining aridity during the Holocene meant that rainforest species may have migrated only tens of kilometers to replace the sclerophyll vegetation that dominated during Glacial times (Kershaw, 1993; Hopkins *et al.*, 1990). Mountains of southern Europe (Tzedakis, 1993), western North America (Barnosky *et al.*, 1987), South America (Hoogheimstra, 1984), and Africa (Street-Perrott *et al.*, 1997) support, within a given region, most of the same species today that they did during the last glacial maximum (LGM) (*see* **Last Glacial Maximum**, Volume 1). Topographic complexity provides for a range of local climatic conditions that buffer the effects of climate change.

In areas of low relief, such as eastern North America and western Eurasia, suitable habitats for many species shifted across continents. Populations that have survived in these regions migrated repeatedly over successive glacial cycles, perhaps at rates exceeding 10^2 m year^{-1} (Davis, 1986; Huntley and Birks, 1983). Ever since a rough time scale for Pleistocene climate changes became available, ecologists have been impressed with the seemingly impossible dispersal distances required to explain post-glacial spread of plant populations at these continental scales (Reid, 1899; Davis, 1987; Clark *et al.*, 1998b, Figure 8). In eastern North America and western Europe, glacial distributions of temperate species are thought to have been well south of modern distributions. Although the fossil evidence for glacial distributions is spotty, the southern edge of the Laurentide ice sheet in North America represents an extreme northern range limit for most species. Populations that now occupy regions north of the southern ice margin must

have migrated at least that far since the LGM, and most temperate species are thought to have come from refuges much farther south.

Diffusive spread is too slow to account for migration of trees (Skellam, 1951; Clark, 1998), and they are especially inadequate for herbaceous plants. Cain *et al.* (1998) concluded that there is no documented mechanism by which most woodland herbs could have reached their modern geographical ranges since the LGM. For many woodland herbs, ant dispersal is inadequate, and seeds released only centimeters above the forest floor are not susceptible to transport at wind speeds typical of forest understories. Occasional long-distance dispersal events appear to be the only explanation for Holocene colonization of northern temperate forest by woodland herbs.

The fact that dispersal data from modern plant populations do not agree with the rapid spread inferred from the paleo record has been termed *Reid's Paradox* (Clark *et al.*, 1998). Davis (1987) envisioned migration occurring as a series of long-distance leaps by a few propagules that disperse well beyond the typical seed shadow (Figure 1). Birds (Reid, 1899; Webb, 1987; Wilkinson, 1997), wind storms (King and Herstrom, 1997), and water transport (Firbas, 1948) are all cited as potential dispersal vectors. Clark (1998) showed that a small amount of long-distance dispersal is consistent with actual dispersal data that might agree with the rapid spread of some paleo-species.

There is increasing evidence for barriers to migration that limited spread of species or genotypes. Molecular (chloroplast DNA) data from tree populations in western Europe suggest that east–west oriented mountain ranges profoundly affected dispersal and, thus, migration at the end of the last ice age. For example, during the LGM, European beech (*Fagus grandifolia*) was present in both Italy and the Carpathians. But the Italian populations do not appear to have traversed the Alps, and northern European populations originated in the Carpathians (Hewitt, 1999).

Some of these same geographic boundaries bolster the argument that long-distance dispersal contributed to past migrations. Fossil pollen data indicate that the Baltic and North Seas (Kullman, 1996) and the Great Lakes (Webb, 1997; Woods and Davis, 1989) did not represent important obstacles for many species, but oceans did. In contrast to European beech, oak species in western Europe appear to have followed several migrational pathways (Figure 3b). A decline of genetic diversity with distance away from Pleistocene refugia (Ibrahim *et al.*, 1996; LeCorre *et al.*, 1997) and highly structured regional populations (Petit *et al.*, 1997) have been interpreted as consistent with long-distance dispersal events.

Although they represent one of the few plausible alternatives, extreme events, such as those described by fat-tailed dispersal kernels, may not be the complete solution to Reid's Paradox. Clark *et al.* (2001) demonstrate that traditional ways to estimate spread from dispersal data overestimate the potential velocity. A reassessment of migration potential parameterized with modern dispersal data predicts much slower spread than has been interpreted from the paleorecord. No model can rule out the possibility of past long-distance events, but these new analyses suggest that rapid migration is harder to achieve than we previously thought.

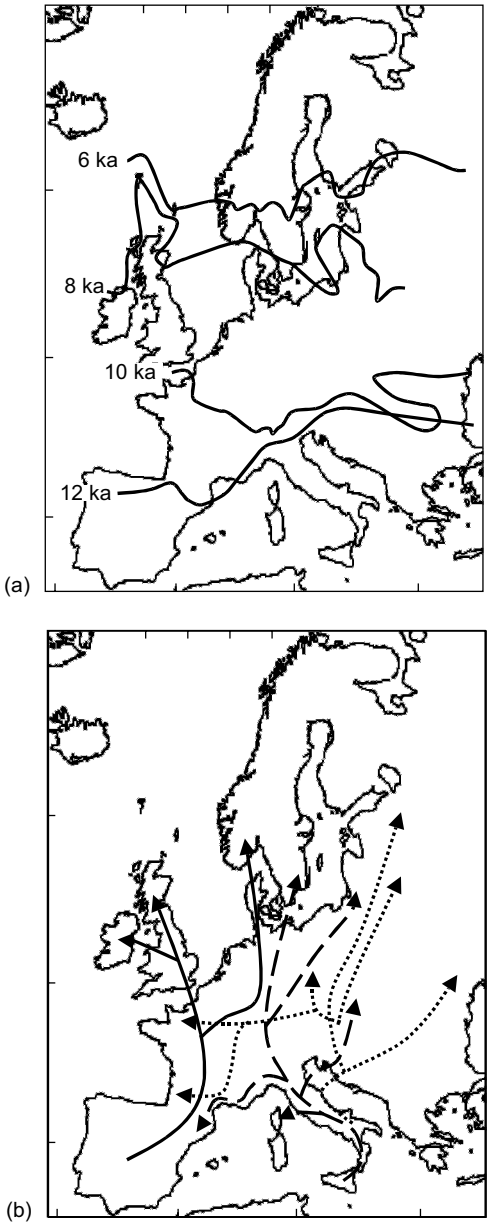

Figure 3 Two perspectives on Holocene oak migration in Europe. (a) The 2% deciduous oak isopols contoured from oak pollen recovered from sediment cores (adapted from Huntley and Birks, 1983). (b) Migration routes reconstructed from cpDNA of modern oaks (adapted from Dumolin-Lepegue *et al.*, 1997)

The reanalysis that revises lower predicted rates of spread suggests that the interpretation of the fossil record could bear further consideration. Moreover, not all interpretations of the paleorecord imply the high rates of spread that seem necessary to explain migration of temperate trees from the southern US to temperate latitudes. Bennett (1985) argues that temperate species may have existed at temperate latitudes (albeit, south of the Laurentide ice margin) before the Holocene. He points out that the fossil pollen data that have been used to interpret spread do not provide concrete evidence for the presence of populations at low density. In North America, two recent studies suggest the presence of temperate hardwoods at least as far north as 35 °N during the LGM (Russell and Sanford, 2000; Jackson *et al.*, 2000), which does not imply migrations rates as high as those needed if populations were much further south. In western Europe the LGM climate was more extreme than in North America, so it is likely that many populations did indeed migrate from southern Europe.

If migration potential represented an important constraint during past climate change, then glacial transitions might be times of extinction. The fossil record does not provide detailed evidence for past extinctions, because fossil pollen resolve most taxa only to family or genus level. Thus, we could detect extinctions only of species that can be resolved in the fossil record. Despite the limitations of the fossil record, several extinctions near the LGM suggest that dispersal limitation during times of rapid warming might be a contributing factor. The rainforest genus *Dacrydium* disappeared from northern Queensland near the LGM when rainforest contracted due to climate change (Kershaw *et al.*, 2000). Fossil cones and needles suggest that *Picea critchfeldii* may have been both abundant and widespread in eastern North America during the LGM, but the fossil evidence disappears at the time of most rapid climate change from 12 to 9 ka. Timing of the event suggests that migration potential might have been a contributing factor (Jackson and Weng, 1999) as may have been the case for *Sequoia*, *Tsuga*, *Carya*, and *Nyssa* during earlier glacial cycles in Europe (West, 1970).

Contemporary Invasions

Because contemporary invasions can be documented, they hold promise for improving our understanding of how dispersal contributes to migration. Most intercontinental invasions begin with human dispersal. Countless examples of non-native invasive species in America have attended globalization of trade, including ornamental plantings (e.g., Brazilian pepper (*Schinus terebinthifolius*), salt cedar (*Tamarix*), velvet leaf (*Miconia calvescens*)), accidental escapes or contaminants (e.g., leafy spurge *Eupohorbia esula*, cogon grass *Imperata cylindrica*, cheat grass *Bromus tectorum*), and erosion control (e.g., mangroves *Rhizophora mangle*, iceplant *Carpobrotus edulis*, kudzu *Pueraria lobata*) (Plant Conservation Alliance, 2000).

Once introduced, aliens have spread at very different rates. The large numbers of recent alien introductions should provide a rich data source concerning the role of dispersal. Unfortunately, the dispersal biology of invading species has seldom been studied in the context of the spatial pattern of spread (Parendes and Jones, 2000), and there are few examples of migrations that can be linked to dispersal data. Most contemporary invasions are known from anecdotal information on time and location of introduction, mode of spread, and impacts on native communities (Mack, 1986). Studies of the invasions themselves tend to focus on the characteristics that make ecosystems prone to invasion (Hobbs and Huenneke, 1992; Lonsdale, 1999) or on characteristics of species that make for successful invaders (Perrins *et al.*, 1992). Several studies that have examined seed dispersal after invasions (Van Wilgen and Siegfried, 1986; Malo and Suarez, 1997) focus on characteristics of seeds rather than on the spatial aspects of spread. While experience with contemporary invasions becomes the basis for assessing invasive potential and for restrictions on the import of exotic species (Ruesink *et al.*, 1995; Ewel *et al.*, 1999), poor understanding of dispersal partly explains our low predictive capability, even *post hoc*.

Several examples where dispersal biology has been reconstructed *post hoc* illustrate the idiosyncrasies of individual invasions. Some species that are absent from suitable habitats, upon introduction, expand rapidly. In 1902, the American Sugar Corporation introduced *Rhizophora mangle*, a Florida mangrove, to Molokai, Hawaii, in an effort to mitigate coastal erosion. The islands had not supported mangrove species prior to this time, presumably due to dispersal limitation. *R mangle* dispersal depends on ocean currents, and those that affect Hawaii flow from the direction of Alaska. However, once introduced, the species has spread by natural drift throughout the archipelago (Wester, 1982). The *R mangle* example illustrates that even a broadly dispersed species can be dispersal-limited, depending on the details of the dispersal process.

High fecundity can interact with novel dispersal vectors to accelerate the spread of alien species. *Purple loosestrife* (*Lythrum salicaria*) came to American shores in the early 1800s in contaminated ship ballast from the European coast (Stuckey, 1980). The plant thrives in marshes, wetlands, and riparian zones, and it spreads rapidly along waterways. The plant produces $>100\,000$ seeds per stem that can disperse short distances by winds and as buoyant seeds and seedling cotyledons in flowing waters and ditches (Balogh, 1986), and along highways in high winds created by trucks (Wilcox, 1989). Once established, purple loosestrife propagates vegetatively and rapidly chokes out native plants. This rapid spread illustrates the importance of high fecundity, the effects of which are amplified by the rare,

extreme dispersal events made possible by water transport and human vectors.

The rate and pattern of spread can be highly variable. Cheatgrass (*Bromus tectorum*) migration throughout the intermountain West represents one of the best-documented alien invasions (Carpenter and Murray, 2000). A reconstruction by Mack (1986) suggests that cheatgrass probably arrived in the 1880s as a seed contaminant from Europe. Before 1900, it was noted from photographs, in collections, and by wheat growers from British Columbia to Utah. An annual with wind dispersed seeds, cheatgrass spread was accelerated by rail transport of livestock, as seeds adhere to fur, and they survive in dung. Following an initial lag phase, cheatgrass range expansion was rapid, but patchy. Centers of abundance spread to several western states in the early 1900s and coalesced over the next few decades to form a relatively continuous range in the Intermountain West. By 1930, cheatgrass had reached its current distribution across the Great Basin. The initial lag has been observed for a number of invasions (e.g., Pitelka *et al.*, 1997). The patchy spread is consistent with fat-tailed dispersal with infilling being more representative of a diffusion process.

The potential to learn from contemporary invasions is unrealized, in part, due to limited study of dispersal. When dispersal is available, it may not be enough to predict rates of spread, because disturbance and species interactions have profound effects on establishment success.

WHAT TO EXPECT: GLOBAL WARMING, MASS INTRODUCTIONS, AND HUMAN DISTURBANCE REGIMES

Dispersal is critical for plant migration, representing the first step in a complex process that involves establishment, growth, and survival. We cannot yet expect to accurately predict many new invasions. Because dispersal is too poorly understood, especially the long-distance events that disproportionately control invasion speed, migrations will be so variable that forecasts will be of limited use for any specific invasion that occurs. Global changes in disturbance, land cover, dispersal vectors, and climate interact with plant migrations, many involving scales of space and time that are not yet well-understood: in addition biotic interactions may play an overriding role in many migrations. These may not be predictable from dispersal potential or from those interactions in their places of origin.

The first two of these concerns deal directly with the relationship between dispersal and migration and are the focus of this review. Too few studies have attempted to quantify dispersal and seed production at necessary spatial and temporal scales (Clark *et al.*, 1999b). Maximum dispersal distances estimated by direct or inverse methods range to several hundred meters, although indirect evidence indicates that propagules sometimes travel much farther. Average dispersal distances are negatively correlated with seed size and positively correlated with fecundity, and fecundity is highly variable. Models lead us to expect erratic migrations with mean rates controlled by extreme dispersal events. High propagule producers have the clear advantage in this process, much more so than would be expected by a process of diffusion. Although dispersal data will allow us to develop estimates of spread potential based on dispersal ability, those estimates will have broad variance. Thus, the rates for any given species in any given environment will deviate from the expectation.

The latter two concerns are not the focus of this review, but they play such a large role in migrations that they will ultimately determine our understanding of population spread. We briefly summarize some of the changes in our biotic and physical environment that will have profound impacts on future plant dispersal and migration.

Interactions with Global Change

Changing chemistry of the atmosphere and climate present new sources of uncertainty for plant migrations. Despite interpretations that past migrations may have occurred rapidly, long distance dispersal may not save many species from the climate change associated with greenhouse warming. The rates of 21st century climate change pose unprecedented challenges to migration, perhaps requiring species ranges to shift at rates of $1-5\,\mathrm{km\,year^{-1}}$ (Davis, 1986; Dyer, 1995; Sykes and Prentice, 1996; King and Herstrom, 1997). Analyses of dispersal consequences for tree migration rates (Clark *et al.*, 2001) suggest that a number of species simply may not disperse far enough. The molecular evidence suggesting the importance of corridors for migration in Europe (Figure 3) raises additional concerns for future migrations.

A changing physical environment is complicated by a shifting biotic one. For predicting migrations, dispersal information from extant ecosystems is not enough. Contemporary invasions have surprised us before, due to unexpectedly high competitive abilities of alien species and novel dispersal vectors. Although we might have been able to quantify dispersal reasonably well in some of these cases, the migration potential often depends on interactions.

Climate change may reorganize food webs in ways that impact migration rates, as some species outrun their mutualists and natural enemies, while others become limited by new biotic settings. Vertebrate dispersal vectors and pollinators may not respond to climate change in step with the plants that would benefit from them (Bethke and Nudds, 1995; Bawa and Dayanandan, 1998; Bazzaz, 1998; Sorenson *et al.*, 1998; Visser *et al.*, 1998; Dunn and Winkler, 1999). For example, droughts that reduce wetlands and the migratory waterfowl that depend on them (Bethke and

Nudds, 1995; Sorenson *et al.*, 1998) will ultimately reduce transport of seed (Ehrlich *et al.*, 1988). Likewise, extreme winter storms reduce passerine densities and their ranges (Mehlman, 1997). Recent global warming in temperate regions has already accelerated some phenological events that affect dispersal. For example, Estonian springs have advanced eight days over the last 80 years, with the last 40 years being particularly warm (Ahas, 1999). In seasonal environments, avian reproduction is successful if timed to food availability. Future increases in spring temperature could result in a mismatch between the timing of egg laying and the availability of food (Visser *et al.*, 1998). Increasing springtime temperatures from 1959 to 1991 have caused North American tree swallows (*Tachycineta bicolor*) to lay eggs nine days earlier (Dunn and Winkler, 1999). The potential decoupling of plant-animal phenologies may be particularly important in the Tropics, where the links among plant reproductive effort, pollination, and vertebrate seed dispersal are strong (Bawa and Dayanandan, 1998; Bazzaz, 1998), and many plant species and their propagules are locally rare (Clark *et al.*, 1999a). If increased temperatures result in increased fire, then not only will fire-adapted species become more abundant (e.g., Starfield and Chapin, 1996), but animal seed dispersers may respond. For example, Johnson *et al.* (1997) have observed that blue jays (*Cyanocitta cristata*) cache more nuts in grasslands following fires.

Given the importance of fecundity for dispersal when kernels are fat-tailed, the effects of changing atmospheric chemistry on seed production could impact on migration potential. Elevated atmospheric carbon dioxide (CO_2) may cause seed production to increase (Farnsworth and Bazzaz, 1995; Schaeppi, 1996; Thomas *et al.*, 1999; LaDeau and Clark, 2001), to decrease (Farnsworth and Bazzaz, 1995; Fischer *et al.*, 1997; Thomas *et al.*, 1999) and/or to occur at an earlier age (Farnsworth *et al.*, 1996; LaDeau and Clark, 2001). Increased nitrogen deposition may have no reproductive impact or it may increase plant fecundity (Gordon *et al.*, 1999), whereas increased tropospheric ozone (O_3) may damage vegetative tissue and reduce reproductive success (Musil *et al.*, 1999; Bergweiler and Manning, 1999). Interactions among climate, CO_2, nitrogen, O_3, and ultraviolet-B radiation could result in surprises.

Land cover change and human disturbance have many indirect consequences for recent migrations in ways that facilitate spread of some and slow spread of others. Disturbance has hastened the spread of many introduced aliens, with temperate agricultural and urban sites being among the most invaded areas (Lonsdale, 1999). In some arid and semiarid lands, land clearance and changes in fire regime have facilitated the expansion of exotic grasses (D'Antonio and Vitousek, 1992). In others, humans have promoted the spread of woody vegetation. For example, 20th century livestock grazing, removal of native Americans, and fire suppression have promoted the spread of shrubs and trees in pygmy woodlands of western North America (Chambers *et al.*, 1999). Damming of the Colorado River reduced water table fluctuations, resulting in replacement of riparian hardwoods by the introduced saltcedar (Vitousek *et al.*, 1996). Eurasian aliens may have flourished in the intermountain West, in part because large, congregating mammals were absent in pre-settlement time. Lack of summer rainfall limited productivity of the warm-season C_4 grasses and, thus, green forage for grazers in summer. The native bunchgrasses did not respond well to introduced livestock and were replaced by Eurasian exotics adapted to both climate and grazers (Mack and Thompson, 1982; Mack, 1986).

On the other hand, human disturbance will hinder spread of many native and exotic species. For many species, land cover change will have the simple consequence of removing much of the area needed for population spread. The alien invader *Lonicera maacki* appears to spread fastest where forest cover is connected; large expanses of agricultural land act as a barrier to dispersal of this species (Hutchinson and Vankat, 1998). Many tree species will experience similar effects. Models incorporating fragmentation often predict delayed invasion due to a simple reduction in available habitat (Higgens and Richardson, 1999). Often the effects are more complex involving alterations in animal vector behavior (Verboom *et al.*, 1991; Pitelka *et al.*, 1997) and presenting novel establishment options, both positive and negative.

The natural dispersal kernels most often studied by ecologists are supplemented by a host of new modes of seed dispersal. Human activities have escalated and spread far beyond those that prevailed in the past. The occurrence of weedy species in charred remains of Neolithic grain stores of central Europe shows that broad, inadvertent dissemination has a history and a prehistory (Behre, 1981; Gluza, 1983). Establishment of towns and trade allowed for introductions as contaminant crop seed, fodder, or as escapes from horticultural plantings (Parker, 1977). Many Eurasian weeds in the western US were introduced as contaminants. Humans disperse propagules in a number of ways, but species producing large numbers of propagules tend to be best represented in two of the most important dispersal pathways in Britain, topsoil transport and cars (Hodkinson and Thompson, 1997). The number of exotic species in nature reserves is correlated with visitation rates (Lonsdale, 1999), which supports the importance of vehicular transport.

Improving Our Understanding

The importance of dispersal for plant migration is sufficiently uncertain that simulations involving future climate change often contrast scenarios of no dispersal with ones

that assume global dispersal (e.g., Sykes and Prentice, 1996; Pitelka *et al.*, 1997). By bracketing reality between extremes, we gain insight into migration potential at scales relevant for some of the most profound environmental challenges to plant populations since the end of the Pleistocene. The simulations that explore these effects demonstrate the importance of dispersal and highlight our inadequate characterization of it.

Understanding plant population spread is a realistic goal that requires realistic expectations. The contribution of dispersal limitation is knowable, but it will require more analysis at the appropriate spatial and temporal scales (Clark *et al.*, 1999b). We know enough now to appreciate its central role in migration potential. We should not expect precise forecasts of spread rate, due to its highly stochastic nature. But we can expect that a better understanding of fecundity and dispersal biology will help us identify species having potential for rapid spread given suitable conditions for growth and survival.

Plants – from Cells to Ecosystems: Impacts of Global Environmental Change

F A BAZZAZ AND S CATOVSKY

Harvard University, Cambridge, MA, USA

Human activities are leading to dramatic changes in the physical and chemical structure of the Earth's atmosphere, which will in turn, affect the functioning of the biosphere. As a result of complex feedbacks between atmospheric processes and natural ecosystems, an integrated perspective on future global dynamics should explicitly consider such bidirectional interactions. Many novel human-induced perturbations involve changes in resources and environmental conditions that directly affect basic plant processes. As the behavior of individual plants ultimately determines many key ecosystem characteristics, it is critical that we examine how major environmental changes will in uence plant function. In this review, we discuss how one of the most immediate and certain global environmental changes, rising atmospheric carbon dioxide (CO_2), will affect plant physiological processes. We focus particularly on processes that directly feedback to in uence atmospheric conditions.

Elevated CO_2 is a primary substrate for photosynthesis, and has many far-reaching effects on plant function. Carbon uptake rates for plants exposed to increased CO_2 concentrations invariably increase, although the degree of enhancement varies between plants with different photosynthetic pathways. This effect is often accompanied by a suite of other leaf-level changes that may modify the exchange of carbon and water between plants and the atmosphere, e.g., respiratory carbon losses, reduced transpiration, and increased water use ef ciency. The degree of photosynthetic enhancement is variable, and is commonly correlated with the extent to which photosynthesis acclimates to rising CO_2 levels. Excess carbohydrates that accumulate in leaf mesophyll cells inhibit manufacturing of the small subunit of ribulose-1,5-bisphosphate carboxylase (Rubisco), a major photosynthetic enzyme, and thus lead to reduced photosynthetic capacity. Despite a good physiological understanding of controls on photosynthesis, we have been unable to relate these mechanisms to the large variation in CO_2 responsiveness observed across species and environmental conditions.

Leaf-level activities do not take place in isolation, but rather depend on processes in other parts of the plant. A full understanding of the effects of elevated CO_2 on plant function should incorporate physiological processes that take place at the whole-plant level. As with photosynthesis, growth responses are generally enhanced by elevated CO_2. The degree of enhancement, however, can be very variable, showing dependence on both species identity and environmental growth conditions. Other whole-plant traits may also be modi ed under elevated CO_2, e.g., development, architecture, timing of growth events, but general trends in these responses are not yet well established. Of particular interest are the CO_2-induced changes in plant traits that feedback to in uence ecosystem-level nutrient availability. Understanding the responses of this suite of interacting traits is critical for our ability to predict long-term ecosystem responses to elevated CO_2, and thus to ascertain the nature of feedback between ecosystem function and atmospheric processes. Studies rarely focus on simultaneous changes in many potential positive and negative feedbacks. Thus, there is still uncertainty on whether processes leading to increased or decreased nutrient availability will predominate. For example, increased foliar carbon/nitrogen (C/N) ratios will act to slow decomposition rates, and thus represent a negative feedback to CO_2 enhancements of productivity. Increased root biomass, increased mycorrhizal infection, and increased soil microbial activity (from increased loss of carbon from roots into the soil) will likely increase nutrient availability to plants, and thus act as a positive feedback. The relative importance of these processes in different systems and under different environmental conditions must now be established.

PLANTS AND THE GLOBAL CARBON CYCLE

Plants represent the primary pathway for the transfer of carbon from the atmosphere into the terrestrial biosphere. By utilizing light energy from the sun, plants are able to reduce atmospheric carbon dioxide (CO_2) into energy-rich carbohydrates and other metabolic by-products. This process forms the basis for all life on Earth, but also represents an important feedback on the global carbon cycle. Interactions between plant processes and global biogeochemical cycles are of particular concern, because anthropogenic perturbations are causing extensive modification of natural ecosystems. Such changes have heightened interest in understanding current and future controls on biosphere activity (Mooney, 1996). Terrestrial ecosystems have the potential to slow future increases in atmospheric CO_2 (Woodwell *et al.*, 1998), but inevitable changes in the structure and function of such ecosystems make it difficult to predict their future role in the global carbon cycle. Increases in the magnitude of seasonal changes in global CO_2 concentrations highlight both the importance of terrestrial vegetation in regulating atmospheric CO_2 and dynamic changes in the functioning of the biosphere (Keeling *et al.*, 1996).

Realization of the tight coupling between human activities and large-scale biogeochemical processes has led to a large increase in studies focusing on the impacts of global environmental changes on natural ecosystems (Koch and Mooney, 1996; Walker *et al.*, 1999). There are close connections between anthropogenic perturbations and ecological processes, as many global changes directly in uence environmental conditions and availability of resources essential to basic plant functioning. The best-documented recent global environmental change is the annual increase in atmospheric CO_2 concentrations (Vitousek, 1994). Measurements of CO_2 levels from air bubbles trapped in ice cores and from direct atmospheric sampling since 1958 clearly demonstrate that atmospheric CO_2 concentrations have increased by almost 30% in the past 100 years (from $280\,\mu l\,l^{-1}$ at the beginning of the industrial revolution to current concentrations of $360\,\mu l\,l^{-1}$) (Schimel *et al.*, 1996). CO_2 is a primary substrate for photosynthesis, and thus changes in atmospheric CO_2 concentrations are likely to have profound impacts on plant function.

CO_2 is also a radiatively active gas that plays an important role in global climate patterns. As a result, elevated CO_2 levels have been predicted to cause increases in the mean and variability of global temperatures, and alterations to global rainfall patterns (Houghton *et al.*, 1996). The complexity of the global climate system, however, increases the uncertainty in such predictions. Nevertheless, recent work has found that the correlation between CO_2 levels and predicted temperature perturbations has increased through this century, suggesting that increasing CO_2 concentrations are having an increasingly important role in climate patterns (Wigley *et al.*, 1998). Many plant processes are sensitive to external temperatures, and so these predicted climate changes might significantly alter plant performance. Changes in rainfall patterns, along with increased atmospheric deposition of pollutants (e.g., sulfur, nitrogen) (Vitousek *et al.*, 1997) may also affect plant behavior within ecosystems, as water and nutrients are both essential requirements for basic plant function.

The multiple, simultaneous environmental perturbations currently facing natural ecosystems make it challenging to predict the state of the biosphere in the future. We believe that, rather than becoming overwhelmed with the complexity of the situation, we can make a valuable contribution to the development of our predictive capabilities by addressing tractable aspects of global change in turn. In this paper, we primarily focus on the impacts of elevated CO_2 on plants, as increases in atmospheric CO_2 concentrations are one of the most direct, immediate and certain changes that we face in the future. We consider direct effects of elevated CO_2 on plant function, highlighting the current state-of-knowledge on the subject. We address how our understanding of CO_2 effects on plants has developed since some recent, prominent reviews on the subject (Eamus and Jarvis, 1989; Bazzaz, 1990; Woodward *et al.*, 1991; Ceulemans and Mousseau, 1994; Amthor, 1995). We discuss effects of CO_2 on both leaf-level and whole-plant physiology, emphasizing the importance of understanding down-regulation of photosynthesis and feedback to the carbon cycle for a more complete view of potential impacts of elevated CO_2 on natural ecosystems in the future. Towards the end of the paper, we discuss how other anthropogenic perturbations may interact with elevated CO_2 to in uence plant performance in the future.

ELEVATED CO_2 AND LEAF-LEVEL PROCESSES

Leaves are the primary point of exchange of energy and matter between plants and the atmosphere, and thus changes in atmospheric CO_2 concentrations are likely to affect leaf-level processes most directly. Elevated CO_2 may in uence both the rate of CO_2 uptake (photosynthesis and respiration), as well as the rate of water exchange and leaf energy balance through effects on stomatal aperture.

Photosynthesis

From a basic understanding of the physiology of photosynthesis, we can make predictions about how increasing CO_2 levels might in uence carbon uptake rates (Pearcy and Bjorkman, 1983). CO_2 plays a number of critical roles in the process of carbon uptake.

1. CO_2 is a primary substrate for Rubisco. At low CO_2 concentrations, the enzyme ribulose-1,5-bisphosphate

(RuBP) is in excess and carbon fixation depends almost completely on CO_2 concentration. As CO_2 concentration increases, however, other processes become limiting, and carbon fixation becomes relatively insensitive to increases in CO_2 concentration. Initially, light-dependent reactions are unable to produce enough adenosine tri-phosphate (ATP) and the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) for RuBP regeneration. This process may often be quite transient, as substantial Rubisco deactivation follows shortly after this situation is reached (Sage *et al.*, 1988). As CO_2 levels increase further, carbon fixation becomes limited by the capacity of cytosolic enzymes to utilize triose phosphates for sucrose and starch synthesis (Sharkey, 1985).

2. CO_2 competes with O_2 for active sites on Rubisco. Carbon fixation is a relatively inefficient process, as Rubisco may bind O_2 and catalyze photorespiratory reactions that lead to the net release of CO_2 (Lorimer, 1981). This competitive inhibition depends on substrate concentrations, and is reduced as CO_2 concentrations increase (Sharkey, 1988).
3. CO_2 is required for Rubisco activation. Along with Mg^{2+} ions, additional CO_2 is required for photosynthesis to activate Rubisco (Portis, 1995).

These considerations highlight the dependence of photosynthetic activity on CO_2 concentration and suggest that increasing CO_2 above 350 $\mu l\, l^{-1}$ will increase carbon uptake rates until CO_2 ceases to limit photosynthesis. This point varies between species with different photosynthetic pathways (Figure 1). The *Michaelis rate constant* (K_m) for CO_2 fixation is much lower in C_4 plants than in C_3 plants, as C_4 plants have a CO_2 concentrating mechanism. Thus, for C_4 plants, photosynthesis saturates at a CO_2 concentration slightly above current atmospheric levels, while C_3 photosynthesis continues to increase until much higher CO_2 concentrations (Figure 1). Empirical evidence strongly supports these basic predictions (Carlson and Bazzaz, 1980; Bazzaz, 1990; Curtis, 1996) at least in the short-term (see the section on Down-Regulation of Photosynthesis). Photosynthesis of C_3 plants almost invariably increases in elevated CO_2 to some degree, while that of C_4 plants rarely shows much enhancement (Poorter *et al.*, 1996) (*see* C_3 and C_4 Photosynthesis, Volume 2).

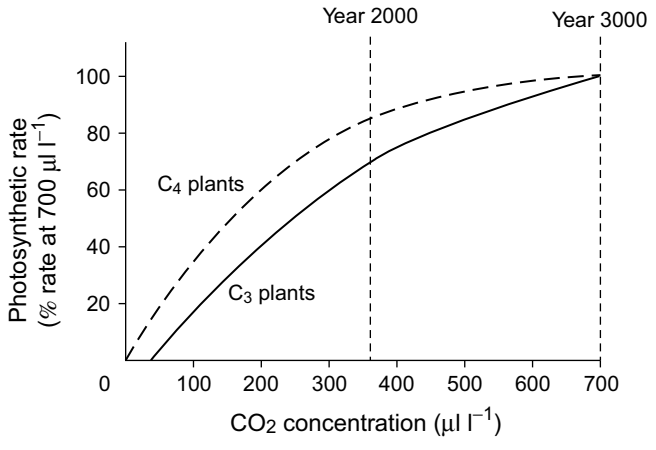

Figure 1 Dependence of CO_2 assimilation rate on atmospheric CO_2 concentration for both C_3 and C_4 plants. Vertical lines mark current and future CO_2 levels. (Redrawn from Woodward *et al.*, 1991)

Respiration

CO_2 induced increases in carbon uptake rates may be offset if elevated CO_2 causes concomitant changes in leaf respiration rates. CO_2 effects on respiration may additionally in uence plant growth and development, as energy from respiration is used to support these processes. Atmospheric CO_2 concentrations may have direct effects on plant respiration through inhibition of mitochondrial enzymes, particularly cytochrome *c* oxidase and succinate dehydrogenase (Drake *et al.*, 1999). These direct effects may be observed in relatively short-term CO_2 enrichment studies but often become a minor component of the response in the longer term as indirect effects come to dominate (Gonzàlez-Meler *et al.*, 1996). Plant respiration is a highly regulated and coordinated process, with multiple feedback controls determined proximally by ATP and NAD(P)H levels, and ultimately by plant carbon status. The complexity of the process makes it difficult to generate *a priori* predictions about the in uence of elevated CO_2 on respiration. To date, results have been equivocal, with both CO_2-induced stimulation and inhibition of respiration documented (Amthor, 1995). It is likely that both the size and composition of carbohydrate pools within plants determine these responses.

Stomatal Conductance and Water Use Efficiency

Elevated CO_2 may not only directly affect leaf metabolic processes, but it may also alter the pathway for gas exchange. Guard cell activity, and hence stomatal conductance, may be sensitive to atmospheric CO_2 concentrations (Mott, 1990). Optimality models suggest that, with rising CO_2 levels, stomatal conductance should decline to maintain a constant water loss for a given amount of carbon fixed (Cowan and Farquhar, 1977). Many studies do indeed find this predicted decline in conductance (Drake *et al.*, 1997; Morison, 1998) and even observe reductions in stomatal density in the longer-term (Woodward and Bazzaz, 1988; Woodward and Kelly, 1995). A recent meta-analysis by Curtis (1996), however, found no significant CO_2 effect on stomatal conductance in tree species. It is now important to repeat this statistically rigorous analysis for all plant species.

These changes in stomatal aperture and density may both serve to reduce water loss from plants. Increase in photosynthetic capacity and reduction in water loss combine to increase plant water use efficiency (Eamus and Jarvis, 1989; Tyree and Alexander, 1993). Whole-plant water use may not always be reduced, as plants often develop a higher leaf area in elevated CO_2 due to their larger size (Field *et al.*, 1995; Keeling *et al.*, 1996). In general, however, increased levels of atmospheric CO_2 do improve plant water relations, especially under water stress conditions (Morse *et al.*, 1993; Jackson *et al.*, 1994). This effect may be an important mechanism by which plants become better able to tolerate water stress conditions (Polley *et al.*, 1996; Catovsky and Bazzaz, 1999).

DOWN-REGULATION OF PHOTOSYNTHESIS: WHAT ARE THE MECHANISMS?

Global change research has focused particularly on effects of CO_2 on carbon uptake rates, both because of the sensitivity of photosynthesis to atmospheric CO_2 concentrations and because of the critical role of photosynthesis in regulating future carbon uxes through terrestrial ecosystems. Recognition of potential feedbacks between the atmosphere and biosphere has increased interest in determining how much of the extra CO_2 released into the atmosphere as a result of human activities will be sequestered by terrestrial vegetation. One of the principal debates in CO_2 research is the degree to which carbon fixation will be stimulated by elevated CO_2 (Idso, 1991; Fajer and Bazzaz, 1992). Although enhancement of photosynthesis is almost invariably observed in CO_2 experiments, the magnitude and duration of enhancement is very variable, and the mechanisms underpinning responses uncertain.

After long-term exposure to elevated CO_2, plants often show acclimation responses to elevated CO_2, such that photosynthetic enhancement declines over time (DeLucia *et al.*, 1985). Photosynthetic capacity for plants grown in elevated CO_2 is typically lower than for plants in ambient CO_2 (Sage, 1994). This is known as *down-regulation*. This phenomenon is one of the most critical for predicting the degree of CO_2 stimulation of terrestrial vegetation, and there is still considerable debate about its importance in determining future ecosystem productivity. Recently, it has been suggested that the degree of down-regulation in trees growing under elevated CO_2 in the field is less than once thought (Ceulemans *et al.*, 1999; Norby *et al.*, 1999). It is now essential that we consider the key factors determining down-regulation so that we can better predict how terrestrial ecosystems will respond to changing atmospheric CO_2 concentrations.

Much evidence points to the importance of sinks within the plant for substantially reducing photosynthetic down-regulation (Arp, 1991; Stitt, 1991). Sinks are non-photosynthetic tissues that act as a constant draw on photosynthetic products produced in the leaves, and thus prevent end-product inhibition of carbon fixation. The relationship between sink strength and plant responses to elevated CO_2 was recently demonstrated with seven different *Brassica* cultivars (Reekie, 1996). Two of the cultivars had large in orescence sinks, two had major carbon sinks in the stem, one of the cultivars had a root sink, and the remaining two had no substantial carbon sinks. Early in the experiment, growth of all cultivars was significantly enhanced in elevated CO_2. As the plants developed, however, only those cultivars with a substantial carbon sink continued to show significant CO_2 growth enhancements, presumably because down-regulation of photosynthesis was avoided. Sink size is clearly a more important control on photosynthetic responses to elevated CO_2 than sink location.

Photosynthesis is a highly regulated process with controls at many different stages. How do sinks in uence down-regulation? In the short-term, it is thought that acclimation occurs as a result of carbohydrate accumulation in leaves (Stitt, 1991). When there are not sufficient sinks within the plant for complete utilization of the products of photosynthesis, starch may build up in chloroplasts of photosynthetic cells (Woodrow and Berry, 1988). If the processes of carbon fixation and sucrose synthesis are not in balance, end-products of photosynthesis, such as triose phosphates, will accumulate in the chloroplast and lead to starch formation through up-regulation of the enzyme adenosine diphosphate (ADP) glucose pyrophosphorylase (Preiss, 1982). Build-up of starch in the chloroplast of photosynthetic cells clearly inhibits subsequent carbon fixation (Signora *et al.*, 1998) although the exact molecular mechanisms are currently unclear. Large starch grains may disrupt chloroplast membrane processes, or direct inhibition of photosynthesis may occur as light-dependent reactions become limited by the availability of molecular precursors (Stitt, 1991).

In the longer term, down-regulation of photosynthesis in elevated CO_2 is likely the result of a decline in Rubisco concentrations in chloroplasts. Transcripts of nuclear DNA coding the small subunit of Rubisco (rbcS) have been shown to decline in leaves exposed to elevated CO_2 (Webber *et al.*, 1994; Van Oosten and Besford, 1996; Cheng *et al.*, 1998). This effect is particularly pronounced when leaves are detached from the plant and thus any carbohydrate sinks removed, and these changes can be mimicked by supplying sucrose or glucose to leaves (Van Oosten *et al.*, 1994). Recent work suggests that these responses are directly regulated by the concentration of 6−carbon sugars (the hexoses, glucose and fructose) in photosynthetic cells (Sheen, 1994). There is now good evidence that plant cells can detect internal sugar concentrations and that such information closely regulates photosynthetic processes through the activity of

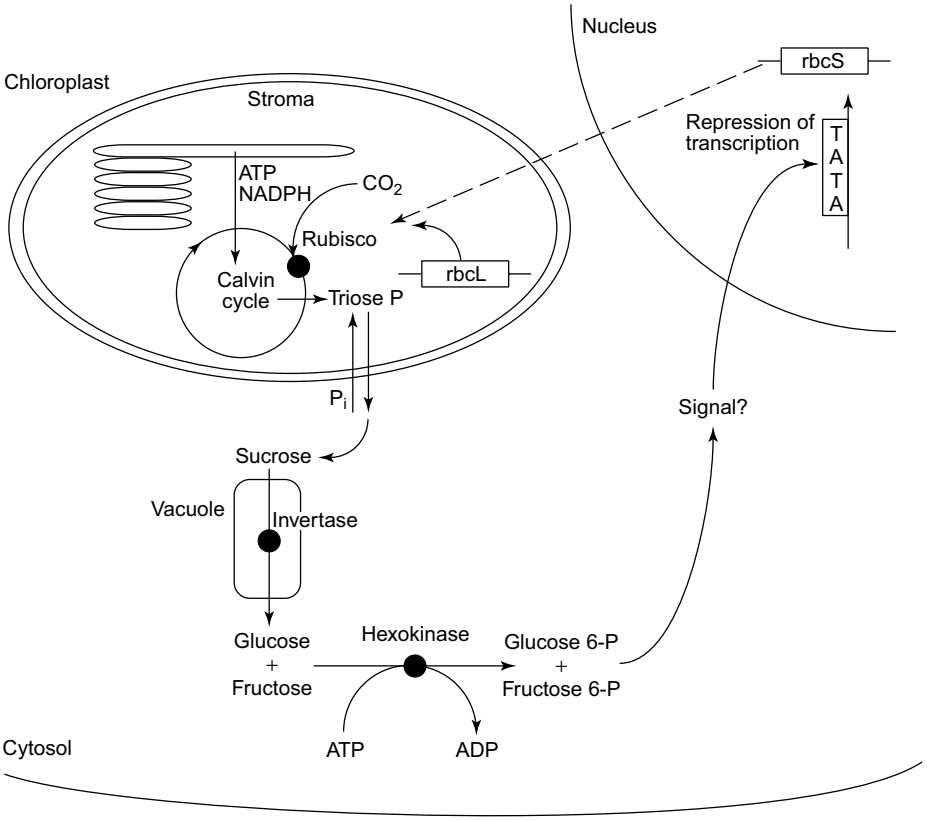

Figure 2 Proposed mechanism for long-term photosynthetic down-regulation in elevated CO_2. Components of pathway are discussed in text. (Redrawn from Van Oosten and Besford, 1996)

hexokinase enzymes (Jang and Sheen, 1997; Moore *et al.*, 1999). When sucrose accumulates in photosynthetic cells, invertase enzymes catalyze its break-down to glucose and fructose (Figure 2). Hexokinases then phosphorylate these metabolic by-products, which may then act to regulate future Rubisco transcription rates.

Now that much of the molecular biology behind photosynthetic down-regulation in elevated CO_2 is well understood, it is critical that we ascertain the significance of these processes in more natural situations and determine the sensitivity of such processes to environmental conditions. The key role of terrestrial ecosystem carbon uptake in the current global carbon cycle makes it particularly important that we address the degree to which photosynthesis is enhanced in elevated CO_2. To date, field-based studies generally support the model for carbohydrate control of photosynthesis (Figure 2), although links between different stages of regulation are less tightly coupled (e.g., Nie *et al.*, 1995). It is now well established that both low nutrient availability and lack of adequate carbon sinks may limit plant responses to elevated CO_2 (Arp, 1991; Pettersson and McDonald, 1994). In the future, we must focus on the underlying molecular mechanisms behind these empirical observations.

ELEVATED CO_2 AND WHOLE-PLANT PHYSIOLOGY

Leaf-level processes represent the primary site of activity for increases in CO_2 concentrations. The short-term physiological changes we have described, however, may not directly relate to whole-plant responses to elevated CO_2. Processes that involve the transport and partitioning of carbon, nutrients and water between different parts of the plant may decouple leaf and plant level activities (Wolfe *et al.*, 1998). The time scale for events at the leaf level and for whole-plant processes may also be different, and complex feedbacks may alter the relationship between processes at multiple scales. In this section, we summarize the major changes that plants undergo when grown in elevated CO_2, emphasizing perturbation of whole-plant physiological processes.

Growth: Dependence on Environmental Conditions and Species Identity

Changes in photosynthesis and respiration generally lead to some degree of growth enhancement in elevated CO_2, as extra assimilate can be allocated to structural or functional tissues. Numerous studies have recorded CO_2-induced

growth increases, with average enhancements of 25–50% for tree seedlings (Eamus and Jarvis, 1989; Celemans and Mousseau, 1994; Wullschleger *et al.*, 1995), 35% for C_3 wild herbaceous species (Poorter *et al.*, 1998) and 40–60% for C_3 crop species (Cure and Acock, 1986; Poorter *et al.*, 1996). We should be cautious, however, of using these average enhancement ratios for predicting ecosystem responses to elevated CO_2. These summary data are based on many studies with methodological problems, especially pseudoreplication (Jas enski *et al.*, 1998). In addition, the time dependence of enhancement ratio calculations makes it very difficult to extrapolate from generally short-term experiments to growth responses throughout an individual's life span, especially when the plants are perennial and long-lived (Thomas *et al.*, 1999). We have demonstrated that, even within the first three years of a tree's life, CO_2 responsiveness generally declines with time and in a species-specific manner (Figure 3) (Bazzaz *et al.*, 1993).

There is huge variation in plant growth responses between experiments, and as a result, average enhancement ratios do not adequately represent the complete picture. It is now well established that species differ significantly in their responses to elevated CO_2 (Bazzaz, 1990). A common goal in much CO_2 research is determining if we can identify species' traits that are well correlated with CO_2 responsiveness. In this way, we could make predictions about how particular communities will respond to future atmospheric CO_2 concentrations without growing every species in an elevated CO_2 environment. To date, it has only been possible to identify very broad functional response groupings of species (Catovsky, 1998) in relation to CO_2 concentration. There is good evidence for differences in CO_2 growth responses between species with different photosynthetic pathways. C_3 plants have consistently higher CO_2 growth increases (47%) than either C_4 (10%) or crassulace acid metabolism (CAM) (19%) species (Poorter *et al.*, 1996). Other CO_2 response groups have been more difficult to distinguish, with analyses producing contradictory findings. Ceulemans and Mousseau (1994) presented evidence that broad leaved tree species respond more strongly to elevated CO_2 than do coniferous species (63% vs. 38%), while Saxe *et al.* (1998) find the opposite result in a more recent review (49% vs. 130%). Similarly, life history strategy does not provide a clear axis on which to distinguish species' CO_2 responsiveness. Substantial evidence suggests that faster growing, early successional species are more responsive to elevated CO_2 than slow growing, late successional species (Hunt *et al.*, 1991; Bazzaz and Miao, 1993; Poorter, 1998). Again, however, this result does not always hold true (Bazzaz *et al.*, 1990; Stirling *et al.*, 1997), and an alternative hypothesis has recently been suggested (Kerstiens, 1998). Research from our lab suggests that there is an interaction between leaf habit and shade tolerance in determining CO_2 responsiveness (S Catovsky, C C Muth and F A Bazzaz, unpublished data). Growth enhancement in elevated CO_2 increased with increasing shade tolerance for seedlings of coniferous species, while CO_2 growth

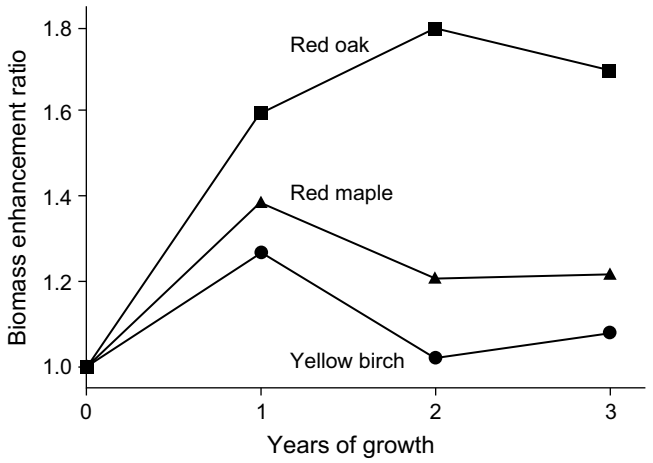

Figure 3 Change in total biomass enhancement ratio (final seedling biomass at 700 µl l^{-1}/biomass at 350 µl l^{-1}) over three consecutive growing seasons for three temperate tree species. Points represent means for species across four combinations of light and nutrient availability. (Redrawn from Bazzaz *et al.*, 1993)

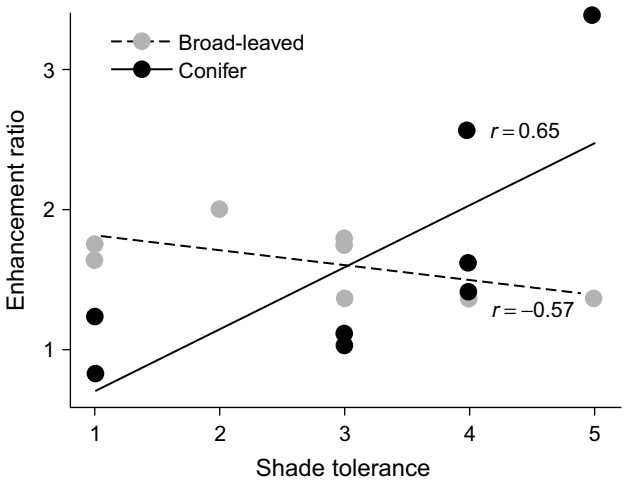

Figure 4 Relationship between species' tolerance ranking (based on Baker's Table) and CO_2 responsiveness (measured as growth enhancement ratio: mean final seedling biomass at 700 µl l^{-1}/biomass at 375 µl l^{-1}) for coniferous and broad-leaved tree species after one growing season. Product-Moment correlation coefficients (r) are shown for each relationship separately (coniferous: solid line; broad-leaved: dashed line). Species included in the study (in order of increasing tolerance): *Larix laricinia*, *Pinus banksiana*, *Pinus rigida*, *Pinus strobus*, *Picea rubens*, *Thuja occidentalis*, *Picea mariana*, *Abies balsamea* (coniferous); *Betula populifolia*, *Populus tremuloides*, *Betula papyrifera*, *Quercus rubra*, *Betula alleghaniensis*, *Quercus bicolor*, *Acer rubrum*, *Acer saccharum* (broad-leaved). (Unpublished data from S Catovsky, C C Muth, and F A Bazzaz)

enhancement decreased with increasing shade tolerance for seedlings of broad-leaved species (Figure 4).

The complex task of identifying functional CO_2 response groups is often made more challenging by substantial intra-group variation in CO_2 responsiveness. For example, we have observed signi cant differences in the responses of C_4 grasses to elevated CO_2 (Kellog *et al.*, 1999). This variation was present both between and within different genera, and between and within different C_4 lineages (Figure 5). C_4 species may be divided into three subtypes based on the acceptor molecule used during carbon x-ation: nicotinamide adenine dinucleotide phosphate-malic enzyme (NADP-ME), nicotinamide adenine dinucleotide-malic enzyme (NAD-ME), and (PCK). This difference in biochemistry may explain some of the variation in CO_2 responsiveness between C_4 species (LeCain and Morgan, 1998), but did not correlate with responsiveness in our experiment. To date, even less attention has been paid to intra-speci c variation in CO_2 responsiveness, which could also be substantial (Korner and Bazzaz, 1996). For example, Thomas and Jas enski (1996) showed that variation in CO_2 responsiveness between different genotypes of *Abutilon theophrasti* equaled the level of variation observed for tree seedlings and saplings in 153 studies.

Ecosystem responses to elevated CO_2 will not only be determined by the species present, but also by the environmental conditions that the plants experience. Growth conditions have very signi cant effects on an individual s response to atmospheric CO_2 concentration. Because

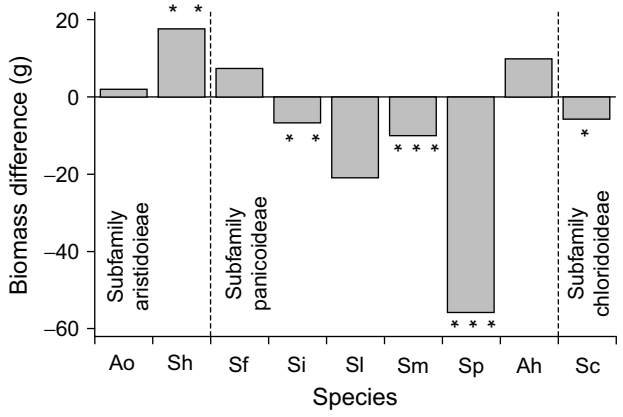

Figure 5 Differences in total biomass for grass species grown under ambient and elevated CO_2 after one growing season (total biomass at elevated CO_2 minus biomass at ambient CO_2). Significance of each difference was determined with nested Anova post-hoc comparisons: $^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$. Dashed vertical lines delimit separate C_4 lineages. Study species include: *Aristida oligantha* (Ao), *Stipagrostis hirtiglumis* (Sh), *Setaria faberi* (Sf), *Setaria italica* (Si), *Setaria lutescens* (Sl), *Setaria macrostachya* (Sm), *Setaria pumila* (Sp), *Arundinella hirta* (Ah), *Sporobolus cryptandrus* (Sc). (Redrawn from Kellogg *et al.*, 1999)

of the tight coupling and interdependence of above- and below-ground processes, much work has focused on the in uence of soil nutrient availability on plant responses to elevated CO_2. Many empirical studies have demonstrated that low nutrient availability constrains CO_2 responsiveness (Bazzaz, 1990; Poorter, 1998). Photosynthetic acclimation to elevated CO_2 (as discussed in the section on Down-regulation of Photosynthesis) usually appears earlier and is more marked in plants growing under low nutrient conditions (Pettersson and McDonald, 1994). In their meta-analysis of CO_2 effects on tree species, Curtis and Wang (1998) observed that low soil nutrient availability reduced plant responses to elevated CO_2 by 50%. Surprisingly, the mechanistic basis for this limitation is not well understood (Lloyd and Farquhar, 1996). As metabolic processes are reduced under reduced nutrient supply, low nutrient availability may reduce sink strength and increase accumulation of sugars within the plant, leading to a greater degree of photosynthetic down-regulation (Stitt and Krapp, 1999). Alternatively, changes in the allocation of assimilate between different plant parts may be driving these effects. Plants often develop a lower leaf area ratio in elevated CO_2 (Poorter *et al.*, 1996), as more carbon is allocated below ground. This proportional decrease in amount of leaf tissue may become more pronounced in low nutrient soils, causing relative growth increases in elevated CO_2 to be lower. This hypothesis is supported by experiments where plants are given nutrients in relation to their size (Ingestad method), and hence where above- and below-ground processes are more in balance. In such experiments, interactions between nutrient availability and CO_2 responsiveness are not observed (Pettersson *et al.*, 1993; Farage *et al.*, 1998). This suggests that it is the imbalance between above- and below-ground processes that underlies the lack of CO_2 responsiveness with low nutrient availability in most studies.

In contrast to soil nutrient availability, plants seem to respond to elevated CO_2 more strongly at low levels of light availability than at higher levels. For example, for tree seedlings, CO_2 responsiveness was almost 70% greater for plants in low vs. high light (Curtis and Wang, 1998). We do not currently understand the mechanistic basis for these effects, although a number of hypotheses have been proposed, which must now be explicitly tested. Low-light plants may suffer less photosynthetic down-regulation than high-light plants, as carbon assimilation is lower and thus is less likely to exceed demand (sucrose synthesis and export) to such a great a degree. Alternatively, elevated CO_2 could directly affect the light harvesting machinery in plants. Some studies have found that elevated CO_2 can produce decreases in the *light compensation point* (Kubiske and Pregitzer, 1996) or increases in apparent quantum yield (Lewis *et al.*, 1999). These shifts could be a function of nitrogen re-allocation from Rubisco to

light harvesting proteins. In support of this hypothesis, Kubiske and Pregitzer (1997) found a significant increase in photosynthetic nitrogen use efficiency for *Acer rubrum* saplings grown in elevated CO_2.

Water availability is another important resource that varies substantially between and within ecosystems that may in uence plant responses to elevated CO_2. As with light, evidence suggests that CO_2 responsiveness is enhanced at lower soil moisture availability to a greater degree than at high soil moisture (Morison, 1993). Large CO_2 effects under low water conditions are likely brought about through the combined effects of CO_2 on both photosynthesis and water use efficiency (see Stomatal Conductance and Water Use Efficiency section). The issue of contrasting effects of CO_2 on leaf-level instantaneous water use efficiency and whole-plant integrated water use, however, must still be resolved.

Allocation, Architecture, Phenology and Development

The effects of CO_2 concentration on growth may be accompanied by a suite of other changes in whole-plant processes. One of the most common trends observed is increased allocation to roots (Rogers *et al.*, 1994), which fits with resource allocation theory suggesting that plants allocate carbon to tissues such that all resources are equally limiting (Bloom *et al.*, 1985). As CO_2 levels increase, nutrient uptake rates must increase to balance the increased amounts of carbohydrate within the plant. To achieve this goal, plants increase allocation to nutrient acquiring organs at the expense of light capturing organs. Long-term increases in productivity in relation to elevated CO_2 may be constrained under low soil nutrient conditions (see Whole-plant Feedback on the Carbon Cycle section). Increased root to shoot ratios are particularly pronounced in soils of low nutrient availability (Norby, 1994; Curtis and Wang, 1998), again as might be expected from optimality models. Effects of elevated CO_2 on specific root uptake rates of important nutrients, such as (NH_4^+) and (NO_3^-), however, have been variable to date (Stitt and Krapp, 1999). These responses may be related to changes in nutrient concentrations in the soil solution and subsequent feedback mechanisms. Recently, the importance of plant–soil interactions in controlling long-term plant responses to elevated CO_2 has been recognized. In the subsequent section (Whole-plant Feedback on the Carbon Cycle), we discuss the current state of knowledge on these responses, and the implications for whole-ecosystem responses to rising CO_2 levels.

Changes in plant allocation patterns can clearly affect the size and activity of resource capturing parts. In addition to these changes, CO_2 concentration may in uence other whole-plant processes that themselves may determine long-term CO_2 responsiveness. Elevated CO_2 could directly in uence plant developmental patterns, and these changes, in turn, could affect spatial and temporal patterns of growth and tissue maturation. Our knowledge of such changes is still rather limited, with general trends difficult to establish. For example, for short day *Petunia hybrida* individuals, elevated CO_2 decreased branch number and number of days until owering, while plant height was increased (Reekie, 1996). In contrast, other studies have found that elevated CO_2 increases branching or tiller production (Tissue and Oechel, 1987; Rochefort and Bazzaz, 1992). An understanding of the basic physiological processes that regulate plant development is essential for making predictions about CO_2 induced changes in plant developmental patterns. CO_2 effects on plant carbohydrate status could cause major disruption to basic allometric growth patterns, although the nature of the change is currently unclear. Thomas and Bazzaz (1996) found that, under elevated CO_2, leaves of *Taraxacum of cinale* plants exhibited more deeply incised leaf margins and more slender leaf laminae than plants under ambient CO_2. They attributed these changes to effects of carbohydrate status on heteroblastic leaf development, but were unable to establish the exact nature of the link between these different processes.

Changes in developmental patterns, such as those described, could in uence the way plant parts are displayed in space, i.e., architecture. These effects may also ultimately determine long-term plant responses to CO_2 concentration. Elevated CO_2 could alter architectural patterns of both above and below ground parts. For example, Reekie and Bazzaz (1989) found that five tropical tree species showed only moderate biomass responses to elevated CO_2, even when supplied with ample resources, but, in contrast, the species underwent quite substantial architectural responses. In particular, height differences between the species became exaggerated in elevated CO_2 through differential patterns of leaf display and shoot growth. CO_2 concentrations could additionally in uence below-ground architectural patterns. Studies with crop and wild plant species have found that elevated CO_2 increases total root length, branch number and depth of root penetration through the soil (Rogers *et al.*, 1994). Architectural changes could in uence basic plant responses to elevated CO_2, e.g., through increases in total below-ground resource capture (Berntson, 1994), as well as affecting competitive interactions.

Direct effects of elevated CO_2 on plant development may in uence temporal patterns of plant part production, as well as spatial components (architecture). Many studies have recorded changes in the timing of ower, fruit and leaf production, although the direction and magnitude of change is highly variable (Garbutt and Bazzaz, 1984; Reekie and Bazzaz, 1991). Even plants within the same community may show very different phenological responses (Rusterholz and Erhardt, 1998), which, in turn, could in uence competitive interactions, as well as plant-animal

interactions. The mechanistic basis for phenological change is not yet well established, but should be actively addressed in future research if we wish to predict whole-community responses to global environmental change.

WHOLE-PLANT FEEDBACKS ON THE CARBON CYCLE

Plants may directly in uence soil ecosystem processes through litter production and through dynamic interactions between root and soil functioning. Elevated CO_2 may affect numerous whole-plant processes that feedback to in u-ence soil processes (Bazzaz, 1996). Understanding this plant–soil feedback is critical for making long-term predictions about whole-ecosystem responses to elevated CO_2, and, through global biogeochemical feedbacks, how vegetation may affect future levels of atmospheric CO_2. Changes in litter quality and perturbations to plant–soil interactions may both significantly in uence nutrient availability at a site, and thus how plants respond to elevated CO_2 in the long-term (see Growth section). In this section, we highlight the importance of both kinds of feedback for ecosystem CO_2 responsiveness (Figure 6).

Carbon and Nitrogen Partitioning

Rising atmospheric CO_2 concentrations are a direct perturbation on plant function, and, as we have discussed, can lead to multiple changes in leaf and whole-plant level processes. If sufficient sinks exist, elevated CO_2 increases the amount of carbohydrate within the plant, and the concentration of sugar and starch in leaves

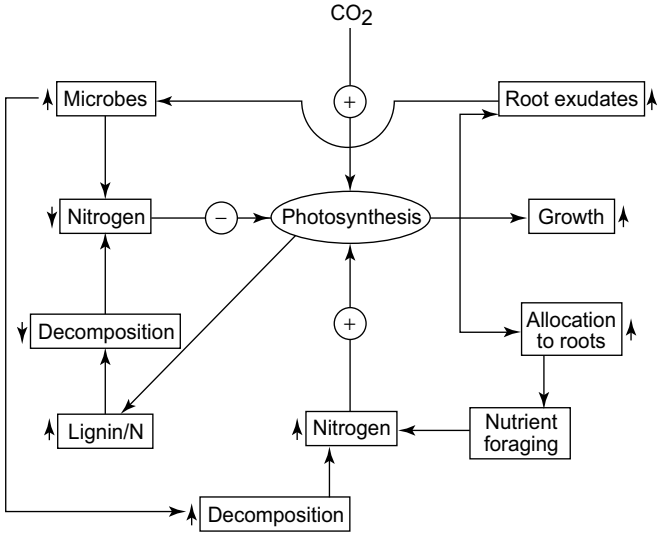

Figure 6 Schematic outlining positive and negative plant–soil feedback processes that determine long-term plant responses to elevated CO_2. (Modified from Bazzaz, 1996)

(see Down-regulation of Photosynthesis section). Nutrient uptake rates rarely increase in direct proportion to the amount of extra carbon taken up by plants in elevated CO_2, and thus tissue carbon/nutrient ratios invariably increase (especially nitrogen) (Lindroth *et al.*, 1993; Traw *et al.*, 1996). A recent review of 75 published studies demonstrated that elevated CO_2 led to an average reduction in tissue nitrogen concentration of 14% (Cotrufo *et al.*, 1998), with the magnitude of decrease varying among species. What mechanisms determine the degree of enhancement of C/N ratio between species? Recently, Bazzaz (2000) proposed that the degree of down-regulation might directly in uence C/N ratios, with plants that show little down-regulation exhibiting the highest degree of nitrogen dilution.

The significance of these changes in tissue chemistry for decomposition processes was recognized early in global change research. Strain and Bazzaz (1983) originally proposed that increased tissue C/N ratios could translate into slower rates of tissue decomposition, and thus act as a negative feedback on CO_2-induced enhancement of productivity. The composition of the additional carbon incorporated into plant tissues will be an important determinant of this relationship. Increases in structural carbohydrates (especially lignin) are more likely to slow decomposition rates than are increases in total non-structural carbon (Melillo *et al.*, 1982).

It is still unclear, however, whether or not increased C/N ratios in living tissues translate into altered chemistry of senesced leaf litter (O'Neill and Norby, 1996). Species have variable patterns of nutrient retranslocation prior to senescence, and rising CO_2 levels could further alter these dynamics. Such changes could decouple the relationship between tissue and litter nutrient concentrations, although they are unlikely to completely reverse trends observed for living tissues. Overall, many studies do find that litter from plants grown in elevated CO_2 decomposes more slowly than litter produced in ambient CO_2 (Cotrufo and Ineson, 1996). In field decomposition studies, we have found species-specific declines in the decomposition rate constant (K) for litter of tree seedlings grown in elevated vs. ambient CO_2 (Figure 7, J M Melillo and F A Bazzaz, unpublished data). Recently, however, results from whole-ecosystem manipulations of atmospheric CO_2 concentration have found only marginal effects of elevated CO_2 on litter decomposition and thus ecologists are beginning to question the generality of the original hypothesis (Norby and Cotrufo, 1998; Couteaux *et al.*, 1999).

These changes in C/N ratio have implications for higher order trophic interactions in ecosystems as well. Nitrogen is often the single most important limiting resource for phytophagous insects, and a reduction in the quality of host plant food (through nitrogen dilution) could significantly affect the dynamics of insect herbivore populations, as well

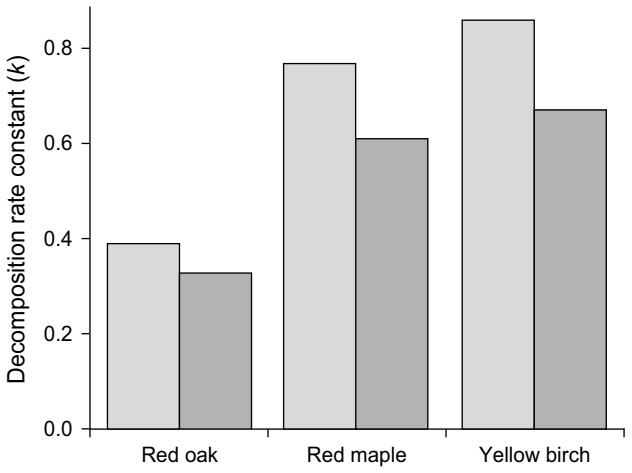

Figure 7 Influence of CO_2 concentration (350 µl l^{-1} = light grey, 700 µl l^{-1} = dark grey) on litter decomposition rate constant ($k = -\ln$ (% litter mass loss)/time) for seedlings of three temperate forest species grown in controlled environment conditions. Leaves were allowed to senesce naturally and then were transferred to litter decomposition bags in Harvard Forest. (Unpublished data from J M Mellilo and F A Bazzaz)

as species further up the food web. From the studies to date, it has been difficult to determine general patterns in herbivore responses to altered host plant quality. Part of the difficulty lies with the wide range of herbivore responses observed, but also with the narrow range of taxonomic and functional diversity sampled in the experiments. Most of the studies have been carried out on leaf-chewing insect herbivores, and for this guild of insects, at least, it is clear that insects fed on leaves from plants grown in elevated CO_2 grow more slowly, and consume more of the host plant. They also take longer to reach maturity, and have lower survival than insects fed on ambient CO_2-grown plants (Bezemer and Jones, 1998; Coviella and Trumble, 1999). Even within this one feeding guild, insect responses vary substantially with host plant species identity and insect developmental stage and sex (Fajer *et al.*, 1989; Traw *et al.*, 1996).

Plant–Soil Interactions

Part of the dif culty with understanding the feedbacks between plant responses to CO_2 concentration and ecosystem-level nutrient availability arises because decomposition rates not only depend on litter chemistry, but also involve a whole series of complex plant soil processes (Figure 6) (Berntson and Bazzaz, 1996). Together, such interactions may substantially alter any potential negative feedback through tissue C/N ratios. Recently, research has focused on CO_2 effects on a number of key plant soil interactions that may signi cantly in uence long-term plant responses to elevated CO_2. Direct effects of elevated CO_2 on plant function may lead to a whole suite of changes in below-ground activities, which themselves in uence processes within the soil itself. It is now well established that elevated CO_2 not only increases the amount of structural carbohydrate allocated to root growth (see Allocation section), but also increases the amounts of labile carbon that pass through the roots. These more transient changes are necessarily harder to detect and measure, as much of the carbon eventually enters the soil organic matter. Nevertheless, such changes play a vital role in determining ecosystem-level feedback to CO_2 growth enhancements and in in uencing carbon ux through soils, which could be a highly signi cant component of total ecosystem carbon gain.

The importance of such changes in labile carbon pools was recognized by Norby *et al.* (1992) in a 3-year eld CO_2 experiment with *Liriodendron tulipifera*. Norby *et al.*, observed signi cant enhancement of leaf-level carbon uptake rates in elevated CO_2, but no concomitant increase in plant biomass. Further exploration suggested that the extra assimilate generated by increased photosynthesis in elevated CO_2 was allocated to ne-root production and turnover (Figure 8). These static measurements of below-ground productivity may, however, substantially underestimate total root turnover rates. Berntson and Bazzaz (1997a) observed increases in both gross ne-root production and loss for *Betula papyrifera* seedlings in elevated CO_2. Effects of CO_2 on these processes were seasonally dependent, with CO_2 enhancement of ne-root production occurring early in the season, while CO_2 enhancement of ne-root loss occurred only in the last half of the growing season. These changes led to a CO_2-induced transient increase in standing root length early in the season that disappeared by the end of the season.

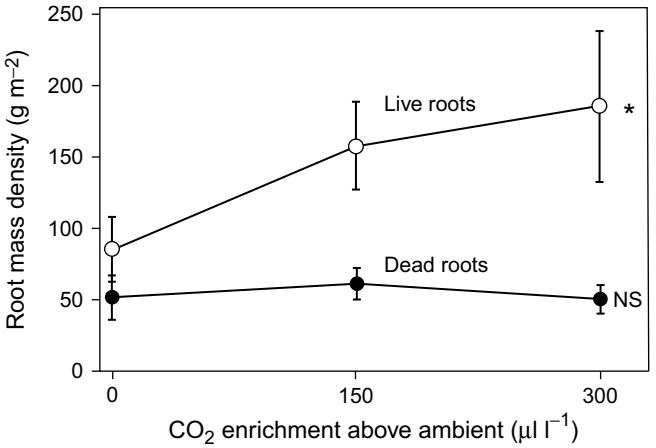

Figure 8 Changes in live and dead root mass density with different levels of CO_2 enrichment for *Liriodendron tulipifera* after three growing seasons (means ± SEM from two replicate open-top chambers). Significance of CO_2 concentration effect shown (NS $P > 0.05$, $^{*}P < 0.05$). (Data taken from Norby *et al.*, 1992)

Elevated CO_2 may also lead to increased losses of carbon from roots into the soil (Cheng, 1999), which together with increases in fine-root turnover, could have important consequences for the dynamics of soil microbial populations (O'Neill, 1994). An increase in the amount of labile carbon entering the rhizosphere is likely to directly stimulate microbial activity and other soil fauna (Jones *et al.*, 1998). As microorganisms play a key role in soil nutrient dynamics, such changes could have significant implications for feedback on plant responses to CO_2. Soil microbe populations are often enhanced following plant exposure to elevated CO_2, although the degree of enhancement may vary substantially with the type of microorganism concerned. For example, elevated CO_2 causes a greater stimulation of root colonization for ectomycorrhizal fungi than for vesicular arbuscular mycorrhizae (O'Neill, 1994; Staddon and Fitter, 1998). Even within one mycorrhizal type, there may be substantial variation in response. Godbold and Berntson (1997) recorded significant changes in the composition of ectomycorrhizal assemblages on *Betula papyrifera* seedlings (Figure 9), with a noticeable shift towards morphotypes with high hyphal density.

Although CO_2-induced changes in microbial abundance and composition have now been recorded in many studies, the functional significance of such changes for plant nutrient dynamics has not been adequately evaluated. This gap in our understanding is well illustrated by considering the opposing hypotheses that have been put forward to link microbial dynamics with soil nutrient processes (Berntson and Bazzaz, 1996). In an open top experiment with *Populus grandidentata* saplings, Zak *et al.* (1993) found that elevated CO_2 increased biomass of soil microorganisms and potential mineralization rates, and hypothesized that increased microbial activity could act as a direct positive feedback on plant responses to elevated CO_2. A contrasting hypothesis was put forward by D az *et al.* (1993) based on an experiment exposing model chalk grassland ecosystems to different CO_2 concentrations. They observed marginal enhancement of above ground biomass growth, finding that much of the additional carbon was entering the soil and stimulating microbial growth. Marked signs of nutrient deficiency in plants grown in elevated CO_2, even following fertilization, suggested that the expanded microbe populations were competing with the plants for soil nitrogen and leading to net nitrogen immobilization.

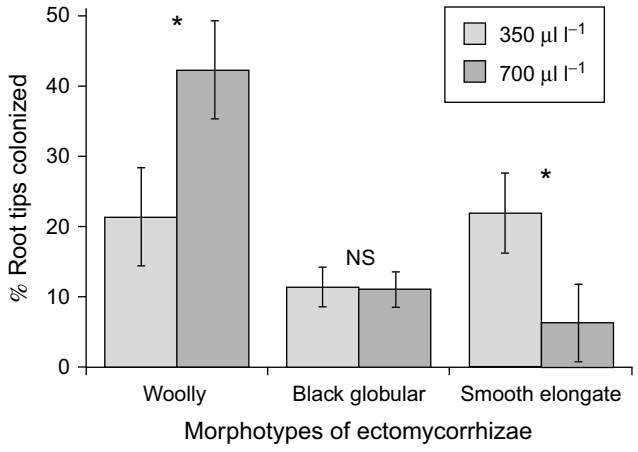

Figure 9 Degree of *Betula papyrifera* root colonization (mean ± SEM) by three different ectomycorrhizal morphotypes under different CO_2 concentrations. (Redrawn from Godbold and Bazzaz, 1997)

Plant responses to elevated CO_2 can clearly lead to simultaneous positive and negative feedback on the global carbon cycle. How do we disentangle these different processes? Now that many of the key processes have been identified, we need to take a mechanistic approach to the issue of plant–soil feedback and determine how the relative importance of different processes changes with ecosystem type and environmental conditions. In two parallel experiments, Berntson and Bazzaz (1997b, 1998) grew stands of *Betula alleghaniensis* and *Betula papyrifera* (planted and natural regeneration from the soil seed bank) and made simultaneous measures of many below-ground processes relating to nutrient availability. They found that, overall, plant nutrient uptake rates were reduced in elevated CO_2. The increases in potential uptake from greater root biomass and increased mycorrhizal colonization (positive feedback) were not sufficient to compensate for reduced mineralization rates (a negative feedback through increased litter C/N). We are likely to reach different conclusions in other systems, and thus we need to determine what ecosystem characteristics determine the relative importance of different feedback components.

INTERACTIONS BETWEEN GLOBAL ENVIRONMENTAL CHANGES

Human activities now have far-reaching consequences for fundamental atmospheric, geological and biological processes. For most of this paper, we have considered plant responses to one of the best documented, most certain global environmental changes that will likely in uence natural ecosystems in the coming decades, i.e., rising atmospheric CO_2 concentrations. These effects, however, will not take place in isolation, as other environmental perturbations will also have substantial impacts on terrestrial ecosystems. In this section, we discuss how two other major environmental changes (nitrogen deposition and climate change) may modify effects of elevated CO_2 on plant function.

Nitrogen Deposition

Substantial quantities of inorganic nitrogen are being deposited in terrestrial ecosystems across much of the industrialized world, as a result of fertilizer production, legume

cultivation and fossil fuel burning (Galloway *et al.*, 1995). As nitrogen is an essential nutrient for plant function and one that may be limiting productivity in many terrestrial ecosystems (Vitousek and Howarth, 1991), this additional nitrogen may increase plant growth in natural systems. Nitrogen fertilization commonly increases foliar nitrogen concentrations (Boxman *et al.*, 1998), which leads to increased rates of photosynthesis through increases in leaf chlorophyll and Rubisco (Field and Mooney, 1986). Nitrogen additions, however, may not consistently increase ecosystem productivity, as high levels of nitrogen deposition could detrimentally in uence plant function through creation of nutrient imbalances within plants (Schulze, 1989; Aber *et al.*, 1998).

Nitrogen deposition and elevated CO_2 may act synergistically to increase ecosystem-level net primary production (Lloyd, 1999), as nitrogen limitation often constrains plant and ecosystem responses to increasing atmospheric CO_2 (see Growth' section). Recently, spatially explicit global carbon models have combined three-dimensional chemical transport models with an analysis of C/N ratios in different plant and soil compartments to estimate the contribution of nitrogen deposition to terrestrial carbon storage (Holland *et al.*, 1997). Many such models suggest that nitrogen deposition may be responsible for over half of the global carbon sink in terrestrial ecosystems ($1\,Pg\,C\,yr^{-1}$) (Norby, 1998), although recent empirical work throws these estimates into question (Nadelhoffer *et al.*, 1999). These models provide good preliminary evidence for potential synergisms between elevated CO_2 and nitrogen deposition. On the whole, however, the models lack an underlying mechanistic basis, and still rely on some broad generalizations. We need to improve our physiological understanding of interactions between carbon and nitrogen dynamics within plants to provide a better framework for future global-scale models.

Climate Change

Anthropogenic perturbations to the physical and chemical structure of the atmosphere are likely to bring about associated changes in large-scale climatic patterns. As we discussed earlier, the precise nature of such changes are difficult to predict accurately. It is likely, however, that elevated CO_2 will increase mean global temperatures, as well as increasing the frequency of extreme weather events (Houghton *et al.*, 1996). Despite its potential importance, we know relatively little about plant responses to the combination of elevated atmospheric CO_2 and higher temperature.

Heat is not a resource that is directly used by plants, rather it is a controller that regulates the rate and direction of different physiological processes within plants (Bazzaz,

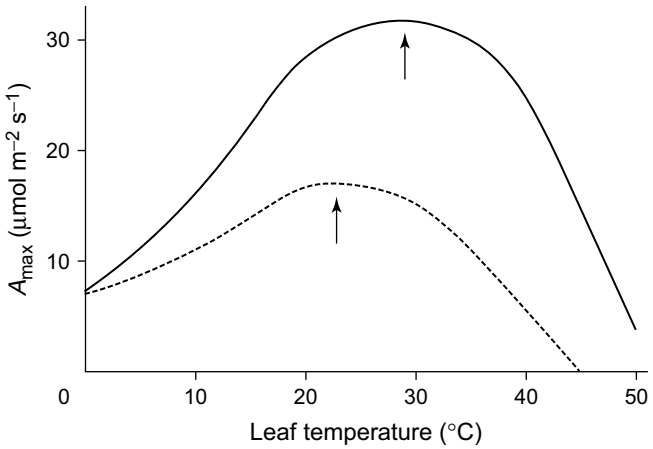

Figure 10 Predicted light-saturated photosynthetic rates (A_{max}) as a function of leaf temperature and CO_2 concentration ($350\,\mu l\,l^{-1}$ = dashed line; $700\,\mu l\,l^{-1}$ = solid line), based on a Farquhar-type leaf photosynthesis model. Arrows mark temperature optima for each CO_2 concentration. (Redrawn from Long, 1991)

1996). Temperature may act directly at the leaf-level to regulate carbon uptake rates. Increased temperature reduces the solubility of CO_2 in the cellular matrix and reduces Rubisco specificity for CO_2 vs. O_2 (Jordan and Ogren, 1984). Together, these processes reduce the efficiency of photosynthesis, although these changes may be countered to some extent by temperature-related increases in the rate of Calvin cycle reactions (Berry and Bjorkman, 1980). Theoretical photosynthesis models suggest that there is some degree of synergism between CO_2 and temperature perturbations (Long, 1991). Elevated CO_2 causes a greater degree of photosynthetic enhancement at higher temperatures and the temperature optimum for photosynthesis increases with increasing CO_2 concentration (Figure 10). This synergism arises because elevated CO_2 counters photorespiratory carbon losses (see Photosynthesis' section), which increase with increasing temperature. Experiments exclusively addressing short-term gas exchange responses to elevated CO_2 and temperature do support the synergistic effects predicted by the models (Morison and Lawlor, 1999).

A suite of other leaf-level and whole plant processes are in uenced by temperature, and these additional temperature effects may uncouple the synergism between temperature and CO_2 suggested by the leaf-level model. For example, increased temperature invariably increases both dark respiration rates and transpiration rates (because of higher vapor pressure deficit), and as a result decreases whole-plant water use efficiency (Eamus, 1991). Temperature may also in uence patterns of carbon allocation within plants (Farrar and Williams, 1991), as well as advancing the timing of many developmental events, such as seedling emergence (Farnsworth *et al.*, 1995), bud break (Ackerly *et al.*, 1992)

and owering (Price and Waser, 1998). All these effects add to the mechanistic complexity of CO_2-temperature interactions. Although some studies have found that elevated CO_2 causes a greater proportional enhancement of growth at higher temperatures as predicted by the model, overall there is little consensus amongst studies that address whole-plant responses to CO_2 and temperature (Morison and Lawlor, 1999).

Our inability to detect clear trends in the way that CO_2 concentration and temperature interact to in uence plant growth and development stems from both conceptual and methodological difficulties. We currently lack mechanistic models that adequately address the complexity of the interactions between these perturbations at the whole-plant level. To achieve this goal, we need to incorporate an understanding of plant developmental patterns, nutrient use patterns and carbon partitioning into current models of leaf-level photosynthesis. Empirical support for these models may be difficult to achieve because of a lack of consensus on temperature regimes to be used in experiments. Elevated CO_2 studies tend to use standard ambient ($350-375\,\mu l\,l^{-1}$) and twice-ambient ($700-800\,\mu l\,l^{-1}$) treatments, while ranges in temperature studies vary from 2 to 40 °C. The reference temperature used is also highly variable, and does not always relate to the natural conditions experienced by the species across its range. We clearly need to resolve these methodological issues before we can begin to validate theoretical predictions about CO_2-temperature interactions.

An increase in global mean temperature will clearly have some far-reaching consequences for plant function in natural ecosystems. Another area of concern relates to extreme temperature events, which may increase in frequency as a consequence of climatic change, e.g., El Nino years (Timmermann *et al.*, 1999). Short periods of extreme cold or heat could have a lasting impact on plant growth and development, and could ultimately in uence the regional distribution and abundance of species. Through its effects on plant function, elevated CO_2 could in uence plant responses to extreme temperature events. The limited evidence we have to date suggests that elevated CO_2 may improve frost hardiness and mitigate freezing stress (Repo *et al.*, 1996; Wayne *et al.*, 1998), while it may sometimes exacerbate heat stress, depending on the species (Coleman *et al.*, 1991; Bassow *et al.*, 1994). Mechanisms for these observations are currently not well established, although some hypotheses have been suggested. CO_2-induced freezing tolerance may arise from synthesis of additional protective carbohydrates during the growing season, while elevated CO_2 may increase the frequency of heat stress, because the cooling benefits of transpiration are reduced as stomatal conductance declines.

CONCLUSIONS

The widespread, rapid and dramatic changes that natural ecosystems are undergoing as a result of human activities make it essential that we understand the responses of ecological systems to novel perturbations. As the behavior of individual plants will ultimately determine many of the key ecological processes that take place within ecosystems, it is critical that we examine how major environmental changes will in uence plant function. We have observed that many human-induced perturbations directly affect basic plant processes, and we can learn much by addressing the impact of global change on underlying physiological mechanisms within plants. Research in this area has progressed by developing hypotheses about future effects of environmental perturbations from first-hand physiological principles, then testing these hypotheses with experimental work (normally at the level of individual tissues, e.g., leaves, fine roots, followed by whole-plant, integrated research), and then re-evaluating the hypotheses based on the degree of agreement between theory and empirical evidence.

Due to the importance of rising levels of atmospheric CO_2 for natural ecosystems in the future, we have focused most of this review on the effects of elevated CO_2 on plants. Increased CO_2 levels are a particularly significant novel perturbation because of potential feedback between CO_2-induced enhancements of ecosystem productivity and the slowing of atmospheric CO_2 increases through uptake by vegetation. Many of the direct and indirect effects of elevated CO_2 on plants have implications for these feedback processes. Developing an understanding of the mechanisms underlying these feedback will allow us to better predict the future role of terrestrial vegetation in the global carbon cycle.

One of the most critical areas of current global change research concerns the degree to which elevated CO_2 will stimulate leaf-level photosynthesis. The magnitude of photosynthetic enhancement is largely determined by the extent to which down-regulation occurs. Plants that undergo strong acclimation responses to elevated CO_2 typically show small CO_2 growth enhancements. We now have a relatively good understanding of the physiological mechanisms underlying down-regulation. To date, however, we have been unable to link this mechanistic understanding with explaining the large variation in CO_2 responsiveness observed across species and environmental conditions. Establishing these connections should be a priority in future CO_2 research.

Interactions between plant and soil processes also form a critical component of potential biosphere-atmosphere feedback. Nutrient availability often constrains plant responses to elevated CO_2, but could, itself, be influenced by the activity of plants within the ecosystem. Elevated CO_2 influences a number of whole-plant processes that themselves determine patterns of ecosystem-level nutrient cycling. Again, developing a mechanistic understanding of the suite of CO_2-induced changes in plant physiological processes is essential for improving our ability to predict long-term ecosystem responses to rising atmospheric CO_2. Different plant processes lead to both positive and negative feedback on ecosystem nutrient availability. The relative importance of these processes in different systems and under different environmental conditions must now be established. Examining these feedbacks and connections becomes particularly important when we consider the suite of other global environmental perturbations that are also likely to affect terrestrial ecosystem functioning. For example, nitrogen deposition may interact synergistically with elevated CO_2 to enhance plant growth and development by countering these negative feedbacks on plant productivity. Depending on future rates of deposition, however, additional nitrogen in natural ecosystems could have a detrimental impact prior to potential beneficial effects in conjunction with elevated CO_2.

Our understanding of CO_2 effects on plants has advanced considerably since the field emerged over two decades ago. We are still hindered, however, by the difficulty of connecting theoretical predictions with empirical evidence and of considering many interacting processes simultaneously. We must now make a concerted effort to improve the gaps in our knowledge, particularly by focusing on processes that relate directly to interactions between the atmosphere and natural ecosystems.

Sedimentary Records of Long-term Ecological Change

JOHN DEARING

University of Liverpool, Liverpool, UK

The geological record has long been a rich source of information about ancient environments. Fossil remains of plant and animal species and the nature of sediments can give a remarkable view of past ecosystems and climate. Such records provided the stimulus for Darwin's theory of evolution and they continue to drive research into evolutionary trends and the causes of extinctions. In the 19th century, geologists interpreted the ancient conditions by making comparisons with modern sediments and processes. But during the 20th century, these so-called palaeorecords have been increasingly used to provide a long time perspective on global environmental change that may actually help us to understand modern environments and to manage future ones. The palaeoecological method stems from an increasing need to understand how human activities and climate may alter processes in the natural environment, especially over periods of time that are too long to have been monitored. For this human dimension, scientists have turned to the soft and unconsolidated deposits of mud and peat, and to ice cores, spanning the past few thousand years. In many parts of the world, these sedimentary archives are rich in information about the effects our ancestors had on the environment, the way in which climate affected vegetation and hydrology and the trends of environmental processes right up to the present day. Other important environmental archives include the annual and seasonal growth increments in tree-rings, coral and speleothems that are providing climate records of high resolution. Without this package of archives we have only a limited timespan of recorded knowledge, often no more than a few decades, about climate, hydrology and even pollution. When used in conjunction with historical documents, archaeological records, instrumental records of climate, and mathematical models, sedimentary archives may provide not only a historical perspective but also a fuller understanding of how the environments around us function and react to impacts.

PALAEOECOLOGICAL METHODS

The strength of palaeoecological research lies in the fact that natural environments are open systems that transport energy across their boundaries in the form of water, nutrients, heat and particles. Particles transported in the air and owing water are trapped in several types of environmental sinks – lakes, reservoirs, peat surfaces, river oodplains, river deltas, etc. (Oldfield, 1977). Thus, peat bogs may preserve the partially decomposed, but identifiable, remains of vegetation growing at the bog surface. Similarly, the microscopic organic remains of aquatic organisms that accumulate at lake beds and river oodplains may show layers of silt brought down by successive oods within the surrounding catchment. Some sediment contents, like microscopic algal fossils, may tell us not just about which species were living in the lake in the past but may be used to infer past lake conditions. For example, some algae (diatoms) are tolerant of highly acid water and their presence in lake mud tells us that the lake water must have been acidic when they were living. This indirect process of reconstruction uses the sediment components as environmental indicators or *proxies* of past conditions (see Figure 1). In some studies, the proxy in modern sediments is calibrated against modern conditions to produce a transfer function that may then be applied to earlier sediments. This approach has allowed diatom counts to be translated into lake pH values and pollen frequencies into landscape types. *See also* **Natural Records of Climate Change**, Volume 1.

The reconstruction of past environments is never perfect. Some outputs from systems are altered before or after they are laid down, some proxies such as airborne pollen grains, are not always easily linked to the place of their origin, and some processes simply leave no direct trace. But the ingenuity of palaeoecologists has led to a surprisingly large number of environmental states and processes that may be reconstructed (Lowe and Walker, 1997). A thimble full of lake sediment can easily contain the

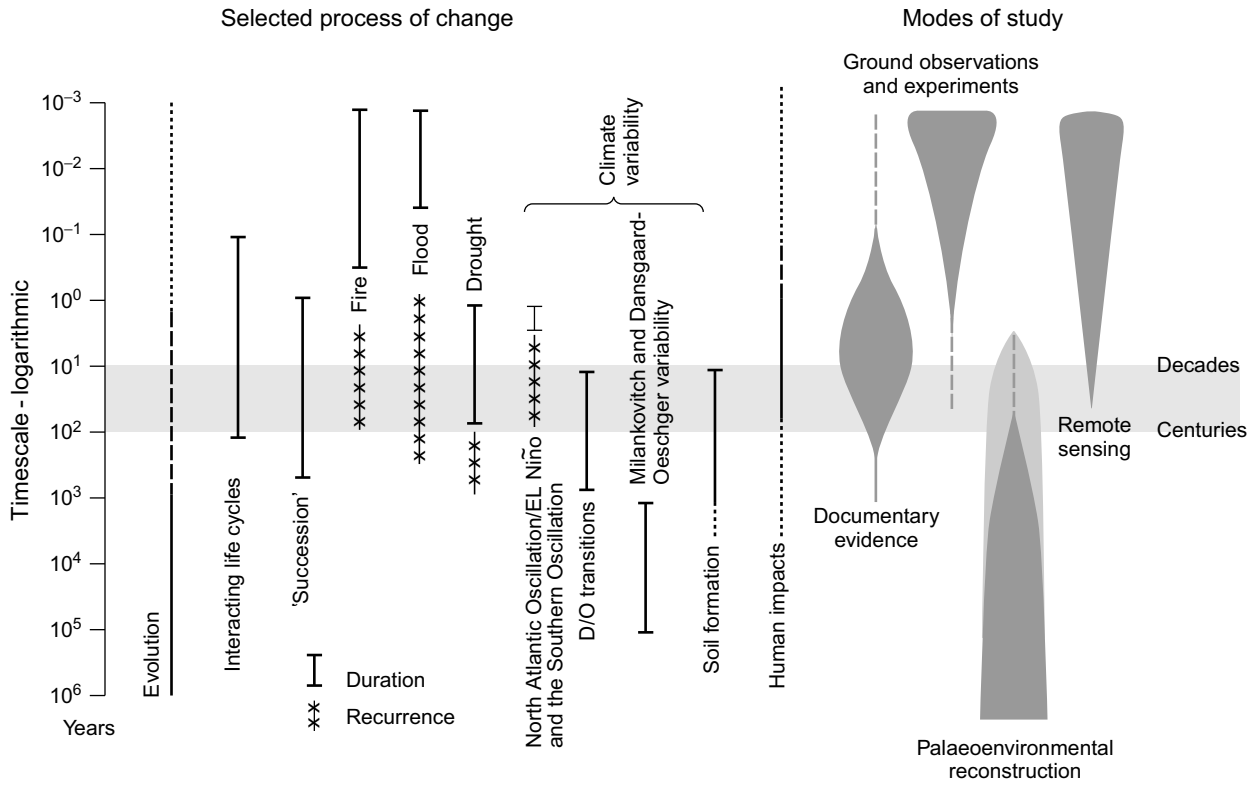

Figure 1 Timescales of environmental change and alternative approaches to their study used by the International Geosphere Biosphere Programme's Past Global Changes (PAGES) core project. Sediments represent a unique means for reconstructing environmental processes and conditions beyond the periods represented by conventional modes of study, monitoring, remote sensing and historical documentation. (Reproduced from Oldfield, 2001)

microfossils linked to more than 100 species of aquatic organisms and terrestrial plants, and the signatures of 20 or so environmental processes like river flooding, eroding soils, volcanic eruptions and industrial pollution (Table 1).

The key to the whole approach is sediment dating. Typically, around 5–15 m of mud have accumulated at the bottom of lakes during the Holocene, the geological period covering the past 11 000 years. A similar thickness of peat has developed in temperate environments. In some lakes the mud is deposited with a seasonal cycle that gives rise to visible layers known as *laminations* which afford a means of dating – one can count back the seasonal layers from the present to find the sediment age for any particular depth. But in the majority of sedimentary archives, dating relies on analytical procedures such as ^{14}C dating of organic remains (c. 40 000–300 years ago), and ^{210}Pb dating that gives sediment ages over the past 100–150 years. Other dating techniques utilize pollution markers like the radioactive fallout from Chernobyl (1986) and early bomb tests (1963), or other markers in the sediment that have a known and often local date, such as pollen linked to the introduction of an exotic plant species.

NATURAL ENVIRONMENTAL VARIABILITY

The first palaeoecologists were particularly interested in reconstructing past vegetation and climate. More than 50 years ago, Johannes Iversen showed through pollen diagrams the major shifts in northern European vegetation through glacial and interglacial periods, and used the climatic range of species such as holly, ivy and mistletoe to calibrate pollen records in terms of annual temperatures (Iversen, 1944). In rain-fed peat bogs and blanket mires, stratigraphic changes in the degree of organic decomposition were interpreted to have been caused by shifts in humidity. Since these early studies, improved methods and investigations at hundreds of sites have produced climate and vegetation records for many regions of the world. Generally, the results show that climate variability in many regions during the past 10 000 years is probably greater than previously believed. There is now a consensus of evidence for a thermal optimum 9000–5500 years before present (BP) that was followed by cooler and, in middle latitudes at least, wetter conditions. Studies of peat stratigraphy, lake sediment laminations and tree-rings also confirm the later fluctuations in climate related to the Medieval Warm Period, the Little Ice Age and

Table 1 Properties of sediments used to reconstruct past ecosystems and environmental processes

Environmental state or process	Example of sediment property, signature or proxy in peat (P), floodplains (F) or lake sediments (L)
Terrestrial ecosystem	
Vegetation type	Pollen (P, F and L) Organic chemistry (P, F and L) Stable isotope chemistry (P and L)
Soil type	Geochemistry (L, F) Mineral magnetism (L, F) Organic chemistry (L, F)

Pollution	
Particles	Heavy metals (P and L) Soot/inorganic particles (P and L) Magnetic spheres (P and L) Polycyclic aromatic hydrocarbons (P and L) Radioisotopes (P and L)
Gases (acid rain)	Diatoms algae (L)

global warming since the late 19th century, that have also been recorded in historical documents and instrumental records (Figure 2a) (*see* Little Ice Age, Volume 1; Medieval Climatic Optimum, Volume 1). The effects of climate on vegetation is often seen most strongly across steep environmental gradients, like mountain slopes or the narrow boundary (ecotone) between the grassland and forest zones of North America (*see* Ecotones, Volume 2).

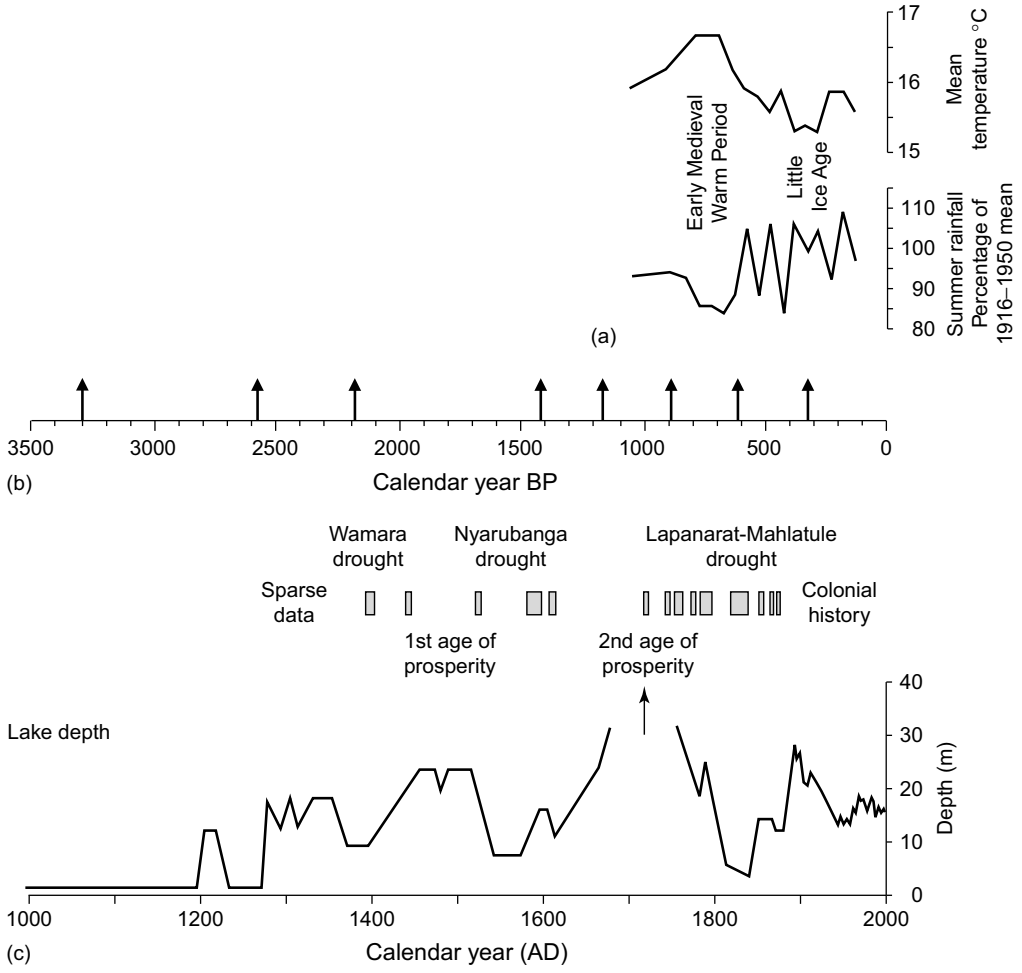

Figure 2 Climate variability recorded in documentary and sedimentary archives: (a) summer rainfall and mean annual temperature in England derived from historical documents in the 900 calibrated (calendar) years BP (Lamb, 1977); (b) mean dates of increased wetness/coldness (arrows) inferred from studies of British and Irish peat in the 3500 cal. year BP (Ellis and Tallis, 2000); (c) reconstructed records of lake water levels in Crescent Island Crater lake, Kenya, for the past 1000 years, where low levels are associated with drought and times of historically recorded poor prosperity and political upheaval (grey bars) (Verschuren *et al.*, 2000)

In these areas, the results from multiple investigations are used to map the changes in the altitude of natural tree-lines or the ebb and ow of ecosystems in response to climate change. In some regions, there have been particularly strong responses to Holocene climate. Lakes that are essentially closed to surface streams are sensitive to climate-controlled groundwater and display evidence for uctuating water levels in the sediments. A recent review of these records in North Africa shows that the monsoonal rains reached a maximum between 9000 and 5000 years ago, and since then the whole region has become progressively drier – showing that recent desertification during the 20th century may be part of a long-term trend. There is strong evidence that arid phases in Kenya caused a worsening agricultural economy and political unrest (Figure 2b). In other regions, the impact of quite modest climate variability has been significant. For example, in the Mississippi catchment, the size and shape of ood sediments and abandoned river channels have been used to estimate the magnitude of extreme oods in the past. The results of James Knox's work shows that the oods were extremely sensitive to small changes in past climate – changes that are actually smaller than those anticipated for the 21st century (Knox, 2000). Fire has had an impact on the large majority of global ecosystems. Counts of charcoal preserved in sediments provide historical records of the frequency and sometimes the intensity of fires in these regions. Some analyses have shown just how common natural fires have been, and in some areas have led to changes in nature conservation policy. Nowadays small wildfires at ground level are encouraged and managed in order to mimic the natural condition and to avoid the devastating effects of large but rare canopy fires.

HUMAN IMPACT ON TERRESTRIAL ECOSYSTEMS

There are few areas on Earth that show no evidence of past human impact on ecosystems. Human impact on vegetation, especially, is recorded widely in pollen diagrams. For example, the cyclical nature of slash and burn methods used in shifting cultivation is recorded as a recognizable sequence of pollen assemblages. The first permanent farmers typically cleared native woodland or scrub, introduced cultivated crops and inadvertently aided the success of weed species, effects that are all recorded. We are able to deduce not only the farming methods but identify the start and subsequent history of the impact in

many parts of the world (Figure 3). For example, the advent of farming in the Near East (>10 000 year BP); the ancient civilizations of the Egyptians, Greeks and Maya; the successive episodes of deforestation stretching across northwest Europe from c. 3500 year BP; the introduction of European agricultural techniques to North America and Australia in the past 250 years; and the recent commercial logging of tropical forests. Recently, the use of pollen data has been extended to recreate aspects of past vegetation cover and land use. For example, in Denmark calibration of modern pollen assemblages to landscapes shows that the major features of land cover patterns have been in existence for more than 3000 years. When set within an archaeological context or when compared with complementary information about climate, these records can help us to understand the links between human activities and climate, and even the feedback on subsequent farming generations. There are several well-established examples of poor farming practices or deteriorating climate (often towards a drier climate) leading to unsustainable agriculture, social unrest, war or migration (Redman, 1999).

Palaeorecords also help us to understand the reasons behind the loss of certain ecosystems and changes in biodiversity. In doing so, we are able to place present trends of species loss in a long time perspective. It is clear from pollen evidence that, perhaps contrary to instinct, human impact often causes biodiversity to increase due to the creation of new habitats. We also now know that many of our wildernesses are in fact the product of human activities or climate, and sometimes a combination of the two. For example, the upland heath ecosystems of northwest Europe are at least 3000 years old, but are the result of the loss of native woodland. As another example palaeoecological evidence from once-thought examples of pristine montane forest in east Africa shows that these environments have often been disturbed over the past 2000 years. We can be sure that future debates about how we manage wildernesses, biodiversity hotspots and National Parks will involve an interrogation of their histories to a far greater extent than before.

HUMAN IMPACT ON SOILS

Farming destabilizes soil structure and may alter soil fertility. Flood layers, increased sedimentation rates and changes in water quality (Table 1) all provide evidence for accelerated soil erosion and nutrient losses, and some generalizations about long-term trends are now possible (Dearing, 1994). What becomes very clear is the close link between erosion and human habitation (Figure 4). For pre-European North America, erosion values are low or declining under limited human impact. The rise and fall of the Classic Maya Civilization in Guatemala is mirrored in the shape of the erosion curve and is also linked to dramatic shifts in the loss of nutrients, especially phosphorus. Erosion values in lowland Europe between c. 10 000 and 3500 years ago are also low, but from c. 3500 BP they tend to show a step-wise pattern of increasing soil losses, where each step is often linked to technological innovation or inward migration. If we focus on a particular step, erosion rates initially rise dramatically but then often decline to a new balanced state, but at a higher level than before the whole transition in

erosion rates typically taking several decades longer than the period of land use change.

Taking the long-term view suggests that in the absence of soil conservation measures, modern erosion rates in some parts of North Europe and North America may be some of the highest recorded. The rates may approach those calculated for the same landscapes at the end of the last Ice Age when there was a bare tundra environment. More than 10-fold increases in erosion over the figure for undisturbed environments are not uncommon. A few studies in Europe, Australia and the US have compared the lake records with recent monitored records of river sediment discharge and source fingerprints in the lake catchment. The results suggest that the eroded sediment found in oodplains and lake muds may come from both river channels and field surfaces. Farming may have had as much impact on runoff, ooding and river channel erosion as it has had on soil erosion. By comparing erosion records from lakes with catchments of different sizes, we can begin to explore the dependence of erosion responses on a spatial scale. It seems that deforestation in small catchments causes not just the largest erosion rates per unit area but also a much larger increase of erosion over the pre-disturbance figure. These findings have clear implications for the impact of modern forest management on reservoir sedimentation, the sustainability of oodplains and on sediment concentrations in coastal ecosystems. What we can also say with some certainty, is that rising curves of erosion associated with some intensive Western agriculture and tropical farming practises suggest strongly that modern soil losses are often unsustainable.

AIR AND WATER POLLUTION

There are now numerous sedimentary records that have helped identify the magnitude, timing, source and causes of pollution. Atmospheric pollution is not new, as demonstrated by analyses of lead (and its isotopes) trapped in cores of glacier ice from Greenland. The results provide a Northern Hemisphere record of atmospheric lead deposition from the first significant rise during the Roman Empire to the switch from leaded to non-leaded petrol in the late 20th century (Boutron *et al.*, 1991). But the majority of pollution studies have focused on pollution in the last two centuries, particularly the causes and rates of change up to the present. The impact of pollution on water quality has been studied using the assemblages of diatom algae, preserved in lake sediments, that are particularly responsive to acidity and dissolved nutrients. Through transfer functions, they allow historical changes in pH and nutrients to be quantified. In the 1980s, one of the hottest environmental debates was the cause of lake acidification, a process that was linked to losses of freshwater fish stocks, rapid changes in aquatic ecosystem communities and increased concentrations of dissolved metals, such as aluminum. Rick Battarbee and his team used diatom transfer functions to show that lakes in Galloway, southwest Scotland had acidified only from the late 19th or early 20th century (Battarbee, 1985), irrespective of the type of vegetation cover in the catchment (Figure 5). Additional evidence from geochemical analyses of the sediments showed that the start of acidification usually coincided with the first significant deposition of heavy metals, such as copper and lead, and soot particles – all indicative of industrial pollution sources. These studies and others in Scandinavia, northwest Europe and North America quickly provided a set of compelling arguments to refute claims that long-term natural processes of acidification or certain types of land use had caused acidification. In fact, some reconstructions showed that far from air pollution accelerating a natural acidification process, long-term natural trends in lake pH were towards increasing alkalinity. Air-borne pollutants often transported long distances from major centres of industrialization, probably aided by the construction of tall chimneys, were clearly implicated as the main causes of lake acidification in many parts of the world. The results had a significant impact on government policy and helped accelerate the reductions in pollution emissions, particularly from large coal-burning power generation plants.

At many sites world-wide, there is clear evidence that major increases in aquatic biomass and shifts in ecological communities in lakes, rivers and coastal zones have been responses to the release of soil nutrients following deforestation or the increased ow of nutrients from fertilizers, sewage and urban runoff. Eutrophication of lakes by nutrients is, in contrast to lake acidification, more often linked to local catchment conditions, but may also cause damage to fisheries and even constitute a health hazard to recreational users and farm animals. Some lake sediment studies have now succeeded in reconstructing not just the impact on aquatic organisms but also the amount of nutrients, particularly phosphorus, that have owed into the lake. The ability to calculate past loading of acidity and nutrients has allowed management programs to estimate the critical loads to a particular site that should not be exceeded.

FROM THE PAST TO THE FUTURE

Over the last decade, the idea of a rapidly changing global environment has not only become the major focus of environmental research, but has also become a permanent part of the public consciousness. Concepts of new weather regimes, sustainable agriculture, and the causes of natural hazards are now commonly discussed by the media. The questions that are now being asked by society will challenge scientists to inform about the future to a far more accurate degree. How will landscapes respond to new weather conditions? Will extreme ood events become more frequent? If we have the opportunity to adopt alternative agricultural

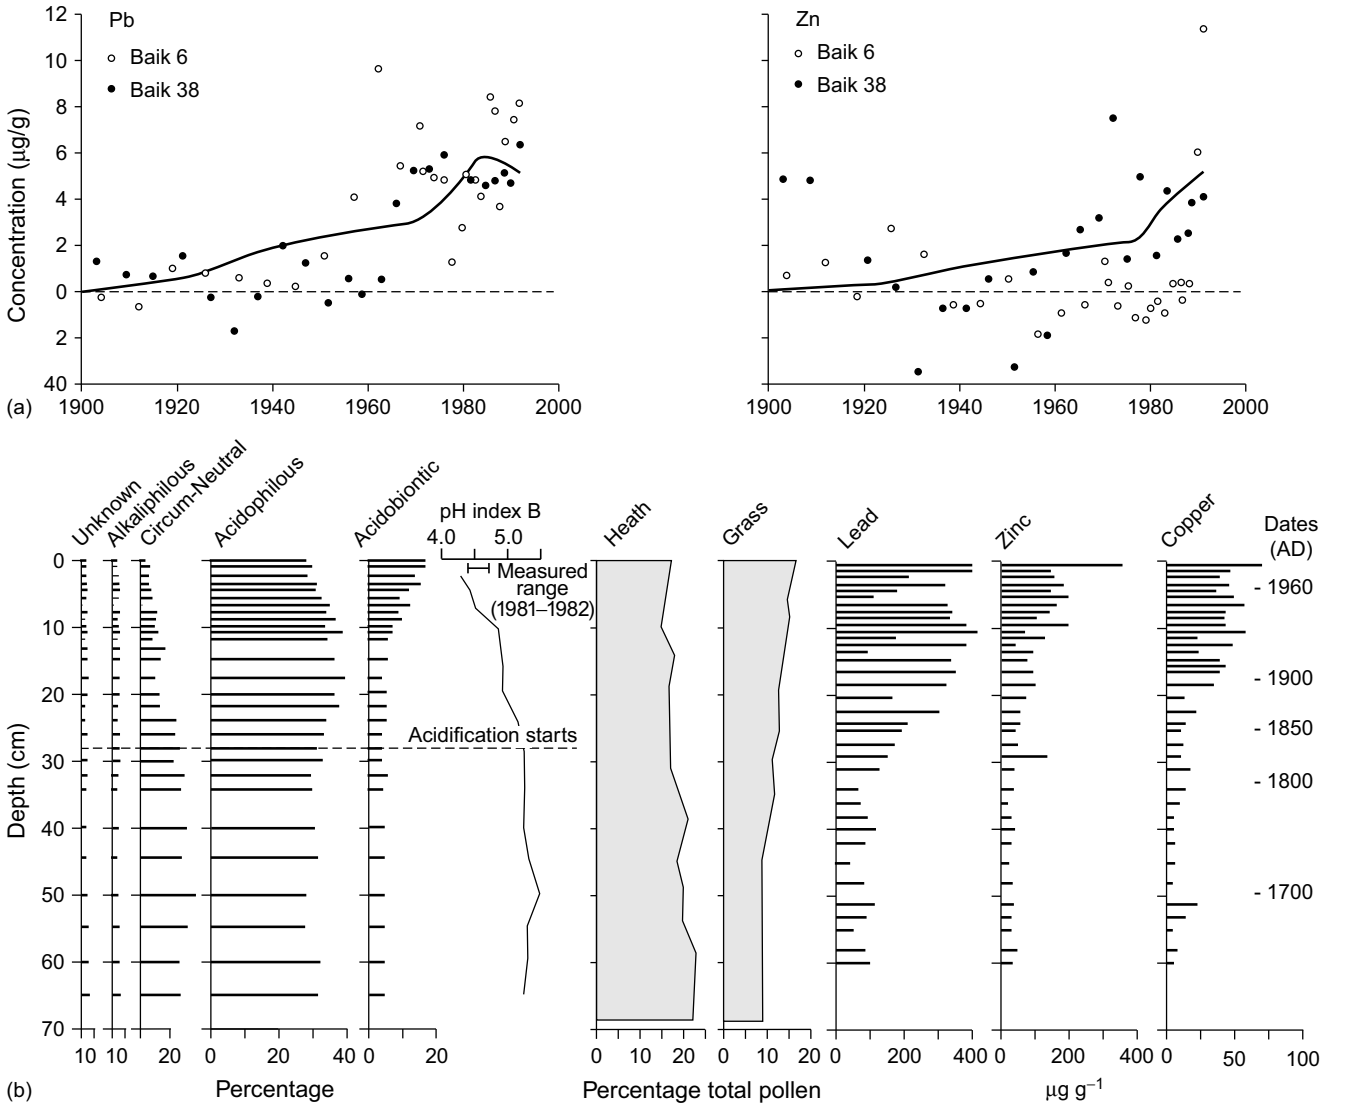

Figure 5 Recent records of pollution derived from lake sediments: (a) reconstructed records in two sediment cores (Baik 6 and 38) of lead (Pb) and zinc (Zn) supply to the southern basin of Lake Baikal, Siberia, with trend line showing evidence for enrichment from local industrial sources after 1940–1950 and again after c. 1970 (Boyle *et al.*, 1998) (*see* **Lake Baikal**, Volume 3); (b) diatom-based reconstruction of lake pH (solid line) in northwest Scotland showing initial decline in pH beginning after 1840 caused by atmospheric emissions, supported by pollen evidence for unchanging heathland species, and correlations with enhanced sediment concentrations of atmospherically-derived heavy metals. The labels *unknown*, *alkaliphilous*, *circum-neutral*, *acidophilous* and *acidobiontic* describe pH classes of diatoms (Battarbee *et al.*, 1985)

responses, how do we judge which is the most appropriate? If we do invest in pollution control, how long will it take to see the benefits? The previous sections have provided a glimpse of the wealth of information that now exists about past environments and the implications for their future, but much more can be learned from the past using a number of alternative approaches. One approach will be to use palaeorecords to test the accuracy of predictive models. Mathematical models that predict the effects of pollution controls on long-term acidification of surface waters and the soil erosion response to climate have already been retrospectively tested using lake sediment records. The models can be modified until they match the historical records, and then be used with much more confidence to project future conditions, or scenarios. For surface water acidification, the MAGIC model (Battarbee, 1994) accurately simulates the acidification that has taken place since the 1850s and provides predictions for future lake pH status under different levels of sulfur emissions. We may increasingly wish to identify systems whose behavior is very difficult to predict, and some new work in this area is based on the idea of comparing palaeorecords with theoretical views

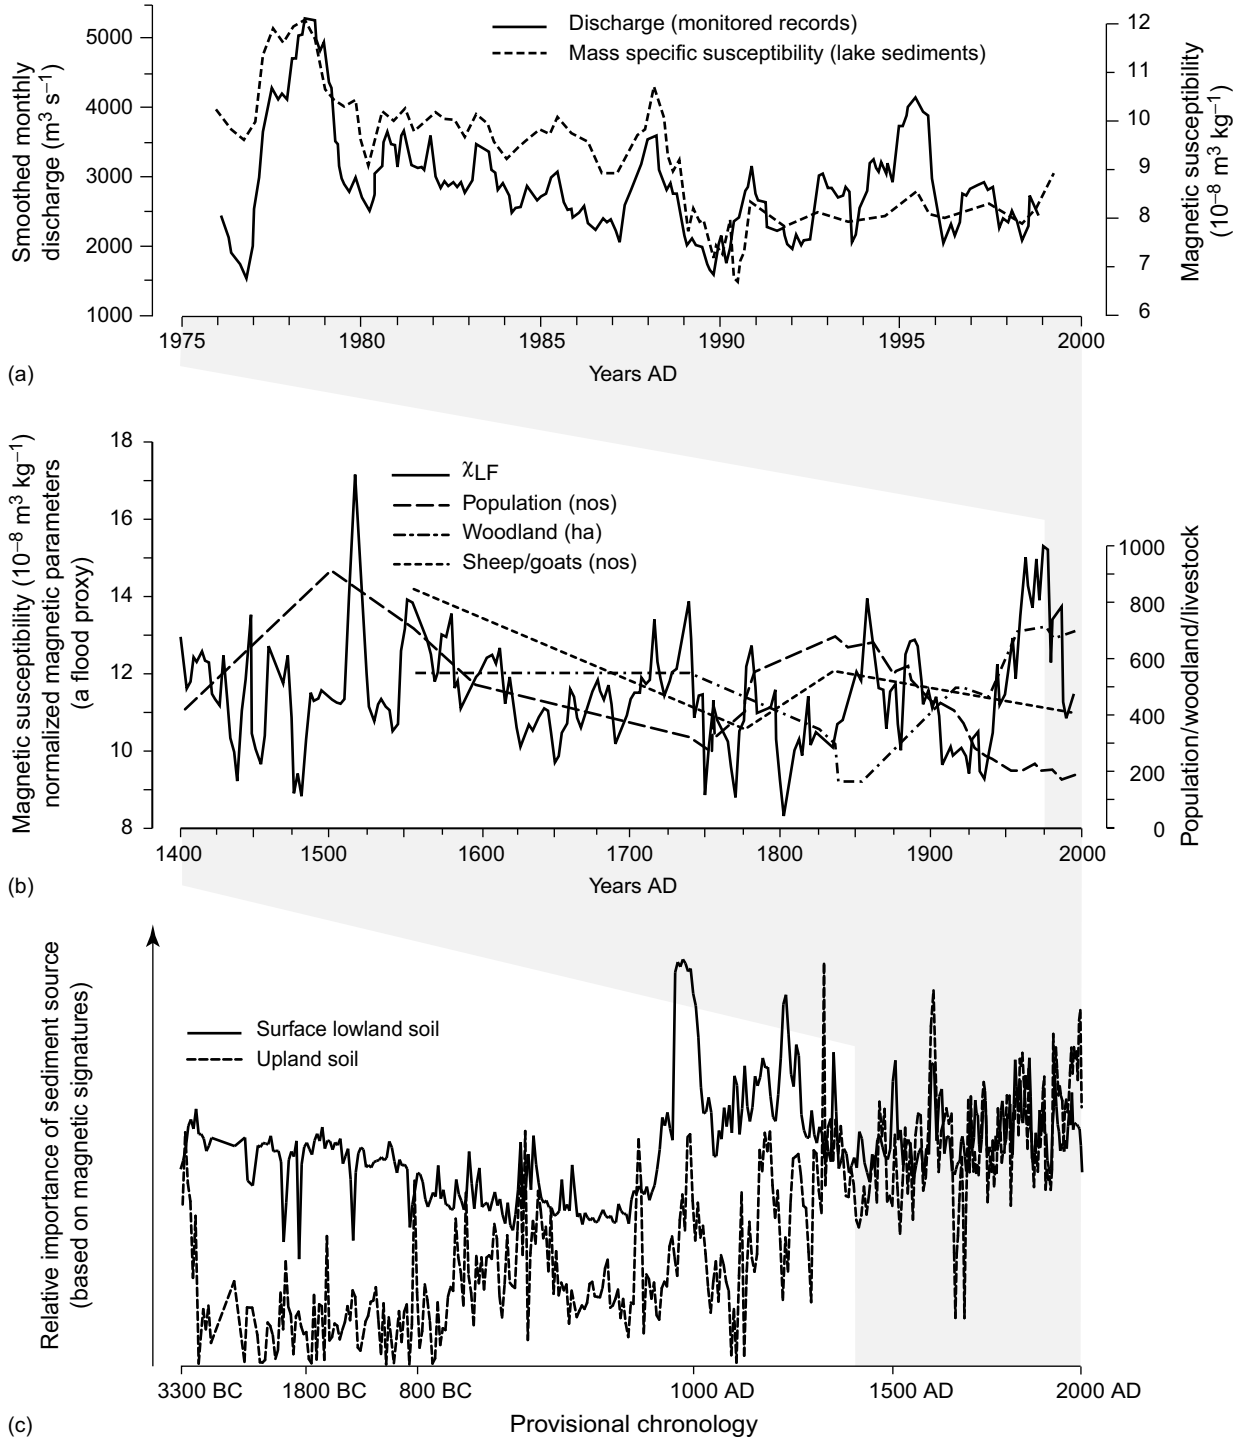

Figure 6 Reconstructing the interactions between human activities and climate on modern and historical flooding at Lac d' Annecy, French Alps, based on a combination of lake sediments, monitored process data and historical documents (author's unpublished data): (a) the magnetic properties of lake sediment deposited 1970–1998 are broadly correlated with monitored records of monthly river discharge, giving a magnetic proxy for flooding in older sediments; (b) the magnetic flood proxy for sediment spanning the past 600 years plotted against historical records of land use and human population showing complex associations between land use change and flooding; (c) magnetic signatures for the transport of surface lowland soil and upland soil from the catchment to the lake since c. 5500 BP showing that major changes, which occurred c. 1000 years ago in response to deforestation, may still exert a significant control on the progressive erosion of upland soil and the modern flood responses to climate and human impact

on how systems in general change. Theories about chaotic behavior and self-organized systems imply that some features of today's environment are not directly linked to easily definable external forces or may be caused by the internal organization of the system (*see* Monitoring in Support of Policy: an Adaptive Ecosystem Approach, Volume 4). Thus, the occurrence of a catastrophic landslide may be part of a long-term underlying system property, and not simply a consequence of a certain set of weather and land use conditions that we can measure. So another approach is to use palaeorecords in conjunction with historical documents and instrumental records in order to learn about the long term relationships between human actions, climate and environmental processes. One obstacle in this kind of study is the tightly woven roles of climate and human activities in controlling the structure and functioning of environmental systems. A recent example from Lac d'Annecy in the French Alps (Figure 6) shows that while modern ood events obviously re ect extreme rainfall events, their magnitude has changed in complex ways partly as a result of land use. In particular, the study traces the modern sensitivity of ood-water generation, erosion, and, possibly, avalanches in the high montane zone back to high altitude forest clearance and grazing that started 1000 years ago. This study, and others, suggest that the way in which present and future environments will respond to, or recover from, a changing climate or a new land use is at least partly conditioned by their history. An extension of this approach is to find historical examples, or analogues, of present day environmental change and observe the responses in the system that have already occurred. As we have seen, the Mayan populations cleared large tracts of tropical forest and caused significant erosion. The lake sediment record showed that erosion levels did eventually decline, but over several centuries. We may propose that erosion under today's logged forest will also take a similar timescale to recover – assuming that, as in the past, clearance and farming virtually cease.

Timescales of natural change and the speed of environmental responses and recoveries to impacts vary with different landscapes and with different environmental processes. The length of this history can vary from a few years to millennia. Managing our global environments so that the worst, destructive aspects of change are limited remains a major challenge, and one that will be increasingly dependent upon the reconstruction and detailed analysis of past ecosystems.

Terrestrial and Freshwater Ecosystems: Impacts of Global Change

BRUCE A HUNGATE AND JANE C MARKS

Northern Arizona University, Flagstaff, AZ, USA

Humans are altering the environment in many ways. While local environmental damage (land lls, oil spills, urban smog) is still prevalent, we now also realize that human activities are altering the Earth System as a whole, that our environmental crisis has become truly global. For example:

- *Our growing use of automobiles, air conditioners, jet planes, and other amenities of modern industrial society has caused the composition and chemistry of the atmosphere to change.*
- *The increasing concentration of heat-trapping gases in the atmosphere (carbon dioxide (CO_2), nitrous oxide (N_2O), methane (CH_4) and others) is already increasing global temperatures, and the rate of change is likely to increase in the future.*
- *The increasing concentration of ozone-depleting gases (chloro uorocarbons and nitrous oxide) in the stratosphere is weakening the ozone shield, allowing more and more damaging ultraviolet (UV-B) radiation to reach the Earth s surface.*
- *Growing food demand, greater use of irrigation, fertilizer and pesticides in agriculture, and the expansion of food production into previously uncultivated lands has increased the inputs of sediments, nutrients, and other pollutants into watersheds and the inputs of greenhouse and chemically active gases into the atmosphere.*
- *Of all the available freshwater on the Earth, humans now appropriate 23% for industrial, municipal, and agricultural uses, thereby altering natural hydrologic regimes and threatening freshwater ecosystems and the services those ecosystems provide.*
- *The spread of exotic species into terrestrial and freshwater ecosystems poses a growing threat to biodiversity conservation and to the services that ecosystems provide to humans.*

Such changes in the Earth s environment are collectively referred to as global change. The nature and magnitude of global change has raised the question, how does global change affect the ecosystems upon which we depend? Ecosystems supply humanity s food, clean water, and clean air and also are important sources of recreation and aesthetic value. Global changes threaten the ability of ecosystems to continue to provide these services. Our understanding of these threats will provide a foundation for determining the in uence of our activities on the Earth System: and for future decisions we must change our lifestyles and use of resources. This article provides an overview of the effects of global change on terrestrial and freshwater ecosystems in coming decades. Many such effects have been postulated or observed in manipulative experiments, but one of the more serious ecological concerns is the possibility of marked shifts in plant species composition due to differing responses of individual members of ecosystems to major changes in carbon dioxide concentrations, temperature, nitrogen emissions and other elements of the global environment.

ECOSYSTEM PROCESSES AND EFFECTS OF GLOBAL CHANGE: AN OVERVIEW

Considering the effects of global change from an ecosystem perspective warrants an overview of the terms and concepts of *ecosystem* ecology. An ecosystem comprises all the organisms in an area and the physical environment with which they interact. *Ecosystem structure* describes the spatial distribution of organisms, elements, and materials in ecosystems, including, for example, above- and below-ground biomass of plant species, soil carbon and nutrient mass, leaf area index in terrestrial ecosystems, or total

biomass of macrophytes and epiphytes and nutrient stores in freshwater ecosystems. By contrast, *ecosystem processes* are the uxes of materials and energy among ecosystem components and between ecosystems and the surrounding environment. For example, rates of photosynthesis and respiration, predation and herbivory, and nutrient turnover and loss are all ecosystem processes (*see* **Ecosystem Structure and Function**, Volume 2).

Ecosystems are not static; rather, disturbances, such as fires or insect outbreaks in forests, or scouring oods in rivers, occur in all ecosystems. *Disturbance* in ecology is defined as the catastrophic removal of biomass that creates space available for recolonization. Succession follows disturbance and involves species progressively recolonizing the disturbed area and being excluded from it (primarily through competition for resources by other species), resulting in a pattern of species replacements and changing species composition through time. Global change can alter the frequency and intensity of disturbances (increasing ood frequency and intensity, for example), but few global changes (excepting perhaps some land-use changes) constitute ecological disturbances in the strict sense. In ecological parlance, global changes are anthropogenic perturbations to ecosystems, human-caused changes in the conditions (temperature, pH, etc.) or resources (nutrients, carbon dioxide, light, water, etc.) that in uence ecosystem structure and processes.

Central to ecosystem ecology is the cycling of biologically essential elements, beginning with carbon. Carbon enters the biosphere through the process of photosynthesis (primary production) by plants and algae, converting atmospheric carbon dioxide to organic forms of carbon. This organic carbon resides in ecosystem compartments, both living (living tissue of plants, animals, and microorganisms) and non-living (as detritus and humus in terrestrial ecosystems and as dissolved or particulate organic matter in aquatic ecosystems). Within ecosystems, carbon is transferred between compartments through trophic interactions (herbivory, predation), senescence, and death. Through respiration by plants, animals, and particularly decomposer microorganisms, organic carbon is returned to the atmosphere as carbon dioxide. *Net primary production* (NPP) is the amount of carbon dioxide taken up by plants through photosynthesis minus respiration by plants, whereas *net ecosystem production* (NEP) is the amount of carbon dioxide taken up by plants through photosynthesis minus the respiration of all organisms in the ecosystem. Ecosystem carbon balance is equivalent to NEP, except when disturbances cause carbon losses by means other than decomposition (fire, for example, which converts organic carbon to carbon dioxide through the process of combustion). As described in detail below, global change can affect all of these important ecosystem processes; carbon gain through photosynthesis, loss through decomposition, and rates of transfers among ecosystem compartments. Changes in these process rates can alter components of ecosystem structure that depend directly on carbon cycling, such as stores of carbon in organic matter and vegetation.

Transfers of carbon dioxide between ecosystems and the atmosphere through photosynthesis and respiration are large enough, for example, that during the Northern Hemisphere summer, the seasonal peak in photosynthesis reduces the temperate zone carbon dioxide concentration by several parts per million, whereas when respiration becomes a relatively larger ux in the winter, atmospheric carbon dioxide concentration increases. These oscillations are mirrored (but more damped because of the smaller land masses) in the Southern Hemisphere, and are much less apparent in tropical regions, where the activities of photosynthesis and respiration are more synchronous throughout the year. These seasonal changes in atmospheric carbon dioxide concentration re ect the breathing of the biosphere and underscore the importance of biological control over atmospheric carbon dioxide concentrations. Because carbon dioxide is a greenhouse gas (increasing in the atmosphere due to fossil fuel burning, cement manufacture, and deforestation, and the major cause of global warming) there has been tremendous interest in understanding how global changes will alter carbon cycling in terrestrial ecosystems and, ultimately, the balance between carbon dioxide release to the atmosphere versus carbon dioxide uptake and storage in ecosystems. Such changes could strongly in uence the trajectory of rising carbon dioxide and associated global warming over the next few centuries.

In terrestrial plants, carbon uptake through photosynthesis is coupled to *transpiration*, the evaporation of water from the internal surfaces of leaves to the atmosphere and the major ux in the water cycle directly mediated by biota. Together, transpiration and the evaporation of water from exposed surfaces constitute *evapotranspiration*, the total ux of water from ecosystems to the atmosphere (*see also* **PET (Potential Evapotranspiration)**, Volume 2). Water not lost through evapotranspiration can be stored in soil and vegetation or lost as surface runoff to aquatic ecosystems and as percolation to groundwater. Precipitation returns water in the atmosphere to the Earth's surface, completing the water cycle. Climate change can alter water cycling through climate-driven shifts in the amount and distribution of precipitation, subsequently affecting ecosystem processes sensitive to water availability, including evapotranspiration, thereby altering surface runoff and percolation. Global changes such as rising carbon dioxide, warming, nitrogen deposition, and increased UV-B radiation can also alter water cycling through their effects on plant transpiration.

Evapotranspiration is regulated by the difference in water vapor pressure between the atmosphere and air above ecosystems and the resistance to water vapor ux between

the ecosystem and the atmosphere. Evapotranspiration occurs when solar radiation striking an ecosystem drives water from liquid to gas, an energy conversion (called *latent heat flux*, λE) that dissipates solar energy that might otherwise have increased the surface temperature of the ecosystem. *Convection* (the upward transfer of heat, also called *sensible heat flux*, C) is also an important way that heat is transferred from ecosystems to the atmosphere. The transfer can also occur in the other direction, if the surface of the ecosystem is colder than the surrounding atmosphere, as is often the case at night. The sum of sensible and latent heat fluxes, along with conduction into the ground (also termed storage, G), balances the net input of radiation (R_n) into terrestrial ecosystems: $R_n = C + \lambda E + G$. Structural and physiological features of ecosystems, including leaf area, stomatal conductance, canopy roughness, and rooting depth, strongly influence the relative importance of these terms, and thus the way in which energy is partitioned in ecosystems. By altering ecosystem structure or physiology through changes in growth or species composition, global change can alter energy partitioning. Such changes have important implications for ecosystem processes sensitive to temperature and moisture availability, as well as for regional climate patterns.

Global change can also alter the cycling of mineral nutrients (such as nitrogen, phosphorus, and others) upon which plant and ecosystem production depend. Indeed, global changes such as nitrogen deposition involve direct changes in the amounts of nutrients added to ecosystems from the atmosphere. Nutrients are made available to primary producers by decomposer organisms in the processes of *mineralization* (release of mineral nutrients through decomposition of dead organic matter); *weathering* (release of nutrients from parent material through chemical and physical reactions); *biological fixation* in the case of nitrogen (conversion of atmospheric N_2 to NH_3, a form usable by plants and microorganisms), and *atmospheric deposition* (in which readily available forms of nutrients enter ecosystems through rainfall or dry deposition). Nutrients are removed from this available pool through microbial immobilization or uptake by plants, chemical sorption reactions (formation of covalent bonds with mineral particles or precipitation with other minerals into unavailable forms), leaching and biotic and abiotic transformations to gaseous forms.

Gaseous fluxes of nitrogen from ecosystems to the atmosphere represent not only losses of an essential nutrient but also inputs to the atmosphere of reactive (nitric oxide and nitrogen dioxide) and radiatively active (nitrous oxide) trace gases. Fluxes of other trace gases, such as methane (CH_4), carbon monoxide (CO), and carbonyl sulfide (COS), while relatively small compared to carbon dioxide fluxes in photosynthesis and respiration, for example, are critical in the chemistry and radiation balance of the atmosphere. Through changes in trace gas fluxes, the responses of ecosystems to global change create feedbacks that can further amplify or mitigate global changes in the atmosphere.

ASSESSING THE EFFECTS OF GLOBAL CHANGE

The scientific community has taken three complementary approaches to assessing the effects of global change on ecosystems: experiments, observations, and models. (1) *Manipulative experiments* compare a set of test plots experiencing current normal conditions to another set where one aspect of the environment is modified to simulate a particular global change factor (e.g., global warming, nitrogen deposition, or the presence of an invading species). The advantage of the experimental approach is that it explicitly identifies the global changes that cause particular ecosystem responses. More complicated experiments involve manipulating two or more global change factors singly and in combination, allowing investigators to test whether knowledge of responses to each factor alone can predict their combined effects, or whether factors interact in surprising ways. Experiments examining full combinations of many factors can address very complex interactions and are extremely valuable in assessing effects of global change. However, such experiments are large and expensive and thus few and far between. Global change experiments are typically long term (1–10 years); they measure responses of ecosystems to a step change, an instantaneous doubling, for example, of atmospheric carbon dioxide concentrations (from 365 to $730\,\mu l\,l^{-1}$). This approach is necessary to be able to discern changes in ecosystem properties against a background of high natural variation. Actual global changes, however, occur more gradually and over longer periods of time (e.g., $3\,\mu l\,l^{-1}\,year^{-1}$, perhaps not reaching $730\,\mu l\,l^{-1}$ until the year 2100). Results from experiments must therefore be interpreted within a framework that accounts for these differences in time scale.

(2) *Observations* allow the impact of actual global changes on ecosystems to be observed. This may be carried out by reconstructing global changes that occurred in the past and examining evidence of their effects on ecosystems, through comparing ecosystems that occur along natural climatic or other gradients in space, or by monitoring ecosystems in the present as they are increasingly affected by global change. For example, the concentration and isotopic composition of gases trapped in air bubbles within ice near the poles provide records of atmospheric composition and temperature, and shows how the accumulation of greenhouse gases in the atmosphere in the past has coincided with increases in global temperatures. By combining such records of past temperatures and atmospheric composition with analyses of pollen in lake sediments, one can understand how plant species shifted in distribution

when, or shortly after, the climate changed. This approach has the considerable advantage of revealing how species composition in an area (an important component of ecosystem structure) has changed over hundreds to thousands of years in response to changes in climate. The gradient approach essentially substitutes space for time using, for example, a transect across the landscape along which mean annual temperature changes systematically, such that observations comparing the colder and warmer sites serve as an analog for ecosystem responses to global warming. Another approach is to monitor current ecosystems directly, to observe their responses to year-to-year variations in climate and to ongoing global changes. This type of approach is central to efforts to document global changes *per se* (e.g., rising global temperatures, atmospheric carbon dioxide concentrations, sea levels, rates of nitrogen and acid deposition and glacial retreat, etc.) and is also becoming more important for understanding ecosystem responses to these changes. One of the challenges associated with this observation approach is that, because many kinds of global change are occurring simultaneously, it is difficult to discern which particular change is causing a particular ecosystem response (though this can be overcome with the gradient approach, for example, if only one variable changes along the gradient). Another challenge is that while current rates of global change are unprecedented, they are slow for even a long-term (10–50 years) campaign of observations. This makes it difficult to distinguish the signal caused by global change from the noise associated with natural variation in ecosystem processes in space and time.

(3) *Mathematical models* are an essential component of efforts to understand the effects of global change on ecosystems. Models provide access to responses of ecosystems to global change that neither manipulative experiments nor observations allow. For example, a manipulative experiment to explore the interactive effects of warming, altered precipitation, increased nitrogen deposition, increased atmospheric carbon dioxide concentrations, and enhanced UV-B radiation on forest ecosystems in the field would be prohibitively expensive, yet models that incorporate information from single-factor manipulative experiments can explore such interactive effects. Similarly, models allow the study of responses over temporal and spatial scales that are impractical with manipulative experiments or observations. Ecosystem models incorporate state-of-the-art scientific understanding of controls over ecosystem processes, and as such, their simulations and predictions are limited by this understanding. Nevertheless, models are one of the more powerful tools available to global change scientists for taking complex and variable processes and translating them to larger spatial and temporal scales.

Efforts to understand ecosystem responses to global change through experiments, observations, or models shed light on the problem, but limitations are associated with each approach. For this reason, where possible, integrated assessments that take advantage of all three approaches are more powerful than any one approach alone.

ELEVATED ATMOSPHERIC CARBON DIOXIDE

The concentration of CO_2 in the atmosphere has increased by 30% since the mid-1800s and is perhaps the most certain component of atmospheric change. Direct measurements of atmospheric carbon dioxide over the past 50 years show this increase clearly (Keeling and Whorf, 2000), and measurements of the concentrations of carbon dioxide in gas bubbles trapped in ice provide a robust record of carbon dioxide concentrations for the past 420 000 years (Petit *et al.*, 1999). Carbon dioxide is the entry point for carbon into the biosphere because it is the substrate for primary production by plants, algae, and some bacteria. Rising carbon dioxide thus represents an increase in resource availability for primary producers, a change with effects that can cascade through ecosystems.

Effects on Terrestrial Ecosystems (*see also* Plant Growth at Elevated CO_2, Volume 2)

Plants usually respond to elevated carbon dioxide by increasing photosynthesis and growth, decreasing transpiration, and by altering patterns of carbon and nutrient use and allocation, patterns that are most clear in short-term laboratory or greenhouse studies. While these physiological changes often lead to responses at the community and ecosystem levels, feedbacks and environmental constraints strongly shape these responses. Indeed, one of the more important conclusions from the past several decades of research on this topic is that, while the short-term physiological responses of plants to elevated carbon dioxide can sometimes guide our predictions of larger-scale responses, in many cases they are misleading about the magnitude (and even the direction) of these responses at the ecosystem scale. For example, in the field, the photosynthetic response to elevated carbon dioxide and the fate of assimilated carbon are sensitive to temperature, water stress, and nutrient availability, and thus the growth responses of plants to elevated carbon dioxide ranges from none to modest to quite large.

Plants grown in elevated carbon dioxide usually have lower nitrogen concentrations, both because the requirement for rubisco and other enzymes (major nitrogen containing compounds) is reduced in elevated carbon dioxide, and because elevated carbon dioxide often causes accumulation of starch and sugars, diluting the amount of nitrogen they contain. Similarly, plants collected over the past several hundred years and stored in herbaria show a consistent decline in nitrogen concentrations in concert with increasing

atmospheric carbon dioxide since the industrial revolution. Reduced nitrogen concentration in litter usually slows the rate at which that litter decomposes and releases nitrogen in plant-available forms, so the commonly observed reduction in green-leaf nitrogen concentration was expected to reduce decomposition rate and nitrogen availability. This effect is only sometimes observed: litter produced by plants grown in elevated carbon dioxide does not usually decompose more slowly, contrary to previous predictions based on the physiological responses of plants (Norby and Cotrufo, 1998).

However, there are other mechanisms through which elevated carbon dioxide can affect nutrient cycling. By increasing root growth and the ow of labile organic compounds into the soil, elevated carbon dioxide can stimulate microbial nutrient immobilization, thereby exacerbating plant nutrient deficiencies, and decreasing nutrient availability for other microbial processes as well, such as nitrification. By increasing plant growth, elevated carbon dioxide can increase nutrient uptake and nutrient accumulation in biomass and soils, eventually increasing nutrient pools in unavailable, organic forms. On the other hand, elevated carbon dioxide can also increase nutrient availability to plants, both through changes in internal cycling rates and through changes in nutrient inputs and losses. For example, by stimulating microbial turnover, elevated carbon dioxide can increase soil nitrogen mineralization. Elevated carbon dioxide also often favors the growth of plants in association with nitrogen-fixing bacteria, as long as other factors (such as low phosphorus availability) do not limit nitrogen fixation. Nitrogen inputs to ecosystems can therefore increase with enhanced growth of nitrogen-fixing species. Elevated carbon dioxide has been shown to increase plant exudation of phosphatase, enzymes that convert soil phosphorus into a plant available form.

Carbon uptake through photosynthesis ultimately feeds all trophic levels in ecosystems, so it is not surprising that changes in carbon uptake in response to elevated carbon dioxide can alter trophic interactions. For example, the reduction in leaf nitrogen concentrations alters herbivore behavior and survival. Insect herbivores growing on leaves produced by plants grown at high carbon dioxide concentration levels usually consume more leaf tissue, but have slower rates of growth and development because of the lower quality of that tissue. Changes in the performance of herbivores can also alter trophic interactions that amplify the detrimental effects of elevated carbon dioxide on insect herbivores. In one case, elevated carbon dioxide caused a two-fold increase in mortality of insect herbivores because of reduced food quality, but also caused a four-fold increase in mortality because these herbivores are more vulnerable to attack by predators and parasitoids (Stiling *et al.*, 1999). In this case, the indirect effect mediated by predators substantially amplified the direct effect of reduced forage quality on herbivore mortality. Again, simple extrapolations of responses in the laboratory may differ substantially from responses observed in the field. Elevated carbon dioxide can also affect ruminant herbivores, and studies in tall grass prairie predict that forage produced in elevated carbon dioxide will cause a reduction in ruminant growth rate (Owensby *et al.*, 1996). In contrast to insects, ruminant tissue consumption declines with forage quality, so wild ruminants will likely suffer reduced growth and reproduction as carbon dioxide continues to rise (Owensby, 1996), with possible implications for higher trophic levels. Increased carbon inputs below ground can also alter soil food webs, changing the activity and abundances of bacteria and fungi, their protozoan and nematode predators, and mites and other organisms occupying higher trophic levels as well. Such changes in soil trophic structure could in uence nutrient cycling and decomposition rates.

As carbon dioxide diffuses from the atmosphere into leaves through stomata, water vapor diffuses from the leaves to the atmosphere, the process of transpiration. Increasing the concentration of atmospheric carbon dioxide strengthens the air-to-leaf concentration gradient of carbon dioxide, thereby increasing carbon dioxide supply to leaves, allowing stomata to close to save water, and resulting in lower rates of transpiration. While herbaceous species and tree seedlings often show strong reductions in stomatal conductance and transpiration in response to elevated carbon dioxide, responses in mature trees are more variable, and in some species there is no response to elevated carbon dioxide. Differences among species is at least partly related to growth form, as the stomatal response of coniferous trees to elevated carbon dioxide tends to be smaller than the response of herbs, and deciduous trees tend to be intermediate (Saxe *et al.*, 1998). The reduction in plant transpiration in response to elevated carbon dioxide can cause a reduction in evapotranspiration (the ux of water from the ecosystem to the atmosphere). Reduced evapotranspiration (latent heat ux) is usually compensated by increased canopy temperature and thus increased sensible heat ux. The ecosystem level consequences of reduced evapotranspiration include increased soil water storage, leaching, and/or runoff, and these changes, in turn, can alter a number of ecosystem processes sensitive to soil moisture, including plant growth, nutrient mineralization and trace gas uxes.

Elevated carbon dioxide usually increases photosynthesis at the canopy scale in both managed (e.g., a wheat field) and unmanaged (e.g., an alpine grassland) ecosystems, leading to the suggestion that terrestrial ecosystems could sequester some of the carbon dioxide being added to the atmosphere from fossil fuel burning, cement manufacturing and deforestation. However, observing carbon accumulation in ecosystem components in quantities

that match carbon uptake inferred by measurements of canopy photosynthesis has so far proven elusive. To date, there have been no publications in which these independent measures of carbon uptake can be balanced from a field experiment, but convergence of these approaches will provide greater confidence in our understanding of carbon dioxide effects on carbon uptake. Carbon uptake in elevated carbon dioxide experiments also illustrates the problem of scaling step-change experiments to the more gradual reality of global change. In response to a sudden increase in atmospheric carbon dioxide concentration, plant production can increase immediately, increasing NEP or carbon uptake. However, because the rate of carbon dioxide release from soil through decomposition increases as the amount of carbon in soil increases, carbon dioxide release through decomposition will eventually catch up, though with a lag period as the carbon is transferred from plants to soil pools of varying turnover times. All ecosystem carbon cycling models agree on this point. The ability of ecosystems to hold carbon over long periods requires large carbon reservoirs in pools that cycle slowly, such as wood and soil. Greater distribution to these pools in response to elevated carbon dioxide, and thus increased carbon storage, will be apparent in carbon dioxide doubling experiments if there is a relatively long lag period between increased carbon dioxide uptake and carbon dioxide release. If this lag period is shorter than expected, the extra carbon taken up in elevated carbon dioxide environments is being preferentially distributed to carbon pools with rapid turnover that quickly return carbon dioxide to the atmosphere. Few experiments have tried to determine the patterns of carbon distribution between carbon pools for short vs. long turnover times, but several have shown that elevated carbon dioxide tends to favor carbon distribution to rapidly cycling pools, limiting potential increases in carbon storage.

Effects on Freshwater Ecosystems

Freshwater ecosystems are frequently supersaturated with carbon dioxide, making direct effects of increasing atmospheric carbon dioxide on these ecosystems unlikely. However, freshwater ecosystems receive water, the dissolved nutrients and organic matter contained therein, and dead leaves, stems, and other plant parts from terrestrial ecosystems. Because terrestrial and aquatic ecosystems are linked in this way, effects of elevated carbon dioxide on production, water use, and nutrient cycling in terrestrial systems can have important consequences for freshwater ecosystems. For example, reductions in transpiration due to elevated carbon dioxide could increase stream flow and water yield from watersheds (though increases in evapotranspiration in response to warming will more than compensate for this in many cases). Increased plant production in response to elevated carbon dioxide could translate into greater inputs of plant litter into aquatic ecosystems, and changes in the chemical composition of that litter (e.g., concentrations of phenolic and other secondary compounds) could affect decomposition rates in aquatic ecosystems. Changes in the balance of microbial mineralization and immobilization of nitrogen in soils, along with changes in nitrification and plant uptake, could alter the export of inorganic nitrogen to streams and lakes. Such effects are only beginning to be documented in global change research.

EUTROPHICATION AND ACIDIFICATION (*see also* Eutrophication, Volume 2; Nitrogen Cycle, Volume 2; Phosphorus Cycle, Volume 2)

Human production of fertilizer nitrogen, cultivation of nitrogen-fixing crops, livestock husbandry, and fossil fuel burning have dramatically increased the inputs of fixed nitrogen (available for plant and microbial uptake) to terrestrial and aquatic ecosystems. These changes in land-use in watersheds have greatly increased inputs of phosphorus into aquatic ecosystems. These inputs constitute the phenomenon of eutrophication, a global change that alters the balance of nutrients that support ecosystem productivity. Atmospheric deposition of nitric and sulfuric acid is responsible for the acidification of terrestrial and freshwater ecosystems, often with deleterious effects.

Effects on Terrestrial Ecosystems

Current global inputs of anthropogenic nitrogen to terrestrial ecosystems match or exceed, natural preindustrial inputs through biological nitrogen fixation and lightning. Human-caused changes in the global nitrogen cycle have profound and widespread effects on ecosystems (Vitousek *et al.*, 1997). Of all the resources that plants require, nitrogen most commonly limits plant growth and NPP in terrestrial ecosystems. For this reason, increased inputs of nitrogen often stimulate NPP and carbon uptake by forest, grassland, and tundra ecosystems, as shown by a number of experiments. By stimulating NEP in these ecosystems, nitrogen deposition has likely contributed to the uptake of carbon dioxide derived from fossil fuels.

In ecosystems where nitrogen availability is naturally low, nitrogen deposition can favor the establishment, growth, and reproduction of introduced species adapted to high nitrogen levels over native species adapted to low nitrogen, causing marked shifts in plant transpiration composition, plant species often leading to biodiversity losses and local extinctions. For example, in the Netherlands, where rates of nitrogen deposition are the highest in the world, nitrogen deposition has converted

species-rich heathlands into species-poor grasslands, a complete change in the structure of the ecosystem (Aerts and Berendse, 1988). Nitrogen deposition can also affect an ecosystem's ability to withstand and recover from perturbations. For example, perennial grasslands in the US subjected to nitrogen addition had higher productivity in favorable years, but were affected more severely and recovered more slowly from drought than control plots without nitrogen addition (Tilman *et al.*, 1994).

Continuous additions of nitrogen will eventually cause some other resource to become more limiting to photosynthesis and growth, so that these processes will no longer show a positive response to nitrogen additions. At this point, the ecosystem is considered to be nitrogen-saturated. Nitrogen added to a nitrogen-saturated ecosystem is often matched by an equivalent amount of nitrogen leaving the system through leaching and gaseous pathways. In many other cases, though, not all nitrogen added through deposition (experimental or otherwise) to nitrogen-saturated ecosystems can be accounted for in increased biomass production, leaching, or trace gas losses. It appears that a substantial amount remains in the soil, immobilized either biotically or abiotically, and unavailable for plant or microbial uptake. This suggests that not all the nitrogen added through deposition will support extra plant growth, but it also suggests that some soils can absorb more ammonium than previously thought.

Not only will the productivity of nitrogen-saturated ecosystems no longer increase with nitrogen additions, but nitrogen saturation can also actually lead to system decline through several mechanisms. First, acid deposition, either as nitric acid (HNO_3) or sulfuric acid (H_2SO_4), directly leads to soil acidification. Even when nitrogen deposition occurs as ammonium (NH_4^+), the NH_4^+ is often quickly converted to nitrate (NO_3^-) via nitrification, a process releasing hydrogen ions and thus increasing soil acidity. Aluminum is biologically available at low pH, and can build up to toxic levels when soils are acidified. Second, nitrogen-saturated ecosystems lose added nitrogen through nitrate leaching and in gaseous forms through microbial transformations (nitrification and denitrification). Leaching losses of nitrate can substantially reduce soil fertility, because positively charged base cations (potassium, calcium, and magnesium) are carried away with the negatively charged nitrate as it leaches. Gaseous losses of nitrogen through microbial processes occur as dinitrogen gas (N_2), which is inert in the atmosphere, but also as nitric oxide (NO), nitrogen dioxide (NO_2), and nitrous oxide (N_2O). Nitric oxide and nitrogen dioxide are reactive trace gases that contribute to photochemical smog and acid rain. Nitrous oxide, by contrast, is a very stable radiatively active greenhouse gas, 200 times more effective at trapping heat than carbon dioxide. Through increased nitrous oxide ef ux from soils (a major source of nitrous oxide to the atmosphere), ecosystems effectively translate one facet of global change, nitrogen deposition, to another, global warming.

Effects on Freshwater Ecosystems

Runoff from urban and agricultural areas transports nutrients (nitrogen and phosphorus) from terrestrial to aquatic ecosystems, leading to *eutrophication*, by many accounts the most widespread and severe type of global change affecting lakes (Lodge, 2001) (*see* **Eutrophication**, Volume 2). Phosphorus is the nutrient most commonly limiting to NPP in freshwaters, particularly in temperate latitudes, so added phosphorus generally increases algal productivity. Nitrogen is often the next most limiting nutrient, so freshwater ecosystems already affected by increased phosphorus inputs are likely to also be very responsive to increased inputs of nitrogen from the atmosphere. Eutrophication, in addition to increasing NPP, can also alter algal species composition, favoring those species better able to take advantage of the higher nutrient levels.

Increased algal productivity in response to moderate eutrophication can stimulate productivity of higher trophic levels in aquatic ecosystems, but more often eutrophication favors particular species of algae that may be inedible and/or toxic, causing noxious *algal blooms*; extremely dense mats of algae that decrease light penetration and alter thermal structure. When these algae die, the input of organic matter fuels decomposition and depletes oxygen concentrations, killing fish and other organisms (Carpenter *et al.*, 1998).

Deposition of sulfuric and nitric acid to lakes causes acidification, particularly in lakes which are low in alkalinity (the chemical capacity to buffer changes in pH in response to acid inputs), such as those in the northeastern part of North America and in Scandinavia (Schindler, 1998). Most organisms are sensitive to changes in pH, so the effects of acidification on species distributions and abundances are often quite direct. For example, crustaceans and mollusks are particularly sensitive to the direct effects of acidification, because it reduces the availability of the calcium and carbonates required to build their exoskeletons. Acidification can reduce algal productivity and alter species composition, indirectly affecting higher trophic levels. Acidification of lakes also increases water clarity and reduces concentrations of dissolved organic carbon (DOC) (Schindler, 1998). Finally, the effects of acidification can be indirect as well. In lakes of the Laurentian Shield, with low-buffering capacity, for example, the increase in hydrogen ion concentration leads to mobilization from the sediments of toxic heavy metals such as mercury. These subsequently accumulate in fish, which then fail to reproduce.

GLOBAL WARMING

Effects on Terrestrial Ecosystems

Global warming will likely alter many ecosystem processes in terrestrial ecosystems, including increasing decomposition, increasing evapotranspiration, altering NPP, and shifting species composition in ways that can substantially modulate the initial direct responses. Potential effects of global warming on terrestrial ecosystems have been investigated in the field by experimentally warming the air around vegetation (using greenhouses or infrared heaters), by warming the soil using heat tape, or by studying natural gradients in temperature across the landscape.

As with elevated carbon dioxide and nitrogen deposition, understanding how global warming will alter the carbon balance of terrestrial ecosystems is a major focus of global change research. In laboratory incubations, microbial respiration responds exponentially to increasing temperature, and litter decomposition in the field shows a similar trend. By contrast, photosynthesis has a saturating relationship with temperature for most plant species, with optimal temperatures close to those typical of the environment in which the plant is found. Warming will likely increase rates of litter decomposition, stimulating a release of carbon dioxide from ecosystems to the atmosphere, and across 30 different ecosystem warming experiments, the ux of carbon dioxide from soil to the atmosphere increased (Rustad *et al.*, 2000). But photosynthesis can increase as well: in tundra, warming did not change the carbon balance; the effects of increased decomposition were counterbalanced by increased photosynthesis (Hobbie and Chapin, 1998). Increased carbon dioxide ef ux from arctic and alpine tundra in response to recent warming trends and to experimental manipulations appears to be due to warmer temperatures causing soil drying. In high latitudes, drying of waterlogged peat soils could release large amounts of carbon dioxide to the atmosphere. Increased decomposition should also increase nutrient mineralization and nutrient availability to plants, an effect that could ultimately enhance carbon uptake, as plants sequester nutrients in higher carbon-to-nutrient ratios than those in soils. However, this effect does not seem to have strongly in uenced results from warming experiments to date.

Global circulation models predict that warming will be most pronounced in upper latitudes. In tundra ecosystems, the indirect effects of increased temperature may more strongly determine the responses of tundra ecosystems to climate change than the direct effects. For example, the temperature controls depth of thaw, soil nutrient availability, and growing season length, all of which exert greater control over tundra plant growth than does temperature directly (Chapin, 1983). Growth responses to temperature vary among tundra species, and increased abundance of shrubs and decreases in mosses and other non-vascular species in response to experimental warming (and that observed over the last decade, a period when mean annual temperatures have also increased) suggest that shifts in species composition in tundra ecosystems will be one of the critical drivers of changes in ecosystem processes in response to global warming (Chapin and Shaver, 1996). In lower latitudes, too, warming could cause shifts in species composition that alter ecosystem processes. For example, warming could favor biological invasions by weedy C4 grasses in hotter climates, because of their higher temperature optimum for photosynthesis and their greater drought tolerance compared to C3 and C4 plants (Dukes and Mooney, 1999; *see* C_3 and C_4 Photosynthesis, Volume 2).

Experimental warming usually results in drying as well, and often the latter is the more critical driver of changes in ecosystem structure and processes, particularly in arid and semi-arid ecosystems. One of the challenges in this research area is to disentangle direct and indirect effects. Climate models predict that changes in precipitation caused by global warming will be regionally specific, increasing in some areas and decreasing in others, and thus are not always well-represented by the drying that occurs with experimental warming.

Effects on Freshwater Ecosystems

Global warming will almost certainly alter the hydrologic cycle, directly altering the amount and distribution of water on the terrestrial surface and thus the extent of freshwater ecosystems. While warming will increase evapotranspiration globally, changes in precipitation will vary from region to region. Thus, regionally-specific climate change scenarios are needed to predict where increases and decreases in the extent of freshwaters are likely to occur. For example, warming is predicted to reduce runoff and lake water levels in the Great Lakes region (Mortsch and Quinn, 1996), but to increase runoff and possibly ood intensity in the Amazon Basin (Neilson and Marks, 1994). Overall, however, evaporation will increase more than precipitation, reducing the extent of freshwater ecosystems globally. In arid and semi-arid regions, as well as in high latitudes, some freshwater habitats could disappear (Schindler *et al.*, 1996).

The paleo record indicates that changes in global temperatures and regional precipitation patterns have strongly affected ood magnitude and frequency (Ely *et al.*, 1993). Global warming is thus likely to alter the *disturbance regime*, an important regulator of ecosystem structure and function in many streams and rivers. Increased temperatures will also likely increase the extent and duration of thermal stratification in lakes (*see also* Disturbance, Volume 2).

Changes in the distribution and abundance of aquatic organisms will likely accompany global warming, leading to increases in the ranges of organisms where corridors between habitats allow migration; and to extinctions where

corridors to habitats with appropriate thermal regimes do not exist. Direct effects of warming on organisms are likely to be greatest in high latitudes, where warming is predicted to be greater and where native biota are more sensitive to increased temperatures. For example, model simulations suggest that warming will increase food requirements of lake trout in arctic lakes, but long-term observations over a recent warming period revealed no changes in primary production to fuel this greater food demand, thus threatening the top trophic level in arctic lakes (McDonald *et al.*, 1996). Such changes are likely to have strong impacts on ecosystem processes, because top predators often are major determinants of nutrient cycling, water clarity, and net ecosystem productivity in freshwater ecosystems (Schindler *et al.*, 1996).

Changes in runoff and in terrestrial ecosystem processes caused by warming could alter the amounts and forms of nutrient and plant litter inputs to freshwaters, affecting production, decomposition, and the food webs these processes fuel in streams, rivers, and lakes. As mentioned above, warming can reduce DOC supply to lakes and streams from terrestrial ecosystems (Schindler *et al.*, 1996), but could cause the opposite effect in northern latitudes, where melting permafrost and increased decomposition of old peat (e.g., Oechel *et al.*, 1993) could enhance DOC transport from tundra to arctic lakes and streams.

ENHANCED UV-B RADIATION

As a direct consequence of human production of ozone-depleting chemicals, such as chloro uorocarbons and nitrous oxide (N_2O), concentrations of ozone (O_3) in the stratosphere (the ozone shield) are currently at their lowest recorded values. Lower levels of stratospheric ozone allows greater penetration of UV-B radiation (280–315 nm) to the Earth's surface where it can damage deoxyribonucleic acid (DNA), proteins, lipids, and other UV-B absorbing compounds in living tissues, alter tissue composition and growth, and cause photolysis of non-living organic matter, all of which have important consequences for terrestrial and freshwater ecosystems.

Effects on Terrestrial Ecosystems

In terrestrial ecosystems, inhibition of photosynthesis by UV-B reduces leaf area and stem growth in many species, potentially reducing NPP. Water stress can mitigate these effects, because water-stressed plants often produce higher concentrations of UV-B absorbing compounds. The effects of enhanced UV-B radiation on plant growth can also interact with elevated carbon dioxide concentrations.

Some plants tolerate UV-B more than others, such that shifts in species composition are a likely consequence of enhanced UV-B radiation. In some cases, these changes can buffer reductions in NPP, if UV-B induced reductions in plant growth lead to the acquisition and growth of more tolerant species (Caldwell *et al.*, 1998).

Organisms vary in their natural abilities to cope with enhanced UV-B radiation. Some, particularly microbes and insects in early stages of development (early instars), are not well protected against UV-B, having little ability to adjust concentrations of UV-B absorbing compounds, and are therefore quite sensitive to UV-B damage. This susceptibility is exacerbated when the natural habitats of those organisms, such as the surfaces of leaves, soils or biological crusts in the desert, involve direct exposure to UV-B radiation. Plants often alter their chemical composition in response to enhanced UV-B radiation, producing greater amounts of phenolic compounds (tannins, lignins, and other refractory materials) or antioxidants (e.g., avenoids) that can absorb some of the damaging radiation and thereby protect the plant. Plants can also alter morphological properties, such as leaf thickness, which offers greater resistance to UV-B damage.

Changes in plant chemistry and morphology can in turn alter rates of herbivory and decomposition processes that are very sensitive to leaf thickness and chemical composition. UV-B can also increase litter decomposition directly, through photolysis, when solar radiation breaks chemical bonds. In these ways, enhanced UV-B radiation can alter the cycling of carbon and nutrients in ecosystems, but the direction of these effects is difficult to predict. For example, in some cases, litter produced under enhanced UV-B decomposes more slowly because the UV-B treatment alters the chemical composition of litter. But in other cases, UV-B increases decomposition, possibly because of the direct effects of photolysis. Enhanced UV-B radiation can also affect nitrogen cycling by inhibiting biological nitrogen fixation.

Effects on Freshwater Ecosystems

In contrast to terrestrial ecosystems, where UV-B radiation is attenuated only by the atmosphere, UV-B penetration into freshwater ecosystems declines with water depth and with increasing concentrations of DOC, particularly DOC high in UV-B absorbing chemical structures (phenols, humins, and other aromatics). Much of this DOC is of terrestrial origin–byproducts of the decomposition of terrestrial plant litter. The water-soluble portion of this material can be transported into freshwater ecosystems and there serve an important role in absorbing UV-B radiation. Through photolysis, UV-B radiation breaks down this DOC into smaller organic compounds that are usually more susceptible to microbial decomposition. Increased photolysis and decomposition in response to enhanced UV-B allow greater penetration of UV-B into the water column and further DOC photolysis, creating a positive feedback cycle. Freshwaters

naturally vary in DOC concentrations, so the penetration of UV-B into the water column, and the potential for detrimental effects of enhanced UV-B on ecosystems, also vary among habitats.

Increased processing of DOC and altered rates of microbial metabolism can in turn affect nutrient cycling and primary production in freshwater ecosystems. For example, photolysis can release nitrogen compounds (ammonium and amino acids) that stimulate microbial activity and turnover, and thus the rates of nitrogen cycling. Many of the enzymes involved in nitrogen transformations, however, such as nitrogenase (nitrogen fixation) and glutamine synthetase (ammonium uptake) are inhibited by UV-B radiation, such that the overall effects of UV-B on rates of nitrogen cycling are difficult to predict. Changes in algal production in response to enhanced UV-B radiation, likewise, will re ect the direct negative impacts of enhanced UV-B on photosynthesis and growth, as well as any indirect effects on the availability of nutrients limiting to production. UV-B also affects zooplankton, both directly, by damaging tissues, and indirectly, by affecting the amount and quality of primary production upon which these grazers depend.

For both phytoplankton and zooplankton, enhanced UV-B often results in a shift in community composition, because species differ in sensitivity to UV-B damage. In some ecosystems, entire trophic levels vary in sensitivity to UV-B damage. For example, algal production increased in response to enhanced UV-B in a stream habitat (Hader *et al.*, 1998). Although the algae in isolation were negatively affected by UV-B, the dominant grazers (larval chironomids) were even more sensitive, and largely eliminated by the UV-B treatment, releasing the algae from grazing pressure. These observations highlight the danger in predicting ecosystem responses to global change by examining any part of the system in isolation.

Because of the central role of DOC in attenuating UV-B penetration into aquatic ecosystems, any global change factor that in uences DOC concentrations will interact with enhanced UV-B radiation. A number of such interactions have been identified and observed through both experiments and observations in the Experimental Lakes Area in Canada. Here, observations over two decades, along with a number of long-term experiments showed that increases in lake temperatures and lake acidification occurred in concert with reductions in DOC concentrations, allowing greater penetration of UV-B into the water column. The reductions in DOC were caused by reduced inputs of DOC through runoff (particularly during drought years), increased microbial processing of DOC, decreased primary productivity, and greater lake stratification, which reduced the transfer of UV-B absorbing compounds from deeper water into the upper layers.

LAND-USE CHANGE

More and more land is used for livestock grazing, agriculture, forestry, and settlement, and these changes in land use and land cover are projected to increase. Land-use change is currently the most severe global change affecting terrestrial ecosystems, and it is likely to remain the dominant one in tropical regions over the next several decades.

Land-use change alters both ecosystem structure and ecosystem processes. For example, land-clearing removes vegetation, and such clearing is often accomplished by burning, so the carbon stored in the plants is thereby released to the atmosphere as carbon dioxide. Similarly, tillage in agriculture disrupts soil associations that stabilize soil organic matter, stimulating decomposition and releasing carbon dioxide to the atmosphere. Largely due to these processes, past land-use changes have already substantially increased carbon losses from ecosystems to the atmosphere, accounting for nearly half of the observed increase in atmospheric carbon dioxide concentrations between 1750 and the present (Houghton, 1994).

Greater rates of nutrient losses often occur after land clearing or conversion to agriculture, due to both higher microbial activity and lower plant nutrient uptake. When land is cleared for agriculture, higher rates of nutrient losses are usually compensated by application of fertilizers and lime, allowing such ecosystems to maintain equal or even higher rates of NPP (particularly where agricultural fields are also irrigated). Nutrient cycling in agricultural ecosystems is thus fundamentally different from that in the natural terrestrial ecosystems they replaced. Typical rates of fertilizer application in intensive agriculture far exceed natural rates of nutrient importation (e.g., through natural nitrogen fixation), and losses of fertilizer also greatly exceed natural rates of nutrient loss (e.g., through leaching and gaseous pathways). For these reasons, managed ecosystems (particularly agricultural ones) are said to save *open nutrient cycles*, where inputs to and losses from the ecosystem are the dominant transfers. By contrast, nutrient cycles in natural terrestrial ecosystems are *closed*, in the sense that inputs and losses are far smaller than exchanges within ecosystems (e.g., mineralization of organic to inorganic forms). Nutrient losses from agricultural ecosystems contribute to a number of global changes: 1) losses of gaseous nitrous oxide contribute to global warming, as nitrous oxide has nearly 200 times more warming potential than carbon dioxide, molecule for molecule; 2) losses of gaseous nitric oxide and nitrogen dioxide contribute to photochemical smog and acidic nitrogen deposition; and 3) leaching losses of nutrients (e.g., NO_3^- and PO_4^{2-}) from agriculture contribute substantially to eutrophication of aquatic ecosystems.

Other changes in ecosystem structure and processes accompany land-use changes. For example, converting a native forest to a pasture reduces canopy height and rooting depth, thereby altering water and energy exchange with

the atmosphere (reducing latent heat flux and increasing sensible heat flux, for example). Over large enough scales, such changes in energy partitioning can change regional and potentially even global climate (Shukla *et al.*, 1990). Land-use changes also alter connections between habitats, converting, for example, a large homogenous forest stand to a patchwork mosaic of managed ecosystems and remnant forest. Such changes in ecosystem structure can threaten animal species that require large ranges and can facilitate species invasions.

Rates of soil erosion driven by both wind and water are also typically much higher as a result of land-use change. Losses of soil are not easily replaced, so increasing soil erosion caused by land-use change remains a serious global problem, affecting the long-term fertility of agricultural ecosystems, as well as the integrity of ecosystems downstream and downwind.

HYDROLOGIC ALTERATIONS

Direct human changes in the global water cycle (through impoundments (dams), surface water diversions, and groundwater extraction) have dramatically altered freshwater ecosystems. Globally, nearly a million dams interrupt natural river flows, appropriating more than half of the available global runoff for human use (Postel *et al.*, 1996).

Water impoundment through dam building converts upstream rivers to reservoirs, and dampens the natural variation in flow regimes downstream, both of which constitute fundamental changes in the structure of river ecosystems. Upstream, converting a river to a reservoir introduces thermal stratification, drastically reduces water flow, and changes the light environment, leading to a complete change in the structure of the producer community with associated changes in food web structure. Additionally, buried terrestrial vegetation and soil organic matter decomposes in reservoirs, releasing carbon dioxide to the atmosphere, and also methane (CH_4), a greenhouse gas produced when decomposition proceeds in the absence of oxygen (St. Louis *et al.*, 2000). Downstream, dams largely eliminate natural flooding regimes, seasonal fluctuations in water temperature, and sediment loads, often endangering or causing the extinction of the native species that were adapted to such fundamental characteristics of the river, including species important to fisheries (Postel, 1998). Such changes in water flow regimes can detrimentally affect important habitat, including floodplains, riparian zones, wetlands, and estuaries, all of which are particularly sensitive to changes in water flow. Reduced water flow can also impair water quality, as pollutants become less and less dilute. The dam itself also constitutes a formidable barrier to species migration, leading to genetic isolation and potentially to extinction (Pringle, 1997). Nutrient delivery (particularly of silicates) is interrupted by impoundments, with detrimental effects on marine algae and associated food webs. For a larger-scale example, see Humborg *et al.* (1997), who reported on the impacts of a recently constructed dam on the Danube River between Hungary and Slovakia, on ecosystem structure in the Black Sea.

INVASIVE SPECIES

Through intentional introductions and through accidental hitchhikers in our global transportation systems, humans have dramatically redistributed the species on earth. Some of these species introductions are relatively benign, but other invasive species detrimentally affect native species and ecosystems. Invasive species are first transported to a new geographic area, they survive and persist in this new area, and eventually they thrive, reproducing successfully, spreading in areal extent, and outcompeting native species, not infrequently driving some native species to extinction. The species that make up an ecosystem strongly influence that ecosystem's structure and processes, so the changes in species composition caused by invasions can have ecosystem-scale effects. In general, invasive species can alter ecosystem processes by changing trophic structure, resource availability, or disturbance frequency or intensity (Vitousek, 1989).
